Age-related changes in renal function vary tremendously. Some older adults experience little change, whereas others can have devastating, life-threatening change. On average glomerular filtration rate, measured in creatinine clearance rates, declines by approximately 8 to 10 mL/min/1.73m<sup>2</sup>/decade after age 30 to 35. The resulting increase in serum creatinine concentrations should be considered when determining medication dosages. The progressive decline in renal function can lead to an inability to excrete concentrated or dilute urine, a delayed response to sodium deprivation or a sodium load, and delayed response to an acid load. Renal function is also affected by dehydration, diuretic use, and medications, especially antibiotics.

## Neurologic

There can be significant age-related declines in neurologic processes. Cognition, steadiness, reactions, coordination, gait, sensations, and daily living tasks can decline as much as 90% or as little as 10%. On average, the brain loses 5% to 10% of its weight between the ages of 20 and 90, but most if not all neurons are functional until death unless a specific pathologic condition is present.

It is important to make the distinction between normal, age-related decline and impairment from conditions such as dementia, a disease process. Memory difficulties do not necessarily indicate dementia, Alzheimer's disease, Parkinson's disease, or any mental disorder (see Chapter 41). Many changes in memory can be attributed to environmental factors, including stress, chemical exposure, and poor diet rather than to physiologic processes. However, even mild cognitive impairment that affects approximately 20% of those older than age 70 may affect eating, chewing, and swallowing, thus increasing the risk of malnutrition.

## COMMON HEALTH PROBLEMS

### Eye Disease

**Age-related macular degeneration (AMD)** is the leading cause of blindness in people older than age 65 in the United States; it may also be linked to an increased risk for stroke (Wong, 2006). AMD occurs when the macula, the center part of the retina, degrades. The result is central vision loss. The macular pigment is composed of two chemicals, lutein and zeaxanthin. A diet rich in fruits and vegetables may help delay or prevent the development of AMD. Zinc has also been shown to decrease the risk of developing AMD. Finally, correcting obesity and smoking are modifiable factors that can reduce progression of AMD (Clemons, 2006).

**Glaucoma** is damage to the optic nerve resulting from high pressure in the eye. It is the second most common cause of vision loss in the United States and affects approximately 3 million Americans. Hypertension, diabetes, and CVD all increase the risk of glaucoma.

A **cataract** is a clouding of the lens of the eye. Approximately half of Americans 65 and older have some degree of

clouding of the lens. The most common treatment is surgery; the clouded lens is removed and replaced with a permanent prosthetic lens. A diet high in antioxidants such as beta-carotene, selenium, resveratrol, and vitamins C and E may delay cataract development. Studies show that a high sodium intake may increase risk of cataract development. Ultraviolet (UV) radiation exposure is directly related to 5% of worldwide cataracts. When the UV index is 3 and above, protective sunglasses are recommended (World Health Organization, 2009).

**Diabetic retinopathy** is a complication of diabetes (see Chapter 31). It occurs when blood vessels of the retina leak and produce spotty hemorrhages. Not all persons with diabetes develop retinopathy; blood glucose control can help protect the retina from damage.

All forms of vision loss can negatively affect nutritional status. Those with moderate-to-severe vision loss may have difficulty shopping for, identifying, and preparing foods and self-feeding.

### Depression

Psychological changes often manifest as depression and its extent can vary widely from person to person. Among older persons depression is often caused by other conditions such as heart disease, stroke, diabetes, cancer, grief, or stress. Depression in older people is frequently undiagnosed or misdiagnosed because symptoms are confused with other medical illnesses. Untreated depression can have serious side effects for older adults. It diminishes the pleasures of living, including eating; it can exacerbate other medical conditions; and it can compromise immune function. It is associated with decreased appetite, weight loss, and fatigue. Nutritional care plays an important role in addressing this condition (see Chapter 42). Providing nutrient- and calorie-dense foods, additional beverages, texture-modified foods, and favorite foods at times when people are most likely to eat the greatest quantity can be very effective. In that comorbidities lead to polypharmacy and concern regarding drug-drug interactions, providers may choose to omit antidepressants, which leaves the depression untreated.

### Pressure Ulcers

**Pressure ulcers**, formerly called *bedsores* or *decubitus ulcers*, develop from continuous pressure that impedes capillary blood flow to skin and underlying tissue. Several factors contribute to the formation of pressure ulcers, but impaired mobility and urinary incontinence are key. Older adults with neurologic problems, those heavily sedated, and those with dementia are often unable to shift positions to alleviate pressure. Paralysis, incontinence, sensory losses, and rigidity can all contribute to the problem. Notably malnutrition (inadequate protein) and undernutrition (inadequate energy intake) set the stage for its development and can delay wound healing. The escalating chronic nature of pressure ulcers in bed-ridden or sedentary elderly requires vigilant attention to nutrition.

Several classification systems exist to describe pressure ulcers. The four stages of pressure ulcers, based on the

depth of the sore and level of tissue involvement, are described in Table 21-2. Thomas (2009) suggests that wound nutrition equals whole-body nutrition, and coordinated efforts of a multidisciplinary treatment team are important. Nutrition recommendations for the treatment of pressure ulcers are as follows (Doley, 2010; Thomas, 2009):

- Optimize protein intake with a goal of 1.25 to 2 g/kg/day.
- Meet calorie requirements at 30-40 kcal/kg/day.
- Assess the effect of medications on wound healing and supplement if indicated.
- Replace micronutrients if depleted—routine supplementation is not warranted.

## Frailty and Failure to Thrive

The four syndromes known to be predictive of adverse outcomes in older adults that are prevalent in patients with frailty or “geriatric failure to thrive” include impaired physical functioning, malnutrition, depression, and cognitive impairment. Symptoms include weight loss, decreased appetite, poor nutrition, dehydration, inactivity, and impaired immune function. Interventions should be directed at easily remediable contributors in the hope of improving overall functional status. Nutrition interventions, especially those rectifying protein-energy malnutrition (PEM), are essential.

## QUALITY OF LIFE

**Quality of life** is a general sense of happiness and satisfaction with one's life and environment. Health-related quality of life is the personal sense of physical and mental health and the ability to react to factors in the physical and social environments. To assess health-related quality of life, common measures and scales, either general or disease-specific, can be used. Because older age is often associated with health problems and decrease in functionality, quality-of-life issues become relevant.

Food and nutrition contribute to one's physiologic, psychological, and social quality of life. A measure of nutrition-related quality of life has been proposed to document quality-of-life outcomes for individuals receiving medical nutrition therapy. Effective strategies to improve eating and thereby improve nursing home residents' quality of life are well established but could be more widely implemented (Kamp et al., 2010; Neidert, 2005).

## Functionality

*Functionality* and *functional status* are terms used to describe physical abilities and limitations in, for example, ambulation. **Functionality**, the ability to perform self-care, self-maintenance, and physical activities, correlates with independence and quality of life. Disability rates among older adults are declining, but the actual number considered disabled is increasing as the size of the aging population grows. Limitations in **activities of daily living (ADLs)**

(toileting, bathing, eating, dressing) and **instrumental activities of daily living (IADLs)** such as managing money, shopping, telephone use, travel in community, housekeeping, preparing meals, taking medications correctly, and other individual self-performance skills needed in everyday life, are used to monitor physical function.

Many nutrition-related diseases affect functional status in older individuals. Inadequate nutrient intake may hasten loss of muscle mass and strength, which can have a negative effect on performing ADLs. Among the older adults who have one or more nutrition-related chronic diseases, impaired physical function may cause greater disability, with increased morbidity, nursing home admissions or death.

## Weight Maintenance

### Obesity

The prevalence of obesity in all ages has increased during the past 25 years in the United States; older adults are no exception. Obesity rates are greater among those ages 65 to 74 than among those age 75 and older. Obesity is associated with increased mortality and contributes to many chronic diseases: type 2 diabetes, heart disease, hypertension, arthritis, dyslipidemia, and cancer. Obesity causes a progressive decline in physical function, which may lead to increased frailty. Overweight and obesity can lead to a decline in IADLs.

Current data demonstrate that weight-loss therapy improves physical function, quality of life, and reduces the medical complications associated with obesity in older persons (Villareal, 2005). Accordingly, weight loss therapies that maintain muscle and bone mass are recommended for obese older adults. Lifestyle changes that include diet, physical activity, and behavior modification techniques are the most effective. The goals of weight loss and management for adults are the same for the general population, and should include prevention of further weight gain, or reduction of body weight, and maintenance of long-term weight loss.

Weight loss of 10% of total body weight over 6 months should be the initial goal. After that, strategies for maintenance should be implemented. Dietary changes include an energy deficit of 500-1000 kcal/day. Usual caloric goals range from 1200-1800 kcal/day but should not be less than 800 kcal/day. It is critical for the older adult on a calorie-restricted diet to meet nutrient requirements. This may necessitate the use of a multivitamin or mineral supplement as well as nutrition education.

### Underweight and Malnutrition

The actual prevalence of underweight among older adults is quite low; older women older than age 65 are three times as likely as their male counterparts to be underweight (Federal Interagency Forum, 2008). However, many older adults are at risk for undernutrition and malnutrition. Among those hospitalized, 40% to 60% are malnourished or at risk for malnutrition, 40% to 85% of nursing home residents have malnutrition, and 20% to 60% of home care

**TABLE 21-2****Pressure Ulcer Stages and Nutritional Recommendations****Suspected Deep Tissue Injury**

Purple or maroon localized area of discolored intact skin or blood-filled blister caused by damage of underlying soft tissue from pressure or shear. The area may be preceded by tissue that is painful, firm, mushy, boggy, warmer, or cooler as compared with adjacent tissue.

Deep tissue injury may be difficult to detect in individuals with dark skin tones. Evolution may include a thin blister over a dark wound bed. The wound may further evolve and become covered by thin eschar. Evolution may be rapid, exposing additional layers of tissue even with optimal treatment.

**Stage I**

Intact skin with nonblanchable redness of a localized area, usually over a bony prominence. Darkly pigmented skin may not have visible blanching; its color may differ from the surrounding area.

The area may be painful, firm, soft, warmer, or cooler as compared with adjacent tissue. Stage I may be difficult to detect in individuals with dark skin tones. May indicate “at-risk” persons (a heralding sign of risk).

**Stage II**

Partial thickness loss of dermis presenting as a shallow open ulcer with a red pink wound bed without slough. May also present as an intact or open or ruptured serum-filled blister.

Presents as a shiny or dry, shallow ulcer without slough or bruising. This stage should not be used to describe skin tears, tape burns, perineal dermatitis, maceration, or excoriation.

Bruising indicates suspected deep tissue injury.

**Stage III**

Full-thickness tissue loss. Subcutaneous fat may be visible but bone, tendon, or muscle are not exposed. Slough may be present but does not obscure the depth of tissue loss. May include undermining and tunneling.

The depth of a stage III pressure ulcer varies by anatomic location. The bridge of the nose, ear, occiput, and malleolus do not have subcutaneous tissue, and stage III ulcers can be shallow. In contrast, areas of significant adiposity can develop extremely deep stage III pressure ulcers. Bone and tendon are not visible or directly palpable.

Energy: 30 calories/kg BW

Normal protein requirements in healthy adults are approximately 0.8 g/kg of body weight and 1 g/kg BW in the elderly.

Energy: 30 to 35 calories/kg BW

Protein: 1.25 to 1.5 grams/kg BW

Fluid: 30 to 33 cc/kg BW; possibly less fluid for patients with severe renal disease or congestive heart failure.

Energy: 30 to 35 calories/kg BW

Protein: 1.25 to 1.5 grams/kg BW

Fluid: 30 to 33 cc/kg BW; possibly less fluid for patients with severe renal disease or congestive heart failure.

Energy: 35 to 40 calories/kg BW

Protein: 1.5 to 1.75 g/kg BW (Note: Assessment of protein needs should be determined after an assessment of visceral protein status has been completed, keeping in mind that stressed patients with protein depletion usually cannot metabolize more than 2 g/kg BW per day.)

Fluid: 30 to 33 cc/kg BW; possibly less fluid for patients with severe renal disease or congestive heart failure.

Additional fluids are needed for patients with draining wounds, fever, and other fluid losses. Patients on air-fluidized beds may become dehydrated because of increased evaporative water loss; extra 10 to 15 mL/kg BW may be needed.

A multivitamin with 15 mg of zinc will be adequate for most patients.

**TABLE 21-2****Pressure Ulcer Stages and Nutritional Recommendations—cont'd****Stage IV**

Full-thickness tissue loss with exposed bone, tendon, or muscle. Slough or eschar may be present on some parts of the wound bed. Often include undermining and tunneling.

The depth of a stage IV pressure ulcer varies by anatomic location. The bridge of the nose, ear, occiput, and malleolus do not have subcutaneous tissue, and these ulcers can be shallow. Stage IV ulcers can extend into muscle and supporting structures (e.g., fascia, tendon, or joint capsule), making osteomyelitis possible. Exposed bone or tendon is visible or directly palpable.

Energy: 35 to 40 calories/kg BW

Protein: 1.75 to 2 g/kg BW (Note: Assessment of protein needs should be determined after an assessment of visceral protein status has been completed, keeping in mind that stressed patients with protein depletion usually cannot metabolize more than 2 g/kg of body weight each day.)

Fluid: 30 to 33 cc/kg BW; possibly less fluid for patients with severe renal disease or congestive heart failure. Additional fluids are needed for patients with draining wounds, fever, and other fluid losses. Patients on air-fluidized beds may become dehydrated because of increased evaporative water loss; extra 10 to 15 mL/kg body weight may be needed.

A multivitamin with 15 mg of zinc/day may be adequate for most patients; some may require more zinc.

Often treated as a stage IV.

**Unstageable**

Full-thickness tissue loss in which the base of the ulcer is covered by slough (yellow, tan, gray, green, or brown) or eschar (tan, brown, or black) in the wound bed. Until enough slough or eschar is removed to expose the base of the wound, the true depth, and therefore stage, cannot be determined. Stable (dry, adherent, intact without erythema or fluctuance) eschar on the heels serves as “the body’s natural (biologic) cover” and should not be removed.

BW, Body weight.

patients are malnourished. Many community-residing older persons consume fewer than 1000 kcal/day, an amount not adequate to maintain good nutrition. Some causes of under-nutrition include medications, depression, decreased sense of taste or smell, poor oral health, chronic diseases, dysphagia, and other physical problems that make eating difficult. Social causes may include living alone, inadequate income, lack of transportation, and limitations in shopping for and preparing food.

Health care professionals frequently overlook PEM. The physiologic changes of aging, as well as changes in living conditions and income, all contribute to the problem. Symptoms of PEM are often attributed to other conditions, leading to misdiagnosis. Some common symptoms are confusion, fatigue, and weakness. Older adults with low incomes, who have difficulty chewing and swallowing meat, who smoke, or engage in little or no physical activity are at increased risk of developing PEM.

Strategies to decrease PEM include increased caloric and protein intake. In a clinical setting nutritional oral supplements and enteral feedings may be used. Frailty is often

related to micronutrient deficiencies, especially in women (Michelon, 2006). Older malnourished adults are at risk of refeeding syndrome when they begin to receive nutrition support, and this should be assessed (see Chapter 14).

In a community setting older adults should be encouraged to eat energy-dense and high-protein foods. Diet restrictions should be liberalized to offer more choices. Adding gravies and creams can increase calories and soften foods for easier chewing (Joshi, 2009). Federal food and nutrition services are also available for older adults.

## NUTRITION SCREENING AND ASSESSMENT

The Mini Nutritional Assessment (MNA) (Bauer, 2008) includes two sections: screening and assessment. The Short Form is the most widely used screening method to identify malnutrition in noninstitutionalized older adults. It includes six questions and a body mass index (BMI) evaluation, or a calf circumference, if a BMI is not possible. The MNA

Short Form has been validated (Kaiser, 2009). For a complete nutrition assessment, the full MNA is used. It is the most commonly used assessment tool in long-term care (see [Figures 4-4 and 4-5](#)).

Some assessment measures are not necessarily accurate or feasible to use with older adults (Morley, 2009). Physical and metabolic changes of aging can yield inaccurate results. An illustration of this is anthropometric measurements such as height and weight, and BMI. With aging, fat mass increases and height decreases as a result of vertebral compression (Villareal, 2005). An accurate height measure may be difficult in those unable to stand up straight, the bed bound, those with spinal deformations such as a dowager's hump, and those with osteoporosis. Measuring arm span or knee height may give more accurate measurements. See [Appendix 20](#). BMIs based on questionable heights are inaccurate. Clinical judgment is needed for accuracy.

Body composition measures may also be ineffective. Skin-fold thickness and mid-arm circumference used to detect changes in body fat are limited in their ability to distinguish between changes in fat and muscle mass, because of decreased elasticity and increased compressibility of older skin. Mid-arm muscle circumference measures may be more accurate and sensitive to weight change than overall body composition measurements.

## NUTRITION NEEDS

Many older adults have special nutrient requirements because aging affects absorption, use, and excretion of nutrients (Kuczmarski and Weddle, 2005). The dietary reference intakes (DRIs) separate the cohort of people age 50 and older into two groups, ages 50-70 and 71 and older. Based on the Healthy Eating Index, older Americans need to increase their intakes of whole grains, dark green and orange vegetables, legumes, and milk; choose more nutrient-dense forms of foods, that is, foods low in solid fats and free of added sugars; and lower their intake of sodium and saturated fat (Juan, 2008). Other studies show that older persons have low intakes of calories, total fat, fiber, calcium, magnesium, zinc, copper, folate, and vitamins B<sub>12</sub>, C, E, and D ([Box 21-1](#)).

The Mifflin-St. Jeor energy equation can be used to assess calorie needs in older adults (see [Chapter 2](#)). DRI tables ([Table 21-3](#); see inside cover) can also be used. Here, DRIs for energy suggest 3067 kcal/day for men and 2403/day for women 18 years; subtract 10 kcal/day for men and 7 kcal/day for women for each year of age older than 19 years.

The DRIs are not specific for protein in older adults. After age 65, the minimum protein requirement is 1 g protein/kg of body weight (Chernoff, 2004). New evidence

### BOX 21-1

#### Dietary Guidelines for Americans

##### KEY RECOMMENDATIONS FOR OLDER ADULTS

- **Maintain calorie balance over the lifetime to achieve and sustain a healthy weight.** Healthy eating patterns limit intake of sodium, solid fats, added sugars, and refined grains. Increased physical activity and reduced time spent in sedentary behaviors are also desired.
- **Focus on consuming nutrient-dense foods and beverages.** A healthy eating pattern emphasizes nutrient-dense foods and beverages. Select fat-free or low-fat milk and milk products, seafood, lean meats and poultry, eggs, beans and peas, and nuts and seeds. Choose vegetables, fruits, whole grains, and milk and milk products for more potassium, dietary fiber, calcium, and vitamin D as nutrients of concern. Eat a variety of vegetables, especially dark-green and red and orange vegetables, beans and peas. Consume at least half of all grains as whole grains.
- **Nutrient needs should be met primarily through consuming foods.** When needed, fortified foods and dietary supplements may be useful in providing one or more nutrients that otherwise might be consumed in less than recommended amounts. Consume foods fortified with vitamin B<sub>12</sub>, such as fortified cereals, or dietary

supplements. Two eating patterns that are beneficial are Vegetarian adaptations and the DASH (Dietary Approaches to Stop Hypertension) Eating Plan.

- **A healthy eating pattern should prevent foodborne illness.** Four basic food safety principles (Clean, Separate, Cook, and Chill) work together to reduce the risk of foodborne illnesses. In addition, some foods (such as milks, cheeses, and juices that have not been pasteurized, and undercooked animal foods) pose high risk for foodborne illness and should be avoided.
- **Use alcohol in moderation.** If alcohol is consumed, it should be consumed in moderation—up to one drink per day for women and two drinks per day for men—and only by adults of legal drinking age.
- Individuals should meet the following recommendations as part of a healthy eating pattern while staying within their calorie needs.
- Information on the type and strength of evidence supporting the Dietary Guidelines recommendations can be found at <http://www.nutritionevidencelibrary.gov>.

Source: U.S. Department of Health and Human Services, U.S. Department of Agriculture: Dietary Guidelines for Americans, 2010, ed 7, Washington, DC, 2010, U.S. Government Printing Office.

supports 1 g/kg, even up to 1.2 gm/kg. In those individuals with impaired renal function or long-standing diabetes, .8g/kg to 1.0 g/kg may be more appropriate. Even protein distribution throughout the day with no single serving exceeding 30 g (Symons et al., 2009) should be a goal.

## MEDICARE BENEFITS

The Social Security Act of 1965 created the Medicare program to cover most of the health care costs of those 65 and older and persons with disabilities. However, this federally funded health insurance program does not cover the entire cost of long-term care (LTC). A portion of payroll taxes and monthly premiums deducted from Social Security payments finance Medicare.

Medicare benefits are provided in four parts. *Part A* covers inpatient hospital care, some skilled nursing care, hospice care, and some home health care costs for limited periods of time. It is premium-free for most citizens. *Part B* has a monthly premium that helps pay for doctors, outpatient hospital care, and some other care not covered by Part A (physical and occupational therapy, for example). *Part C* allows private insurers, including health maintenance organizations (HMOs) and referred provider organizations (PPOs), to offer health insurance plans to Medicare beneficiaries. These must provide the same benefits the original Medicare plan provides under Parts A and B. Part C HMOs and PPOs may also offer additional benefits, such as dental and vision care. *Part D* provides prescription drug benefits through private insurance companies.

The 2010 health care reform legislation changed Medicare to include an annual wellness visit and a personalized prevention assessment and plan with no copayment or deductible. Prevention services include referrals to education and preventive counseling or community-based interventions to address risk factors. The new law mandates the creation of the Independence at Home Demonstration Project, a demonstration program to begin by 2012. It will enroll chronically ill Medicare beneficiaries to test a payment incentive and service delivery system that uses physician- and nurse practitioner-directed home-based primary care teams aimed at reducing costs and improving health outcomes. The 2010 law expands medical nutrition therapy reimbursement for registered dietitians to cover therapy considered reasonable and necessary for the prevention of an illness or disability.

The Home and Community-Based Services (HCBS) Waivers, Section 1915 (c), provide service to nursing home-appropriate older adults to help prevent or decrease nursing home or LTC institutionalization. States may offer an unlimited variety of services under this waiver. These waiver programs may provide both traditional medical services (dental, skilled nursing) and nonmedical services (meal delivery, case management, environmental modifications). States have the discretion to choose the number of older persons served. Forty-eight states (Michigan and Utah are the exceptions) and the District of Columbia offer services

through HCBS waivers; currently there are approximately 287 active programs.

## NUTRITION SUPPORT SERVICES

### U.S. Department of Health and Human Services Older Americans Act Nutrition Program (OAA)

The OAA Nutrition Program is the largest, most visible, federally funded community-based nutrition program for older persons. Primarily a state-run program, it has few federal regulations and considerable variation in state-to-state policies and procedures. This nutrition program provides congregate and home-delivered meals (usually 5 days/week), nutrition screening, education, and counseling, as well as an array of other supportive and health services. Although frequently called *meals on wheels*, that term accurately refers *only* to the home-delivered meals. Participants are poorer, older, sicker, frailer, more likely to live alone, be members of minority groups, and live in rural areas (USAoA, 2008). The OAA Nutrition Program, available to persons age 60 and older, successfully targets those in greatest economic and social need, with particular attention to low-income minorities and rural individuals. More than half of the OAA annual budget supports the Nutrition Program, which provides approximately 240 million congregate and home-delivered meals to 2.6 million older adults annually. Home-delivered meals have grown to more than 60% of all meals served; almost half of the programs have waiting lists. To receive home-delivered meals, an individual must be assessed to be homebound or otherwise isolated. Home-delivered meal recipients are especially frail; half are at high nutrition risk or are malnourished and approximately one-third qualify as nursing-home appropriate.

At congregate sites, the Nutrition Program provides access and linkages to other community-based services. It is the primary source of food and nutrients for many program participants and presents opportunities for active social engagement and meaningful volunteer roles. Participants have higher daily intakes of key nutrients than similar non-participants. The meals are nutritionally dense per calorie and each meal supplies more than 33% of the recommended dietary allowances (an OAA requirement) and provides 40% to 50% of daily intakes of most nutrients (USAoA, 2008). Otherwise, inadequate nutrient intake affects approximately 37% to 40% of community-dwelling individuals 65 years of age and older (Federal Interagency Forum, 2008).

The OAA Nutrition Program has neither received the research or evaluation attention that a program its size deserves, nor the growth in federal funding to keep pace with inflation and the growing numbers of older adults (Wellman, 2010). The program reaches fewer than 5% of older Americans, and those served average fewer than three meals per week. The OAA Nutrition Program is closely linked to **home- and community-based services (HCBS)** through cross-referrals through the Aging Network. Because older adults are being discharged earlier from hospitals and

**TABLE 21-3**

<b>Nutrient</b>	<b>Nutrient Needs Change With Aging</b>	<b>Changes with Aging</b>	<b>Practical Solutions</b>
Energy	Basal metabolic rate decreases with age because of changes in body composition.	Encourage nutrient-dense foods in amounts appropriate for caloric needs.	
Protein 0.8 g/kg minimum	Energy needs decrease ~3% per decade in adults. Minimal change with age but research is not conclusive. Requirements vary with chronic disease, decreased absorption, and synthesis.	Protein intake should not be routinely increased; excess protein could unnecessarily stress aging kidneys.	
Carbohydrates 45%-65% of total calories Men 30 g fiber Women 21 g fiber Lipids 20%-35% total calories	Constipation may be a serious concern for many.  Heart disease is a common diagnosis.	Emphasize complex carbohydrates: legumes, vegetables, whole grains, fruits to provide fiber, essential vitamins, minerals. Increase dietary fiber to improve laxation especially in older adults. Overly severe restriction of dietary fats alters taste, texture, and enjoyment of food; can negatively affect overall diet, weight, and quality of life.	
Vitamins and Minerals	Understanding vitamin and mineral requirements, absorption, use, and excretion with aging has increased but much remains unknown.	Emphasize healthy fats rather restricting fat. Encourage nutrient-dense foods in amounts appropriate for caloric needs.	Oxidative and inflammatory processes affecting aging reinforce the central role of micronutrients, especially antioxidants.
Vitamin B <sub>12</sub> 2.4 mg	Risk of deficiency increases because of low intakes of vitamin B <sub>12</sub> , and decline in gastric acid, which facilitates B12 absorption.		Those 50 and older should eat foods fortified with the crystalline form of vitamin B <sub>12</sub> such as in fortified cereals or supplements.

Vitamin D 800-1,000 IU	Risk of deficiency increases as synthesis is less efficient; skin responsiveness as well as exposure to sunlight decline; kidneys are less able to convert D3 to active hormone form. As many as 30%–40% of those with hip fractures are vitamin D insufficient.	Supplementation may be necessary. This supplement is inexpensive, whereas testing for vitamin D deficiency is costly and the laboratory methods are not completely assured at this point. A supplement is indicated in virtually all institutionalized older adults.
Folate 400 µg	May lower homocysteine levels; possible risk marker for atherothrombosis, Alzheimer disease, and Parkinson disease.	Fortification of grain products has improved folate status. When supplementing with folate, must monitor B <sub>12</sub> levels.
Calcium 1200 mg	Dietary requirement may increase because of decreased absorption; only 4% of women and 10% of men age 60 and older meet daily recommendation.	Recommend naturally occurring and fortified foods. Supplementation may be necessary.
Potassium 4700 mg	Potassium-rich diet can blunt the effect of sodium on blood pressure.	Recommend meeting potassium recommendation with food, especially fruits and vegetables.
Sodium 1500 mg	Risk of hypernatremia caused by dietary excess and dehydration.	Recommend consuming 1500 to no more than 2300 mg/d.
Zinc Men 11 mg Women 8 mg Water	Risk of hyponatremia caused by fluid retention. Low intake associated with impaired immune function, anorexia, loss of sense of taste, delayed wound healing, and pressure ulcer development.  Hydration status can easily be problematic. Dehydration causes decreased fluid intake, decreased kidney function, increased losses caused by increased urine output from medications (laxatives, diuretics).  Symptoms: electrolyte imbalance, altered drug effects, headache, constipation, blood pressure change, dizziness, confusion, dry mouth and nose.	Encourage food sources: lean meats, oysters, dairy products, beans, peanuts, tree nuts and seeds.  Encourage fluid intake of at least 1500 mL/day or 1 mL per calorie consumed.  Risk increases because of impaired sense of thirst, fear of incontinence, and dependence on others to get beverages. Dehydration is often unrecognized; it can present as falls, confusion, change in level of consciousness, weakness or change in functional status, or fatigue.

nursing homes, many require a care plan that includes home-delivered meals and other nutrition services (e.g., nutrition screening, assessment, education, counseling, and care planning). Many states are creating programs to provide necessary medical, social, and supportive HCBS, including home-delivered meals, nutrition education, and counseling services (Kuczmarski and Weddle, 2005).

## USDA Food Assistance Programs

Several U.S. Department of Agriculture (USDA) food and nutrition assistance programs ([www.fns.usda.gov/fns/default.htm](http://www.fns.usda.gov/fns/default.htm)) are available to older adults. All USDA programs are means tested (i.e., recipients must meet income criteria). These programs are discussed further in Chapter 10.

### Supplemental Nutrition Assistance Program

The Supplemental Nutrition Assistance Program (SNAP) program (formerly Food Stamps) is designed to end hunger and improve nutrition and health of low-income Americans. Beneficiaries use electronic benefit transfer (EBT) cards to purchase certain foods at authorized retail food stores. The program is operated by state and local welfare offices under USDA guidance. Currently SNAP serves less than one third of eligible older adults—the lowest participation rate of all demographic groups. Reasons for the low participation rate include the myth that only a \$10 monthly benefit is provided, feeling stigmatized as a welfare recipient, feeling the application process is overly intrusive, eligibility confusion, mistrusting the EBT cards, and lack of outreach.

The goal of SNAP nutrition education is to make healthy choices within a limited budget and choose active lifestyles consistent with the current Dietary Guidelines for Americans and MyPlate. State cooperative extension offices, nutrition education networks, public health departments, welfare agencies, and university centers generally provide the nutrition education. Unfortunately, little outreach specific to older adults is offered.

### Commodity Supplemental Food Program

The Commodity Supplemental Food Program (CSFP) strives to improve the health of low-income Americans by supplementing their diets with nutritious USDA commodity foods. It provides food and administrative funds to states, but not all are enrolled. In states, CSFP administration may be located in diverse sites such as public health, nutrition services, or agriculture departments. Eligible populations include adults age 60 and older with incomes less than 130% of the poverty level. Local CSFP agencies determine eligibility, distribute the foods, and provide nutrition education. The food packages do not provide a complete diet, but may be good sources of nutrients frequently lacking in low-income diets.

### Seniors' Farmers Market Nutrition Program

The Seniors' Farmers Market Nutrition Program (SFMNP) is administered by state departments of agriculture, aging

and disability services, health and human service, markets, public health, state units on aging, or state food and nutrition services. SFMNP provides coupons to low-income older individuals to purchase fresh, unprepared foods at farmers' markets, roadside stands, and community-supported agriculture programs. It provides eligible older adults with local, seasonal access to fresh fruits, vegetables, and herbs.

## Medicaid and Nutrition Services

The Social Security Act suggests seven core HCBS waiver program services: case management, homemaker services, home health aide services, personal care services, adult day health, rehabilitation, and respite care. Note that nutrition service is not a core Medicaid service. Older persons who are eligible for nursing home placement are not usually able to shop for food, store food safely, or plan and prepare nutritionally appropriate meals. Thus a strong argument can be made to fund all or some meals and nutrition services based on health and nutrition risk criteria. Yet only 38 states include meals or nutrition services among the specified benefits available through Medicaid waivers. Approved nutrition services include home-delivered meals, nutrition risk reduction counseling, and nutritional supplements as appropriate.

## ASSISTED LIVING AND SKILLED CARE FACILITIES

Several million older adults live in senior housing of various types, (assisted living or residential care communities, skilled senior apartments, continuing care communities, independent retirement living). Some sites have supportive services available to their residents, including meals and services through the older adult nutrition program.

**Assisted living communities (ALCs)** generally serve the fastest growing population segment—those ages 85 and older. The estimated 33,000 licensed ALCs are home to approximately 1 million persons. They combine housing and personalized supportive and health care for those who need help with ADLs. Often residents move to ALCs when they can no longer safely live alone, have some cognitive impairment, and require supervision and “cueing” about their daily routine. ALCs usually involve the resident's family, neighbors, and friends. Care is provided in ways that promote maximum independence and dignity. Assisted living residences cost less than nursing home care. Residents are encouraged to maintain active social lives with planned activities, exercise classes, religious and social functions, and field trips directed by the facilities. These facilities are not required to provide therapeutic diets and can be a problem for patients with special requirements, such as those with heart failure.

Comprehensive state regulations for food and nutrition services in ALCs are rare, but there is early consensus of what should be regulated (Chao, 2009). Emphasizing that food and nutrition matter at every age, it is essential that

support for nutrition and quality of life extend beyond food availability and safety. Dietitian expertise is needed for nutrition assessment and care planning to meet special needs such as type and amounts of macronutrients and micronutrients, texture modifications, and quality of food choices and presentation.

Surprisingly, fewer than 4% or 1.4 million seniors live in the approximately 15,730 **skilled nursing facilities (SNFs)** or LTC facilities (Centers for Medicare and Medicaid Services, 2010). The percentage of the population that lives in institutional settings, including nursing homes, increases dramatically with age, especially for those older than age 85. These percentages have declined since 1990, likely because of healthier aging, the federal cost-containment policy to rebalance LTC away from nursing homes to HCBS, and increased availability of hospice (He, 2005).

Skilled nursing facilities are federally regulated under the auspices of the Centers for Medicare and Medicaid Services; ALCs are subject to individual state regulations. More residents are there for short-stay, postacute care; thus more comprehensive medical nutrition therapy is needed. Nutritional care within long-term living facilities must be directed toward identifying and responding to changing physiologic and psychological needs over time that protect against avoidable decline. Attractive and palatable food served in an atmosphere that encourages eating independence, or assistance with eating provided when necessary, helps to promote nutritional well-being. For older adults, overall health goals may not warrant implementation of strict therapeutic diets that are often unpalatable and lessen quality of life. In terminal care for hospice patients, interventions include providing comfort foods and emotional support for family and friends.

In 1987 Congress approved reform legislation as a part of the **Omnibus Reconciliation Act (OBRA)** to improve quality of care in SNFs by strengthening standards that must be met for Medicare and Medicaid reimbursement. SNFs are required to conduct periodic assessments to determine the residents' needs; to provide services that ensure residents maintain the highest practical physical, mental and psychological well being; and to ensure that no harm is inflicted. This is accomplished using the **Minimum Data Set (MDS)**, which is part of the federally mandated process for clinical assessment of residents of LTC facilities licensed under Medicare or Medicaid. Section K of the MDS is specific to nutrition and is generally the responsibility of the dietitian to complete, but can be done by nursing staff (Figure 21-4). This form documents "triggers" that may place a resident at nutrition risk and therefore requires an intervention. This assessment must be done at admission and if there is a significant change in the resident's condition such as weight loss or skin breakdown. Reassessment is required quarterly and annually. The entire process is known as the **Resident Assessment Instrument (RAI)**. It provides the individual assessment of each resident's functional capabilities and helps identify problems and develop a care plan.

## CLINICAL SCENARIO

**M**F is an 84-year-old white woman resident in a skilled nursing facility with unintentional weight loss. She was admitted 3 months ago from the hospital after a hip fracture. She had been residing in an independent living facility for several years. She reports she has been eating poorly because of difficulty moving around, being generally uncomfortable, and states, "If I am not active I don't need to eat so much." Intake is less than 50% of regular diet. No problems chewing or swallowing are noted after a speech language pathologist's evaluation. Admission weight was 112 pounds; current weight is 95 pounds. Self-reported height is 5'3"; albumin, 3.2; Hgb/Hct, normal; total cholesterol, 135; and Mini Nutrition Assessment score, 3. Hip scans show slow fracture healing and no improvement in bone density; currently being supplemented with calcium 1000 mg/d and vitamin D 400 IU/d. Blood pressure, 128/80 with furosemide (Lasix); other medications are lorazepam (Ativan), oxydone, senna (Senokot-S), docusate (Colace), and megestrol acetate (Megace).

### Nutrition Diagnostic Statement

Unintentional weight loss related to intake of less than 50% at meals with limited physical activity as evidenced by weight loss of 17 lb.

### Nutrition Care Questions

- Comment on the appropriateness of and use for each medication. Would you suggest any changes or additional medications?
- What strategies could you use to help improve this resident's food and fluid intake?
- What suggestions are appropriate to promote fracture healing and increase bone density?
- Do you suspect that this client is constipated? What would you recommend in terms of food choices to deal with this?

## Nutrition for Health and Fitness

The chapters in this section reflect the evolution of nutritional science, from the identification of nutrient requirements and the practical application of this knowledge to the concepts that relate nutrition to the prevention of chronic and degenerative diseases and optimization of health and performance.

The relationship between nutrition and dental disease has long been recognized. In more recent decades the possibility of reducing the incidence of osteoporosis by emphasizing appropriate nutrition has accumulated supportive evidence. Medical research now shows the role of nutrition on gene expression; dietary intake can turn on or turn off the inflammatory process, a key factor in disease onset and management.

Weight management and exercise form the basis for a great deal of nutrition in health, fitness, and disease prevention. Understanding the role of nutrition in sports and in optimizing performance has led to dietary and exercise practices generally applicable to a rewarding, healthy lifestyle.

The opportunities for members of an affluent society to choose from a great variety of foods has led to an overabundant intake of energy for many individuals. Efforts to reduce body weight, widely pursued with varying degrees of enthusiasm and diligence, are often disheartening, making the knowledge presented here so important. Frustration with dieting and stress often lead to eating disorders, which are increasing in frequency and require attention and understanding from the nutrition professional.

## CHAPTER 22

Lucinda K. Lysen, RD, RN, BSN  
Donna A. Israel, PhD, RD, LD, LPC, FADA

# Nutrition in Weight Management

### KEY TERM

activity thermogenesis (AT)

insulin  
lean body mass (LBM)  
leptin  
lifestyle modification  
lipogenesis  
lipoprotein lipase (LPL)  
liposuction  
metabolic syndrome (MetS)  
morbid obesity  
night-eating syndrome (NES)  
nonalcoholic fatty liver disease (NAFLD)  
nonexercise activity thermogenesis (NEAT)  
obesity  
obesogen  
orlistat  
overweight  
sensory-specific satiety  
sibutramine  
storage fat  
semivolatile organic compounds (SVOCs)  
underweight  
vagus nerve  
very-low-calorie diet (VLCD)  
visceral adipose tissue (VAT)  
white adipose tissue (WAT)  
yo-yo effect

Sections of this chapter were written by Molly Gee, MED, RD for the previous edition of this text.

Body weight is the sum of bone, muscle, organs, body fluids, and adipose tissue. Some or all of these components are subject to normal change as a reflection of growth, reproductive status, variation in physical activity, and the effects of aging. Consistent body weight is orchestrated by neural, hormonal, and chemical mechanisms as well as individual genetic polymorphisms that balance energy intake and expenditure within fairly precise limits (de Luis et al., 2006). Abnormalities of these complex mechanisms can result in weight fluctuations, most commonly overweight and obesity.

On the other end of the weight spectrum is underweight. Although the inability to gain weight can also be a primary problem, low body weight is usually secondary to a disease state, an eating disorder, or a psychological problem (see Chapter 23). In the elderly or in children, unintentional weight loss can be especially detrimental and should be addressed early to prevent malnutrition or other undesirable consequences.

## BODY WEIGHT COMPONENTS

*Body weight* is often described in terms of its composition, and different models have been advanced to estimate body fat. Body composition is discussed in detail in Chapter 6. Traditionally, a two-compartment model divides the body into **fat mass**, the fat from all body sources including the brain, skeleton, and adipose tissue, and **fat-free mass (FFM)**, which includes water, protein, and mineral components (Figure 22-1). The proportions of FFM are relatively constant from person to person.

Although FFM is often used interchangeably with the term *lean body mass*, it is not exactly the same. **Lean body mass (LBM)** is muscle. LBM is higher in men than in women, increases with exercise, and is lower in older adults. It is the major determinant of the resting metabolic rate (RMR). It follows that a decrease in LBM could hinder the progress of weight loss. Therefore, to achieve long-term weight-loss, the loss of fat mass while maintaining FFM and RMR is desirable (Stiegler and Cunliffe, 2006). Water,

which makes up 60% to 65% of body weight, is the most variable component of LBM, and the state of hydration can induce fluctuations of several pounds.

### Body Fat

Total body fat is the combination of “essential” and “storage” fats, usually expressed as a percentage of total body weight that is associated with optimum health. Muscle and even skeletal mass adjust to some extent to support the burden of adipose tissue.

**Essential fat**, necessary for normal physiologic functioning, is stored in small amounts in the bone marrow, heart, lung, liver, spleen, kidneys, muscles, and the nervous system. In men, approximately 3% of body fat is essential. In women, essential fat is higher (12%) because it includes body fat in the breasts, pelvic regions, and thighs that support the reproductive process.

**Storage fat** is the energy reserve, primarily as triglycerides (TGs) in adipose tissue. This fat accumulates under the skin and around the internal organs to protect them from trauma. Most storage fat is “expendable.” The fat stores in adipocytes are capable of extensive variation. This allows for the changing requirements of growth, reproduction, aging, environmental and physiologic circumstances, the availability of food, and the demands of physical activity. Total body fat (essential fat plus storage fat) as a percentage of body weight that is associated with optimal health is 10% to 25% in men and 18% to 30% in women, although professional and elite athletes have body fat levels much lower than those of the average person, with an average for optimal fitness of 12% to 18% for men and 16% to 25% for women (Wilmore et al., 1986).

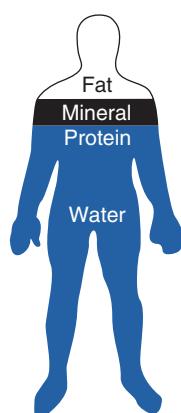

### Adipose Tissue Composition

Adipose tissue exerts a profound influence on whole-body homeostasis. Adipose tissue is located primarily under the skin, in the mesenteries and omentum, and behind the peritoneum. Although it is primarily fat, it also contains small amounts of protein and water. **White adipose tissue (WAT)** stores energy as a repository for TGs, serves as a cushion to protect abdominal organs, and insulates the body to preserve heat. Carotene gives it a slight yellow color.

**Brown adipose tissue (BAT)** is a rapid source of energy for infants, found primarily in the scapular and subscapular areas as 5% of their body weight. The brown color is due to extensive vascularization for energy and heat production. Its function in humans remains poorly understood, and by adulthood BAT is no longer available (Hansen and Kristiansen, 2006).

### Adipocyte Size and Number

The mature fat cell (**adipocyte**) consists of a large central lipid droplet surrounded by a thin rim of cytoplasm, which contains the nucleus and the mitochondria. These cells can store fat equal to 80% to 95% of their volume. Gains in weight and adipose tissue occur by increasing the number of cells, the size of cells as lipid is added, or a combination of the two.

**FIGURE 22-1** The components of fat-free mass in the body.

**Hyperplasia** (increased number of cells) occurs as a normal growth process during infancy and adolescence. Cell number increases in both lean and obese children into adolescence, but the number increases faster in obese children. In teens and adults, increases in fat cell size are more common, but hyperplasia can also occur after the fat content of existing cells has reached capacity.

During normal growth, the greatest percentage of body fat (approximately 25%) is set by 6 months of age. In lean children, fat cell size then decreases; this decrease does not occur in obese children. At the age of 6 years in lean children, **adiposity rebound** occurs, especially in girls, with an increase in body fat. An early adiposity rebound occurring before 5.5 years is predictive of a higher level of adiposity at 16 years of age and in adulthood; a period of later rebound is correlated with normal adult weight (Rolland-Cachera, 2005).

With **hypertrophy** (increased cell size), fat depots can expand as much as 1000 times at any age as long as space is available. With weight loss as a result of trauma, illness, or starvation, fat cell size decreases but cell numbers remain the same (Björntorp and Sjöström, 1971). Although weight loss of any amount in severely obese individuals improves basic adipocyte physiology, a weight loss of at least 5% is required to decrease fat cell size (de Luis et al., 2006; Varady et al., 2009).

## Fat Storage

Most depot fat comes directly from dietary TGs. The fatty acid composition of adipose tissue mirrors the fatty acid composition of the diet. Even excess dietary carbohydrate and protein are converted to fatty acids in the liver by the comparatively inefficient process of **lipogenesis**. Under normal conditions, little dietary carbohydrate is used to produce adipose tissue; it requires three times more energy to convert excess energy from carbohydrate to fat storage as that from dietary fat. Recommendations simply to reduce dietary fat are ineffective; total reduction of calories is needed for weight loss to occur.

**Semivolatile organic compounds (SVOCs)** accumulate in adipose tissues from exposure to toxins, chemicals, and pesticides.

When adipose tissue is mobilized during weight loss, SVOCs are released. See *Clinical Insight: What's in That Fat When You Lose It?* Obese women should lose weight before becoming pregnant because the effect of SVOCs on the developing fetal brain is not yet known (see Chapter 16).

## Lipoprotein Lipase

Dietary TG is transported to the liver by chylomicrons. Endogenous TGs, synthesized in the liver from free fatty acids, travel as part of very-low-density lipoprotein particles. The enzyme **lipoprotein lipase (LPL)** moves lipid from the blood into the adipose cell where it hydrolyzes TG into free fatty acids and glycerol. Glycerol proceeds to the liver; fatty acids enter the adipocyte and are reesterified into TGs. When needed by other cells, TGs are hydrolyzed once again

## CLINICAL INSIGHT

### What's in That Fat

### When You Lose It?

*Sheila Dean, DSc, RD, LD, CCN, CDE*

The role of toxins in obesity development and later fat loss is becoming of increasing concern as the emerging evidence forms a plausible link between toxins and obesity. Exposure to toxins comes from two main sources: the environment (external toxins) and the gut (breakdown products of our metabolism) or internal toxins. Both can overload the body's endogenous detoxification mechanisms. When this happens these toxins are stored in the body's depot fat. This can necessitate the deposition of more fat and obesity development, or, in the case of weight or fat loss, the release of these toxins can interfere with the body's functioning and even its ability to continue to lose more fat (Barouki, 2010; Imbeault et al., 2002; Tremblay et al., 2004).

Toxins alter metabolism, disrupt endocrine function, damage the mitochondria, increase inflammation and oxidative stress, lower thyroid hormones, and alter circadian rhythms and the autonomic nervous system. These all interfere with key weight control mechanisms in the body. Using a comprehensive approach to obesity, including the assessment and treatment of toxin-mediated effects can result in more effective body fat and weight management. Simple lifestyle choices, as well as medical detoxification, can reduce exposure to toxins and enhance mobilization and elimination of stored and external toxins (Hyman, 2006).

to fatty acids and glycerol by **hormone-sensitive lipase (HSL)** within the adipose cell; they are then released into the circulation.

Hormones affect LPL activity in different adipose tissue regions. Estrogens stimulate LPL activity in the gluteofemoral adipocytes and thus promote fat storage in this area for childbearing and lactation. In the presence of sex steroid hormones, a normal distribution of body fat exists. With a decrease in sex steroid hormones, as occurs with menopause or gonadectomy, there is a tendency to increase central obesity.

## REGULATION OF BODY WEIGHT

Regulatory systems such as neurochemicals, body-fat stores, protein mass, hormones, and post-ingestion factors all play a role in regulating intake and weight. Regulation takes place on both a short- and a long-term basis. Short-term regulation governs consumption of food from meal to meal; long-term regulation is controlled by the availability of adipose stores and hormone responses.

## Metabolic Rate and Voluntary Activity

The RMR explains 60% to 70% of total energy expenditure. RMR declines with age or with restriction of energy intake. When the body is suddenly deprived of adequate energy from involuntary or deliberate starvation, the RMR conserves energy by dropping rapidly, by as much as 15% in 2 weeks.

**Activity thermogenesis (AT)** is the energy expended in voluntary activity, the most variable component of energy expenditure. Under normal circumstances physical activity accounts for 15% to 30% of total energy expenditure. Yet all activity counts. **Nonexercise activity thermogenesis (NEAT)** is the energy expended for everything that is not sleeping, eating, or sportslike exercise. It includes going to work, typing, doing yard work, toe-tapping, even fidgeting (see Chapter 2). NEAT and a sedentary lifestyle may have profound importance in weight management. NEAT varies as much as 2000 kcal/day between individuals (Levine et al., 2007). To reverse obesity, individual strategies should promote standing and ambulating for 2.5 hours per day and should also reengineer work, school, and home environments to support a more active lifestyle (Levine, 2007).

## Short- and Long-Term Regulation

Short-term controls are concerned primarily with factors governing hunger, appetite, and satiety. Satiety is associated with the postprandial state when excess food is being stored. Hunger is associated with the postabsorptive state when those stores are being mobilized. Physical triggers for hunger are much stronger than those for satiety, and it is easier to override the signals for satiety.

When either overfeeding or underfeeding occurs, younger individuals exhibit spontaneous **hypophagia** (under-eating) or **hyperphagia** (overeating) accordingly. Older individuals do not have the same responsiveness; they are more vulnerable to unexplained weight losses or gains because they are unable to control spontaneous, short-term changes in food intake.

Long-term regulation seems to involve a feedback mechanism in which a signal from the adipose mass is released when “normal” body composition is disturbed, as when weight loss occurs. **Adipocytokines** are proteins released by the adipose cell into the bloodstream that act as signaling molecules. Younger persons have more responsiveness to this feedback than do older adults. See Table 22-1 and Focus On: Signals from a Host of Hormones.

## Set Point Theory

Fat storage in nonobese adults appears to be regulated in a manner that preserves a specific body weight. In both animals and humans, deliberate efforts to starve or overfeed are followed by a rapid return to the original body weight, a “set point.” Body weight remains remarkably stable from internal regulatory mechanisms that are genetically determined. Some studies suggest that body weight can be displaced only temporarily and that RMR lowers, resulting in

## FOCUS ON

### Signals from a Host of Hormones

A host of hormones—insulin, leptin, adiponectin, and ghrelin, among others—communicate with the hypothalamus to control a person’s intake and weight. These regulatory hormones govern feeding in response to signals originated in affected body tissues.

**Insulin** controls the amount of glucose in the blood by moving it into the cells for energy. **Leptin**, which is produced mainly by fat cells, contributes to long-term fullness by sensing the body’s overall energy stores. **Adiponectin** is also made by fat cells and apparently helps the body respond better to insulin by boosting metabolism. **Ghrelin**, the hunger hormone, tells the brain when the stomach is empty, prompting hunger pangs and a drop in metabolism.

The stomach communicates with the brain via the **vagus nerve**, part of the autonomic nervous system that travels from the brain to the stomach. When filled with food or liquid, the stomach’s stretch receptors send a message to the brain indicating satiety. Gastric bypass surgery reduces the stomach to the size of an egg, and triggers a sharp drop in ghrelin levels, which lessens hunger and oral intake (Blackburn, 2008). Unfortunately, traditional dieting tends to boost ghrelin levels.

a regain of lost weight; other studies have not shown this adaptive metabolic response.

## WEIGHT IMBALANCE: OVERWEIGHT AND OBESITY

Overweight occurs as a result of an imbalance between food consumed and physical activity. Obesity is a complex issue related to lifestyle, environment, and genes. Environmental and genetic factors have a complex interaction with psychological, cultural, and physiologic influences. Over the years, many hypotheses have evolved to explain why some people become fat and others remain lean, and why it is so difficult for reduced-obese persons to maintain weight loss. No single theory can completely explain all manifestations of obesity or apply consistently to all persons.

## Prevalence

The United States has the highest prevalence of obesity among the developed nations. However, increases in the prevalence of overweight and obesity have been observed throughout the world. The international trend is often called “globesity.”

The estimates of overweight and obesity among children and adults are based on measured weights and heights from the National Health and Nutrition Examination Survey

**TABLE 22-1****Regulatory Factors Involved in Feeding and Weight Management**

<b>Brain Neurotransmitters</b>	<b>Characteristics and Function</b>
Norepinephrine and dopamine	Released by the SNS in response to dietary intake; mediate the activity of areas in the hypothalamus that govern feeding behavior. Fasting and semistarvation lead to decreased SNS activity and increased adrenal medullary activity with a consequent increase in epinephrine, which fosters substrate mobilization. Dopaminergic pathways in the brain play a role in the reinforcement properties of food.
Serotonin, neuropeptide Y, and endorphins	Decreases in serotonin and increases in neuropeptide Y have been associated with an increase in carbohydrate appetite. Neuropeptide Y increases during food deprivation; it may be a factor leading to an increase in appetite after dieting. Preferences and cravings for sweet, high-fat foods observed among obese and bulimic patients involve the endorphin system.
CRF	Involved in controlling adrenocorticotropic hormone release from the pituitary gland, CRF is a potent anorexic agent and weakens the feeding response produced by norepinephrine and neuropeptide Y. CRF is released during exercise.
<b>Gut Hormones</b>	
<b>Incretins</b>	
CCK	Gastrointestinal peptides increase the amount of insulin released from the beta cells of the pancreas after eating, even before blood glucose levels become elevated. They also slow the rate of absorption by reducing gastric emptying and may directly reduce food intake. Incretins also inhibit glucagon release from the alpha cells of the pancreas. (See GLP-1 and GIP.)
Bombesin	Released by the intestinal tract when fats and proteins reach the small intestine, receptors for CCK have been found in the gastrointestinal tract and the brain. CCK causes the gallbladder to contract and stimulates the pancreas to release enzymes. At the brain level, CCK inhibits food intake.
Enterostatin	Released by enteric neurons; reduces food intake and enhances the release of CCK.
Adiponectin	A portion of pancreatic lipase involved specifically with satiety following the consumption of fat. An adipocytokine secreted by the adipose tissue that modulates glucose regulation and fatty acid catabolism. Levels of this hormone are inversely correlated with BMI. The hormone plays a role in metabolic disorders such as type 2 diabetes, obesity, and atherosclerosis. Levels drop after gastric bypass surgery for up to 6 months (Couce et al., 2006).
Glucagon	Increased secretion of glucagon is caused by hypoglycemia, increased levels of norepinephrine and epinephrine, increased plasma amino acids, and cholecystokinin. Decreased secretion of glucagon occurs when insulin or somatostatin is released.
Apolipoprotein A-IV	Synthesized and secreted by the intestine during lymphatic secretion of chylomicrons. After entering the circulation, a small portion of apolipoprotein A-IV enters the CNS and suppresses food consumption.
Fatty acids	Free fatty acids, triglycerides, and glycerol are factors that also affect uptake of glucose by peripheral tissues.
GLP-1 and GIP	Released by intestinal mucosa in presence of meals rich in glucose and fat; stimulate insulin synthesis and release; GLP-1 decreases glucagon secretion, delays gastric emptying time, and may promote satiety; examples of incretin hormones.
Insulin	Acts in the CNS and the periphery nervous system to regulate food intake. Insulin is involved in the synthesis and storage of fat. Impaired insulin activity may lead to impaired thermogenesis. It is possible that obese persons with insulin resistance or deficiency have a defective glucose disposal system and a depressed level of thermogenesis. The greater the insulin resistance, the lower the thermic effect of food. Fasting insulin levels increase proportionately with the degree of obesity; however, many obese persons demonstrate insulin resistance because of a lack of response by insulin receptors, impaired glucose tolerance, and associated hyperlipidemia. These sequelae can usually be corrected with weight loss.
Leptin	An adipocytokine secreted by the adipose tissue, correlated with percent of body fat. Primary signal from energy stores; in obesity loses the ability to inhibit energy intake or to increase energy expenditure (Enriori et al., 2006). Compared with men, women have significantly higher concentrations of serum leptin.

**TABLE 22-1****Regulatory Factors Involved in Feeding and Weight Management—cont'd**

<b>Brain Neurotransmitters</b>	<b>Characteristics and Function</b>
Resistin	An adipocytokine expressed primarily in adipocytes; antagonizes insulin action (Goldstein and Scalia, 2007).
Ghrelin	Produced primarily by the stomach; acts on the hypothalamus to stimulate hunger and feeding. Ghrelin levels are highest in lean individuals and lowest in the obese. Increased levels are seen in people who are dieting, and suppressed levels are noted after gastric bypass, possibly counteracted by adiponectin (Couce et al., 2006).
PYY <sub>3-36</sub>	Secreted by endocrine cells lining the small bowel and colon in response to food; a “middle man” in appetite management. PYY seems to work opposite from ghrelin; it induces satiety.
IL-6 and TNF- $\alpha$	Both are gut hormones. Cytokines secreted by adipose tissue and participate in metabolic events. Impair insulin signals in muscle and liver. Levels are proportional to body fat mass (Thomas et al., 2010).
<b>Other Hormones</b>	
Thyroid hormones	Modulate the tissue responsiveness to the catecholamines secreted by the SNS. A decrease in triiodothyronine lowers the response to SNS activity and diminishes adaptive thermogenesis. Women should be tested for hypothyroidism, particularly after menopause. Weight regain after weight loss may be a function of a hypometabolic state; energy restriction produces a transient, hypothyroid, hypometabolic state.
Visfatin	An adipocytokine protein secreted by visceral adipose tissue that has an insulin-like effect; plasma levels increase with increasing adiposity and insulin resistance (Stevens and Vidal-Puig, 2006).
Adrenomedullin	A new regulatory peptide secreted by adipocytes as a result of inflammatory processes.

BMI, Body mass index; CCK, cholecystokinin; CNS, central nervous system; CRF, corticotropin-releasing factor; GIP, glucose-dependent insulinotropic peptide; GLP-1, glucagon-like peptide 1; IL-6, interleukin-6; PYY<sub>3-36</sub>, peptide YY<sub>3-36</sub>; SNS, sympathetic nervous system; TNF- $\alpha$ , tumor necrosis factor- $\alpha$ .

(NHANES), conducted by the National Center for Health Statistics (Centers for Disease Control and Prevention [CDC], 2007). An estimated 66% of U.S. adults are overweight, and 32% are obese. In Canada 36% of adults are overweight and another 23% are obese (Statistics Canada, 2010). In Europe between 15% and 25% of adults are obese. In the United States, prevalence of obesity is higher in black and Hispanic populations, especially among Mexican-American women (CDC, 2007; Figure 22-2).

Unfortunately, children are not immune to the epidemic. Obesity is now the most common pediatric nutritional problem in the United States. Nearly 1/3 of children and adolescents between ages 2 and 19 years are overweight. See *New Directions: Organizing to Solve the Childhood Obesity Problem “Within a Generation.”*

## Causes of Overweight and Obesity

### Heredity and Nutrigenomics

Many hormonal and neural factors involved in weight regulation are determined genetically. These include the short- and long-term signals that determine satiety and feeding activity. Small defects in their expression or interaction could contribute significantly to weight gain.

The number and size of fat cells, regional distribution of body fat, and RMR are also influenced by genes. Studies of

twins confirm that genes determine 50% to 70% of the predisposition to obesity (Prentice, 2005). Although numerous genes are involved, several have received much attention—the Ob gene, the adiponectin (ADIPOQ) gene, the FTO gene, and the  $\beta 3$ -adrenoreceptor gene. The Ob gene produces leptin. Mutations in the Ob gene, leptin receptor (LEPR), or ADIPOQ genes can result in obesity or metabolic syndrome (MetS), especially if diet provides too much saturated fat (Ferguson et al., 2010). The  $\beta 3$ -adrenoreceptor gene, located primarily in the adipose tissue, is thought to regulate RMR and fat oxidation in humans. The FTO gene predisposes to diabetes by its effect on body mass (Frayling et al., 2007).

Nutritional or lifestyle choices can activate or deactivate those obesity-triggering genes. Thus the answer to successful long-term weight management is likely to include behavioral application of individual genetics. One day soon, specific deoxyribonucleic acid tests may give accurate predictions about an individual's response to a low-fat diet, a low-carbohydrate diet, or a balanced diet (Ashley et al., 2010). Nutritional counseling can truly be personalized (see Chapter 5).

### Inadequate Physical Activity

Lack of exercise and a generally sedentary lifestyle, compounded by chronic overeating, are also causes of weight

## NEW DIRECTIONS

### Organizing to Solve the Childhood Obesity Problem “Within a Generation”

Because the number of obese children in the US has tripled since 1980, and obesity now rivals smoking as the largest cause of preventable death and disease (Ogden et al., 2002 and Ogden et al., 2010), a new foundation was launched in the spring of 2010 to address this serious epidemic of childhood obesity. This foundation—*Partnership for a Healthier America* has as its mission, the simple concept that children should have good, nutritious food to eat and the chance to be physically active every day in order to become healthy adults.

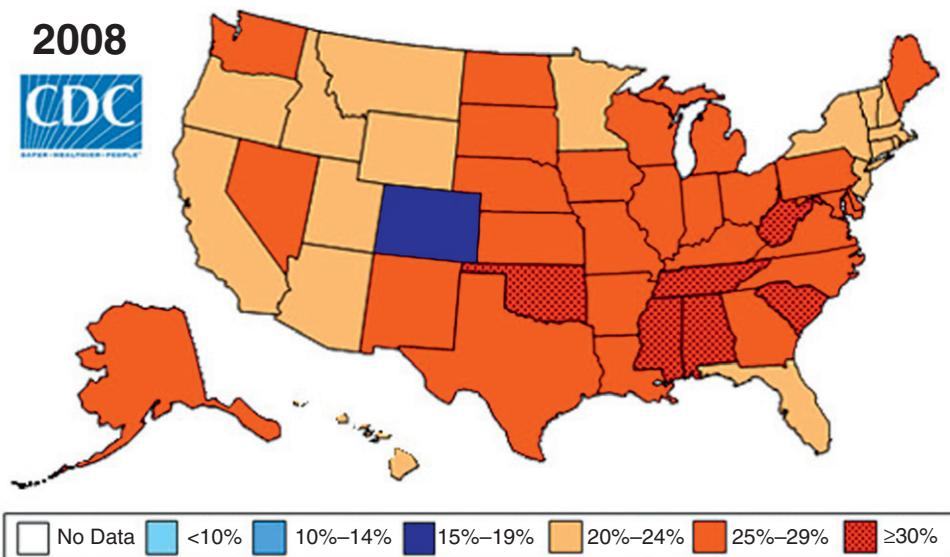

The objectives of the partnership are to support the national goal of solving the childhood obesity challenge “within a generation” set by First Lady Michelle Obama who also serves as Honorary Chair of the new organization. The Partnership brings together the public and private sectors, organizations, business and thought leaders, the media, and states and local communities to make meaningful and

measurable commitments for fighting childhood obesity. The plan has four pillars:

- Offering parents the tools and information they need to make healthy choices for their children
- Getting healthier food into the nation’s schools
- Ensuring that all families have access to healthy, affordable food in their communities
- Increasing opportunities for children to be physically active, both in and out of school.

The partnership will support, unite and inspire families from every corner of the United States to implement and sustain the 4 pillar plan. The initiative was started with the *Let’s Move!* Campaign. [www.letsmove.gov/](http://www.letsmove.gov/)

The White House Task Force on Childhood Obesity—Report to the President “Solving the Problem of Childhood Obesity within a Generation” (Task Force, 2010) can be accessed at [www.nj.gov/health/fhs/shapingnj/pdf/wh\\_obesity\\_report.pdf](http://www.nj.gov/health/fhs/shapingnj/pdf/wh_obesity_report.pdf)

**FIGURE 22-2** Prevalence of obesity among U.S. adults in 2008. (*Centers for Disease Control and Prevention (CDC) Behavioral Risk Factor Surveillance System Survey, June 13, 2010.*)

gain. The sedentary nature of society is a factor in the growing problem of obesity. Fewer people are exercising, and more time is being spent in low-energy, screen-watching activities such as watching television or movies, using the computer, playing video games, and sitting in cars driving to work or events.

#### Inflammation

Adipose tissue actively secretes a wide range of pro- and antiinflammatory cytokines that are influenced by

single-nucleotide polymorphisms in the cytokine genes; effects include insulin insensitivity, hyperlipidemia, muscle protein loss, and oxidant stress (Grimble, 2010). Scientists have found a direct relationship between obesity and inflammatory diseases such as cardiovascular disorders, some cancers, and type 2 diabetes.

Metabolic signals are triggered in the hypothalamus of obese individuals, laying the groundwork for chronic inflammation and tissue damage during a prolonged period. In mice fed a high-fat diet, the “master switch” of

inflammation turns on the hypothalamus. In humans, chronic overeating “flips on” the inflammation switch, leading to weight gain and insulin resistance. In insulin-resistant individuals on a weight-loss diet, ezetimibe (Zetia) reduces hepatic steatosis and inflammatory markers (Chan et al., 2010).

A combined approach of diet and drug is likely to improve health outcomes. Simple diet and lifestyle changes can alter obesity-related inflammation. Foods such as oranges are antiinflammatory, whereas cream may be proinflammatory and red wine is neutral. Genotypic factors influence the effectiveness of immunonutrients; antioxidants and ω-3 polyunsaturated fatty acid decrease the intensity of the inflammatory process (Grimble, 2010). For further information on inflammation, see Chapter 6.

### Sleep, Stress, and Circadian Rhythms

Shortened sleep alters the endocrine regulation of hunger and appetite. Hormones that affect appetite take over and may promote excessive energy intake. Thus recurrent sleep deprivation can modify the amount, composition, and distribution of food intake and may contribute to the obesity epidemic. It is estimated that more than 50 million Americans suffer from sleep deprivation. Others may have shift work or exposure to bright light at night, increasing the disruption of circadian rhythms and enhancing the prevalence of adiposity (Garaulet et al., 2010).

There is also a relationship between sleep, disrupted circadian rhythm, genes, and the metabolic syndrome. The cellular lipid membrane content of monounsaturated fatty acids from the diet may be protective against development of metabolic syndrome (Garaulet et al., 2009). Stress is another factor. Cortisol is released under stress; it stimulates insulin release to maintain blood glucose levels in the “fight-or-flight” response. Thus an increase in appetite occurs. Cortisol levels are typically high in the early morning and low around midnight. Individuals with **night-eating syndrome (NES)** have a delayed circadian rhythm of meal intake as a result of genetically programmed neuroendocrine factors, including altered cortisol levels (Stunkard and Lu, 2010).

### Taste, Satiety, and Portion Sizes

Food and its taste elements evoke pleasure responses. The endless variety of food available at any time at a reasonable cost can contribute to higher calorie intake; people eat more when offered a variety of choices than when a single food is available. Normally, as foods are consumed, they become less desirable; this phenomenon is known as **sensory-specific satiety**. Overriding this principle is the “all-you-can-eat buffet” in which the diner reaches satiety for one food but has many choices for the “next course.” Although sensory-specific satiety can promote the intake of a varied or nutritionally balanced diet, it can also lead to overconsumption of energy.

Active overeating is partly the result of excessive portion sizes that are now accepted as normal. The portions and calories that restaurants and fast-food outlets offer in one

meal often exceed a person’s energy needs for the entire day. High intake of energy-dense food can also be problematic.

### Obesogens

**Obesogens** are chemical compounds foreign to the body that act to disrupt the normal metabolism of lipids, ultimately resulting in over fatness and obesity (Grun and Blumberg, 2006). Obesogens can be called “endocrine disruptors” in that they alter lipid homeostasis and fat storage, change metabolic set points, disrupt energy balance, or modify the regulation of satiety and appetite to promote accumulation of fat and obesity. Examples of suspected obesogens in the environment and food supply are bisphenol A and phthalates which are found in many plastics used in food packaging and which migrate into foods processed or stored in them (Grun, 2010). See *Clinical Insight: What’s in That Fat When You Lose It?*

### Viruses and Pathogens

In the last two decades, at least ten adipogenic pathogens have been identified, including viruses, scrapie agents (spongiform encephalopathies from sheep or goats), bacteria, and gut microflora (Pasarica and Dhurandhar, 2007). Whether or not “infectobesity” is a relevant contributor to the obesity epidemic remains to be determined. A human adenovirus, adenovirus-36, is capable of inducing adiposity in experimentally infected animals by increasing the replication, differentiation, lipid accumulation, and insulin sensitivity in fat cells and reduces leptin secretion and expression (van Ginneken et al., 2009).

### Assessment

**Overweight** is a state in which the weight exceeds a standard based on height. **Obesity** is a condition of excessive fatness, either generalized or localized. Overweight and obesity usually parallel each other, but it is possible to be overweight according to standards, but not be overfat or obese. It is also possible to have excessive fatness, and yet not be overweight.

It is important to assess body fatness or adiposity to determine the health risks as explained in detail in Chapter 6. Clinically practical assessment tools are: 1) the **body mass index (BMI)** or  $W/H^2$ , in which W= weight in kg and H = height in meters, 2) the waist circumference, 3) the waist-to-hip ratio, and 4) the Deurenberg equation which predicts body fat percentage (Deurenberg and Deurenberg-Yap, 2003).

The NIH guidelines classify individuals with a BMI of 25 as overweight and those with a BMI of 30 or more as obese (Table 22-2). Optimal BMI for longevity varies with race, gender, and age. BMI that increases over time have a substantial effect on health outcomes (Newby et al., 2006). See Chapter 6 and Appendix 23.

Waist circumference of more than 40 inches in men and more than 35 inches in women signifies increased risk, equivalent to a BMI of 25 to 34. When waist circumference and percentage of fat are both high, they are significant predictors of heart failure and other risks associated with

obesity (Nicklas et al., 2007). Waist circumference is a strong correlate of insulin sensitivity index in older adults; measurement of waist circumference is helpful to assess disease risk (Racette et al., 2006). Waist/hip ratio (WHR) is a measurement in which a ratio of more than 0.8 for women and 1 for men is also associated with high risk for cardiovascular events.

**TABLE 22-2****Classification of Overweight and Obesity**

Classification	Body Mass Index (kg/m <sup>2</sup> )
Underweight	<18.5
Normal	18.5-24.9
Overweight	25.0-29.9
Obesity, class I	30.0-34.9
Obesity, class II	35.0-39.9
Extreme obesity, class III	>40

From National Institutes of Health, National Heart, Lung, and Blood Institute: Clinical guidelines on the identification, evaluation, and treatment of overweight and obesity in adults—the evidence report, NIH Publication No. 98-4083, 1998.

The Deurenberg equation using the BMI, age, and gender of an individual to determine body fatness is as follows (Deurenberg and Deurenberg-Yap, 2003):

$$\% \text{ body fat} = (1.2 \times \text{BMI}) + (0.23 \times \text{age in yrs}) - (10.8 \times G) - 5.4$$

G = 1 for male; G = 0 for female

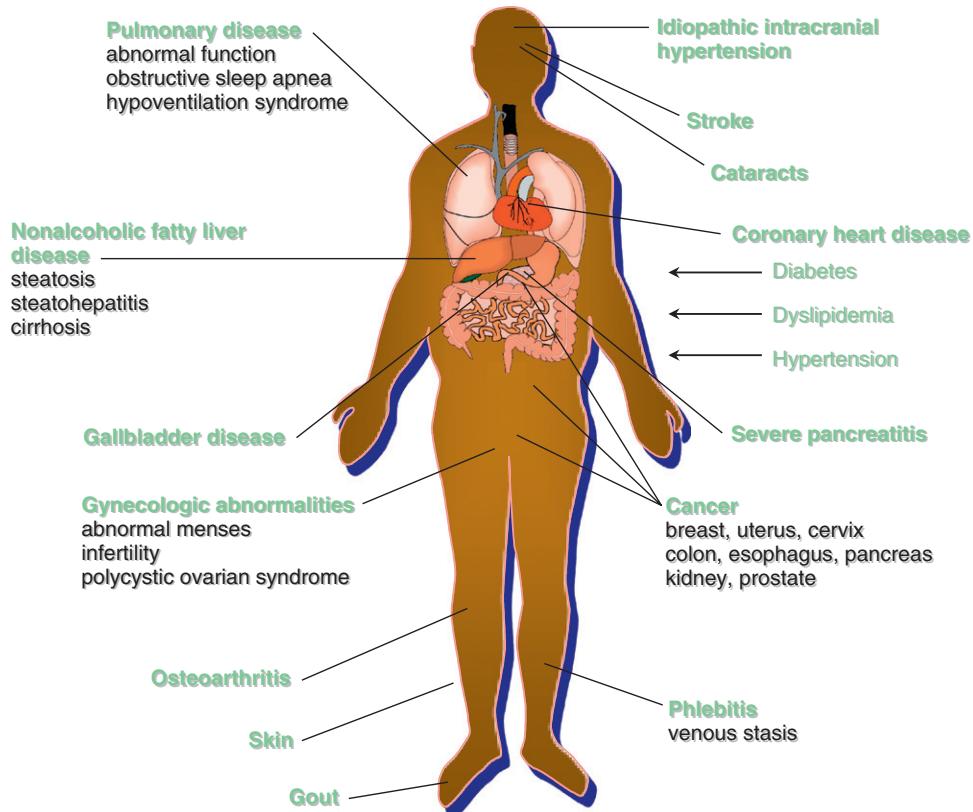

For example if BMI = 28, age = 21 and G = female:

$$\begin{aligned}\% \text{ body fat} &= (1.2 \times 28) + (0.23 \times 21) - (10.8 \times 0) - 5.4 \\ &= 33.6 + 4.83 - 0 - 5.4 \\ &= 33\%\end{aligned}$$

A body fat percentage of 20% to 25% or more in a male and 25% to 32% or more in a female is usually considered to be excessive and associated with the metabolic and health risks of obesity.

**Health Risks and Longevity**

In general, obesity can be viewed as metabolically unhealthy. Chronic diseases such as heart disease, type 2 diabetes, hypertension, stroke, gallbladder disease, infertility, sleep apnea, hormonal cancers, and osteoarthritis tend to worsen as the degree of obesity increases (Figure 22-3).

**Medical Complications of Obesity**

**FIGURE 22-3** The medical complications of obesity are extensive. (Reprinted with permission from Delichatsios HK: Obesity assessment in the primary care office, Harvard Medical School. 23rd Annual International Conference—Practical approaches to the treatment of obesity, Boston, June 18-20 2009, GL Blackburn, course director.)

A subset of obese persons who are metabolically normal seems to exist. This subgroup has uncomplicated, early-onset obesity, hyperplastic adipocytes, and normal quantities of visceral fat. However, they are the exception and not the rule. Estimates using mortality data from the NHANES surveys show that thousands of deaths are related to obesity. Moderately high BMI in adolescence is correlated with premature death in younger and middle-age women (van Dam et al., 2006). Increased adiposity and reduced physical activity are strong independent risk factors for death in women.

A huge study of more than 100,000 U.S. men and women age 50 and older who took part in a 9-year Cancer Prevention Study II Nutrition Cohort found that obesity is linked to death. Those individuals with very large waists (at least 47 inches in men and 43 inches in women) had twice the risk of mortality compared with those with small waists (35 inches or less for men and 30 inches or less for women). This was true at all BMIs, but was strongest in women of normal weight, indicating the danger of waistline, abdominal, or visceral fat (Jacobs et al., 2010).

Several large studies have determined that the optimal BMI with the least risk for mortality is a BMI of 23 to 24.9. BMI above or below this range seems to increase mortality risk (Adams et al., 2006; Jee et al., 2006). The optimal range for longevity appears to be within the range of 20.5 to 24.9.

**Nonalcoholic fatty liver disease (NAFLD)** is associated with obesity and may progress to end-stage liver disease. Obesity is also a risk factor for cancer, infertility, poor wound healing, and poor antibody response to hepatitis B vaccine. Thus the costs of obesity are staggering. Health economists estimate costs of overweight and obesity to account for nearly 10% of total annual U.S. medical expenditures. The Internal Revenue Service issued a rule in 2002 qualifying obesity as a disease, allowing taxpayers to claim weight loss expenses as a medical deduction if undertaken to treat an existing disease.

The U.S. government recognizes the immense effect of obesity on the health and financial well-being of its citizens. Healthy People 2020 objectives also identify the implications of overweight and obesity (see Chapter 12). The objectives include targets to increase the proportion of adults who are at a healthy weight and to reduce the proportion of adults, children, and adolescents who are obese. Overweight adolescents often become obese adults; obese individuals are at increased risk for **comorbidities** of type 2 diabetes, hypertension, stroke, certain cancers, infertility, and other conditions.

### Fat Deposition and the Metabolic Syndrome

Regional patterns of fat deposit are controlled genetically and differ between and among men and women. Two major types of fat deposition are currently recognized: excess subcutaneous truncal-abdominal fat (the apple-shaped **android fat distribution**) and excess gluteofemoral fat in thighs and buttocks (the pear-shaped **gynoid fat distribution**). The android shape is more common among men. The fat

deposits support the demands of pregnancy and lactation. Women with the gynoid type of obesity do not develop the impairments of glucose metabolism in those with an android deposition. Postmenopausal women more closely follow the male pattern of abdominal fat stores.

Visceral obesity, or excessive **visceral adipose tissue (VAT)** under the peritoneum and in the intraabdominal cavity, is highly correlated with insulin resistance. Individuals diagnosed with the **metabolic syndrome (MetS)** have three or more of the following abnormalities: waist circumference of more than 102 cm (40 in) in men and more than 88 cm (35 in) in women, serum TGs of at least 150 mg/dL, high-density lipoprotein (HDL) level less than 40 mg/dL in men and less than 50 mg/dL in women, blood pressure 135/85 mm Hg or higher, or fasting glucose 100 mg/dL or higher. Increased visceral fat is a risk factor for coronary artery disease, dyslipidemia, hypertension, stroke, type 2 diabetes, and MetS (Goodpaster, 2005; Gower et al., 2006). By the same token, both VAT and low cardiorespiratory fitness (CRF) levels are associated with a deteriorated cardiometabolic risk profile. Achieving a low level of VAT and a high level of CRF are important targets for cardiometabolic health (Rheaume, 2011).

### Calorie Restriction and Longevity

Balancing energy intake and energy expenditure is the basis of weight management throughout life. **Lifestyle modification**, becoming aware of eating behavior triggers to manage them more effectively, is vital for permanent change to occur. A key recommendation is to prevent gradual weight gain over time by making small decreases in overall calories and increasing physical activity. Patterns of healthful eating and regular physical activity should begin in childhood and continue throughout adulthood. The aging process with a lower RMR introduces special challenges. Energy balance must be maintained by adjusting or reducing caloric intake and increasing physical activity to prevent weight gain.

Prolonged calorie restriction (CR) increases life span and slows aging in animals. The apparent generality of the longevity-increasing effects of CR has prompted speculation that similar results could be obtained in humans. Two biomarkers of longevity (fasting insulin level and body temperature) are decreased by prolonged CR in humans (Heilbronn et al., 2006). Proponents of CR for antiaging believe that cutting caloric intake reduces aging and chronic disease development. In rodents with Alzheimer disease, heart disease, and stroke, decreased deterioration of nerves and increased nerve creation was also demonstrated (Mayo Clinic, 2010). Whether CR can slow the aging process, however, remains an important question (Fontana, 2009; Phelan, 2006). The Calorie Restriction (CR) Society International ([www.crsociety.org](http://www.crsociety.org)) supports the efforts of people who practice CR for current health, future longevity, or other benefits; those curious about or interested in understanding the effects of the diet; and those interested in the development of related, science-based health-enhancing and life-extension technologies.

## Weight Discrimination

Widespread bias and discrimination based on weight have been documented in education, employment, and health care. Like other forms of prejudice, this stems from a lack of understanding of the chronic disease of obesity and its medical consequences. Despite laws designed to prevent discrimination based on appearance, unfavorable attitudes and practices still persist. Overweight children experience adverse social, educational, and psychological consequences as a result of weight bias (Latner et al., 2005). There are automatic negative associations for obese people among health professionals, exercise science students, and obese individuals themselves (Brown, 2006; Carr and Friedman, 2005). It is essential to break down the barriers caused by ignorance and indifference. Patient support groups help to correct the negative effect of this type of discrimination.

## MANAGEMENT OF OBESITY IN ADULTS

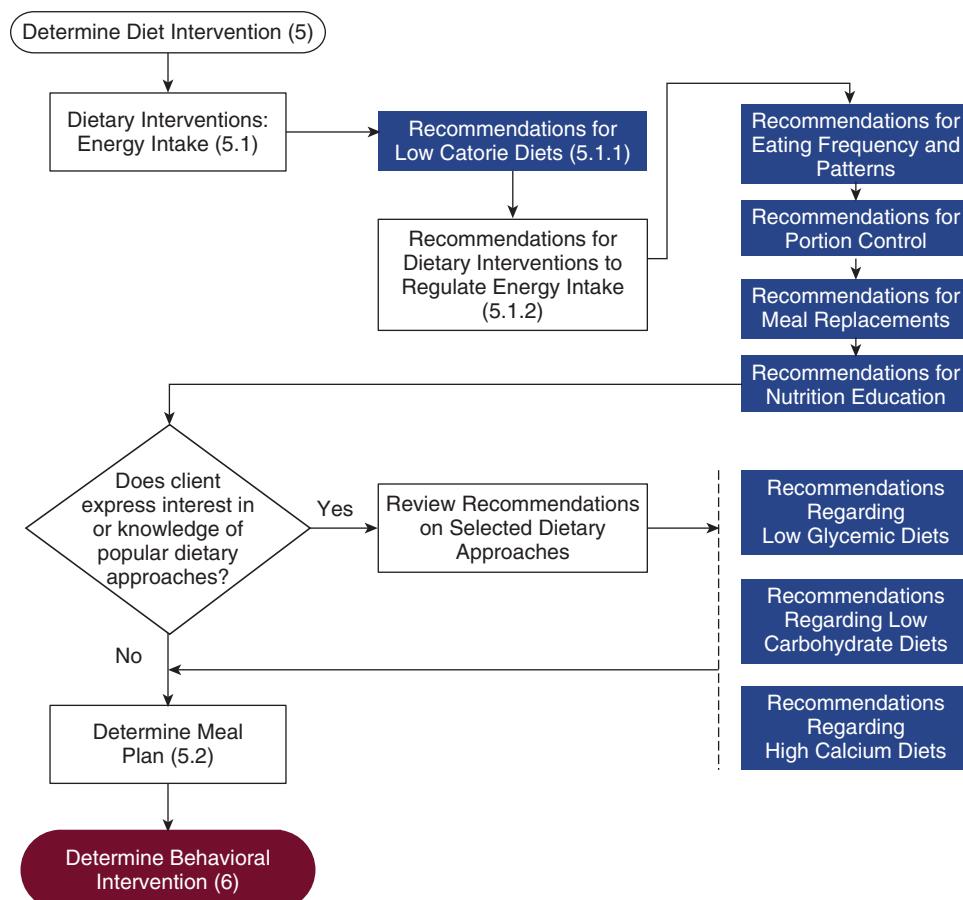

The management of obesity has evolved over the years. Initially, clinicians focused entirely on weight loss, and little was known about weight maintenance. It soon became clear that focusing on weight loss without attention to weight maintenance was inappropriate, unfair, and possibly harmful to anyone trying to manage his or her weight.

Treatment has also evolved. Years ago, an energy-restricted diet was the only treatment. Eventually, lifestyle modifications were added. The importance of physical activity was recognized as an essential ingredient for weight maintenance after weight loss. Today, a chronic disease-prevention model incorporates both lifestyle interventions and interdisciplinary therapies from physicians, dietitians, exercise specialists, and behavior therapists. Weight-reduction programs with the most promise of success integrate healthier food choices, exercise, and lifestyle modification. Pharmacologic treatment and surgical intervention are appropriate in some circumstances but are not a substitute for the necessary changes in eating and physical activity pattern. The American Dietetic Association (ADA) Evidence Analysis Library (EAL) provides reliable treatment guidelines (Figure 22-4).

## Goals of Treatment

The goal of obesity treatment should focus on weight management, attaining the best weight possible in the context of overall health. Achieving an “ideal” body weight or percentage of body fat is not always realistic; under some circumstances, it may not be appropriate at all. Depending on the type and severity of the obesity and the age and lifestyle of the individual, successfully reducing body weight varies from a being relatively simple to being virtually impossible.

**FIGURE 22-4** Algorithm for managing obesity using nutrition care process intervention terms.  
*(© American Dietetic Association. Reprinted with permission.)*

Maintaining present body weight or achieving a moderate loss is beneficial. Obese persons who lose even small amounts of weight (5% to 10% of initial body weight) are likely to improve blood glucose, blood pressure, and cholesterol levels.

Despite the recognition that modest weight loss is beneficial and may be more achievable, obese persons usually have self-defined goal weights that differ considerably from the goals suggested by professionals. Therefore health professionals must help their patients accept more modest, realistic weight-loss goals.

### Rate and Extent of Weight Loss

Reduction of body weight involves the loss of both protein and fat, in amounts determined to some degree by the rate of weight reduction. A drastic reduction in calories resulting in a high rate of weight loss can mimic the starvation response. Tissue response to starvation is one of adaptation to an anticipated period of deprivation. The classic starvation studies done by [Keys \(1950\)](#) found that during the first 10 days of a fast and after use of glycogen stores, approximately 8% to 12% of the energy expenditure is from protein and the balance is from fat. As starvation progresses, up to 97% of energy expenditure is from stored TG. Metabolic aberrations during starvation include bradycardia, hypotension, dry skin and hair, easy fatigue, constipation, nervous system abnormalities, depression, and even death.

Mobilizing fat, with more than twice the kilocalories of protein, is more efficient and also spares vital LBM. Steady weight loss over a longer period favors reduction of fat stores, limits the loss of vital protein tissues, and avoids the sharp decline in RMR that accompanies rapid weight reduction. Calorie deficits that result in a loss of approximately 0.5 to 1 lb per week for persons with a BMI of 27 to 35, and 1 to 2 lb per week for those with BMIs greater than 35, should continue for approximately 6 months for a reduction of 10% of body weight ([American Dietetic Association \[ADA\], 2010](#)). For the next 6 months the focus changes from weight loss to weight maintenance. Following this phase, further weight loss may be considered.

Even with the same caloric intake, rates of weight reduction vary. Men reduce weight faster than women of similar size because of their higher LBM and RMR. The heavier person expends more energy than one who is less obese, and loses faster on a given calorie intake than a lighter person. Many obese persons who fail to lose weight on a diet actually consume more energy than they report and overestimate their physical activity levels.

Weight goals should be individualized and realistic, with reduction of body fat as the focus. For example, neither the morbidly obese nor the gynoid types will be able to maintain a large weight loss. Female models of dress sizes 6 to 10 and male models with 30-inch to 34-inch waists are not appropriate role models for the obese population; even BMIs of 25 are unreasonable goals for many dieters. See *Focus On: The Influence of Fashion on Societal Food Patterns*.

## The Influence of Fashion on Societal Food Patterns

*Contributed by Mousavi Jazayeri, PhD*

The media can influence attitudes toward appearance and the body. Historically, the meaning of art and beauty has differed across cultures ([Barber, 1995](#)). The international reach of today's media, which features images of slim models and athletes, has shifted norms of beauty and changed attitudes about attractiveness. In most of the world, being thin and slim has become a symbol of beauty. Fashion models, celebrities, gymnasts, runners, skaters, divers and dancers are often underweight when compared with the recommended guidelines for a healthy body mass index. Susceptibility to the media's thin ideal and body dissatisfaction leads to restraint or emotional eating behaviors ([Anschutz et al., 2008](#)). Images of ultrathin models may exert strong pressure on young girls to lose weight. For young women who wish to bear children, maintaining a sufficient amount of body fat is necessary. Thus a more sensible perception of an attractive body image may help to change attitudes ([Bonafini and Pozzilli, 2010](#)). The need for "normal-weight" role models is highlighted by a series of weight loss-related deaths of young models. Models and athletes who maintain a healthy weight could help to reduce the ill effects of the media on body image and health outcomes.

### Lifestyle Modification

Behavior modification is the cornerstone of lifestyle intervention. It focuses on restructuring a patient's environment, nutritional intake, and physical activity by using goal setting, stimulus control, problem solving, cognitive restructuring, self-monitoring, and relapse prevention ([Berkel et al., 2005](#)). It also provides feedback on progress and places the responsibility for change and accomplishment on the patient.

In goal setting, most behavioral programs try to achieve a 0.5- to 1-lb weight loss per week by providing calorie, fat grams, and physical activity targets. It is important to identify goals that support a client's sense of self-efficacy.

*Stimulus control* involves modification of (1) the settings or the chain of events that precede eating, (2) the kinds of foods consumed when eating does occur, and (3) the consequences of eating. Patients are taught to slow their rate of eating to become mindful of satiety cues and reduce food intake. Strategies such as putting down the utensils between bites, pausing during meals, and chewing for a minimum number of times are some ways to slow the eating process.

*Problem solving* is the process of defining the intake problem, generating possible solutions, evaluating and choosing the best solution, implementing the new behavior,

**BOX 22-1****Lifestyle Modification Strategies****Setting Easy-To-Achieve Short-Term Goals**

Increase number of minutes of walking on weekends.  
Include one fruit at lunch.  
Trim regular food portions.

**Self-Monitoring**

Use a food and activity log.  
Use a daily planner.  
Perform a regular weigh-in (i.e., daily or weekly).

**Stimulus Control**

Shop when not hungry and with a grocery list.  
Make eating a singular activity (e.g., turn off the television).

**Confronting Barriers**

Practice problem-solving steps.  
Plan ahead (e.g., keep healthful snacks on hand).

**Sleep and Stress Management**

Increase sleep and rest.  
Practice a daily exercise routine.  
Practice daily meditation or yoga.  
Practice progressive relaxation and visual imagery exercises.

**Social Support**

Attend organized commercial support meetings or classes.  
Use family, friends, and co-workers as support systems.

**Contracting**

Make realistic, simple, and achievable healthful goals.  
Useful for short-term change.

Modified from Foreyt JP: Need for lifestyle intervention: how to begin, Am J Cardiovasc 96:11E, 2005.

evaluating outcomes, and reevaluating alternative solutions if needed.

*Cognitive restructuring* teaches patients to identify, challenge, and correct the negative thoughts that frequently undermine their efforts (see Chapter 15). Some lifestyle modification strategies are listed in Box 22-1.

Self-monitoring with daily records of place and time of food intake, as well as accompanying thoughts and feelings, helps identify the physical and emotional settings in which eating occurs. Physical activity is typically recorded in minutes or calories expended. Self-monitoring also gives clues to the occurrence of relapses and consequent guilt and how they can be prevented.

A comprehensive program of lifestyle modification produces a loss of approximately 10% of initial weight in 16 to 26 weeks, as revealed by a review of recent randomized controlled trials (RCTs), including the Diabetes Prevention Program. Long-term weight control is facilitated by

continued patient-therapist contact, whether provided in person or by telephone, mail, or e-mail. Multiple strategies for behavioral therapy are often needed (ADA, 2010).

Technology shows promise as a delivery mechanism. Both e-mail and phone consults appear to be viable methods for contact and support as part of structured behavioral weight loss programs. Future treatment methods may include augmenting behavioral interventions with specific stimulus controls, self-monitoring with pharmacotherapy, targeted interventions available from the Internet, meal replacements, and telephone interventions. Nontraditional behavioral interventions for children and culturally sensitive interventions for racial and ethnic minority populations are needed (Berkel et al., 2005).

**Dietary Modification Recommendations**

Weight-loss programs with any degree of success integrate food-choice changes with exercise, behavior modification, nutrition education, and psychological support. When these approaches fail to bring about the desired reduction in body fat, medication may be added. For **morbid obesity** (BMI of 40 or greater), surgical intervention may be required.

Weight-loss programs should combine a nutritionally balanced dietary regimen with exercise and lifestyle modification at the least possible expense. Selecting the appropriate treatment strategy depends on the goals and health risks of the patient. Treatment options include:

- A low-calorie diet, increased physical activity, and lifestyle modification
- The preceding plus pharmacotherapy
- Surgery plus an individually prescribed dietary regimen, physical activity, and lifestyle modification program
- Prevention of weight regain through energy balance.

**Restricted-Energy Diets**

A balanced, restricted-energy diet is the most widely prescribed method of weight reduction. The diet should be nutritionally adequate except for energy, which is decreased to the point at which fat stores must be mobilized to meet daily energy needs. A caloric deficit of 500 to 1000 kcal daily usually meets this goal. The energy level varies with the individual's size and activities, usually ranging from 1200 to 1800 kcal daily. Regardless of the level of CR, healthful eating should be taught and recommendations for increasing physical activity should be included.

The low-calorie diet should be individualized for carbohydrates (50% to 55% of total kilocalories), using sources such as vegetables, fruits, beans, and whole grains. Generous protein, approximately 15% to 25% of kilocalories, is needed to prevent conversion of dietary protein to energy. Fat content should not exceed 30% of total calories. Extra fiber is recommended to reduce caloric density, to promote satiety by delaying stomach-emptying time, and to decrease to a small degree the efficiency of intestinal absorption. New food products made from oats and beverages with coconut oil may promise to enhance satiety by intake before a meal, with the expectation of reduced overall caloric

intake. There are no current studies that suggest that coconut oil is effective for weight loss and it may contribute to weight gain with its 120 kcal and 13 g of fat per tablespoon. Otherwise, by combining oats with other fiber-rich foods, satiety may be increased.

Calculating fat as a percentage of calories is useful. A simple rule is to divide ideal calorie level by 4 for a 25% fat intake (e.g., an 1800-kcal intake needs 450 kcal from fat, or, at approximately 9 kcal/g, approximately 50 g of fat). Giving the person license to distribute fat grams throughout the day makes the approach more appealing, involves the person in the process, and decreases energy intake without hunger. Total calories must also be considered.

Alcohol and foods high in sugar should be limited to small amounts for palatability. Alcohol makes up 10% of the diet for many regular drinkers and contributes 7 kcal/g. Heavy drinkers who consume 50% or more of daily calories from alcohol may have a depressed appetite, whereas moderate users tend to gain weight with the added alcohol calories. Habitual use of alcohol may result in lipid storage, weight gain, or obesity.

Artificial sweeteners and fat substitutes improve the acceptability of limited food intakes for some people. There is no evidence that using artificial sweeteners reduces food intake or results in weight loss.

Vitamin and mineral supplements that meet age-related requirements are usually recommended with less than 1200 kcal for women or 1800 kcal for men. It is difficult to choose foods to maintain this calorie level and meet all nutritional requirements every day.

### Formula Diets and Meal Replacement Programs

Formula diets are commercially prepared, ready-to-use, portion-controlled meal replacements. These meal replacements can be found over the counter (OTC) in drug stores, supermarkets, and franchised weight loss centers or in a clinical setting as drinks, prepackaged meals (entrees), or meal bars. The goal is to provide structure and replace other higher calorie foods. Per serving, most meal replacements include 0 to 5 g of fiber, 10 to 14 g of protein, various amounts of carbohydrate, 0 to 10 g of fat, and 25% to 30% of recommended dietary allowances for vitamins and minerals. Usually shakes are milk or soy based and are high in calcium with 150 to 250 kcal/8 oz. Some shakes are prepared using a blender at home and are made with a purchased powder. People who have difficulty with self-selection or portion control may use meal replacements as part of a comprehensive weight management program. Substituting one or two daily meals or snacks with meal replacements is a successful weight loss and weight maintenance strategy (ADA, 2010).

### Commercial Programs

Millions of Americans turn to commercial weight-loss or self-help programs in search of permanent weight loss. The more caloric-restricted programs are usually medically supervised in a health care setting. As Table 22-3 illustrates, the programs vary considerably. Some require the use of

proprietary prepackaged low-fat meals. Prepackaged diets appeal to some people because they allow them to avoid making choices about food. Some provide classes on self-introspection, behavior modification, and nutrition.

Use of the Internet has spawned a new generation of commercial programs. The importance of a tailored approach was the conclusion of an RCT comparing an Internet-based tailored weight management program with an information-only Internet weight management program based in an integrated health care setting (Rothert, 2006).

With the exception of Weight Watchers, the evidence to support the use of the major commercial and self-help weight loss programs is suboptimal. The reported results are probably a best-case scenario because many studies do not control for high attrition rates. More controlled trials are needed to assess the efficacy and cost-effectiveness of commercial programs. Thus it is important to evaluate all weight loss programs for sound nutritional practices. Consumers are savvy, and many programs have begun to report data on dropout or success rates, as well as weight maintenance.

### Extreme Energy Restriction and Fasting

Extreme energy-restricted diets provide fewer than 800 kcal per day, and starvation or fasting diets provide fewer than 200 kcal per day. Fasting is seldom prescribed as a treatment; however, it is frequently invoked as a part of religious or protest regimen or in a personal effort to lose weight. Under these circumstances it is seldom continued long enough to produce the serious neurologic, hormonal, and other side effects that accompany prolonged starvation. More than 50% of the rapid weight reduction is fluid, which often leads to serious hypotension. Accumulation of uric acid can precipitate episodes of gout; gallstones can also occur. Also, as fat stores diminish, molecules are released that can affect further weight loss. See *Clinical Insight: What's in That Fat When You Lose It?* Sometimes what starts as extreme energy restriction to lose weight leads to more disordered eating patterns (see Chapter 23).

### Very-Low-Calorie Diets

Diets providing 200 to 800 kcal are classified as **very-low-calorie diets (VLCDs)**. Little evidence suggests that intakes of fewer than 800 calories daily are of any advantage. Most VLCDs are hypocaloric but relatively rich in protein (0.8-1.5 g/kg IBW per day). They are designed to include a full complement of vitamins, minerals, electrolytes, and essential fatty acids, but not calories; they are given in a form that completely replaces usual food intake; and they are usually given for a period of 12 to 16 weeks. Their major advantage is rapid weight loss. Because of potential side effects, prescription of these diets is reserved for persons with a BMI of more than 30 for whom other diet programs with psychotherapy have been unsuccessful. Occasionally VLCDs may be indicated for persons with a BMI of 27 to 30 who have comorbidities or other risk factors.

The VLCD that first became popular in the early 1970s resulted in several deaths; however, improved protein formulations have increased acceptability and safety for

**TABLE 22-3****Popular Commercial Diet Programs**

Name	Foods or Products	Education	Teachers/ Counselors	Maintenance
<b>VLCD Programs</b>				
Medifast <a href="http://www.medifast.net">www.medifast.net</a>	Special drink; physician supervised	Weekly individual sessions Weekly group meetings	Supervised by MDs	Weekly meetings for 5 mo

MD, Medical doctor; RD, registered dietitian; VLCD, very-low-calorie diet.

those with morbid obesity. The VLCDs can lead to an increase of urinary ketones that interfere with the renal clearance of uric acid, resulting in increased serum uric acid levels or gout. Higher serum cholesterol levels resulting from mobilization of adipose stores pose a risk of gallstones. Additional adverse reactions include cold intolerance, fatigue, light-headedness, nervousness, euphoria, constipation or diarrhea, dry skin, anemia, and menstrual irregularities; some of these are related to triiodothyronine (thyroid) deficiency.

Even though there are significantly greater weight losses with VLCDs in the short term, there are no significant differences in the weight losses in the long term (Gilden and Wadden, 2006). Thus there does not seem to be reason to recommend these VLCDs over more moderate CR except rarely. For those who have lost weight on a VLCD, limiting dietary fat intake and maintaining physical activity are both important factors for the prevention of weight regain. To promote better weight loss, patients should limit their fat intake to less than 30% of calories and increase activity levels.

## Popular Diets and Practices

Each year, new approaches to weight loss find their way to the consumer through the popular press and media. Some of the programs are sensible and appropriate, whereas others emphasize fast results with minimum effort. Some of the proposed diets would lead to nutritional deficiencies over an extended period; however, the potential health risks are seldom realized because the diets are usually abandoned after a few weeks. Diets that emphasize fast results with minimum effort encourage unrealistic expectations, setting the dieter up for failure, subsequent guilt, and feelings of helplessness at ever managing the weight problem.

The low-carbohydrate, high-fat diet restricts carbohydrates to less than 20% of calories (and often less than 10% in the beginning), and fat constitutes 55% to 65% of calories, with protein making up the balance. Protein obtained from animal sources means that fat, saturated fat, and cholesterol intakes are high. Although these diets feature high ketone production, they suppress appetite to only a minor degree. The initial rapid weight loss from diuresis is secondary to the carbohydrate restriction. Examples of severe carbohydrate-restricted diets include *Dr. Atkins' New Diet Revolution* and *The Carbohydrate Addict's Diet*. The *Zone* and the *South Beach Diet* both restrict carbohydrates to no more than 40% of total calories, with fat and protein providing 30% of calories each. This diet composition is claimed to keep insulin in check, which is blamed for fat storage. The diet includes generous amounts of fiber and fresh fruits and vegetables. There is attention to the kind of fat, with emphasis on monounsaturated and polyunsaturated fat and limitation of saturated fat. Weight loss ensues not because insulin is kept in a narrow range, but because calories are restricted.

The EAL examined 14 studies on the effectiveness of the low-carbohydrate diets (Atkins, South Beach). Consumption of ad libitum low-carbohydrate diets (only limiting

carbohydrate) and reduced-calorie diets both lower total caloric intake. However, ad libitum low-carbohydrate diets often result in greater body weight loss and fat loss in the first 6 months. After 1 year the differences are no longer significant (ADA, 2010).

Very-low-fat diets contain less than 10% of calories from fat, such as *Dr. Dean Ornish's Program for Reversing Heart Disease* and *The Pritikin Program*. These diets produce rapid weight loss and are very restrictive. A more popular variation limits fat to 20% of total energy intake. Because fat provides more than two times the energy per gram as protein or carbohydrate (9 kcal versus 4 kcal), an effective diet can be one that includes extensive controls on this nutrient.

Moderate-fat, balanced-nutrient reduction diets contain 20% to 30% of calories from fat, 15% to 20% of calories from protein, and 55% to 60% of calories from carbohydrate. *Volumetrics*, a program in this category, focuses on the energy density of foods (Rolls et al., 2005). Foods high in water content have a low energy density. These include fruits, vegetables, low-fat milk, cooked grains, lean meats, poultry, fish, and beans. Low-water containing foods that are energy dense such as potato chips, crackers, and fat-free cookies are restricted.

The U.S. Department of Agriculture (USDA) supported a scientific review of popular diets to assess their efficacy for weight loss and weight maintenance, as well as their effect on metabolic parameters, psychological well being, and reduction of chronic disease. A summary is shown in Table 22-4.

## Physical Activity

Physical activity is the most variable component of energy expenditure. Increases in energy expenditure through exercise and other forms of physical activity are important components of interventions for weight loss and its maintenance. By increasing LBM in proportion to fat, physical activity helps to balance the loss of LBM and reduction of RMR that inevitably accompany intentional weight reduction. Other positive side effects of increased activity include strengthening cardiovascular integrity, increasing sensitivity to insulin, and expending additional energy and therefore calories.

Adequate levels of physical activity appear to be 60 to 90 minutes daily, as recommended by the USDA. This is also the amount of activity reported by those in the National Weight Control Registry (NWCR) who have kept off at least 10% of their weight for at least a year. Overweight and obese adults should gradually increase to these levels of physical activity. There is evidence that, even if an overweight or obese adult is unable to achieve this level of activity, significant health benefits can be realized by participating in at least 30 minutes of daily activity of moderate intensity (ADA, 2010). Therefore it is important to target these levels of physical activity to improve health-related outcomes and to facilitate long-term weight control (Jakicic, 2006).

Both aerobic and resistance training should be recommended. Resistance training increases LBM, adding to

**TABLE 22-4****Results of U.S. Department of Agriculture Scientific Review of Popular Diets**

Area	Finding
Weight loss	Diets that reduce caloric intake result in weight loss; all popular diets result in short-term weight loss if followed.
Body composition	All low-calorie diets result in a loss of body fat. In the short term, high-fat, low-carbohydrate ketogenic diets cause a greater loss of body water than body fat.
Nutritional adequacy	<ul style="list-style-type: none"> <li>• High-fat, low-carbohydrate diets are low in vitamins E and A; thiamin; B<sub>6</sub>; and folate; and the minerals calcium, magnesium, iron, and potassium. They are also low in dietary fiber.</li> <li>• Very-low-fat diets are low in vitamins E and B<sub>12</sub> and the mineral zinc.</li> <li>• With proper food choices, a moderate-fat, balanced nutrient-reduction diet is nutritionally adequate.</li> </ul>
Metabolic parameters	<ul style="list-style-type: none"> <li>• Low-carbohydrate diets cause ketosis and may significantly increase blood uric acid concentrations.</li> <li>• Blood lipid levels decline as body weight decreases.</li> <li>• Energy restriction improves glycemic control.</li> <li>• As body weight declines, blood insulin and plasma leptin levels decrease.</li> <li>• As body weight declines, blood pressure decreases.</li> </ul>
Hunger and compliance	No diet was optimal for reducing hunger.
Effect on weight maintenance	Controlled clinical trials of high-fat, low-carbohydrate, low-fat, and very-low-fat diets are lacking; therefore no data are available on weight maintenance after weight loss or long-term health benefits or risk.

From Freedman M et al: Popular diets: a scientific review, *Obes Res* 9:1S, 2001.

the RMR and the ability to use more of the energy intake, and it increases bone mineral density, especially for women (see [Chapter 24](#)). Aerobic exercise is important for cardiovascular health through elevated RMR, calorie expenditure, energy deficit and loss of fat. In addition to the physiologic benefits of exercise are relief of boredom, increased sense of control, and improved sense of well-being. The whole family can get involved in pleasurable activities ([Figure 22-5](#)).

Consistency is the key to realizing the health and weight-management benefits of exercise. Previous exercise recommendations for health called for 20 to 60 minutes of moderate- to high-intensity endurance exercise performed three or more times weekly. It now appears that most health benefits can be gained by physical activity of moderate intensity (enough to expend 200 kcal daily) accumulated in intermittent short bouts, such as 20 to 30 minutes of high-intensity activity 4 to 7 days per week ([Institute of Medicine, 2002](#)). High-intensity activity is not required. Contrary to popular belief, spot reduction (i.e., reducing fat in one area of the body) is not possible with exercise; fat is burned from the largest concentrations of adipose tissue.

## Pharmaceutical Management

Appropriate pharmacotherapy can augment diet, physical activity, and behavior therapy as treatment for patients with a BMI of 30 or higher or patients with 27 or higher who also have significant risk factors or disease. These agents can decrease appetite, reduce absorption of fat, or increase

**FIGURE 22-5** Jogging is an excellent aerobic activity for the whole family. (Photo printed with permission from Dr. David Rivera, 2010.)

energy expenditure. As with any drug treatment, physician monitoring for efficacy and safety is necessary. Pharmacotherapy is not a “magic pill”; dietitians should collaborate with other health professionals regarding the use of Food and Drug Administration (FDA)-approved pharmacotherapy. Not all individuals respond, but for patients who do

respond, clinical trials suggest that a weight loss of approximately 2 to 20 kg can be expected usually during the first 6 months of treatment. Medication without lifestyle modification is less effective.

Medications currently available can be categorized as central nervous system (CNS)-acting agents and non-CNS-acting agents. The CNS-acting agents fall into the categories of catecholaminergic agents, serotonergic agents, and combination catecholaminergic-serotonergic agents. Common side effects of CNS-acting agents are dry mouth, headache, insomnia, and constipation. Only sibutramine (Meridia) and orlistat are approved by the FDA for long-term use in the treatment of obesity (Food and Drug Administration, 2009).

**Catecholaminergic** drugs act on the brain, increasing the availability of norepinephrine. Drug Enforcement Agency Schedule II anorexic agents such as amphetamines have a high potential for abuse and are not recommended for obesity treatment.

Serotonergic agents act by increasing serotonin levels in the brain. Two drugs in this category, fenfluramine (commonly used in combination with phentermine, known as “fen-phen”) and dexfenfluramine, were removed from the market in 1997 after concerns were raised regarding the possible side effects of cardiac valvulopathy, regurgitation, and primary pulmonary hypertension.

**Sibutramine** is a combination of catecholaminergic and serotonergic agents, which inhibit the reuptake of serotonin and norepinephrine in the CNS to increase satiety, reduce hunger, and lessen the drop in metabolic rate that often occurs with weight loss. Because it stimulates the sympathetic nervous system, patients taking sibutramine may experience cardiovascular side effects; it is not appropriate for patients with a history of cardiovascular disorders. Sibutramine should not be used in combination with certain antidepressant agents such as monoamine oxidase inhibitors, selective serotonin reuptake inhibitors or other central-acting agents such as pseudoephedrine (Ephedra). The interaction may cause a hypertensive crisis.

**Orlistat** inhibits gastrointestinal lipase, which reduces approximately one third the amount of fat that is absorbed from food. Depending on the fat content of a person’s diet, this lowered absorption can represent 150 to 200 kcal/day. With lowered fat-soluble vitamin absorption, supplements are typically recommended, separated by 2 hours or more. Weight loss of 3 to 5 kg in orlistat-treated patients is common. Side effects are gastrointestinal: oily spotting, fecal urgency, and flatus with discharge. Health benefits include reduced low-density lipoprotein (LDL) cholesterol and elevated HDL cholesterol, improved glycemic control, and reduced blood pressure.

Other drugs targeting weight loss and obesity through the CNS pathways or peripheral adiposity signals are in early-phase clinical trials. Currently, the only FDA-approved OTC weight-loss product is Alli, which contains 50% of the prescription dose of orlistat. OTC and natural weight-loss products hold varying degrees of efficacy (Table 22-5).

## Other Nonsurgical Approaches

The “non-diet” paradigm maintains that the body will attain its natural weight if the individual eats healthfully, becomes attuned to hunger and satiety cues, and incorporates physical activity. This approach focuses on achieving health rather than attaining a certain weight. Advocates for this approach promote size acceptance and respect for the diversity of body shapes and sizes. Given the evidence that a 5% to 10% loss of initial weight can result in health benefits, that many persons set weight-loss goals that are unrealistic, and that fat discrimination continues to plague society, this approach may help some persons to develop a better relationship with food and a healthier perspective about their bodies.

## Bariatric Surgery

**Bariatric surgery** is an accepted form of treatment for extreme or class III obesity with a BMI of 40 or greater, or a BMI of 35 or greater with comorbidities. Gastroplasty procedures are restrictive because they decrease the amount of food entering the gastrointestinal tract. Other surgical procedures, such as Roux-en-Y, are restrictive and cause malabsorption because they also prevent food from being absorbed from the gastrointestinal tract.

Before any extremely obese person is considered for surgery, failure of a comprehensive program that includes CR, exercise, lifestyle modification, psychological counseling, and family involvement must be demonstrated. *Failure* is defined as an inability of the patient to reduce body weight by one third and body fat by one half and an inability to maintain any weight loss achieved. Such patients have intractable morbid obesity and should be considered for surgery.

If surgery is chosen, the patient is evaluated extensively with respect to physiologic and medical complications, psychological problems such as depression or poor self-esteem, and motivation. Counseling sharply improves the outcomes for dieting and drug therapy in this population (Wadden and Sarwer, 2006). Postoperative follow-up requires evaluation at regular intervals by the surgical team and a registered dietitian. In addition, behavioral or psychological support is necessary. Generally, bariatric surgery improves self-image and may alleviate depression.

## Gastric Bypass, Gastroplasty, and Gastric Banding

Both gastroplasty and gastric bypass procedures reduce the amount of food that can be eaten at one time and produce early satiety (Figure 22-6). The new stomach capacity may be as small as 1 oz (20 to 30 mL) or approximately 2 tablespoons. After surgery the patient’s diet progresses from clear liquid, to full liquid, to puree, soft, and finally to a regular diet as tolerated, with emphasis on protein intake (Table 22-6). The results of gastric surgery are more favorable than those from the intestinal bypass surgery practiced during the 1970s. On average the reduction of excess body weight after

**TABLE 22-5****Nonprescription Weight Loss Products**

<b>Product</b>	<b>Claim</b>	<b>Effectiveness</b>	<b>Safety</b>
Alli: OTC version of prescription drug orlistat (Xenical)	Decreases absorption of dietary fat	Effective; weight-loss amounts typically less for OTC versus prescription	FDA investigating reports of liver injury, pancreatitis
Bitter orange	Increases calories burned	Insufficient reliable evidence to rate	Possibly unsafe
Chitosan	Blocks absorption of dietary fat	Insufficient reliable evidence to rate	Possibly safe
Chromium	Increases calories burned, decreases appetite, and builds muscle	Insufficient reliable evidence to rate	Likely safe
CLA	Reduces body fat and builds muscle	Possibly effective	Possibly safe
Country mallow (heartleaf)	Decreases appetite and increases calories burned	Insufficient reliable evidence to rate	Likely unsafe and banned by FDA
Ephedra (Ma Huang)	Decreases appetite	Possibly effective	Likely unsafe and banned by FDA
Green tea extract	Increases calorie and fat metabolism and decreases appetite	Insufficient reliable evidence to rate	Possibly safe
Guar gum	Blocks absorption of dietary fat and increases feeling of fullness	Possibly ineffective	Likely safe
Hoodia	Decreases appetite	Insufficient reliable evidence to rate	Insufficient information
Senna	Cathartic; causes diarrhea	Insufficient reliable evidence	Likely unsafe

CL<sub>A</sub>, Conjugated linoleic acid; FDA, Food and Drug Administration; OTC, over the counter.

**TABLE 22-6****Diet Progression After Gastric Bypass**

<b>Phases of Diet</b>	<b>Total Quantity</b>	<b>Typical Progression after Surgery</b>	<b>Sample Food Items</b>
Liquid diet	No more than $\frac{1}{2}$ cup total	1-2 days	Plain and flavored waters, broth, unsweetened juices, diet gelatin, noncarbonated diet drinks, strained cream soups
Semisolids and pureed diet	Gradually increase from $\frac{1}{2}$ cup to no more than $\frac{3}{4}$ cup total	Day 3 to 3 weeks	Blenderized or pureed soft meats, fish, chicken, turkey. Pureed fruits and tender vegetables. Hot cereals cooked in milk. Yogurt.
Soft foods	Meals should be from $\frac{3}{4}$ cup to no more than 1 cup total	3 to 6 weeks	Foods that can be mashed with a fork, such as ground or finely diced meats, canned or soft, fresh fruit, and cooked vegetables.
Regular small meals and snacks	No more than 1 cup total; meat should be no more than 2 oz	6 weeks and beyond	Firmer foods without being pureed. Avoid popcorn, nuts, meats with gristle, dried fruits, vegetables and fruits that are stringy or coarse, sodas, bread, granola.

**FIGURE 22-6** Bariatric surgeries.

gastric restriction surgery correlates to approximately 30% to 40% of initial body weight. In addition to the greater absolute weight loss observed, the gastric bypass tends to have sustainable results with significant resolution of hypertension, type 2 diabetes mellitus, osteoarthritis, back pain, dyslipidemia, cardiomyopathy, nonalcoholic steatohepatitis, and sleep apnea. However, late complications may be seen, such as vitamin deficiency, electrolyte problems or even intestinal failure.

**Gastropathy** reduces the size of the stomach by applying rows of stainless-steel staples to partition the stomach and create a small gastric pouch, leaving only a small opening (0.8-1 cm) into the distal stomach. This opening may be banded by a piece of mesh to prevent it from enlarging during the years after surgery. Vertical-banded gastroplasty is the most popular surgery. In the lap-band procedure, also called **gastric banding**, the band creating the reduced stomach pouch can be adjusted so that the opening to the

rest of the stomach can be made smaller or enlarged. The band, filled with saline, has a tube exiting from it to the surface of the belly just under the skin; this allows for the injection of additional fluid or reduction of fluid into the lap band. Patients who undergo the banding procedures will not require folic acid, iron, or vitamin B<sub>12</sub> replacements.

**Gastric bypass** involves reducing the size of the stomach with the stapling procedure, but then connecting a small opening in the upper portion of the stomach to the small intestine by means of an intestinal loop. The original operation in the late 1960s evolved into the Roux-en-Y gastric bypass. Because use of the lower part of the stomach is omitted, the gastric bypass patient may have dumping syndrome as food empties quickly into the duodenum (see Chapter 28). The tachycardia, sweating, and abdominal pain are so negative that they motivate the patient to make the appropriate behavioral changes and refrain from overeating. However, patients tend to choose liquids; weight loss can be deterred by drinking too much calorically dense liquid such as milk shakes and soft drinks. Eventually the pouch expands to accommodate 4 to 5 oz at a time. Frequently, gastric bypass surgery leads to bloating of the pouch, nausea, and vomiting. A postsurgical food record noting the tolerance for specific foods in particular amounts helps in devising a program to avoid these episodes.

Completion of bypass surgery leads to malnutrition, which requires lifelong follow-up and monitoring by the multidisciplinary team. Nutritional status should be evaluated periodically by a dietitian. Monitoring should include an assessment of total body-fat loss, potential anemia, and deficiencies of potassium, magnesium, folate, and vitamin B<sub>12</sub>. Ice-cube pica and iron deficiency anemia are possible (Kushner and Shanta Retelny, 2005). Supplementation is necessary. An adult vitamin-mineral supplement (one liquid or chewable tablet twice daily) containing 1200–1500 mg calcium citrate, 1000–2000 IU vitamin D, 500 mcg vitamin B<sub>12</sub>, 400 mcg folic acid, and 65–80 mg elemental iron with vitamin C is suggested (Kuluck et al., 2010; Snyder-Marlow et al., 2010).

## Liposuction

**Liposuction** (or liposculpture) involves aspiration of fat deposits by means of a 1- to 2-cm incision through which a tube is fanned out into the adipose tissue. The most successful operations are performed on younger persons with only small amounts of fat to be removed, where the elastic properties of the skin are able to allow tightening over the aspirated areas. It is not usually a weight-reduction technique but rather a cosmetic surgery because usually only approximately 5 lb of fat are removed at a time. Deaths, severe infections, cellulitis, and hemorrhage have occurred.

## COMMON PROBLEMS IN OBESITY TREATMENT

Prognosis for maintaining reduced weight is typically poor. Continued dieting, with repeated ups and downs, leads gradually to a net increase in body fat and thus to a health

risk for hyperlipidemia, hypertension, diabetes, and even osteoarthritis. Women having bariatric surgery had lower serum 25-hydroxyvitamin D (s25D) and higher parathyroid hormone (sPTH). The major determinant of s25D and sPTH was weight. Hyperparathyroidism in obesity did not indicate vitamin D insufficiency. Low s25D was not associated with comorbid conditions, apart from osteoarthritis (Grethen, 2011).

## Maintaining Reduced Body Weight

Energy requirements for weight maintenance after weight reduction appear to be 25% lower than at the original weight. The net effect is that reduced-obese persons are faced with the necessity of maintaining a reduced energy intake even after the desired weight has been lost. Whether this reduced intake must be maintained indefinitely is not known.

The NWCR consists of more than 5000 individuals who have been successful in long-term weight loss maintenance. The purpose of establishing the NWCR is to identify the common characteristics of those who succeed in long-term weight loss maintenance. There is very little similarity in how these individuals lost weight but there are some common behaviors they all have for keeping their weight off. Lifestyle modification and a sense of self-efficacy appear to be essential. To maintain their weight loss, NWCR participants report:

1. Eating a relatively low-fat (24%) diet
2. Eating breakfast almost every day
3. Weighing themselves regularly, usually once per day to once per week
4. Engaging in high levels (60 to 90 minutes/day) of physical activity

Weight loss maintenance may get easier over time; after individuals have successfully maintained their weight loss for 2 to 5 years, the chance of longer-term success greatly increases (Wing and Phelan, 2005). Support groups are valuable for reduced-obese persons who are maintaining a new lower weight; they help individuals facing similar problems. Two self-help support groups are Overeaters Anonymous and Take Off Pounds Sensibly. These groups are inexpensive, continuous, include a “buddy system,” and encourage participation on a regular basis or as often as needed. Weight Watcher programs offer free lifelong maintenance classes for those who have reached and are maintaining their goal weights.

Interestingly, boring and monotonous diets can be a management strategy. Diets that are repetitious without change from meal to meal are one consideration because people tend to overeat when they have many mealtime choices. Overall, a common sense approach is needed. Some phrases can be shared with individuals who are trying to maintain their weight loss, including:

1. The best diet is “don’t buy it.”
2. “Easy does it”—use moderation at all meals.

3. “Don’t drink your calories.”
4. Keep the “extras” to no more than 200 kcal per day.

## Plateau Effect

A common experience for the person in a weight-reduction program is arrival at a weight plateau, when weight remains at the same level for a long period. Eventually weight loss halts completely. One theory is that interim plateaus reflect a reduction of lipid in individual adipocytes to some level that signals metabolic adjustment and weight maintenance. Another theory is that there is a release of toxins from adipose tissue that act as endocrine disruptors and inflammatory agents and affect subsequent weight loss. See *Clinical Insight: What’s in That Fat When You Lose It?* To move out of this phase usually requires increasing the activity level.

Any weight loss, whether fast or slow, results in a loss of the extra muscle that has developed to support the excess adipose tissue. Because this extra LBM has contributed to an increased metabolic rate, RMR decreases as LBM is lost. The fact that RMR decreases rapidly at the onset of a weight-reduction diet, by as much as 15% within 2 weeks, indicates that other adaptations to the lower weight and the threat of deprivation are taking place.

Other factors join to decrease RMR and limit effectiveness of the restricted energy intake. A decrease in the total kilocalories ingested results in a decrease in total energy expenditure. Because a body that weighs less requires less energy expenditure to move around, the cost of physical activity is also less. A state of equilibrium is eventually reached at which the energy intake is equal to energy expenditure. Unless a change is made in either nutritional intake or physical activity, weight loss stops at this point.

## Weight Cycling

Repeated bouts of weight loss and regain, known as weight cycling or the **yo-yo effect**, occurs in men and women and is common in both overweight and nonoverweight individuals. The effect of weight cycling appears to result in increased body fatness and weight with the end of each cycle. There are metabolic and psychological effects that are undesirable.

## WEIGHT MANAGEMENT IN CHILDREN

Almost 32% of US children ages 2–19 are overweight or obese (Ogden et al., 2010). Obese children are often the targets of discrimination. Childhood obesity increases the risk of obesity in adulthood. For the child who is obese after 6 years of age, the probability of obesity in adulthood is significantly greater if either the mother or the father is obese.

The BMI tables for determining childhood obesity are available for use by health care practitioners (see *Appendices 12 and 16*). Children whose BMI is greater than the 85th

percentile are six times more likely to be overweight later (Nadir et al., 2006). In addition, children who have growth failure and undernutrition in utero or in the early years of life tend to become overweight in later childhood with subsequent risks of elevated blood pressure, lipid, and glucose levels (Stein et al., 2005). Obesity that begins in childhood tends to lead to hypertension, elevated LDL cholesterol, and TGs in adults (Thompson et al., 2007).

Children with a body mass index (BMI) in the 85th percentile or higher with complications of obesity, or with a BMI in the 95th percentile or higher with or without complications, should be carefully assessed for genetic, endocrinologic, and psychologic conditions, and secondary complications such as hypertension, dyslipidemias, sleep apnea, and orthopedic problems. If the complications cause serious morbidity and require rapid weight loss, referral to a pediatric obesity specialist may be necessary. Otherwise, parent and child readiness to make changes should be evaluated and eating and activity patterns carefully assessed.

Once assessment is complete, treatment can begin. The primary goal of treatment is to achieve healthy eating and activity, not to achieve an IBW. For children 7 years of age and younger the goal is prolonged weight maintenance or slowing of the rate of weight gain, which allows for a gradual decline in BMI as children grow in height. This is an appropriate goal in the absence of any secondary complications of obesity. However, if secondary complications are present, children in this age group may benefit from weight loss if their BMI is at the 95th percentile or higher. For children older than 7 years, prolonged weight maintenance is appropriate if their BMI is between the 85th and 95th percentile and if they have no secondary complications. If a secondary complication is present or if BMI is at the 95th percentile or above, weight loss (about 1 lb per month) is advised. If the weight appropriate for the child’s anticipated adult height has already been reached, maintenance at that weight should be the lifetime goal. The child who already exceeds an optimal adult weight can safely experience a slow weight loss of 10 to 12 lb per year until the optimal adult weight is reached. Balanced micronutrient intake for children includes 45% to 60% of kcal from carbohydrate, 25% to 40% from fat, and 10% to 35% from protein.

The child who needs to reduce weight is going to require more attention from family and health professionals. This attention should be directed to all the areas mentioned previously, with family modification of eating habits and increased physical activity. The program should be long term over the entire growth period and perhaps longer.

Inactivity is often coupled with sedentary hobbies, excessive TV watching, or prolonged sitting in front of a computer or game screen. However, there is a new theory that physical inactivity appears to be the result of fatness rather than its cause (Metcalfe et al., 2010). This requires further research, but does suggest that factors other than inactivity may be more important in obesity development in children. See *New Directions—Organizing to Solve the Childhood Obesity Problem “Within a Generation.”*

## WEIGHT IMBALANCE: EXCESSIVE LEANNESS OR UNINTENTIONAL WEIGHT LOSS

Almost eclipsed by the attention focused on obesity is the need for some people to gain weight. The term **underweight** is applicable to those who are 15% to 20% or more below accepted weight standards. Because underweight is often a symptom of disease, it should be assessed medically. A low BMI (<18.5) is associated with greater mortality risk than that of individuals with optimal BMI (18.5–24.9), especially with aging and in the elderly. Undernutrition may lead to underfunction of the pituitary, thyroid, gonads, and adrenals. Other risk factors include loss of energy and susceptibility to injury and infection, as well as a distorted body image and other psychological problems (see Chapter 21).

### Cause

Underweight or unintentional weight loss can be caused by (1) inadequate oral food and beverage intake, with insufficient quantities to match activity; (2) excessive physical activity, as in the case of compulsive athletic training; (3) inadequate capacity for absorption and metabolism of foods consumed; (4) a wasting disease that increases the metabolic rate and energy needs, as in cancer, acquired immune deficiency syndrome (AIDS), or hyperthyroidism; or (5) excess energy expenditure during psychological or emotional stress (see Chapter 23).

### Assessment

Assessing the cause and extent of underweight before starting a treatment program is important. A thorough history

and pertinent medical tests usually determine whether underlying disorders are causing the underweight. From anthropometric data such as arm muscle and fat areas, it is possible to determine whether health-endangering underweight really exists. Assessment of body fatness is useful, especially in dealing with the patient who has an eating disorder (see Chapter 23). Biochemical measurements will indicate whether malnutrition accompanies the underweight (see Chapter 8). Use of an eating inventory questionnaire can identify persons at risk of unintentional weight loss (Hays et al., 2006).

### Management

Any underlying cause of unintentional weight loss or low BMI must be the first priority. A wasting disease or malabsorption requires treatment. Nutrition support and dietary changes are effective along with treatment of the underlying disorder (Table 22-7).

If the cause of the underweight is inadequate oral food and beverage intake, activity should be modified and psychological counseling started if necessary.

### Appetite Enhancers

The FDA has approved orexigenic agents that include corticosteroids, cyproheptadine, loxiglumide (cholecystokinin antagonist), megestrol acetate, mirtazapine, dronabinol, oxoglutarate, anabolic agents (testosterone or Anadrol), oxandrin, and growth hormone. Use of orexigenic agents for weight loss in seniors is saved for those whose conditions are refractory to usual treatments. One third of older adults, especially women, exhibit weight loss in combination with depression. Mirtazapine is an effective antidepressant that is well tolerated and increases appetite. Dronabinol is used for

**TABLE 22-7**

### Nutrition Management of Unintentional Weight Loss

Concern	Tips
Anxiety, stress, depression	Antidepressants can help; monitor choice to be sure they do not contribute to weight loss.
Cancer	Gastrointestinal cancers are especially detrimental. Some treatments and medications can cause loss of appetite, as can the cancer itself.
Celiac disease	Ensure that all gluten-containing foods and ingredients are eliminated from the diet. Avoid skipping meals; prepare foods with high energy density.
Changes in activity level or dietary preparation methods	See a physician; monitor medications and meals accordingly.
Diabetes, new onset	Alter food and liquid textures accordingly to improve chewing and swallowing capability.
Dysphagia or chewing difficulties	Too much thyroxine can cause weight loss.
Hyperthyroidism	Check medications and treatments to determine if new choices are in order.
Inflammatory bowel disease	See a physician.
Intestinal ischemia	Some medications can cause weight loss; check with the physician; add snacks or enhanced meals if needed.
Medications	Infections, other illnesses, hormonal changes, and some medications cause nausea and vomiting; small, frequent meals are useful; serve liquids between meals instead of with meals to reduce fullness.
Nausea and vomiting	Monitor for sufficiency of pancreatic enzyme replacement.
Pancreatitis and cystic fibrosis	

chemotherapy-induced nausea and vomiting in cancer and AIDS patients; it has been shown to induce weight gain in patients with dementia.

## High-Energy Diets

A careful history may reveal inadequacies in dietary habits and nutritional intakes. Meals should be scheduled and relaxed instead of hastily planned or quickly eaten. The underweight person frequently must be encouraged to eat, even if not hungry. The secret is to individualize the program with readily available foods that the individual really enjoys, with a plan for regular eating times throughout the day. In addition to meals, snacks are usually necessary to adequately increase the energy intake. Often a liquid supplement taken with meals or between meals is effective; it is nutritious as well as easy to prepare and consume.

The energy distribution of the diet should be approximately 30% of the kilocalories from fat, with the majority from monounsaturated or polyunsaturated sources and at least 12% to 15% of the kilocalories from protein. A basic vitamin and mineral supplement may be encouraged. In addition to an intake according to estimated energy requirements for the present weight, 500 to 1000 extra kilocalories per day should be planned. If 2400 kcal maintains the current weight, 2900 to 3400 kcal would be required for weight gain. The intake should be increased gradually to avoid gastric discomfort, discouragement, electrolyte imbalances, and heart dysfunction. Step-up plans are outlined in Table 22-8.

In underweight children, nonnutritional factors, insufficient caloric intake, excessive nutrient losses, and abnormal energy metabolism may contribute to growth failure and morbidity. Thus adequate nutritional support should be an integral part of the management plan. Lipid-based nutrient

## CLINICAL SCENARIO

Maria is a 45-year-old Latina woman who has tried numerous weight-loss programs. She has followed strict diets and has never exercised in previous weight-loss attempts. She takes several cardiac medications, none of which she can remember. Her blood pressure is 160/90, she is 5 ft 4 in, and she weighs 195 lb. Her lowest body weight was 130 lb at age 30, maintained for 2 years. Maria mentioned that she tried numerous diets while a teenager, when she weighed 170 lb for 3 years. What guidelines would you offer to Maria at this time?

### Nutrition Diagnostic Statements

1. Limited adherence to nutrition-related recommendations related to multiple failed weight-loss attempts as evidenced by no change in weight
2. Overweight and obesity related to excessive energy intake as evidenced by weight 70 lbs over desirable weight

### Nutrition Care Questions

1. How would you address the concern about medications?
2. What types of exercise would you be likely to discuss?
3. Which macro- and micronutrients would you discuss with Maria (e.g., total fat, saturated fat, sodium, potassium, calcium)?
4. How would you bring up exercise and what would you recommend for Maria?
5. What would be the goals of her treatment?

**TABLE 22-8**

### Suggestions for Increasing Energy Intake

Additional Foods	kcal	Protein (g)
<b>Plus 500 kcal (Served Between Meals)</b>		
1. 1 c dry cereal	110	2
1 banana	80	
1 c whole milk	159	8
1 slice toast	60	2
1 T peanut butter	86	4
	495	16
2. 8 saltine crackers	99	3
1 oz cheese	113	7
1 c ice cream	290	6
	502	16
3. 6 graham cracker squares	165	3
2 T peanut butter	172	8
1 c orange juice	122	
2 T raisins	52	
	511	11

## CHAPTER 23

Janet E. Schebendach, PhD, RD

# Nutrition in Eating Disorders

### KEY TERMS

amenorrhea  
**anorexia nervosa (AN)**  
**binge**  
**binge eating disorder (BED)**  
**body image distortion**  
**bulimia nervosa (BN)**  
**cognitive behavioral therapy (CBT)**

**Diagnostic and Statistical Manual of Mental Disorders, IV, TR (DSM-IV-TR)**  
**eating disorder not otherwise specified (EDNOS)**  
**hypercarotenemia**  
**lanugo**  
**low T3 syndrome**  
**purgings**  
**Russell sign**

Eating disorders (EDs) are debilitating psychiatric illnesses characterized by a persistent disturbance of eating habits or weight control behaviors that result in significantly impaired physical health and psychosocial functioning. American Psychiatric Association (APA) diagnostic criteria are available for anorexia nervosa (AN), bulimia nervosa (BN), eating disorder not otherwise specified (EDNOS), and binge eating disorder (BED). Childhood eating disturbances and the female athlete triad are also characterized by disordered eating and weight control behaviors (see Chapters 22 and 24).

### DIAGNOSTIC CRITERIA

Diagnostic criteria for EDs have been established by the APA and are currently published in the **Diagnostic and Statistical Manual of Mental Disorders IV, TR (DSM-IV-TR)**; however, these criteria are currently under revision. For an update on the status of proposed revisions, the reader is referred to the following APA website: <http://www.dsm5.org>.

### Anorexia Nervosa

A core clinical feature of **anorexia nervosa (AN)** is voluntary self-starvation resulting in emaciation. The reported lifetime prevalence of AN in women is 0.3% to 3.7%, depending on how strictly diagnostic criteria are defined (American Psychiatric Association [APA], 2006). Among men, lifetime prevalence has recently been estimated at 0.3% (Treasure et al., 2010). AN is more prevalent in Westernized, postindustrialized societies; however, more global distribution of EDs (Becker, 2004), including third world countries is expected. Genetic, biologic, and psychosocial factors contribute to the pathogenesis of this disorder (Treasure et al., 2010).

Initial presentation of AN typically occurs during adolescence or young adulthood; however, later onset (i.e., initial onset at age 25 or older) may develop in response to adverse life events. Incidence rates for AN among middle-age women (older than age 50) account for less than 1% of newly diagnosed AN patients (APA, 2006).

**BOX 23-1****American Psychiatric Association (DSM-IV) Criteria****Anorexia Nervosa**

- A.** Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g., weight loss leading to maintenance of body weight less than 85% of that expected; or failure to make expected weight gain during period of growth, leading to body weight less than 85% of that expected)
- B.** Intense fear of gaining weight or becoming fat, even though underweight
- C.** Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight
- D.** In postmenarcheal females, amenorrhea (i.e., the absence of at least three consecutive menstrual cycles)
  - 1.** Restricting type: During the current episode of AN, not regularly engaged in binge eating or purging behavior
  - 2.** Binge eating-purging type: During the current episode of AN, regularly engaged in binge eating and purging behavior

**Bulimia Nervosa**

- A.** Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
  - 1.** Eating, in a discrete period (e.g., within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances
  - 2.** A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating)
- B.** Recurrent inappropriate compensatory behavior to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise
- C.** Binge eating and inappropriate compensatory behaviors both occurring, on average, at least twice a week for 3 months

From American Psychiatric Association: Diagnostic and statistical manual of mental disorders, *DSM-IV-TR*, ed 4, text revision, Washington, DC, 2000, American Psychiatric Association. Changes in these diagnostic criteria are expected in the 5<sup>th</sup> revision of the DSM.

*AN*, Anorexia nervosa, *BN*, bulimia nervosa, *EDNOS*, eating disorder not otherwise specified.

- D.** Self-evaluation unduly influenced by body shape and weight
- E.** Disturbance not exclusively occurring during episodes of AN
  - 1.** Purging type: During the current episode of BN, regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas
  - 2.** Nonpurging type: During the current episode of BN, use of other inappropriate compensatory behaviors such as fasting or excessive exercise but not regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas

**Eating Disorder Not Otherwise Specified**

*EDNOS* is for disorders of eating that do not meet criteria for any specific eating disorder. For example:

- 1.** For females, all of the criteria for AN are met except that the individual has regular menses.
- 2.** All of the criteria for AN are met except that, despite significant weight loss, the individual's current weight is in the normal range.
- 3.** All of the criteria for BN are met except that the binge eating and inappropriate compensatory mechanisms occur at a frequency of less than twice a week or for a duration of less than 3 months.
- 4.** An individual of normal body weight regularly uses inappropriate compensatory behavior after eating small amounts of food.
- 5.** An individual repeatedly chews and spits out, but does not swallow, large amounts of food.

**Binge Eating Disorder**

- A.** Recurrent episodes of binge eating in the absence of the regular use of inappropriate compensatory behaviors characteristic of BN
- B.** Binge episodes occurring at least 2 days per week for a period of 6 months

([APA, 2000](#)). The weight deficit may occur secondary to purposeful weight loss or manifest as failure to gain weight during periods of linear growth in children and adolescents. The *DSM-5* is likely to eliminate the 85% cutoff point for body weight deficit.

Determination of “minimally normal weight” is problematic. Metropolitan Life Insurance Company weight standards are often used; however, recommended weight for height differs between the 1959 and 1983 tables. Dietitians

Criteria for the establishment of a diagnosis of AN were first published in [1972 by Feighner and associates](#). The APA first published criteria for the diagnosis of AN in 1980; however, it was not until 1987 that the APA recognized AN and BN as two separate and distinct clinical entities. See [Box 23-1](#) for the current diagnostic criteria for AN.

The *DSM-IV-TR* defines AN “refusal to maintain a body weight at or above a minimally normal weight for age and height (e.g., body weight less than 85% of that expected)”

often calculate desirable body weight using the Hamwi method.\* This is not recommended in patients with an ED because it calculates a “normal” body weight much lower than other standards. Use of BMI has become increasingly accepted in the management of AN patients. Although a body mass index (BMI) of 19–25 kg/m<sup>2</sup> is considered normal for most healthy individuals, a BMI of 19–20 kg/m<sup>2</sup> represents a low-normal target body weight for AN patients (Royal College of Psychiatrists, 2005).

In children and adolescents, growth records should be obtained to determine if linear growth has deviated from premorbid height curves. If stunting has occurred, calculation of the weight deficit should be based on the premorbid height percentile. In 11- to 17-year-olds a normal body weight can be derived from the National Center for Health Statistics (NCHS) weight and height tables (see Appendixes 11 and 15).

BMI norms (see Appendixes 12 and 16) vary with age; therefore assessment of BMI in children and adolescents should be related to BMI percentiles (Royal College of Psychiatrists, 2005). Once again, if growth retardation is suspected, assessment of BMI should be based on expected rather than actual height. A BMI in the range of the 14th to 39th percentile can be used to assign an initial treatment goal weight, with adjustments made for prior weight, stage of pubertal development, and anticipated growth (Golden et al., 2008).

Patients with AN have **body image distortion**, causing them to feel fat despite their often cachectic state. Some individuals feel overweight all over, whereas others are overly concerned about the fatness of a specific body part such as the abdomen, buttocks, or thighs.

**Amenorrhea**, defined as the absence of at least three consecutive menstrual cycles in postmenarcheal women, is a problematic diagnostic criterion because some patients continue to menstruate regardless of a low body weight (Attia and Roberto, 2009); this criterion will most likely be eliminated from DSM-5 to be released soon. Development of AN during prepubescence may result in arrested sexual maturation and delayed menarche (primary amenorrhea). Young adolescent males with AN may have estrogen and testosterone deficiency and arrested growth and sexual development.

AN is categorized into two diagnostic subtypes: restricting and binge eating and purging. The restricting type is characterized by food restriction without binge eating or purging (self-induced vomiting or misuse of laxatives, enemas, or diuretics). Binge eating and purging is characterized by regular episodes of binge eating or purging behavior. Patients may initially present with the restricting subtype but migrate to the binge-and-purge subtype as the duration of their illness progresses.

\*Hamwi Method for women: 100 lb for the first 5 feet of height plus 5 lb per inch for every inch over 5 feet plus 10% for a large frame and minus 10% for a small frame. For men: 106 lb for the first 5 feet of height plus 6 lb per inch for every inch over 5 feet plus 10% for a large frame and minus 10% for a small frame.

Psychological features associated with AN include perfectionism, compulsivity, harm avoidance, feelings of ineffectiveness, inflexible thinking, overly restrained emotional expression, and limited social spontaneity. Several psychiatric conditions may also coexist with AN, and these include depression, anxiety disorders, obsessive-compulsive disorder (OCD), personality disorders, and substance abuse.

Lifetime comorbid depression has been reported in 50% to 75% of AN patients; however, symptoms may remit during the course of nutrition rehabilitation and weight restoration. Because the rate of suicide is greater among individuals with AN than in the general population, ongoing psychiatric assessment is critical. More than 40% of AN patients also have OCD. Onset of OCD frequently predates AN, and many patients remain symptomatic despite weight restoration (APA, 2006).

Crude mortality rates range from 0% to 8% across studies, with a cumulative mortality rate of 2.8% (Keel, 2010). Malnutrition, dehydration, and electrolyte abnormalities may precipitate death by inducing heart failure or fatal arrhythmias (McCallum et al., 2006). Overall, approximately 50% of deaths are attributed to medical complications directly related to AN (Steinhausen, 2002).

## Bulimia Nervosa

**Bulimia nervosa (BN)** is a disorder characterized by recurrent episodes of binge eating followed by one or more inappropriate compensatory behaviors to prevent weight gain. These behaviors include self-induced vomiting, laxative misuse, diuretic misuse, compulsive exercise, or fasting. The lifetime prevalence of BN among young adult women in the United States is estimated to be 1% to 3%. The rate of occurrence in men is approximately one tenth that in women.

Unlike AN patients with binge-and-purge subtype, patients with BN are typically within the normal weight range. Like their AN counterparts, these individuals place considerable importance on body shape and size, and they are often frustrated by their inability to attain an underweight state.

It is commonly thought that vomiting is the predominant feature of BN; however, it is the binge eating behavior that is central to the diagnosis. A **binge** is consumption of an unusually large amount of food in a discrete period (usually approximately 2 hours). There is a sense of lack of control over the eating episode. Although the amount of food and caloric content of a binge vary, binges are often in the range of 1000 to 2000 calories (Fairburn and Harrison, 2003). Although BN patients typically binge on energy-dense foods like desserts and savory snacks, binges can also include lower-calorie foods like fruit and salad. Patients may report a binge episode when the amount of food consumed is clearly not excessive. Although these “subjective binges” may not support a diagnosis of BN, these individuals have feelings about their eating behavior that merit further exploration.

BN patients engage in compensatory behaviors intended to offset food binges. The choice of compensatory behaviors

further classifies BN into purging and nonpurging subtypes. Patients with **purgung** type BN regularly engage in self-induced vomiting or the misuse of laxatives, enemas, or diuretics. Those with nonpurging-type BN do not regularly engage in purging behaviors but rather fast or excessively exercise to compensate for their binge. To meet full DSM-IV-TR criteria for BN bingeing, both binge eating and recurrent inappropriate compensatory behaviors must occur, on average, at least twice a week for 3 months; the frequency at which these behaviors are required to occur are likely to decrease in the upcoming DSM-5. Current APA diagnostic criteria for BN are listed in **Box 23-1**.

Adverse emotional states such as labile mood, frustration, anxiety, and impulsivity are often found in patients with BN. Psychiatric comorbidities, including depression, anxiety disorders, personality disorders, substance abuse, and self-injurious behaviors, are also common in BN. Compared with AN, BN patients are usually embarrassed and distressed by their symptoms, making it easier to engage them in treatment.

Causal factors proposed for the development of BN include addictive, family, sociocultural, cognitive-behavioral, and psychodynamic models (APA, 2006). BN, with or without comorbid psychiatric illness, should be treated and monitored by a mental health professional.

Mortality rates for BN are lower than those for AN. Crude mortality rates range from 0% to 2% across studies, with a cumulative mortality rate of 0.4% (Keel and Brown, 2010).

### Eating Disorder Not Otherwise Specified

Under DSM-IV, approximately half of the individuals with EDs fall into the **eating disorder not otherwise specified (EDNOS)** diagnostic group. Essentially these individuals meet most, but not all, of the criteria for AN or BN (e.g., a woman might meet all diagnostic criteria for AN except amenorrhea; a previously obese patient who, despite extreme weight loss, pathologic eating behavior, and amenorrhea fails to meet the AN criterion of body weight less than 85% of expected; a person who binges and purges, but with less frequency or for a shorter duration, than is specified for BN; or the individual who does not binge but vomits after eating a normal-size meal or snack). Clinically the EDNOS patient should receive treatment consistent with reasonable and customary care for either AN or BN. Inadequate treatment may lead to the development of full criteria AN or BN. In addition, patients who meet criteria for BED, a diagnostic group for research purposes only, are clinically diagnosed with EDNOS. See **Box 23-1** for APA diagnostic criteria for EDNOS. Proposed revisions to the diagnostic criteria (DSM-V) are likely to result in a greater number of patients meeting criteria for AN and BN, and fewer meeting criteria for a subclinical ED (i.e., EDNOS).

### Binge Eating Disorder

Research criteria for **binge eating disorder (BED)** are listed in **Box 23-1**. Binge eating, similar to that seen in BN, is characteristic of BED; however, there are no inappropriate

compensatory behaviors after the binge. Binge episodes must occur at least 2 days per week for a period of 6 months.

Persons with BED experience a feeling of powerlessness over their eating, similar to that felt by BN patients. Significant emotional distress characterized by feelings of disgust, guilt, and depression occurs after a binge. Onset of BED generally occurs in late adolescence or in the early twenties, with women being 1.5 times more likely to develop this disorder than men.

Most patients with this disorder are overweight, with 15% to 50% prevalence among participants in weight-control programs. Patients with BED may have a higher lifetime prevalence of major depression, substance abuse, and personality disorders.

### Eating Disorders in Childhood

Onset of EDs most typically occurs during adolescence and young adulthood. When an ED is suspected in a child or young teen, use of DSM criteria may be problematic because clinical presentation often differs from that seen in older adolescents and young adults. Complaints of nausea, abdominal pain, and difficulty in swallowing may coexist with concerns about weight, shape, and body fatness. Food avoidance, self-induced vomiting, and excessive exercise may occur, but laxative misuse is uncommon.

Any child or adolescent practicing unhealthy weight-control practices or thinking obsessively about food, body weight or shape, or exercise may be at risk for an ED. Other obsessive behaviors and depression may coexist in these children as well. Early-onset AN may result in delayed or stunted growth, osteopenia, and osteoporosis. AN has been reported in children as young as 7 years of age. The boy/girl ratio may be higher in this younger age group, and it appears in many different cultures and ethnic groups. BN in children is rare (APA, 2006).

The relationship between problematic childhood eating behaviors and subsequent development of EDs in later life is of concern. A longitudinal study of 800 children found that eating conflicts, food struggles, and unpleasant meals were risk factors for the later development of an ED (Kotler et al., 2001).

Childhood eating disturbances described by Bryant-Waugh (2007) include AN and, rarely, BN, as well as food avoidance emotional disorder, selective eating, restrictive eating, food refusal, functional dysphagia, and pervasive refusal syndrome (**Table 23-1**). Changes in the diagnostic criteria for childhood EDs have also been proposed for DSM-5 and are being developed (Bryant-Waugh et al., 2010).

## TREATMENT APPROACH

Treatment of EDs requires a multidisciplinary approach that includes psychiatric, psychological, medical, and nutrition interventions. Treatment, provided at several levels of care depending on severity of illness, includes inpatient hospitalization, residential treatment, day hospitalization, intensive outpatient treatment, and outpatient treatment.

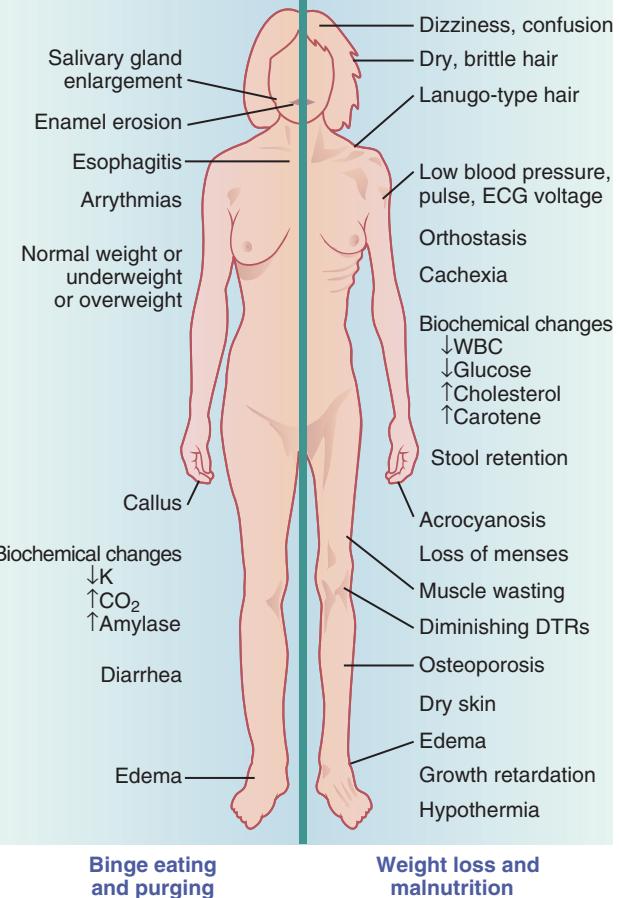

**TABLE 23-1****Eating Disorders in Children Aged 8 to 14 Years**

<b>Eating Disturbance</b>	<b>Characteristics</b>
Anorexia nervosa	Determined weight loss (e.g., through food avoidance, self-induced vomiting, excessive exercising, abuse of laxatives) Abnormal cognitions regarding weight and/or shape Morbid preoccupation with weight and/or shape, food, and/or eating
Bulimia nervosa	Recurrent binges and purges and/or food restriction Sense of lack of control Abnormal cognitions regarding weight and/or shape

From Bryant-Waugh R, and Lask, R: Overview of the eating disorders. In Lask B, Bryant-Waugh R, editors: *Eating disorders in childhood and adolescence*, 3<sup>rd</sup> Ed., East Sussex, UK, 2007, Routledge.

Inpatient treatment can be provided on a psychiatric or medical unit; a behavioral protocol developed specifically for the management of eating-disordered patients is highly recommended. Residential treatment programs also provide 24-hour care, but they are not usually equipped to handle the medically or psychiatrically unstable patient. Day hospital programs are also available. In this setting, patients initially receive 6 to 8 hours of specialized multidisciplinary treatment for 5 to 7 days per week. As treatment progresses, required attendance tapers off. The least intensive form of treatment is outpatient care; however, this still requires the ongoing, coordinated effort of physicians, psychotherapists, and nutritionists. Intensive outpatient treatment programs are also available. In this setting, patients receive several hours of multidisciplinary care each week. This may be scheduled in the late afternoon or early evening so the patient can attend after school or work.

The *Practice Guideline for the Treatment of Patients with Eating Disorders* (APA, 2006) provides comprehensive guidelines for the formulation and implementation of treatment plans in patients with AN, BN, EDNOS, and BED. These guidelines provide specific treatment recommendations (e.g., nutritional rehabilitation, medical management, psychological interventions, medication management) and level-of-care guidelines for patients with EDs. In addition, the Society for Adolescent Medicine (SAM, 2003), the American Academy of Pediatrics (2003), Committee on Adolescence (Rosen et al., 2010) and the American Dietetic Association (ADA, 2006) have published policy statements and positions regarding guidelines for effective treatment of EDs.

## **CLINICAL CHARACTERISTICS AND MEDICAL COMPLICATIONS**

Although EDs are classified as psychiatric illnesses, they are associated with significant medical complications, morbidity, and mortality. Numerous physiologic changes result from the weight-control habits of patients with AN and BN. Some are minor changes that occur secondary to reduced energy intake, some are pathologic alterations that may have long-term consequences, and a few represent potentially life-threatening conditions.

### **Anorexia Nervosa**

Patients with AN have a typical and distinctive appearance (Figure 23-1). Their cachectic and prepubescent body habitus often makes them look younger than their age. Common physical findings include **lanugo**, soft, downy hair growth, dry and brittle hair, hypercarotenemia, cold intolerance, and cyanosis of the extremities.

Protein-energy malnutrition with resultant loss of lean body mass is associated with reduced left ventricular

mass and systolic dysfunction in AN. Cardiovascular complications include bradycardia, orthostatic hypotension, and cardiac arrhythmias. Protein-calorie malnutrition and deficiencies of thiamin, phosphorus, magnesium, and selenium have been associated with heart failure in AN; however, cardiac function is largely reversible with correction of dietary deficiencies and adequate weight restoration (Birmingham and Gritzner, 2007).

Gastrointestinal complications secondary to starvation include delayed gastric emptying, decreased small bowel motility, and constipation. Complaints of abdominal bloating and a prolonged sensation of abdominal fullness complicate the refeeding process.

Significant bone loss occurs frequently and early in the course of illness among both males and females, with an estimated 92% having bone mineral density (BMD) consistent with a diagnosis of osteopenia, and 40% having BMD consistent with a diagnosis of osteoporosis (Mehler and MacKenzie, 2009). Hormone replacement therapy and treatment with bisphosphonates have been found to be ineffective or inadequately studied in AN. Weight restoration is recommended as the first line of treatment for improved BMD in adolescent girls with AN (Golden, 2005). Unfortunately, AN patients often have a protracted course of illness associated with frequent relapse resulting in weight loss. Under these circumstances, reversibility of bone mineralization may be difficult and some studies demonstrate that bone density is not fully recoverable (Mehler and MacKenzie, 2009).

Children and adolescents with AN develop unique medical complications that affect normal growth and development such as growth retardation, reduction in peak bone mass, and structural abnormalities in the brain (SAM, 2003).

### Bulimia Nervosa

Clinical signs and symptoms of BN are more difficult to detect because patients are usually of normal weight and secretive in behavior. When vomiting occurs, there may be clinical evidence such as (1) scarring of the dorsum of the hand used to stimulate the gag reflex, known as **Russell sign**; (2) parotid gland enlargement; and (3) erosion of dental enamel with increased dental caries resulting from the frequent presence of gastric acid in the mouth.

Chronic vomiting can result in dehydration, alkalosis, and hypokalemia. Common clinical manifestations include sore throat, esophagitis, mild hematemesis (vomiting of blood), abdominal pain, and subconjunctival hemorrhage. More serious gastrointestinal complications include Mallory-Weiss esophageal tears, rare occurrence of esophageal rupture, and acute gastric dilation or rupture. Ipecac, used to induce vomiting, may cause irreversible myocardial damage and sudden death.

Laxative abuse may lead to dehydration, elevation of serum aldosterone and vasopressin levels, rectal bleeding, intestinal atony, and abdominal cramps. Diuretic abuse may lead to dehydration and hypokalemia. Cardiac arrhythmias can occur secondary to electrolyte and

acid-base imbalance caused by vomiting, laxative, and diuretic abuse. Although the profound amenorrhea associated with AN is uncommon in BN, menstrual irregularities may occur (see Figure 23-1).

## PSYCHOLOGICAL MANAGEMENT

EDs are complex psychiatric illnesses that require psychological assessment and ongoing treatment. Evaluation of the patient's cognitive and psychological stage of development, family history, family dynamics, and psychopathologic condition is essential for the development of a comprehensive psychosocial treatment program.

The long-term goals of psychosocial interventions in AN are (1) to help patients understand and cooperate with their nutritional and physical rehabilitation, (2) to help patients understand and change behaviors and dysfunctional attitudes related to their EDs, (3) to improve interpersonal and social functioning, and (4) to address psychopathologic and psychological conflicts that reinforce or maintain eating-disordered behaviors.

In the acute stage of illness, malnourished AN patients are typically negativistic and obsessional, making it difficult to conduct formal psychotherapy. At this stage of treatment, psychological management is often focused on positive behavioral reinforcement of weight restoration. This includes praise for positive efforts, reassurance, coaching, and encouragement. Inpatient behavioral management typically uses reinforcers that link attainment of privileges such as physical activity (versus bed rest), off-unit passes, and visitation privileges with attainment of targeted weight gain and improved eating behaviors.

Once acute malnutrition has been corrected and weight restoration is underway, the AN patient is more likely to benefit from psychotherapy. Psychotherapy can help the patient understand and change core dysfunctional thoughts, attitudes, motives, conflicts, and feelings related to his or her ED. Associated psychiatric conditions, including deficits in mood, impulse control, and self-esteem, as well as relapse prevention, should be addressed in the psychotherapeutic treatment plan. Several years of ongoing psychotherapy may be necessary for recovery.

**Cognitive behavioral therapy (CBT)** is a highly effective intervention for treatment of the acute symptoms of BN (Fairburn, 2008). Nevertheless, clinicians may combine elements of several types of psychotherapy during treatment. In some cases, adjunctive family and marital therapy may also be beneficial.

Several validated psychological instruments and questionnaires are available for the assessment of patients with EDs self-report measures may be used for screening purposes, whereas structured interviews are often used to confirm the diagnosis. Representative instruments include the Eating Attitudes Test, Eating Disorder Inventory, Eating Disorder Examination, Eating Disorders Questionnaire, and the Yale-Brown-Cornell Eating Disorder Scale (APA, 2006).

## NUTRITION REHABILITATION AND COUNSELING

Nutrition rehabilitation includes nutrition assessment, medical nutrition therapy (MNT), nutrition counseling, and nutrition education. Although the EDs are distinct illnesses, similarities exist in nutritional consequences and nutritional management.

### Nutrition Assessment

Nutrition assessment routinely includes a diet history and the assessment of biochemical, metabolic, and anthropometric indices of nutrition status.

### Diet History

Guidelines should include assessment of energy intake, macronutrient, micronutrient, and fluid consumption, as well as eating attitudes, and eating behaviors (see Chapter 4).

### Anorexia Nervosa

Patients with restricting subtype AN generally consume less than 1000 kcal/day. Assessment of typical energy intake prevents overfeeding or underfeeding at the inception of nutritional rehabilitation and opens a dialogue regarding caloric requirements during the refeeding and weight-maintenance phases of nutritional rehabilitation. Inadequate energy intake results in decreased consumption of carbohydrate, protein, and fat. Patients with AN were historically described as *carbohydrate restrictors*, but at present there is a tendency to avoid fat-containing foods. Observed food intake in 30 patients revealed that patients with AN consumed significantly less fat (15% to 20% of calories) than healthy controls. Percent of calories contributed by protein may be in the average to above-average range, but the adequacy of intake is relative to total caloric consumption. For example, the percentage of calories may remain the same, but as the calorie intake continues to drop, the actual amount of protein falls also. Patients with binge-purge subtype AN have more chaotic diet patterns, and energy consumption should be assessed across the spectrum of restriction and binge eating (Burd et al., 2009).

Vegetarianism is common among AN patients. The nutritionist should determine if adoption of the vegetarian diet predated the development of AN. A vegetarian diet adopted during the course of AN is a covert means of limiting food choice that may justifiably be considered as part of the psychopathologic findings of the disorder (Royal College of Psychiatrists, 2005). Many treatment programs prohibit vegetarian diets during the weight restoration phase of treatment; others allow it. The relationship of social, cultural, and family influences, as well as religious beliefs relative to the patient's vegetarian status must also be explored. If an AN patient is permitted to follow a vegan or vegetarian diet during weight restoration, care must be taken to provide adequate phosphate for prevention of hypophosphatemia,

particularly during the initial stage of refeeding (Royal College of Psychiatrists, 2005).

Inadequate caloric intake, limited variety in the diet, and poor food group representation result in inadequate vitamin and mineral consumption in AN. In general, micronutrient intake parallels macronutrient intake; thus AN patients who consistently restrict dietary fat are at greater risk for inadequate essential fatty acid intake and fat-soluble vitamin intake. Based on a 30-day diet history, Hadigan and colleagues (2000) found that more than 50% of 30 AN patients failed to meet dietary reference intake requirements for vitamin D, calcium, folate, vitamin B<sub>12</sub>, magnesium, copper, and zinc.

When obtaining a diet history, typical fluid intake should also be determined because abnormalities in fluid balance are prevalent in this population. Some patients severely restrict intake because they are intolerant of feeling full after fluid ingestion, whereas others drink excessive amounts, attempting to stave off hunger. Extremes in fluid restriction or ingestion may require monitoring of urine specific gravity and serum electrolytes.

Many AN patients consume excessive amounts of artificial sweeteners and artificially sweetened beverages (Marino et al., 2009). Use of these products should be addressed during the course of nutrition rehabilitation.

### Bulimia Nervosa

Chaotic eating, ranging from restriction to normal eating to binge eating, is a hallmark feature of bulimia nervosa. Energy intake in BN can be unpredictable. The caloric content of a binge, the degree of caloric absorption after a purge, and the extent of caloric restriction between binge episodes make assessment of total energy intake challenging. Bulimic patients assume that vomiting is an efficient mechanism for eliminating calories consumed during binge episodes; however, this is a common misconception. In a study of the caloric content of foods ingested and purged in a feeding laboratory, it was determined that, as a group, BN subjects consumed a mean of 2131 kcal during a binge and vomited only 979 kcal afterward (Kaye et al., 1993). As a rule of thumb, patients should be advised that approximately 50% of energy consumed during a binge is retained.

Because of day-to-day variability, a 24-hour recall is not a particularly useful assessment tool. To assess energy intake, it is helpful to estimate daily food consumption over the course of a week. First determine the number of non-binge days (which may include restrictive and normal intake days) and approximate their caloric content; then determine the number of binge days and approximate caloric content, and deduct 50% of the caloric content of binges that are purged (vomited); finally, average the caloric intake over the 7-day period. Determination of this average energy intake, as well as the range of intake, will be useful information for the counseling process.

Nutrient intake in patients with BN varies with the cycle of binge eating and restriction, and it is likely that overall diet quality and micronutrient intake is inadequate. A 14-day dietary intake study of 50 BN patients revealed that at least

**BOX 23-2****Assessment of Eating Attitudes, Behaviors, and Habits**

- 1. Eating attitudes**
  - A. Food aversions
  - B. Safe, risky, forbidden foods
  - C. Magical thinking
  - D. Binge trigger foods
  - E. Ideas on appropriate amounts of food
- 2. Eating behaviors**
  - A. Ritualistic behaviors
  - B. Unusual food combinations
  - C. Atypical seasoning of food
  - D. Excessive and atypical use of non-caloric sweeteners
  - E. Atypical use of eating utensils
- 3. Eating habits**
  - A. Intake pattern
    - (1) Number of meals and snacks
    - (2) Time of day
    - (3) Duration of meals and snacks
    - (4) Eating environment—where and with whom
    - (5) How consumed—sitting or standing
  - B. Avoidance of specific food groups, particularly those with higher energy density
  - C. Evidence of diet variety
  - D. Fluid intake—restricted or excessive

Adapted from: Schebendach J, Nussbaum M: Nutrition management in adolescents with eating disorders, *Adolesc Med: State of the Art Rev* 3(3):545, 1992.

50% of participants consumed less than two thirds of the recommended dietary allowance (RDA) for calcium, iron, and zinc on nonbinge days. Furthermore, 25% of participants still had inadequate intakes of zinc and iron when overall intake (i.e., binge and non-binge days) was assessed (Gendall, 1997). It is important to note that even when the diet appears adequate, nutrient loss will occur secondary to purging, thus making it difficult to assess true adequacy of nutrient intake. Use of vitamin and mineral supplements should also be determined but, once again, retention after purging must be considered.

**Eating Behavior**

Characteristic attitudes, behaviors, and eating habits seen in AN and BN are shown in Box 23-2. Food aversions, common in this population, include red meat, baked goods, desserts, full-fat dairy products, added fats, fried foods, and caloric beverages. Patients with EDs often regard specific foods or groups of foods as absolutely “good” or absolutely “bad.” Irrational beliefs and dichotomous thinking about food choices should be identified and challenged throughout the treatment process.

In the assessment it is important to determine unusual or ritualistic behaviors, which may include ingestion of food in an atypical manner or with nontraditional utensils; unusual food combinations; or the excessive use of spices, vinegar, lemon juice, and artificial sweeteners. Meal spacing and length of time allocated for a meal should also be determined. Many patients save their self-allotted food ration until late in the day; others are fearful of eating past a certain time of day.

Many AN patients eat in an excessively slow manner, often playing with their food and cutting it into small pieces. This is sometimes regarded as a tactic to avoid food intake, but it may also be an effect of starvation (Keys et al., 1950). Time limits for meal and snack consumption are frequently incorporated into behavioral treatment plans.

Many BN patients eat quickly, reflecting their difficulties with satiety cues. In addition, BN patients may identify foods they fear will trigger a binge episode. The patient may have an all-or-nothing approach to “trigger” foods. Although the patient may prefer avoidance, assistance with reintroduction of controlled amounts of these foods at regular times and intervals is helpful.

**Biochemical Assessment**

The marked cachexia of AN may lead one to expect biochemical indices of malnutrition (see Chapter 8), but this is rarely the case. Compensatory mechanisms are remarkable, and laboratory abnormalities may not be observed until the illness is far advanced.

Significant alterations in visceral protein status are uncommon in AN. Indeed, adaptive phenomena that occur in chronic starvation are aimed at the maintenance of visceral protein metabolism at the expense of the somatic compartment. Serum albumin levels are generally within normal limits, but may be masked by dehydration in early treatment (Swenne, 2004).

Despite consumption of a typically low-fat, low-cholesterol diet, a high total cholesterol level is commonly found in malnourished AN patients (Rigaud et al., 2009). Despite hyperlipidemia, a fat- and cholesterol-restricted diet is not warranted during nutritional rehabilitation. If hyperlipidemia predicated the development of AN, or if a strong family history of hyperlipidemia is identified, the patient should be reassessed after weight restoration and a period of weight stabilization.

Patients with BN may also have abnormal lipid levels. Patients with BN are prone to eating low-fat, low-energy foods during the restriction phase and high-fat, high-sugar foods during binge episodes. Premature prescription of a low-fat, low-cholesterol diet may only reinforce this dichotomous approach to eating. Care must be taken to balance extremes in the types and amounts of foods consumed. An accurate lipid profile can be obtained only after a period of dietary stabilization. Patients with BN may also have difficulty complying with the fast required for an accurate lipid profile.

Low serum glucose results from a deficit of precursors needed for gluconeogenesis and glucose production.

Thyroid hormone production tends to be normal, but the peripheral deiodination of thyroxine favors formation of the less metabolically active reduced triiodothyronine ( $rT_3$ ) rather than triiodothyronine ( $T_3$ ) resulting in **low  $T_3$  syndrome** (Figure 32-2). This metabolic state is characteristic of AN and typically resolves with weight restoration. Thyroid hormone replacement is not recommended (APA, 2006).

## Vitamin and Mineral Deficiencies

**Hypercarotenemia** is a common finding in AN, attributed to mobilization of lipid stores, catabolic changes caused by weight loss, and metabolic stress. Excessive dietary intake of carotenoids is less common. Normalization of serum carotene occurs during the course of nutrition rehabilitation.

Despite obviously deficient diets, reports of clinical and biochemical findings of true deficiency diseases are uncommon. The decreased need for micronutrients in a catabolic state, use of vitamin supplements, and selection of micronutrient-rich foods may be protective. Documented cases of riboflavin, vitamin B<sub>6</sub>, thiamin, niacin, folate, and vitamin E deficiencies have been reported in lower-weight and more chronically ill patients with AN (Altintayazar et al., 2009; Castro, 2004; Jagielska et al., 2007; Prousky, 2003). Patients avoiding animal foods may also be at risk for B<sub>12</sub> deficiency (Royal College of Psychiatrists, 2005).

Iron requirements in AN are decreased secondary to amenorrhea and the overall catabolic state. At treatment onset, the hemoglobin level may be falsely elevated as a result of dehydration resulting in hemoconcentration. Malnourished patients may also have fluid retention, and associated hemodilution may falsely lower the hemoglobin level. In severely malnourished AN patients, iron use may be blocked. Loss of lean tissue results in decreased red blood cell mass. Iron released from red cell mass is bound to ferritin and stored. Saturated ferritin-bound iron stores increase the risk of unbound iron that may result in cell damage, and use of iron supplements should be avoided at this phase of treatment (Royal College of Psychiatrists, 2005). During nutrition rehabilitation and weight restoration, ferritin-bound iron is taken out of storage; this is generally adequate to meet the need for cellular repair and increased red blood cell mass. Patients should, however, be periodically reassessed for depletion of their reserve and the possible need for supplemental iron later in treatment. Hutter and colleagues (2009) presents a comprehensive review of hematological changes that occur in AN.

Zinc deficiency may occur secondary to inadequate energy intake, avoidance of red meat, and the adoption of vegetarian food choices. Although zinc deficiency may be associated with altered taste perception and weight loss, there is no evidence that deficiency causes or perpetuates symptoms of AN. Although supplemental zinc is purported to enhance food intake and weight gain in AN patients, there is poor evidence to support this claim (Lock and Fitzpatrick, 2009).

Although the high prevalence of osteopenia and osteoporosis in AN is largely due to hormone imbalance and weight

loss, concurrent dietary deficiencies of calcium, magnesium, and vitamin D likely contribute to the overall pathogenesis. Dual x-ray absorptiometry to determine the degree of impaired bone mineralization is recommended (see Chapter 25).

## Fluid and Electrolyte Balance

Vomiting and laxative and diuretic use can result in significant fluid and electrolyte imbalances in patients with EDs. Laxative use may result in hypokalemia, and diuretic use can also cause hypokalemia and dehydration. Vomiting may result in dehydration, hypokalemia, and alkalosis with hypochloremia. Hyponatremia is another serious complication, but is seen less frequently.

Urine concentration is decreased, and urine output is increased in semistarvation. Edema may occur in response to malnutrition and refeeding. Depletion of glycogen and lean tissue is accompanied by obligatory water loss that reflects characteristic hydration ratios. For example, the obligatory water loss associated with glycogen depletion may be in the range of 600-800 mL. Varying degrees of fluid intake, ranging from restricted to excessive, may affect electrolyte values in AN patients (see Chapter 7).

## Energy Expenditure

Resting energy expenditure (REE) is characteristically low in malnourished AN patients (de Zwaan et al., 2002). Weight loss, decreased lean body mass, energy restriction, and decreased leptin levels have been implicated in the pathogenesis of this hypometabolic state. Refeeding increases and normalizes REE in AN patients. An exaggerated diet-induced thermogenesis (DIT) has also been reported in AN during the course of refeeding (de Zwann et al., 2002). This may pose metabolic resistance to weight gain during the course of nutritional rehabilitation in patients with AN (see Chapter 2).

Patients with BN can have unpredictable metabolic rates. Dietary restraint between episodes of binge eating may place bulimic patients in a state of semistarvation (resulting in a hypometabolic rate). However, binge eating followed by purging can increase the metabolic rate secondary to a preabsorptive release of insulin, which activates the sympathetic nervous system (de Zwann et al., 2002).

Baseline and follow-up assessment of REE may be clinically useful throughout the course of nutritional rehabilitation (Dragani et al., 2006; Schebendach, 2003); however, access to standard indirect calorimetry is typically limited to research settings. Although portable, handheld devices like the MedGem have been increasingly popular in the general population, a recent study of AN patients found poor agreement between MedGem and a standard indirect calorimeter measurements of REE (Hlynky et al., 2005).

## Anthropometric Assessment

Patients with AN have protein-energy malnutrition characterized by significantly depleted adipose and somatic protein stores, but a relatively intact visceral protein compartment. These patients meet the criteria for a diagnosis

of severe protein-energy malnutrition. A goal of nutritional rehabilitation is restoration of body fat and fat-free mass. Although these compartments do regenerate, the extent and rate vary.

Percent body fat can be estimated from the sum of four skinfold measurements (triceps, biceps, subscapular, and suprailiac crest) (see Figures 6-4, 6-5, and 6-6) using the calculations of Durnin and colleagues (Durnin and Rahaman, 1967; Durnin and Womersley, 1974) (see Appendix 24). This method has been validated against underwater weighing to assess percentage of body fat in adolescent girls with AN (Probst, 2001). A more accurate measurement of percentage of body fat can be obtained from underwater weighing or from a dual-energy x-ray absorptiometry (DEXA) scan (see Figure 6-10) equipped with body composition software; however, these methods are not generally available in an office or clinic setting (see Chapter 6 on Physical Assessment).

Bioelectrical impedance analysis (BIA) is more readily available, but shifts in intracellular and extracellular fluid compartments in patients with severe EDs may affect the accuracy of body fat measurement. To improve the validity of BIA measurement in AN patients (see Figure 6-9), the measurement should be done in the morning before ingestion of all food and liquid, using a reclining chair that is always reclined to the same position to prevent differential pooling of fluids (Sunday and Halmi, 2003). A comparison of body composition measurements assessed by several impedance methods, as well as DEXA, has been reported in AN patients and healthy controls (Moreno et al., 2008).

For practical purposes the midarm muscle circumference, derived from midarm circumference and triceps skinfold measurements (see Figure 6-7), can be easily obtained and compared with sex- and age-matched population standards (see Appendixes 25 and 26). Baseline and follow-up measurements can be easily obtained during nutritional rehabilitation.

Body weight is assessed and routinely monitored in patients with EDs. In AN weight gain is necessary. In BN the short-term goal should be weight maintenance. Although weight loss may be warranted, this cannot be addressed until chaotic eating patterns are stabilized.

Rate of weight gain in AN may be affected by hydration status, glycogen stores, metabolic factors, and changes in body composition (Box 23-3). Rehydration and replenished glycogen stores contribute to weight gain during the first few days of refeeding. Thereafter weight gain results from increased lean and fat stores. It is generalized that one needs to increase or decrease caloric intake by 3500 kcal to cause a 1-lb change in body weight, but the true energy cost depends on the type of tissue gained. More energy is required to gain fat versus lean tissue, but weight gain may be a mix of fat and lean tissue.

In adult women with AN, short-term weight restoration has been associated with a significant increase in truncal fat with central adiposity (Grinspoon, 2001; Mayer, 2005; Mayer et al., 2009); however, this abnormal distribution appears to normalize within 1 year of weight maintenance (Mayer et al., 2009). In adolescent girls with AN, short-term

## BOX 23-3

### Factors Affecting Rate of Weight Gain in Anorexia Nervosa

1. Fluid balance
  - A. Polyuria seen in semistarvation
  - B. Edema
    - (1) Starvation
    - (2) Refeeding
  - C. Hydration ratios in tissues
    - (1) Glycogen: 3-4:1
    - (2) Protein: 3-4:1
2. Metabolic rate
  - A. Resting energy expenditure
  - B. Postprandial energy expenditure
  - C. Respiratory quotient
3. Energy cost of tissue gained
  - A. Adipose tissue
  - B. Lean body mass
4. Previous obesity
5. Physical activity

Adapted from Schebendach J, Nussbaum M: Nutrition management in adolescents with eating disorders, Adolesc Med: State of the Art Rev 3(3):545, 1992.

weight restoration is associated with normalization of body fat without increased central adiposity (de Alvaro et al., 2007; Misra, 2003).

The anthropometric status of patients with EDs should be assessed and monitored regularly (see Chapter 6). The patient's goal weight can be determined by various methods, none of which is perfect. The height, weight, and BMI percentile tables of the NCHS should be used to assess boys and girls up to 20 years of age (see Appendixes 11 and 12 and 15 and 16). A bone age can be obtained in adolescents with stunted height to determine catch-up growth potential.

If a patient is hospitalized, a daily preprandial, early-morning weight should be obtained. On an outpatient basis a gowned weight should be obtained on the same scale, at approximately the same time of day, at least once a week in early treatment. Before weigh-in the patient should void, and urine specific gravity should be checked for dehydration or fluid loading. If the patient claims to be unable to provide a urine specimen, the physician should examine the patient to see whether the bladder is full. Patients may resort to deceptive tactics (water loading, hiding heavy objects on their person, and withholding urine and bowel movements) to make a mandated weight goal.

### MEDICAL NUTRITION THERAPY AND COUNSELING

Treatment of an ED may begin at one of four levels of care: outpatient, intensive outpatient, day treatment, inpatient. The registered dietitian (RD) is an essential part of the treatment team at all levels of care.

In AN the chosen level of care is determined by the severity of malnutrition, degree of medical and psychiatric instability, duration of illness, and growth failure. In some instances, treatment begins on an inpatient unit but is stepped down to a less intensive level of care as weight restoration progresses. In other instances, treatment begins on an outpatient basis; however, if the rate of weight gain is inadequate, care is stepped up to a more intensive level.

In BN treatment typically begins and continues on an outpatient basis. On occasion a BN patient may be directly admitted to an intensive outpatient or day treatment program. However, inpatient hospitalization is relatively uncommon and generally is of short duration and for the specific purpose of fluid and electrolyte stabilization.

### Anorexia Nervosa

Guidelines for MNT in AN are summarized in **Box 23-4**. Goals for nutrition rehabilitation include restoration of body weight and normalization of eating patterns and behaviors. Although MNT is an essential component of treatment, guidelines are largely based on clinical experience rather than scientific evidence.

Weight restoration is essential for recovery. The medically unstable, severely malnourished, or growth-retarded patient typically requires supervised weight gain in a specialized hospital unit or residential ED treatment program. In these settings, the energy prescription and desired rate of weight gain are usually determined by the medical doctor or the treatment team. Treatment programs often have three phases to the weight restoration process: weight stabilization and prevention of further weight loss, weight gain, and weight maintenance. Although the duration of these phases vary, the weight restoration process is typically the longest and is obviously influenced by patient's state of malnutrition.

Treatment plans typically include a targeted rate of expected rate of weight gain. Gains of 2 to 3 lb/week for the hospitalized patient and 0.5 to 1 lb/week for the outpatient are reasonable and attainable goals. Although the initial calorie prescription may be in the range of 1000 to 1600 kcal/day (30 to 40 kcal/kg of body weight per day), progressive increases in energy intake will be needed to promote a consistent and targeted rate of weight gain. To accomplish this, the caloric prescription is often increased in 100 to 200 calorie increments every 2 to 3 days. In some treatment programs, however, the prescription is increased in larger increments (e.g., in 500-calorie increments) (Yager and Andersen, 2005).

Aggressive refeeding of severely malnourished AN patients (i.e., those weighing less than 70% standard body weight) may precipitate life-threatening complications of the refeeding syndrome during the first week of oral, nasogastric, or intravenous refeeding. Manifestations of the syndrome are fluid and electrolyte imbalance; cardiac, neurologic, and hematologic complications; and sudden death. High-risk patients need to be carefully monitored with daily measurements of serum phosphorus, magnesium,

### BOX 23-4

#### Guidelines for Medical Nutrition Therapy of Anorexia Nervosa

1. Caloric prescription:
  - A. Initial weight gain
    - (1) Initial prescription: 30 to 40 kcal/kg/day (approximately 1000 to 1600 kcal/day)
    - (2) Assess risk for refeeding syndrome
  - B. Controlled weight gain phase
    - (1) Increase calories in small, progressive increments (i.e., 100 kcal) to promote expected rate of controlled weight gain (e.g., 2–3 lb/week for inpatients, 0.5 to 1 lb/week for outpatients)
    - (2) Late treatment: 70 to 100 kcal/kg/day  
Females: 3000 to 4000 kcal/day  
Males: 4000 to 4500 kcal/day
    - (3) If patient requires a higher kcal prescription, evaluate for vomiting, discarding food, increased exercise, increased resting energy expenditure and/or induced thermogenesis
  - C. Weight maintenance phase
    - (1) Adults: 40 to 60 kcal/kg/day
    - (2) Ongoing growth and development in children and adolescents: 40–60 kcal/kg/day
2. Macronutrients
  - A. Protein
    - (1) Minimum intake = RDA in g/kg ideal body weight
    - (2) 15% to 20% kcal
    - (3) High biologic value sources
  - B. Carbohydrate
    - (1) 50% to 55% kcal
    - (2) Provide sources of insoluble fiber for treatment of constipation
  - C. Fat
    - (1) 30% kcal, including sources of essential fatty acids
    - (2) Encourage small increases in fat intake until goal can be attained
3. Micronutrients
  - A. 100% RDA multivitamin with minerals supplement with the exception of iron
  - B. Avoid supplemental iron during initial phase of weight restoration; reassess need during late treatment
  - C. Determine need for supplemental thiamin during course of weight restoration

Adapted from: Luder E, Schebendach J: Nutrition management of eating disorders, *Top Clin Nutr* 8:48, 1993.

RDA, Recommended dietary allowance.

potassium, and calcium for the first 5 days of refeeding and every other day for several weeks thereafter. Supplemental phosphorus, magnesium, and potassium may be given orally or intravenously. Children and adolescents with AN may be at increased risk for refeeding syndrome and care must be taken not to over-prescribe calories in this age group (O'Connor and Goldin, 2010) (see Chapter 14).

Caloric prescriptions in the range of 3000 to 4000 kcal/day (70 to 100 kcal/kg of body weight per day) may ultimately be needed later in the course of weight restoration, and male AN patients may require even more—4000 to 4500 kcal/day (APA, 2006). Changes in REE, DIT, and the type of tissue gained are all factors. In addition, the energy cost of physical activity must be considered because many AN patients expend significant amounts of energy in physical activity or fidgeting behavior (de Zwann et al., 2002).

Patients who require extraordinarily high energy intakes should be questioned or observed for discarding of food, vomiting, exercising, and excessive physical activity, including fidgeting. After the goal weight is attained, the caloric prescription may be slowly decreased to promote weight maintenance. However, caloric prescriptions may remain at higher levels in adolescents with the potential for continued growth and development.

AN patients receiving care in less structured treatment settings such as outpatient treatment programs may be particularly resistant to formalized meal plans. A practical approach may be the addition of 200 to 300 calories per day to the patient's typical (baseline) energy intake. However, the nutritionist must carefully query and assess intake as these patients may overestimate their food and energy consumption.

Once the caloric prescription is calculated, a reasonable distribution of macronutrients must be determined. Patients may express multiple food aversions. Extreme avoidance of dietary fat is common, but continued omission will make it difficult to provide concentrated sources of energy needed for weight restoration. A dietary fat intake of approximately 30% of calories is recommended. This can be accomplished easily when AN patients are treated on inpatient units or in day hospital programs. However, on an outpatient basis small, progressive increases in dietary fat intake rather than a set optimal amount right away may be met with less resistance. Although some patients will accept small amounts of added fat (such as salad dressing, mayonnaise, or butter), many do better when the fat content is less obvious (as in cheese, peanut butter, granola, and snack foods). Encouraging the gradual change from fat-free products (fat-free milk) to low-fat products (1% or 2% milk) and finally to full-fat items (whole milk) is also acceptable to some patients.

A protein intake in the range of 15% to 20% of total calories is recommended. To ensure adequacy the minimum protein prescription should equal the RDA for age and sex in grams per kilogram of ideal body weight (see inside front cover). Vegetarian diets are often requested but should be discouraged during weight restoration.

Carbohydrate intake in the range of 50% to 55% of calories is well tolerated. Sources of insoluble fiber should be included for optimal health, but also to relieve the constipation frequently seen in this population.

Although vitamin and mineral supplements are not universally prescribed, the potential for increased needs during the later stages of weight gain must be considered. Prophylactic prescription of a vitamin and mineral supplement providing 100% of the RDA may be reasonable, but iron supplementation may be contraindicated early in treatment. During weight restoration, prophylactic thiamin supplementation, at a dose of 25 mg/day, may also be warranted; and higher doses may be required if thiamin deficiency is biochemically confirmed (Royal College of Psychiatrists, 2005). Owing to the increased risk of low BMD, liberal amounts of calcium and vitamin D-rich foods must be encouraged. There is, however, no clear consensus on the use of calcium and vitamin D supplements in this population, however vitamin D status should be assessed. See Chapter 8.

Delayed gastric emptying with complaints of abdominal distention and discomfort after eating are common in AN. In early treatment intake is generally low and can be tolerated in three meals per day. However, as the caloric prescription increases, between-meal feedings become essential. The addition of an afternoon or evening snack may relieve the physical discomfort associated with larger meals, but some patients express feelings of guilt for "indulging" between meals. Commercially available, defined-formula liquid supplements containing 30 to 45 calories per fluid ounce are often prescribed once or twice daily. Patients are fearful that they will become accustomed to the large amount of food required to meet increased caloric requirements; thus use of a liquid supplement is appealing because it can easily be discontinued when the goal weight is attained.

Institutions vary with respect to their menu-planning protocol. In some institutions the meal plan and food choices are initially fixed without patient input. As treatment progresses and weight is restored, the patient generally assumes more responsibility for menu planning. In other inpatient programs the patient participates in menu planning from the beginning of treatment. Some institutions have established guidelines that the patient must comply with to maintain the "privilege" of menu planning. Guidelines may require a certain type of milk (e.g., whole versus low fat), and the inclusion of specific types of foods such as added fats, animal proteins, desserts, and snacks. A certain number of servings from the different food groups may be prescribed at different calorie levels. Meal-planning systems also vary among treatment programs. Some design their own, others use food group exchanges or the MyPlate system, and some formulate an individualized meal plan for each patient.

There are no outcome studies to suggest that one method of meal planning is superior to another, and treatment programs tend to have their own philosophy about menu planning. Despite differences in protocol, AN patients

consistently find it difficult to make food choices. The RD can be extremely helpful in providing a structured meal plan and guidance in the selection of nutritionally adequate meals. In a study of recently weight-restored, hospitalized AN patients, those who selected more energy-dense foods and a diet with greater variety had better treatment outcomes during the 1-year period immediately following hospital discharge, and this effect was independent of total caloric intake (Schebendach et al., 2008).

In an outpatient setting the treatment team obviously has less control over the AN patient's food choices, energy intake, and energy distribution. Under these circumstances the RD must use counseling skills to begin the process of developing a plan for nutritional rehabilitation. AN patients are typically precontemplative and, at best, ambivalent about making changes in eating behavior, diet, and body weight; some are defiant and hostile on initial presentation. At this point the nutrition counselor's use of motivational interviewing techniques may help the AN patient resolve ambivalence toward the idea of change and move beyond the precontemplative stage (see Figure 15-3). Use of cognitive behavior therapy may be useful in the nutrition counseling of AN patients (ADA, 2006); the reader is referred to Fairburn (2008) for a thorough review of these techniques.

Effective nutritional rehabilitation and counseling must ultimately result in weight gain and improved eating attitudes and behaviors. A comprehensive review of nutrition counseling techniques can be found in Chapter 15 and in Herrin (2003) and Stellefson Myers (2006).

### Bulimia Nervosa

Guidelines for MNT in BN are summarized in Box 23-5. BN is described as a state of dietary chaos, characterized by periods of uncontrolled, poorly structured eating, which are often followed by a periods of restrained food intake. The nutritionist's role is to help develop a reasonable plan of controlled eating while assessing the patient's tolerance for structure. Because BN patients are hospitalized infrequently, nutrition counseling will most likely begin in an outpatient treatment setting.

In BN much of the patient's eating and purging behavior is aimed at weight loss. Although weight reduction may be a reasonable long-term goal, immediate goals must be interruption of the binge-and-purge cycle, restoration of normal eating behavior, and stabilization of body weight. Attempts at dietary restraint for the purpose of weight loss typically exacerbate binge-purge behavior in BN patients.

Patients with BN have varying degrees of metabolic efficiency, which must be taken into account when prescribing the baseline diet. Assessment of REE along with clinical signs of a hypometabolic state such as a low T<sub>3</sub> level and cold intolerance are useful in determining the caloric prescription. If a low metabolism is suspected, a caloric prescription of 1500 to 1600 calories daily is a reasonable place to start. Another technique that is helpful in establishing an initial caloric prescription is to base it on the patient's present intake by using the following method:

### BOX 23-5

#### Guidelines for Medical Nutrition Therapy of Bulimia Nervosa

1. Caloric prescription for weight maintenance
  - A. If there is evidence of a hypometabolic rate provide 1500 to 1600 kcal/day diet if patient is hypometabolic.
  - B. If metabolic rate appears to be normal, provide DRI for energy if metabolic rate is normal.
  - C. Monitor body weight and adjust caloric prescription for weight maintenance.
  - D. Avoid weight reduction diets until eating patterns and body weight are stabilized.
2. Macronutrients
  - A. Protein
    - (1) Minimum intake is RDA in g/kg of ideal body weight.
    - (2) Provide 15% to 20% kcal.
    - (3) Provide high biologic-value sources.
  - B. Carbohydrate
    - (1) Provide 50% to 55% kcal.
    - (2) Encourage insoluble fiber for treatment of constipation.
  - C. Fat
    - (1) Provide approximately 30% kcal.
    - (2) Provide source of essential fatty acids.
3. Micronutrients
  - A. Provide 100% RDA multivitamin with minerals supplement.
  - B. Note that iron-containing preparation may aggravate constipation.

Adapted from: Luder E, Schebendach J: Nutrition management of eating disorders, *Top Clin Nutr* 8:48, 1993.

DRI, Dietary reference intake; RDA, recommended dietary allowance.

1. For a typical week ask the patient to estimate the number of binge-purge days, binge-nonpurge days, moderate-intake days, and restrained-intake days.
2. Have the patient describe a typical food intake on a binge-purge day, a binge-nonpurge day, a moderate-intake day, and a restrained-intake day.
3. Estimate 50% of the caloric intake on the binge-purge days and 100% of caloric intake on the binge-nonpurge days, moderate-intake days, and restrained-intake days.
4. Calculate the total caloric intake during the 7-day period.
5. Calculate an average daily intake. The RD can then formulate an initial eating and meal plan based on this estimated average daily intake.

Body weight should be monitored with a goal of stabilization. If the patient's weight is stabilized on a lower-than-average caloric intake, small but consistent increases in the caloric intake should be prescribed every 1 to 2 weeks. This

will induce incremental increases in the metabolic rate (Schebendach, 2003).

BN patients need a great deal of encouragement to follow weight-maintenance versus weight-loss diets. They must be reminded that attempts to restrict caloric intake may only increase the risk of binge eating and that their pattern of restrained intake followed by binge eating has not facilitated weight loss in the past.

A balanced macronutrient intake is essential for the provision of a regular meal pattern. This should include sufficient carbohydrates to prevent craving and adequate protein and fat to promote satiety. In general, a balanced diet providing 50% to 55% of the calories from carbohydrate, 15% to 20% from protein, and 25% to 30% from fat is reasonable. Small amounts of dietary fat should be encouraged at each meal. As is the case with AN, this may be better tolerated when provided in a less obvious manner, such as in peanut butter, cheese, or whole milk.

Adequacy of micronutrient intake relative to the caloric prescription and variety of intake should be assessed. A multivitamin and mineral preparation may be prescribed to ensure adequacy, particularly in the initial phase of treatment.

Bingeing, purging, and restrained intake often impair recognition of hunger and satiety cues. The cessation of purging behavior coupled with a reasonable daily distribution of calories at three meals and prescribed snacks can be instrumental in strengthening these biologic cues. Many patients with BN are afraid to eat earlier in the day because they are fearful that these calories will contribute to caloric excess if they binge later. They may also digress from their meal plans after a binge, attempting to restrict intake to balance out the binge calories. Patience and support are essential in this process of making positive changes in their eating habits.

CBT, a highly structured psychotherapeutic method used to alter attitudes and problem behaviors by identifying and replacing negative, inaccurate thoughts and changing the rewards of the behavior, is the treatment of choice in BN (APA, 2006). When applied to an ED, CBT is typically a 20-week intervention that consists of three distinct and systematic phases of treatment: (1) establishing a regular eating pattern, (2) evaluating and changing beliefs about shape and weight, and (3) preventing relapse.

When the BN patient is receiving CBT, the RD can be instrumental in helping the patient establish a regular meal pattern (phase 1). However, the RD and the psychotherapist must maintain active communication to avoid overlap in the counseling sessions. If the BN patient is engaged in a type of psychotherapy other than CBT, the RD should incorporate more CBT skills into the nutrition counseling sessions (Herrin, 2003). See Fairburn (2008) for guidance on CBT techniques.

Patients with BN are typically more receptive to nutrition counseling than AN patients and less likely to present in the precontemplation stage of change. Suggested strategies for nutrition counseling at the precontemplation, contemplation, preparation, action, and maintenance stages are given in Table 23-2 (see Chapter 15).

**TABLE 23-2**

**Counseling Strategies Using the Stages of Change Model in Eating Disorders**

Stage of Change	Counseling Strategies
Precontemplation	<ul style="list-style-type: none"> <li>• Establish rapport.</li> <li>• Assess nutrition knowledge, beliefs, attitudes.</li> <li>• Conduct thorough review of food likes and dislikes, safe and risky foods, forbidden foods (assess reason), binge and purge foods.</li> <li>• Assess physical, anthropometric, metabolic status.</li> <li>• Assess level of motivation.</li> <li>• Use motivational interviewing techniques.</li> <li>• Decisional balance: weigh costs and benefits of maintaining current status versus costs and benefits of change.</li> </ul>
Contemplation	<ul style="list-style-type: none"> <li>• Identify behaviors to change; prioritize.</li> <li>• Identify barriers to change.</li> <li>• Identify coping mechanisms.</li> <li>• Identify support systems.</li> <li>• Discuss self-monitoring tools: food and eating behavior records.</li> <li>• Continue motivational interviewing technique.</li> </ul>
Preparation	<ul style="list-style-type: none"> <li>• Implement nutrition-focused CBT</li> <li>• Implement self-monitoring tools: food and eating behavior records.</li> <li>• Determine list of alternative behaviors to bingeing and purging.</li> </ul>
Action	<ul style="list-style-type: none"> <li>• Develop a plan of healthy eating.</li> <li>• Reinforce positive decision making, self-confidence, and self-efficacy.</li> <li>• Promote positive self-rewarding behaviors.</li> <li>• Develop strategies for handling impulsive behaviors, high-risk situations, and “slips.”</li> <li>• Continue CBT.</li> <li>• Continue self-monitoring.</li> </ul>
Maintenance and relapse	<ul style="list-style-type: none"> <li>• Identify strategies; manage high-risk situations.</li> <li>• Continue positive self-rewarding behaviors.</li> <li>• Reinforce coping skills and impulse-control techniques.</li> <li>• Reinforce relapse prevention strategies.</li> <li>• Determine and schedule follow-up sessions needed for maintenance and reinforcement of positive changes in eating behavior and nutrition status.</li> </ul>

Modified from Stellefson Myers E: Winning the war within: nutrition therapy for clients with anorexia or bulimia nervosa, Dallas, TX, 1999, Helm Publishing.

CBT, Cognitive behavioral therapy.

## Binge Eating Disorder

Strategies for treatment of BED include nutrition counseling and dietary management, individual and group psychotherapy, and medication. Some treatment programs focus primarily on nutrition counseling and weight loss. Although successful weight loss and decreased frequency of binge eating episodes may result, relapse occurs often. Other treatment programs focus primarily on reduction of binge episodes rather than weight loss. Self-acceptance, improved

body image, increased physical activity, and better overall nutrition are also goals of treatment in BED. Several self-help manuals are available for the treatment of BED (Sysko and Walsh, 2008), and these approaches can be augmented with guidance from psychotherapists and nutritionists.

## Monitoring Nutritional Rehabilitation

Guidelines for patient monitoring are indicated in Box 23-6. The health professional, patient, and family must be realistic

### BOX 23-6

#### Patient Monitoring

1. Body weight
  - A. Establish goal weight.
  - B. Determine:
    - (1) Acceptable rate of weight gain in AN
    - (2) Maintenance weight range in BN
  - C. Monitor weight:
    - (1) Inpatient
      - a. Daily, or every other day
      - b. Gowned
      - c. Preprandial
      - d. Postvoid
      - e. Urine specific gravity measured
      - f. Additional, random, afternoon, or evening weight if fluid loading is suspected
    - (2) Day treatment:
      - a. Variable, depending on diagnosis, age of patient, and treatment setting (i.e., daily, several times per week, once per week)
      - b. Gowned
      - c. Postvoid
      - d. Same time of day
      - e. Same scale
      - f. Urine specific gravity measured
    - (3) Outpatient:
      - a. Once every 1-2 weeks in early treatment, less frequently in mid- to late treatment
      - b. Gowned
      - c. Postvoid
      - d. Same time of day
      - e. Same scale
      - f. Urine specific gravity measured
  2. Height
    - A. Obtain baseline (NCHS percentile for children and adolescents).
    - B. Monitor every 1-2 months in patients with growth potential.
  3. Anthropometric measurements (optional)
    - A. Obtain baseline:
      - (1) Skinfolds; triceps, biceps, subscapula, suprailiac
      - (2) Midarm circumference
      - (3) Midarm muscle circumference
    - B. Monitor
      - (1) Inpatient: as medically indicated
      - (2) Outpatient: as medically indicated
  4. Resting and postprandial energy expenditure (optional)
    - A. Obtain baseline
    - B. Monitor
      - (1) Inpatient: as medically indicated
      - (2) Outpatient: as medically indicated
  5. Outpatient diet monitoring
    - A. Anorexia nervosa
 

Daily food record to include:

      - (1) Food
      - (2) Fluid: caloric, noncaloric, alcohol
      - (3) Artificial sweeteners
      - (4) Eating behavior: time, place, how eaten, with whom
      - (5) Exercise
    - B. Bulimia nervosa
 

Daily food record to include:

      - (1) Food
      - (2) Fluid: caloric, non-caloric, alcohol
      - (3) Artificial sweeteners
      - (4) Eating behavior: time, place, how eaten, with whom
      - (5) Emotions and feelings when eating
      - (6) Foods eaten at a binge
      - (7) Time and method of purge
      - (8) Exercise

**BOX 23-7****Topics for Nutrition Education**

1. Guidelines for healthy eating: energy, macronutrients, vitamins, minerals, fluids and electrolytes
2. Impact of malnutrition on adolescent growth and development
3. Impact of malnutrition on behavior
4. Set-point theory and the determination of a healthy body weight goal
5. Impact of dieting on metabolism
6. Restrained eating and disinhibition
7. Causes of bingeing and purging, and techniques to break the cycle
8. Changes in body composition that occur during weight restoration
9. Exercise and energy balance
10. Ineffectiveness of vomiting, laxatives, and diuretics in long-term weight control
11. Portion control
12. Social and holiday dining
13. Hunger and satiety cues
14. Interpreting food labels

Adapted from: Schebendach J, Nussbaum MP: Nutrition management in adolescents with eating disorders, Adolesc Med State Art Rev 3(3):545, 1992.

about treatment, which is often a long-term process. Although outcomes may be favorable, the course of treatment is rarely smooth, and clinicians must be prepared to monitor progress carefully.

### **Nutrition Education**

Patients with EDs may appear quite knowledgeable about food and nutrition. Despite this, nutrition education is an essential component of their treatment plan. Indeed, some patients spend significant amounts of time reading nutrition-related information, but their sources may be unreliable, and their interpretation potentially distorted by their illness. Malnutrition may impair the patient's ability to assimilate and process new information. Early- and mid-adolescent development is characterized by the transition from concrete to abstract operations in problem solving and directed thinking, and normal developmental issues must be considered when teaching adolescents with EDs (see Chapter 19).

Nutrition education materials must be thoroughly assessed to determine if language and subject matter are bias free and appropriate for AN and BN patients. For example, literature provided by many health organizations promotes a low-fat diet and low-calorie lifestyle for the prevention and treatment of chronic disease. This material is in direct conflict with a treatment plan that encourages increased caloric and fat intake for the purpose of nutritional rehabilitation and weight restoration.

Although the interactive process of a group setting may have advantages, these topics can also be effectively

incorporated into individual counseling sessions. Topics for nutrition education are suggested in Box 23-7.

### **Prognosis**

Relapse rates after weight restoration in AN are high, with as many as 50% of patients requiring rehospitalization within 1 year of inpatient treatment (Walsh et al., 2006). Follow-up studies suggest that two thirds of AN patients have enduring morbid food and weight preoccupation (APA, 2006). In general, adolescents have better outcomes than adults, and younger adolescents have better outcomes than older adolescents. Outcomes studies in treated BN patients suggest a short-term success rate of 50% to 70%; however, relapse rates in the range of 30% to 85% have also been reported (APA, 2006).

Proposed revisions to eating disorders diagnostic criteria:

<http://www.dsm5.org/ProposedRevisions>

Jennifer is a 19-year-old woman. Her height is 65" and her weight is 138 lb. Laboratory data: glucose, 82 mg/dL; albumin, 4.2 g/dL; cholesterol, 180 mg/dL; potassium, 2.7 mmol/L; serum CO<sub>2</sub>, 31 mmol/L. Anthropometric status: Skin folds: triceps, 20 mm; biceps, 7 mm; subscapular, 10 mm; suprailiac, 13 mm; midarm circumference, 26.7 cm; midarm muscle circumference, 20.4 cm.

Jennifer has always been unhappy with her weight. She went on every fad diet throughout high school and lost some weight but always regained it. About 1 year ago, Jennifer began binge eating. Binge episodes now occur three to four times per week. During these binges Jennifer consumes about 1500 to 2000 kcal in a 2-hour period. Binge foods include ice cream, cookies, potato chips, and other foods. Jennifer describes them as "fattening and unhealthy." After binge eating Jennifer feels extremely guilty, and vomiting is immediately self-induced. Jennifer always tries to eat as little as possible the next day, sometimes consuming only 700 or 800 kcal. Three months ago Jennifer started to overdose on laxatives about three times a week. She occasionally uses over-the-counter diet pills, but they never really help. Jennifer feels fat in her abdomen, buttocks, and thighs. Her physical activity includes 100 sit-ups and 100 leg lifts three or four times per week.

### Nutrition Diagnostic Statement

Disordered eating pattern related to binging and purging as evidenced by self-induced vomiting following binge episodes accompanied by guilt and restricted eating

### Nutrition Care Questions

1. What are some possible medical complications that Jennifer may develop secondary to binge eating and her compensatory behaviors?
2. Discuss her laboratory values and what you might expect to happen to these indices during rehabilitation.
3. Determine Jennifer's ideal body weight and goal weight for short-term and long-term treatment.
4. Calculate Jennifer's initial caloric prescription and discuss how you arrived at this.
5. Plan a sample menu.
6. Discuss how you would handle foods that Jennifer considers binge "trigger" foods.
7. What would you suggest for Jennifer to help control her episodes of vomiting, laxative use, and diet pill use?

## CHAPTER 24

Lisa Dorfman, MS, RD, CSSD, LMHC

# Nutrition in Exercise and Sports Performance

### KEY TERMS

actomyosin  
adenosine diphosphate (ADP)  
adenosine triphosphate (ATP)  
aerobic metabolism  
anabolic effects  
anaerobic metabolism  
androgenic effects  
creatine phosphate (CP)  
dehydroepiandrosterone (DHEA)  
ergogenic aid  
female athlete triad  
glycemic index  
glycogen  
glycogen loading (glycogen supercompensation)

glycogenolysis  
glycolysis  
high-intensity interval training (HIIT)  
hypohydration  
human growth hormone (HGH)  
lactic acid  
mitochondria  
myoglobin  
preexercise sports drinks (PRXs)  
respiratory exchange ratio (RER)  
reactive oxygen species (ROS)  
sports anemia  
thermoregulation  
 $V_{O_2\text{max}}$

Successful athletic performance is a combination of favorable genetics, desire, proper training, and a sensible approach to nutrition. Whether an athlete is recreational or elite, young or mature, the importance of nutrition as a contributing factor to success in training and competition has been recognized for decades. Athletes attempting to gain a competitive edge will try almost any dietary regimen or artificial means, including nutritional supplements and oral or injectable medications, in the hope of reaching a new level of wellness or physical performance. Unfortunately, there is a plethora of misinformation on the topic of sports nutrition. Among college athletes, men are more likely than women to rely on strength coaches for supplement information. Athletes rely on trainers (71%), coaches (60%), and physicians (41%); they also refer to the

Internet (79%), magazines (68%), and television (52%) for guidance (Malinauskas et al., 2007). Athletes can benefit from nutrition education and intervention by nutrition experts—increasing knowledge, self-efficacy, and dietary improvement.

### ENERGY PRODUCTION

The human body must be supplied continuously with energy to perform its many complex functions. As a person's energy demands increase with exercise, the body must provide additional energy, or the exercise will cease. Two metabolic systems supply energy for the body: one dependent on oxygen (**aerobic metabolism**), and the other independent of oxygen (**anaerobic metabolism**). The use of one system over

the other depends on the duration, intensity, and type of physical activity.

## Adenosine Triphosphate

The body obtains its continuous supply of fuel through **adenosine triphosphate (ATP)**, found within the cells of the body. ATP is the energy currency of the cell. The energy produced from the breakdown of ATP provides the fuel that activates muscle contraction. The energy from ATP is transferred to the contractile filaments (myosin and actin) in the muscle, which form an attachment of actin to the cross-bridges on the myosin molecule, thus forming **actomyosin**. Once activated the myofibrils slide past each other and cause the muscle to contract.

## Resynthesizing Adenosine Triphosphate

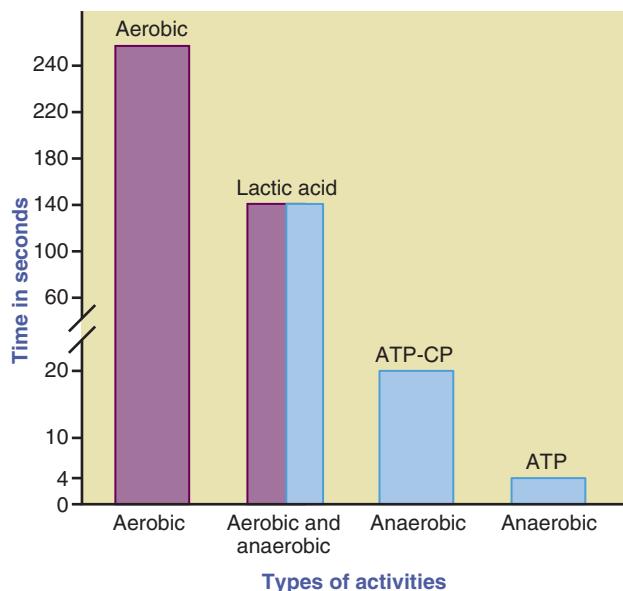

Although ATP is the main currency for energy in the body, it is stored in limited amounts. In fact, only approximately 3 oz of ATP is stored in the body at any one time. This provides only enough energy for several seconds of exercise. ATP must continually be resynthesized to provide a constant energy source during exercise. When ATP loses a phosphate, thus releasing energy, the resulting **adenosine diphosphate (ADP)** is enzymatically combined with another high-energy phosphate from **creatine phosphate (CP)** to resynthesize ATP. The concentration of high-energy CP in the muscle is five times that of ATP.

Creatine kinase is the enzyme that catalyzes the reaction of CP with ADP and inorganic phosphate. It is the fastest and most immediate means of replenishing ATP, and it does so without the use of oxygen (anaerobic). Although this system has great power, it is time-limited because of the concentration of CP found in the muscles (see “**Creatine**” later in the chapter).

The energy released from this ATP-CP system will only support an all-out exercise effort of a few seconds, such as in a power lift, tennis serve, or sprint. If the all-out effort continues for longer than 8 seconds or if moderate exercise is to proceed for longer periods, an additional source of energy must be provided for the resynthesis of ATP (Figure 24-1). The production of ATP carries on within the muscle cells through either the anaerobic or aerobic pathways.

## Anaerobic or Lactic Acid Pathway

The next energy pathway for supplying ATP for more than 8 seconds of physical activity is the process of anaerobic **glycolysis**. In this pathway the energy in glucose is released without the presence of oxygen. **Lactic acid** is the end product of anaerobic glycolysis. Without the production of lactic acid, glycolysis would shut down. The coenzyme called nicotinic acid dehydrogenase (NAD) is in limited supply in this pathway. When NAD is limited, the glycolytic pathway cannot provide constant energy. By converting pyruvic acid to lactic acid, NAD is freed to participate in further ATP synthesis. The amount of ATP furnished is relatively small (the process is only 30% efficient). This pathway contributes energy during an all-out effort lasting

**FIGURE 24-1** Classification of activities based on duration of performance and the predominant pathways of energy production. One can see that the duration of activity can continue much longer when energy is produced by aerobic metabolism.

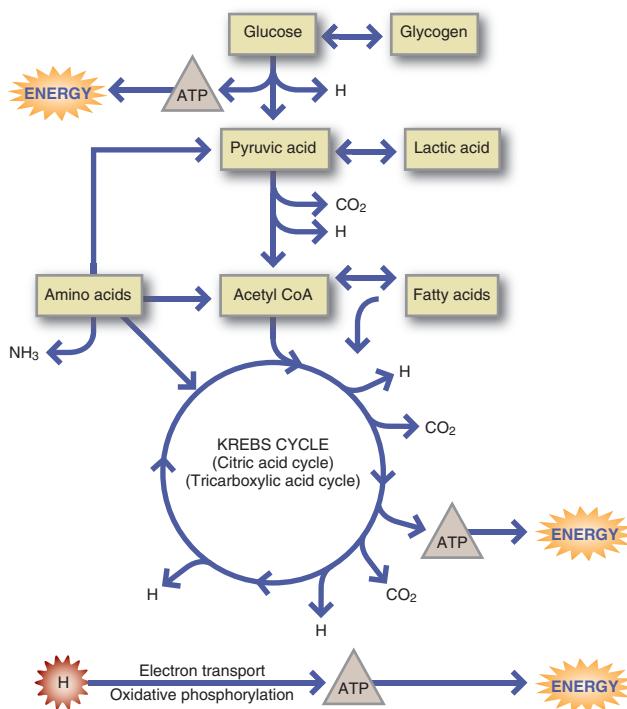

up to 60 to 120 seconds. Examples are a 440-yard sprint and many sprint-swimming events.

Although this process provides immediate protection from the consequences of insufficient oxygen, it cannot continue indefinitely. When exercise continues at intensities beyond the body's ability to supply oxygen and convert lactic acid to fuel, lactic acid accumulates in the blood, lowers the pH to a level that interferes with enzymatic action, and causes fatigue. Lactic acid can be removed from the muscle; transported into the bloodstream; and converted to energy in muscle, liver, or brain. Otherwise, it is converted to glycogen. Conversion to **glycogen** occurs in the liver and to some extent in muscle, particularly among trained athletes.

The amount of ATP produced through glycolysis is small compared with that available through aerobic pathways. Substrate for this reaction is limited to glucose from blood sugar or the glycogen stored in the muscle. Liver glycogen contributes but is limited.

## Aerobic Pathway

Production of ATP in amounts sufficient to support continued muscle activity for longer than 90 to 120 seconds requires oxygen. If sufficient oxygen is not present to combine with hydrogen in the electron transport chain, no further ATP is made. Thus the oxygen furnished through respiration is of vital importance. Here, glucose can be broken down far more efficiently for energy, producing 18 to 19 times more ATP. In the presence of oxygen, pyruvate is converted to acetyl coenzyme A (CoA), which enters the **mitochondria**. In the mitochondria acetyl CoA goes through

**FIGURE 24-2** Pathways of energy production. *ATP*, Adenosine triphosphate; *CoA*, coenzyme A; *H*, hydrogen atoms.

the Krebs cycle, which generates 36 to 38 ATP per molecule of glucose (Figure 24-2).

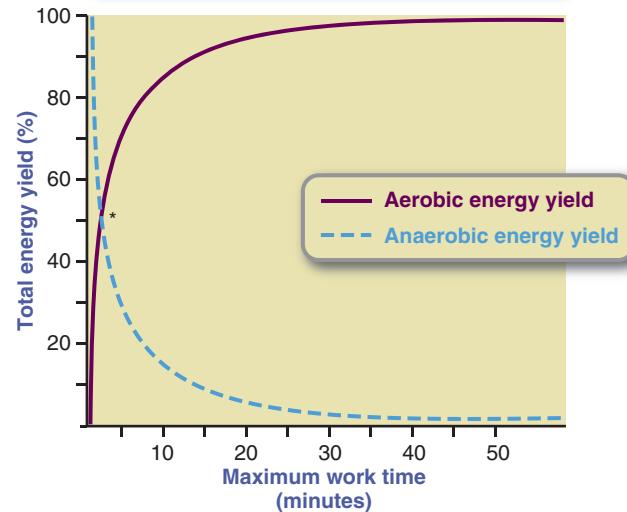

Aerobic metabolism is limited by the availability of substrate, a continuous and adequate supply of oxygen, and the availability of coenzymes. At the onset of exercise and with the increase in exercise intensity, the capability of the cardiovascular system to supply adequate oxygen is a limiting factor, and this is largely due to the level of conditioning. The aerobic pathway can also provide ATP by metabolizing fats and proteins. A large amount of acetyl CoA, which enters the Krebs cycle and provides enormous amounts of ATP, is provided by  $\beta$ -oxidation of fatty acids. Proteins may be catabolized into acetyl CoA or Krebs cycle intermediates, or they may be directly oxidized as another source of ATP.

### Energy Continuum

A person who is exercising may use one or more energy pathways. For example, at the beginning of any physical activity, ATP is produced anaerobically. As exercise continues, the lactic acid system produces ATP for exercise. If the person continues to exercise and does so at a moderate intensity for a prolonged period, the aerobic pathway will become the dominant pathway for fuel. On the other hand, the anaerobic pathway provides most of the energy for short-duration, high-intensity exercise such as sprinting; the 200-meter swim; or high-power, high-intensity moves in basketball, football, or soccer.

The production of ATP for exercise is on a continuum that depends on the availability of oxygen. Other factors

Duration of maximum exercise									
	Seconds	Minutes	Seconds	Minutes	Seconds	Minutes			
Anaerobic (%)	90	80	70	50	35	15	5	2	1
Aerobic (%)	10	20	30	50	65	85	95	98	99

**FIGURE 24-3** Relative contribution of aerobic and anaerobic energy during maximum physical activity of various durations. Note that 90 to 120 seconds of maximum effort requires 50% of the energy from each of the aerobic and anaerobic processes. This is also the point at which the lactic acid pathway for energy production is at its maximum.

that influence oxygen capabilities, and thus energy pathways, are the capacity for intense exercise and its duration. These two factors are inversely related. For example, an athlete cannot perform high-power, high-intensity moves over a prolonged period. To do this, he or she would have to decrease the intensity of the exercise to increase its duration (Figure 24-3).

The aerobic pathway cannot tolerate the same level of intensity as duration increases because of the decreased availability of oxygen and accumulation of lactic acid. As the duration of exercise increases, power output decreases. The contribution of energy-yielding nutrients must be considered also. As the duration of exercise lengthens, fats contribute more as an energy source. The opposite is true for high-intensity exercise; when intensity increases, the body relies increasingly on carbohydrates as substrate.

## FUELS FOR CONTRACTING MUSCLES

### Sources of Fuel

Protein, fat, and carbohydrate are all possible sources of fuel for muscle contraction. The glycolytic pathway is restricted to glucose, which can originate in dietary carbohydrates or stored glycogen, or it can be synthesized from the carbon skeletons of certain amino acids through the process of gluconeogenesis. The Krebs cycle is fueled by three-carbon

fragments of glucose; two-carbon fragments of fatty acids; and carbon skeletons of specific amino acids, primarily alanine and the branched-chain amino acids. All these substrates can be used during exercise; however, the intensity and duration of the exercise determine the relative rates of substrate use.

## Intensity

The intensity of the exercise is important in determining what fuel will be used by contracting muscles. High-intensity, short-duration exercise has to rely on anaerobic production of ATP. Because oxygen is not available for anaerobic pathways, only glucose and glycogen can be broken down anaerobically for fuel. When glycogen is broken down anaerobically, it is used 18 to 19 times faster than when glucose is broken down aerobically. Persons who are performing in high-intensity workouts or competitive races may run the risk of running out of muscle glycogen before the event or exercise is done as a result of its high use.

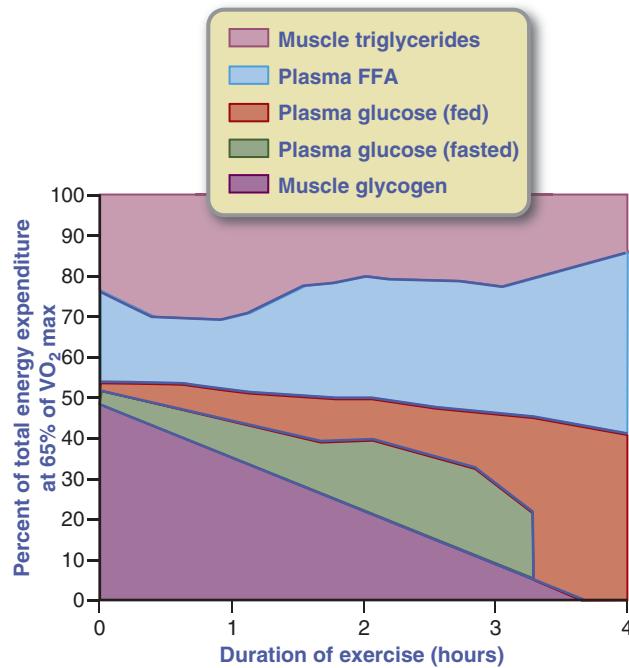

Sports that use both the anaerobic and aerobic pathways also have a higher glycogen use rate and, like anaerobic athletes, athletes in these sports also run the risk of running out of fuel before the race or exercise is finished. Sports such as basketball, football, soccer, and swimming are good examples; glycogen usage is high because of the intermittent bursts of high-intensity sprints and running drills. In moderate-intensity sports or exercise such as jogging, hiking, aerobic dance, gymnastics, cycling, and recreational swimming, approximately half of the energy for these activities comes from the aerobic breakdown of muscle glycogen, whereas the other half comes from circulating blood glucose and fatty acids.

Moderate- to low-intensity exercise such as walking is fueled entirely by the aerobic pathway; thus a greater proportion of fat can be used to create ATP for energy. Fatty acids cannot supply ATP during high-intensity exercise because fat cannot be broken down fast enough to provide the energy. Also, fat provides less energy per liter of oxygen consumed than does glucose (4.65 kcal/L of O<sub>2</sub> versus 5.01 kcal/L of O<sub>2</sub>). Therefore when less oxygen is available in high-intensity activities, there is a definite advantage for the muscles to be able to use glycogen because less oxygen is required (Figure 24-4).

In general, both glucose and fatty acids provide fuel for exercise in proportions depending on the intensity and duration of the exercise and the fitness of the athlete. Exertion of extremely high intensity and short duration draws primarily on reserves of ATP and CP. High-intensity exercise that continues for more than a few seconds depends on anaerobic glycolysis. During exercise of low-to-moderate intensity (60% of maximum oxygen uptake [ $\text{Vo}_2\text{max}$ ]), energy is derived mainly from fatty acids. Carbohydrate becomes a larger fraction of the energy source as intensity increases until, at an intensity level of 85% to 90%  $\text{Vo}_2\text{max}$ , carbohydrates from glycogen is the principal energy source, and the duration of activity is limited (Figure 24-5).

**FIGURE 24-4** Running is a high-intensity exercise in which both carbohydrates and fat are used as fuels, depending on the speed and length of the event. (*Courtesy Richard Andrews, Titusville, Fl.*)

**FIGURE 24-5** Sources of energy during 4 hours of exercise. FFA, Free fatty acid.

## Duration

The duration of a training session determines the substrate used during the exercise bout. For example, the longer the time spent exercising, the greater the contribution of fat as the fuel. Fat can supply up to 60% to 70% of the energy needed for ultra-endurance events lasting 6 to 10 hours. As the duration of exercise increases, the reliance on aerobic metabolism becomes greater, and a greater amount of ATP can be produced from fatty acids. However, fat cannot be

metabolized unless a continuous stream of some carbohydrates is also available through the energy pathways. Therefore muscle glycogen and blood glucose are the limiting factors in human performance of any type of intensity or duration.

### Effect of Training

The length of time an athlete can oxidize fatty acids as a fuel source is related to the athlete's conditioning, as well as the exercise intensity. In addition to improving cardiovascular systems involved in oxygen delivery, training increases the number of mitochondria and the levels of enzymes involved in the aerobic synthesis of ATP, thus increasing the capacity for fatty acid metabolism. Increases in mitochondria with aerobic training are seen mainly in the type IIA (intermediate fast-twitch) muscle fibers. These fibers however quickly lose their aerobic capacity with the cessation of aerobic training, reverting to the genetic baseline.

These changes from training result in a lower **respiratory exchange ratio (RER)**, the amount of CO<sub>2</sub> produced divided by the amount of O<sub>2</sub> consumed, lower blood lactate and catecholamine levels, and a lower net muscle glycogen breakdown at a specific power output. These metabolic adaptations enhance the ability of muscle to oxidize all fuels, especially fat.

## NUTRITIONAL REQUIREMENTS OF EXERCISE

### Energy

The most important component of successful sport training and performance is to ensure adequate calorie intake to support energy expenditure and maintain strength, endurance, muscle mass and overall health. Energy and nutrient requirements vary with weight, height, age, sex, and metabolic rate (see Chapter 2) as well as the type, frequency, intensity, and duration of training and performance.

Individuals who participate in an overall fitness program (i.e., 30 to 40 min/day, three times per week) can generally meet their daily nutritional needs by following a normal diet providing 25 to 35 kcal/kg/day or roughly 1800 to 2400 calories a day. However, the 50-kg athlete engaging in more intense training of 2 to 3 hours/day five to six times a week or high-volume training of 3 to 6 hours in one to two workouts per day 5 to 6 days a week may expend up to an additional 600 to 1200 calories a day, thus requiring 50 to 80 kcal/kg/day or roughly 2500 to 4000 kcal/day. For elite athletes or heavier athletes, daily calorie needs can reach 150 to 200 kcal/kg, or roughly 7500 to 10,000 calories a day, depending on the volume and intensity of different training phases.

Meeting caloric needs for many fitness-minded and or elite, intensely training individuals can be a challenge. For working individuals, balancing daily training schedules with work and family responsibilities can compromise the quantity, quality, and timing of meals, which can greatly affect energy, strength levels, and overall health. In the elite

**TABLE 24-1**

### Comparison of the Electrolyte Content between Standard Sport Drinks and Endurance-Specific Sport Drinks

Electrolyte	Sweat Loss mg/L	Standard Sport Drink mg/L	Endurance Specific Sport Drink mg/L
Sodium	900-2600	200-450	800-1110
Potassium	100-200	80-125	390-650
Magnesium	60-260	0	10-615
Chloride	900-1900	0	390-1550
Calcium	50-100	0	250-500

Source: First endurance. Accessed 14 July 2010 from <http://blog.firstendurance.com/tag/electrolytes/>.

athlete, consuming enough food at regular intervals without compromising performance is challenging, particularly for the collegiate athlete. School schedules, budgets, cafeteria schedules, travel requirements, and a varying appetite can further complicate the situation.

Meeting the daily energy needs and the appropriate macronutrient distribution for active individuals may necessitate the use of sports bars, drinks, and convenience foods and snacks in addition to whole foods and meals. Dietitians need to be flexible in accommodating lifestyles and eating behaviors when designing meal plans for maximum sport performance.

### Sports Supplements

Sports supplements include the easy-to-carry, easy-to-consume, and easy-to-digest meal-replacement powders, ready-to-drink supplements, energy bars, and energy gels. This group represents 50% to 70% of the industry's sales. These products are typically fortified with 33% to 100% of the recommended dietary allowances (RDAs) for vitamins and minerals; provide varying amounts and types of carbohydrates, protein, and fat; and are ideal for athletes on the run. They provide a portable, easy-to-consume food that can be used pericompetitively; while traveling; at work; in the car; or throughout the day at a multievent meet such as in track and field, swimming, diving, or gymnastics.

Many fitness-minded and athletic individuals use these products as a convenient way to enhance their current diet. These products are generally regarded as safe. However, if they are substituted in the place of whole foods on a regular basis, they can deprive the athlete of a well-balanced diet. They may also contain excesses of sugars, fats, and protein and banned substances such as caffeine, Ephedra, and other botanicals. See Table 24-1.

## WEIGHT MANAGEMENT

In efforts to maximize performance, many athletes alter normal energy intake to either gain or lose weight. Although

such efforts are sometimes appropriate, weight-reduction programs may involve elements of risk. For some young athletes achievement of an unrealistically light weight can jeopardize growth and development. Chronic dieting by female athletes can lead to eating disorders, delayed menarche, amenorrhea, and potential osteoporosis (see Chapters 23 and 25).

The goal weight of an athlete should be based on body fatness. Adequate time should be allowed for a slow, steady weight loss of approximately 1 to 2 lb each week over several weeks. Weight loss should be achieved before the competitive season begins to ensure maximum strength. In addition, the exercise should be of moderate intensity because at this level a greater proportion of energy is derived from fat than carbohydrate and the exercise can be sustained longer. When planned school-based activity programs are in effect, up to a 50% reduction in the incidence of overweight is feasible (Foster et al., 2008). Appropriate programs for weight management are discussed in Chapter 22.

Weight gain should be achieved through a gradual increase in energy intake combined with a strength training program to maximize muscle weight gain over fat gain. A realistic goal is  $\frac{1}{2}$  to 1 lb weekly. Fat intake should not exceed 30% of kilocalories from fat, and protein should be 1 to 1.5 g/kg of body weight. The professional working with an elite athlete must remember the tremendous motivation that comes from a desire to perform well in the sport.

## MACRONUTRIENTS

Individuals engaging in a general fitness program can typically meet their macronutrient needs by consuming a normal diet of 45% to 55% of calories from carbohydrates (3 to 5 g/kg/day), 10% to 15% from protein (0.8 to 1 g/kg/day) and 25% to 35% from fat (0.5 to 1.5 g/kg/day). Athletes involved in moderate- to high-volume training need greater amounts of carbohydrates and protein to meet macronutrient needs. An intake of at 60% to 70% of total calories (5 to 8 g/kg/day or 250 to 1200 g/day for 50- to 150-kg athletes) should be met by carbohydrates. The remaining calories should be obtained from protein and fat. These percentages are only guidelines for estimating macronutrient requirements.

Specific macronutrient recommendations should be used when counseling an active individual or athlete. When energy intake is high (more than 4500 calories/day), even a diet containing only 50% of the calories from carbohydrates would provide 500 g of carbohydrates, which is sufficient to maintain muscle glycogen stores. Similarly, if protein intake in this high-calorie diet were low, at 10% of calories, absolute protein intake would still exceed the recommendation for a 70-kg athlete. Thus specific recommendations should be based on an individual's body size, body composition, sport, and gender. Calories and nutrients should come from a wide variety of foods on a daily basis.

## CARBOHYDRATE

The first source of glucose for the exercising muscle is its own glycogen store. When this is depleted, **glycogenolysis** and then gluconeogenesis (both in the liver) maintain the glucose supply (see Chapter 3). During endurance exercise that exceeds 90 minutes, such as marathon running, muscle glycogen stores become progressively lower. When they drop to critically low levels, high-intensity exercise cannot be maintained. In practical terms the athlete is exhausted and must either stop exercising or drastically reduce the pace. Athletes often refer to this as "hitting the wall."

Glycogen depletion may also be a gradual process, occurring over repeated days of heavy training, in which muscle glycogen breakdown exceeds its replacement, as well as during high-intensity exercise that is repeated several times during competition or training. For example, a distance runner who averages 10 miles per day but does not take the time to consume enough carbohydrates in his or her diet, or the swimmer who completes several interval sets at maximum oxygen consumption within hours can deplete glycogen stores rapidly. A high-carbohydrate or **glycogen loading (glycogen supercompensation)** diet can help athletes maximize glycogen stores and be able to continue endurance performance.

The amount of carbohydrate required depends on the athlete's total daily energy expenditure, type of sport, gender, and environmental conditions. Recommendations should provide for daily carbohydrate intake in grams relative to body mass, and allow flexibility for the athlete to meet these targets within the context of their energy needs and other dietary goals. Carbohydrate intake of 5 to 7 g/kg/day can meet general training needs, and 7 to 10 g/kg/day will suffice for endurance athletes. For example, a 70-kg (154-lb) athlete would consume 350 to 700 g of carbohydrate daily (see Table 24-1).

### Types of Carbohydrate

Even though the effects of different sugars on performance, substrate use, and recovery has been studied extensively, the optimal type of carbohydrate for the athlete is debatable. The **glycemic index** represents the ratio of the area under the blood glucose curve resulting from the ingestion of a given quantity of carbohydrate and the area under the glucose curve resulting from the ingestion of the same quantity of white bread or glucose (see Chapter 31 and Appendix 43). Studies concerning whether the glycemic index of carbohydrate in the preexercise meal affects performance are inconclusive (Lin-Wu and Williams, 2006; Wong et al., 2009).

### Carbohydrate Intake Before Exercise

The preevent or pretraining meal serves two purposes: (1) it keeps the athlete from feeling hungry before and during the exercise and (2) it maintains optimal levels of blood glucose for the exercising muscles. A preexercise meal can improve performance compared with exercising in a fasted

state. Athletes who train early in the morning before eating or drinking risk developing low liver glycogen stores that can impair performance, particularly if the exercise regimen involves endurance training. **Preeexercise sports drinks (PRXs)** are commonly used in athletic competitions requiring aerobic power. PRX (containing 14 g/serving of fructose, medium-chain triglycerides, and amino acids mixed with 8 oz of water) given 30 minutes prior to performing enhances indices of aerobic performance, specifically  $\text{Vo}_{\text{2max}}$ , time to exhaustion, and percentage of nonprotein fat substrate use (Byars et al., 2010).

Carbohydrate feedings before exercise can enhance liver glycogen stores. Although allowing for personal preferences and psychological factors, the preevent meal should be high in carbohydrates, nongreasy, and readily digested. Fat should be limited because it delays gastric emptying time and takes longer to digest. A meal eaten 3.5 to 4 hours before competition should be limited to 25% of the kilocalories from fat. Closer to the event, the fat content should be less than 25% (Box 24-1).

Exercising with a full stomach may cause indigestion, nausea, and vomiting. Thus the pregame meal should be eaten 3 to 4 hours before an event and should provide 200 to 350 g of carbohydrates (4 g/kg). Allowing time for partial digestion and absorption provides a final addition to muscle glycogen, additional blood sugar, and also relatively complete emptying of the stomach. To avoid gastrointestinal (GI) distress, the carbohydrate content of the meal should be reduced when the meal is close to the exercise time. For example, 4 hours before the event it is suggested that the athlete consume 4 g of carbohydrate per kilogram of body weight, whereas 1 hour before the competition the athlete would consume 1 g of carbohydrate per kilogram of body weight.

Commercial liquid formulas providing an easily digested high-carbohydrate fluid are popular with athletes and probably leave the stomach faster. Foods high in fiber, fat, and lactose will cause GI distress for some (e.g., bloating, gas, or diarrhea) and should be avoided before competition. Athletes should always use what works best for them by experimenting with foods and beverages during practice sessions and planning ahead to ensure that they have these foods available when they compete.

### **Carbohydrate Intake During Exercise**

Carbohydrate consumed during endurance exercise lasting longer than 1 hour ensures the availability of sufficient amounts of energy during the later stages of exercise, improves performance, and enhances feeling of pleasure during and following exercise (Backhouse et al., 2005). Carbohydrate feeding does not prevent fatigue; rather, it simply delays it. During the final minutes of exercise, when muscle glycogen is low and athletes rely heavily on blood glucose for energy, their muscles feel heavy, and they must concentrate to maintain exercise at intensities that are ordinarily not stressful when muscle glycogen stores are full. Glucose ingestion during exercise has also been shown to spare endogenous protein and carbohydrates in fed

### **BOX 24-1**

#### **Examples of Pre-event Meals**

For athletes who compete in events such as track or swimming meets or soccer, basketball, volleyball, and wrestling tournaments, nutritious, easy-to-digest food and fluid choices require attention. The athlete should consider the amount of time between eating and performance when choosing foods during these all-day events. Suggested precompetition menus include the following:

##### **1 Hour or Less Before Competition—**

###### **Approximately 100 kcal**

One of these choices:

- Fresh fruit such as a banana or orange slices
- Half of a sports energy bar
- $\frac{1}{2}$  plain bagel or English muffin
- Crackers such as saltines or low-fiber cracker
- Small box of low-fiber cereal
- 8-12 oz of a sports drink or endurance sports drink

##### **2 to 3 Hours Before Competition—**

###### **Approximately 300-400 kcal**

One of these choices:

- $\frac{1}{2}$  of turkey sandwich on white bread with baked chips
- $\frac{1}{2}$  bagel with low sugar jelly and 1 banana
- 2 pancakes with lite or sugar-free syrup and berries
- 32 fluid oz of a sports drink or 32-oz endurance drink with protein
- 1 low-sugar smoothie with berries, banana, and 1 scoop soy or whey protein
- 1 sports energy bar, 1 cup sports drink, 1 cup water

##### **3 to 4 Hours Before Competition—**

###### **Approximately 700 kcal**

One of these selections:

- Scrambled egg whites with white toast with low-sugar jam and banana
- 1 bagel with fat-free or low-fat cream cheese and low-sugar jelly and 1 banana
- 1 6-in turkey sub on Italian bread with lettuce, tomato, and mustard
- 1 3-oz grilled chicken breast with small baked potato, roll, and water
- 2 cups plain pasta with 1 plain roll
- 1 can of low fat sport shake with no more than 25 g protein, 1 sports bar, 1 banana, water

cyclists without glycogen depletion (van Hamont et al., 2005). Thus consuming an exogenous carbohydrate during endurance exercise helps to maintain blood glucose and improve performance.

The form of carbohydrate does not seem to matter physiologically. Some athletes prefer to use a sports drink,

whereas others prefer to eat a solid or gel and consume water. If a sports drink with carbohydrates is consumed during exercise, the rate of carbohydrate ingestion should be approximately 26 to 30 g every 30 minutes, an amount equivalent to 1 cup of a 6% to 8% carbohydrate solution taken every 15 to 20 minutes. This ensures that 1 g of carbohydrate will be delivered to the tissues per minute at the time fatigue sets in. It is unlikely that a carbohydrate concentration of less than 5% is enough to help performance, but solutions with a concentration greater than 10% are often associated with abdominal cramps, nausea, and diarrhea.

Combining protein and carbohydrates in a sport fluid or snack may also improve performance, muscle protein synthesis and net balance, and recovery. A small amount of amino acids ingested in small amounts alone or in conjunction with carbohydrates before or after exercise appears to improve net protein balance and may stimulate protein synthesis and improve net protein balance at rest during exercise and postexercise recovery (Millard-Stafford et al., 2005).

### Carbohydrate Intake After Exercise

On average, only 5% of the muscle glycogen used during exercise is resynthesized each hour following exercise. Accordingly, at least 20 hours will be required for complete restoration after exhaustive exercise, provided approximately 600 g of carbohydrates are consumed. The highest muscle glycogen synthesis rates have been reported when large amounts of carbohydrates—1 to 1.85 g/kg/hr—are consumed immediately after exercise and at 15- to 60-minute intervals thereafter for up to 5 hours after exercise. Delaying carbohydrate intake for too long after exercise reduces muscle glycogen resynthesis.

It also appears that the consumption of carbohydrates with a high glycemic index results in higher muscle glycogen levels 24 hours after exercise compared with the same amount of carbohydrates provided as foods with a low glycemic index (Wilson M et al., 2009). Adding approximately 5 to 9 g of protein with every 100 g of carbohydrate eaten after exercise may further increase glycogen resynthesis rate, provide amino acids for muscle repair and promote a more anabolic hormonal profile (Millard-Stafford et al., 2005).

Many athletes find it difficult to consume food immediately after exercise. Usually when body or core temperature is elevated, appetite is depressed, and it is difficult to consume carbohydrate-rich foods. Many athletes find it easier and simpler to drink their carbohydrate or to consume easy-to-eat, carbohydrate-rich foods such as fruit pops, bananas, oranges, melon, or apple slices.

## PROTEIN

There has been considerable debate regarding the protein needs of athletes. The current RDA is 0.8 g/kg bodyweight and the acceptable macronutrient distribution range for protein for 18 years and older is 10% to 35% of total calories. Factors affecting the protein needs of athletes

include age, gender, mass, fitness level, regimen, and phase of training. Nitrogen balance studies in endurance athletes suggest a range of 1.2 g/kg to 1.4 g/kg/day, and for strength athletes 1.2 to 1.7 g/kg/day with the higher end of the range recommended in early season (Rodriguez et al., 2009).

Reports of food intake in athletes and nonathletes consistently indicate that protein represents from 12% to 20% of total energy intake or 1.2 to 2 g of protein per kilogram of body weight daily. The exception to the rule is small, active women who may consume a low-energy intake in conjunction with an exercise or training program. Although these women may consume close to the RDA for protein in conjunction with the restricted energy intake, it may be inadequate to maintain lean body mass.

Intermittent bouts of **high-intensity interval training (HIIT)** depletes energy substrates and allows for metabolite accumulation. Studies suggest that supplementation with beta-alanine may improve endurance performance as well as lean body mass (Smith et al., 2009). However, the need for protein during exercise is just slightly elevated above that for sedentary persons. Consuming more protein than the body can use is not necessary and should be avoided.

When athletes consume diets that are high in protein, they compromise their carbohydrate status, which may affect their ability to train and compete at peak levels. High protein intakes can also result in diuresis and potential dehydration. Protein foods are often also high in fat, and consumption of excess protein can create difficulty in maintaining a low-fat diet.

### Protein Needs for Resistance Exercise

Protein needs for resistance exercise involve maintenance (minimum protein required to accomplish nitrogen equilibrium), and the need for increasing lean tissue (positive nitrogen balance). For bodybuilders or persons interested in increasing body mass, the mythology of increased protein need is rampant. Strategies to increase the concentration and availability of amino acids after resistance exercise such as timing of snacks and meals have become an area of interest. See *Clinical Insight: How Does Type, Timing, and Amount of Protein Affect Muscle Hypertrophy?*

## FAT

Even though maximum performance is impossible without muscle glycogen, fat also provides energy for exercise. Fat is the most concentrated source of food energy, supplying 9 kcal/g. Essential fatty acids are necessary for cell membranes, skin, hormones, and transport of fat-soluble vitamins. The body has total glycogen stores (both muscle and liver) equaling approximately 2600 calories, whereas each pound of body fat supplies 3500 calories. This means that an athlete weighing 74 kg (163 lb) with 10% body fat has 16.3 lb of fat, which equals 57,000 calories.

Fat is the major, if not most important, fuel for light- to moderate-intensity exercise. Although fat is a valuable metabolic fuel for muscle activity during longer aerobic exercise and performs many important functions in the body, more

 CLINICAL INSIGHT

## How Does Type, Timing, and Amount of Protein Affect Muscle Hypertrophy?

**A**lthough many factors appear to contribute to overall muscle hypertrophy, nutritional factors that control protein synthesis during exercise are not well understood, leaving experts in discord about the type, amount, and timing of meals to enhance protein synthesis and muscle hypertrophy (Pennings, 2010). Resistance training and diet consistently appear to play a role in postworkout muscle protein synthesis. Many studies support supplementation of free-form amino acids or whole protein to enhance training. A 2005 study with resistance-trained participants for 14 weeks demonstrated that the administration of a protein supplement resulted in greater increases in cross-sectional muscle size of types I and II fibers and greater increase in squat height (Anderson et al., 2005). In another study, a postexercise trial, including a mixture of carbohydrate and whey protein consumed 1 hour after exercise resulted in a more immediate and overall greater protein synthesis response, whereas the addition of free essential amino acids before and after exercise also was shown to cause a rapid increase in protein synthesis and balance (Kerksick and Leutholtz, 2005). This higher rate of protein

synthesis after exercise has been shown to occur in both young and elderly men (Pennings, 2010).

Although the optimal amount of amino acids to ingest for maximum protein synthesis is not known, a study examined the effect of 25 g of whey and casein protein solution before and after a strength-training session (STS). When consumed 30 minutes before an STS, there were significant increases in growth hormone, testosterone, free fatty acids, and serum insulin, and significantly increased postexercise oxygen consumption and respiratory exchange ratio during the 2 hours after exercise; hence there was a more anabolic environment for muscle growth (Hulmi et al., 2005).

For athletes interested in muscle hypertrophy, it appears that neither the type nor the amount of protein matters if the day's total amount is within the recommended range for resistance-training athletes of 1.2 to 2 g of protein per kilogram of body weight per day. Sports nutrition professionals can use these data to construct pre- and postworkout formulas to enhance the resistance training sessions of their clients.

than the usual recommended amount of fat is not indicated. In addition, athletes who consume a high-fat diet typically consume fewer calories from carbohydrate.

The diet content also determines which substrate is used during an exercise bout. If an athlete is consuming a high-carbohydrate diet, he or she will use more glycogen as fuel for the exercise. If the diet is high in fat, more fat will be oxidized as a fuel source. Fat oxidation rates decline after the ingestion of high-fat diets, partly because of adaptations at the muscle level and decreased glycogen stores. Fasting longer than 6 hours optimizes fat oxidation; however, the ingestion of carbohydrates in the hours before or at the beginning of an exercise session augments the rate of fat oxidation significantly when compared with fasting (Achten and Jeukendrup, 2004).

Exercise intensity and duration are important determinants of fat oxidation. Fat oxidation rates decrease when exercise intensity becomes high. A high-fat diet has been shown to compromise high-intensity performance even when a high-fat diet regimen is followed by carbohydrate loading before high-intensity performance (Havemann et al., 2005). The mode and duration of exercise can also affect fat oxidation; running increases fat oxidation more than cycling (Achten and Jeukendrup, 2004).

### Fats, Inflammation and Sports Injury

When players get injured, they want to heal and get back on the field as soon as possible. Specific foods at the right time can help to provide energy for rehabilitation,

rebuild strength, and ensure a complete, healthy, and faster recovery.

Stress to muscle leads to inflammation, bruising and tissue breakdown. Failure to decrease inflammation can lead to scar tissue, poor mobility, and delayed recovery times. The inflammatory stage is impacted by foods, especially the types of dietary fat consumed. A diet high in trans fats, saturated fats, and some  $\omega$ -6 vegetable oils has been shown to promote inflammation while a diet high in monounsaturated fat and essential  $\omega$ -3 fats has been shown to be anti-inflammatory. Monounsaturated fats like olive, peanut, canola, and sesame oils as well as avocado also inhibit and reduce inflammation by interfering with pro-inflammatory compounds such as leukotrienes, which are produced naturally by the body. Diets high in  $\omega$ -3s have been shown to increase collagen deposition and promote healing. New research also suggests that  $\omega$ -3s may impact healing from concussions.

Supplemental  $\omega$ -3 fat has been recommended during the inflammation stage especially when the diet is deficient. However, there are also concerns regarding the usual source of  $\omega$ -3 fats and fish oils since some have been found to be contaminated with mercury and polychlorinated biphenyls (PCBs), toxins dangerous to humans.

Fruits and vegetables are also good sources of alpha linolenic acid, an  $\omega$ -3. See Appendix 40. However, the conversion to the more active forms of  $\omega$ -3s, DHA and EPA, in the body is very low. Plant-based foods rich in ALA include: kidney beans, navy beans, tofu, winter and

summer squash, certain berries such as raspberries and strawberries, broccoli, cauliflower, green beans, romaine lettuce, and collard greens. Wheat germ and free-range beef and poultry are also good sources of ω-3 fats since they are fed with ω-3 rich food.

## VITAMINS AND MINERALS

Unless an individual is deficient in a given nutrient, supplementation with that nutrient does not have a major effect on performance. Several nutrients are of concern for athletes. A daily intake of less than one third of the RDA for thiamin, riboflavin, B<sub>6</sub>, and vitamin C, even when other vitamins are supplemented, may lead to a significant decrease in Vo<sub>2</sub>max and the anaerobic threshold in less than 4 weeks. Iron and calcium are the two minerals most likely to be low in the diet of young athletes.

Training and work schedules, low-nutrient snacks, infrequent nutrient-dense meals, and overall low calorie intakes may cause inadequate intakes of vitamins and minerals. Because many women athletes are also vegetarians, zinc, iron, and vitamin B<sub>12</sub> may be of concern. In one study, female athletes failed to meet the estimated average requirement for folate in 48% of cases, calcium (24%), magnesium (19%), and iron (4%) (Heaney et al., 2010).

When limited to 100% of the dietary reference intakes (DRIs), vitamin supplementation is generally regarded as safe. Excess amounts may contribute to health problems; athletes need to understand that more is not always better. The DRIs for vitamins and minerals are the guide for determining nutritional needs, and upper levels have been established (see Chapter 12 and inside front cover).

### B Vitamins

Increased energy metabolism creates a need for more of the B vitamins that serve as part of coenzymes involved in the energy cycles. Studies have shown that athletes can become depleted in some B vitamins, and in these athletes dietary change or supplementation improves exercise performance. For some athletes such as wrestlers, gymnasts, or rowers who consume low-calorie diets for long periods, a B-vitamin supplement to meet the RDA may be appropriate. There is no evidence that supplementing the well-nourished athlete with more B vitamins will increase performance.

A deficiency of vitamin B<sub>12</sub> could develop in a vegetarian athlete after several years of a strict vegan intake; thus a vitamin B<sub>12</sub> supplement is warranted. There is a possibility of altered B<sub>12</sub> metabolism based on serum homocysteine concentrations. The intake of folic acid is marginal for a large portion of the U.S. population and could be low in an athlete whose consumption of whole fruits and vegetables is low. A folate supplement to meet the RDA plus wheat, grain, and fortified products can be suggested to boost dietary intake of folate.

### Antioxidants

Antioxidants have been studied individually and collectively for their potential to enhance exercise performance or to prevent exercise-induced muscle tissue damage. Cells continuously produce free radicals and **reactive oxygen species (ROS)** as a part of metabolic processes. The rate of whole-body oxygen consumption during exercise may increase 10- to 15-fold, or as much as 100-fold in active peripheral skeletal muscles. Oxidative stress increases the generation of lipid peroxides and free radicals. The magnitude of stress depends on the ability of the body's tissues to detoxify ROS.

Free radicals are neutralized by antioxidant defense systems that protect the cell membrane from oxidative damage. These systems include catalase; superoxide dismutase; glutathione peroxidase; antioxidant vitamins A, E, and C; selenium; and phytonutrients such as carotenoids (see *Focus On: Eating to Detoxify* in Chapter 20).

Whether exercise increases the need for additional antioxidants in the diet is unclear. Watson and colleagues (2005) compared antioxidant-restricted diets and high-antioxidant diets of trained athletes running for 40 minutes (acute high-intensity exercise); they found an increased rate of perceived exertion, significantly higher levels of oxidative stress markers, and up to 1 hour of recovery in those with antioxidant-deficient diets. In a more recent study, for the first time the antioxidant status of athletes was changed by live-high-train-low (LHTL) conditioning or acute hypoxic exposure, and remained impaired after 14 days of recovery (Pialoux et al., 2010).

Vitamins with antioxidant activity neutralize free radicals. The question is whether they enhance recovery from exercise. Susceptibility to oxidative stress appears to vary from person to person and the effect varies by diet, lifestyle, environmental factors, and training (Pialoux et al., 2009). Antioxidant nutrients may enhance recovery from exercise, maintaining optimal immune response, and lowering lipid peroxidation after exercise.

Evidence suggests that the antioxidant compounds found in tart cherry juice can help to reduce inflammation, muscle damage and oxidative stress following marathon running. An unexpected effect of tart cherry juice is that it may also have beneficial effect on sleep which has been attributed to the high melatonin content of tart cherries and its impact on sleep quality (Howatson et al., 2010; Kuehl et al., 2010; Pigeon et al., 2010). A diet rich in fruits and vegetables can ensure an adequate intake of antioxidants and prudent use of an antioxidant supplement may provide insurance against a suboptimal diet and the increased stress from exercise.

### Vitamin C

Vitamin C is involved in a number of important biochemical pathways that are important to exercise metabolism and the health of athletes. The effect of vitamin C supplementation

on performance has received considerable attention, mainly because athletes consume vitamin C in large quantities, generally because of the volume of food they consume. In studies in which athletes were deficient in vitamin C, supplementation improved physical performance, but a thorough analysis of these studies supports the general conclusion that vitamin C supplementation does not increase physical performance capacity in subjects with normal body levels of vitamin C. On the other hand, because exercise is a stressor to the body, some nutritionists recommend that the active individual may need more vitamin C than the DRI.

## Vitamin E

Vitamin E is used widely as a supplement by athletes who hope to improve performance. Vitamin E may protect against exercise-induced oxidative injury and acute immune response changes. Over the course of an exercise season with intense workouts and competition, vitamin E supplementation of 200 to 450 IU daily may prevent oxidative injury; further studies are recommended.

## Vitamin D

Research has shown that up to 77% of athletes who live in northern climates with little winter sunlight may be affected by deficiencies of vitamin D (Cannell et al., 2009).

Athletes who are at risk for Vitamin D deficiency include those who:

- are lactose intolerant and avoid milk and dairy
- don't consume fish
- live in colder, less sunny climates
- have darker skin, like African-Americans, even if they live and train in sunny climates
- use sun block on exposed areas or wear extensive clothing (Cannell et al., 2009; Larson-Meyer and Willis, 2010)

Blood tests can determine deficiency states. A measurement of 25-(OH) vitamin D levels of 50 ng/mL or less may be cause for concern. The most improvement with supplementation will be for those with a value of 15 to 30 ng/mL, followed by those with 30 to 50 ng/mL (Cannell et al., 2009).

Although the specific amount of vitamin D needed to reverse deficiency states has not been determined, partly because it is dependent on the extent of deficiency, athletes should be tested and guided by a health professional if diagnosed with a deficiency. The RDA for males and females under age 70 is 600 IU and for those 70 and over, 800 IU/day. The tolerable upper intake level (UL) is 4000 IU/day for all individuals age 9 and older (IOM, 2011).

## Iron

Iron is critical for sport performance. As a component of hemoglobin, it is instrumental in transporting oxygen from the lungs to the tissues. It performs a similar role in myoglobin, which acts within the muscle as an oxygen acceptor to hold a supply of oxygen readily available for use by the mitochondria. Iron is also a vital component of the cytochrome enzymes involved in the production of ATP.

Thus it follows that iron-deficiency anemia limits aerobic endurance and the capacity for work. Even partial depletion of iron stores in the liver, spleen, and bone marrow, as evidenced by low serum ferritin levels, can have a detrimental effect on exercise performance, even when anemia is not present (see Chapters 8 and 33).

Although iron-deficiency anemia is not frequent in athletes, suboptimal serum ferritin levels are relatively common (Sinclair and Hinton, 2005). Athletes at risk are the rapidly growing male adolescent; the female athlete with heavy menstrual losses; the athlete with an energy-restricted diet; distance runners who may have increased GI iron loss, hematuria, hemolysis caused by foot impact, and myoglobin leakage; and those training heavily in hot climates with heavy sweating. All athletes, especially female long-distance runners and vegetarians, should be screened periodically to assess their iron status.

Heavy training can also cause a transient decrease in serum ferritin and hemoglobin that may be experienced by some athletes. This was once called **sports anemia**, but erythrocyte morphology remains normal, and performance does not appear to deteriorate. These decreases in serum ferritin and hemoglobin are a result of an increase in plasma volume, which causes a hemodilution and appears to have no effect on performance (see Chapter 33).

Some athletes, especially long-distance runners, experience GI bleeding. Iron loss through GI bleeding can be detected by fecal hemoglobin assays. GI bleeding is related to the intensity and duration of the exercise, the ability of the athlete to stay hydrated, how well the athlete is trained, and whether he or she has taken ibuprofen before the competition.

The iron concentration in sweat is lower in a hot environment. Iron supplementation can be beneficial in improving iron stores of athletes who are iron depleted, but the effects on aerobic performance of nonanemic athletes are equivocal. Because large doses of iron (75 mg/day) may be toxic in persons with the genetic disorder hemochromatosis (see Chapter 33), such supplements should be used only by those diagnosed as iron depleted or anemic.

If true iron depletion is present, iron supplementation along with vitamin C to enhance its absorption is appropriate. Oral iron therapy is effective and maintains performance in runners who are deficient in iron but not anemic (see Chapter 33). Some athletes experience iron deficiency without anemia, a condition with normal hemoglobin levels but reduced levels of serum ferritin (20 to 30 ng/mL; see Chapter 8). Iron supplementation may restore serum ferritin to normal; it may not have an effect on performance (Williams, 2005).

## Calcium

Osteoporosis is a major health concern, especially for women. Although the disease has been regarded as a problem of older women, young women, especially those who have had interrupted menstrual function, may be at risk for decreased bone mass.

The **female athlete triad** is a disturbing pattern in women's athletics (see Chapter 23). Strategies to promote the resumption of menses include estrogen replacement therapy, weight gain, and reduced training. Regardless of menstrual history, most female athletes need to increase their calcium and vitamin D<sub>3</sub> intake, as well as magnesium. Low-fat and nonfat dairy products, calcium-fortified fruit juices, calcium-fortified soy milk, and tofu made with calcium sulfate are all good sources.

## FLUID

Maintaining fluid balance requires the constant integration of input from hypothalamic osmoreceptors and vascular baroreceptors so that fluid intake matches or modestly exceeds fluid loss (Murray, 2006). Proper fluid balance maintains blood volume, which in turn supplies blood to the skin for body temperature regulation. Because exercise produces heat, which must be eliminated from the body to maintain appropriate temperatures, regular fluid intake is essential. Any fluid deficit that is incurred during an exercise session can potentially compromise the subsequent exercise bout.

The body maintains appropriate temperatures by **thermoregulation**. As heat is generated in the muscles during exercise, it is transferred via the blood to the body's core. Increased core temperature results in increased blood flow to the skin; in cool to moderate ambient temperatures, heat is then transferred to the environment by convection, radiation, and evaporation.

Environmental conditions have a large effect on thermoregulation. When ambient temperatures range from warm to hot, the body must dissipate the heat generated from exercise, as well as the heat absorbed from the environment. When this occurs, the body relies solely on the evaporation of sweat to maintain appropriate body temperatures. Thus maintaining hydration becomes crucial when ambient temperatures reach or exceed 36° C (96.8° F). The hotter the temperature, the more important sweating is for body-heat dissipation. Exercise in the heat also affects blood flow and alters the stress response, with modest changes in circulating leukocytes and cytokines. A critical threshold for elevation of body temperature is 6° F (3.5° C), above which the systemic inflammatory response leads to heat-stroke (Peake, 2010).

Humidity affects the body's ability to dissipate heat to a greater extent than air temperatures. As humidity increases, the rate at which sweat evaporates decreases, which means more sweat drips off the body without transferring heat from the body to the environment. Combining the effects of a hot, humid environment with a large metabolic heat load produced during exercise taxes the thermoregulatory system to its maximum. Ensuring proper and adequate fluid intake is key to reducing the risk of heat stress.

### Fluid Balance

Body fluid balance is regulated by mechanisms that reduce urinary water and sodium excretion, stimulate thirst, and

control the intake and output of both water and electrolytes. In response to dehydration, antidiuretic hormone (ADH or vasopressin) and the renin-angiotensin II-aldosterone system increase water and sodium retention by the kidneys and provoke an increase in thirst. These hormones maintain the osmolality, sodium content, and volume of extracellular fluids and play a major role in the regulation of fluid balance (see Chapter 7).

Water losses throughout the course of the day include those from sweat and the respiratory tract, plus losses from the kidneys and GI tract. When fluid is lost from the body in the form of sweat, plasma volume decreases and plasma osmolality increases. The kidneys, under hormonal control, regulate water and solute excretion in excess of the obligatory urine loss. However, when the body is subjected to hot environments, hormonal adjustments occur to maintain body function. Some of these adjustments include the body's conservation of water and sodium and the release of ADH by the pituitary gland to increase water absorption from the kidneys. These changes cause the urine to become more concentrated, thus conserving fluid and making the urine a dark gold color. This feedback process helps to conserve body water and blood volume.

At the same time, aldosterone is released from the adrenal cortex and acts on the renal tubules to increase the resorption of sodium, which helps maintain the correct osmotic pressure. These reactions also activate thirst mechanisms in the body. However, in situations in which water losses are increased acutely such as in athletic workouts or competition, the thirst response can be delayed, making it difficult for athletes to trust their thirst to ingest enough fluid to offset the volume of fluid lost during training and competition. A loss of 1.5 to 2 L of fluid is necessary before the thirst mechanism kicks in, and this level of water loss already has a serious effect on temperature control. Athletes need to rehydrate on a timed basis rather than as a reaction to thirst, and it should be enough to maintain the preexercise weight.

### Daily Fluid Needs

Daily fluid intake recommendations for sedentary individuals vary greatly because of the wide disparity in daily fluid needs created by body size, physical activity, and environmental conditions. The DRI for water and electrolytes identify the adequate intake for water to be 3.7 L/day in men (130 oz/day, 16 cups of fluid/day) and 2.7 L/day for women (95 oz/day, approximately 12 cups/day) (Institute of Medicine, 2004). Approximately 20% of the daily water need comes from water found in fruits and vegetables; the remaining 80% is provided by beverages, including water, juice, milk, coffee, tea, soup, sports drinks, and soft drinks.

When individuals work, train, and compete in warm environments, their fluid needs can increase to more than 10 L/day. The water required to excrete the urea from protein metabolism and excess electrolyte intake adds to the daily needs. However, for active individuals this volume is relatively small (130 mL/1000 kcal) and inconsequential

because usually they are consuming more than 2 L each day (Murray, 2006).

## Fluid Replacement

Several opinions are published by a variety of professional organizations that address fluid and electrolyte replacement before, during, and after exercise. A summary of these recommendations can be found in *Box 24-2*. The groups that developed these statements include the American College of Sports Medicine, the National Athletic Trainers Association, the American Academy of Pediatrics, the American Dietetic Association and the Dietitians of Canada, the International Marathon Directors Association, the Inter-Association Task Force on External Heat Illnesses, and USA Track and Field.

When possible, fluid should be consumed at rates that closely match sweating rate. It appears that plain water is not the best beverage to consume following exercise to replace the water lost as sweat (Murray, 2006). Although specific recommendations differ slightly, the intent is to keep athletes well hydrated.

## Electrolytes

The replacement of electrolytes as well as water is essential for complete rehydration (see *Table 24-1*).

## Sodium

It is important to include sodium in fluid-replacement solutions, especially with excessive intake of plain water (Hew, 2005; Noakes et al., 2005). For events lasting more than 2 hours, sodium should be added to the fluid to replace losses and to prevent hyponatremia. Rehydration with water alone dilutes the blood rapidly, increases its volume, and stimulates urine output. Blood dilution lowers both sodium and the volume-dependent part of the thirst drive, thus removing much of the drive to drink and replace fluid losses.

The potential benefits of temporary hyperhydration with sodium salts is important. Sodium losses can contribute to heat cramping, especially among football players (Stofan et al., 2005). Besides individual variations, the intensity and duration of workouts appear to play a role in the amount of sodium lost.

Water-soluble electrolytes such as sodium can move rapidly across the proximal intestines. During prolonged exercise lasting more than 4 to 5 hours, including sodium in replacement fluids increases palatability and facilitates fluid uptake in the intestines. Both sodium and carbohydrate are actively transported from the lumen to the bloodstream.

Water replacement in the absence of supplemental sodium can lead to decreased plasma sodium concentrations. As plasma sodium levels fall below 130 mEq/L, symptoms can include lethargy, confusion, seizures, or loss of consciousness. Exercise-induced hyponatremia may result from fluid overloading during prolonged exercise over 4 hours. Hyponatremia is associated with individuals who drink plain water in excess of their sweat losses or who are less physically conditioned and produce a saltier sweat.

## BOX 24-2

### Summary of Guidelines for Proper Hydration

#### General Guidelines

Monitor fluid losses: Weigh in before and after practice, especially during hot weather and the conditioning phase of the season.

Do not restrict fluids before, during, or after the event.

Do not rely on thirst as an indicator of fluid losses.

Drink early and at regular intervals throughout the activity.

Do not consume alcohol before, during, or after exercise because it may act as a diuretic and prevent adequate fluid replenishment.

Discourage caffeinated beverages a few hours before and after physical activity because of their diuretic effect.

#### Before Exercise

Drink approximately 400 to 600 mL (14 to 22 oz) of water or sports drink (approximately 17 oz) 2 to 3 hr before the start of exercise.

#### During Exercise

Drink 150 to 350 mL (6 to 12 oz) of fluid every 15 to 20 min, depending on race speed, environmental conditions, and tolerance; no more than 1 C (8 to 10 oz) every 15 to 20 min, although individualized recommendations must be followed.

#### After Exercise

Drink 25% to 50% more than existing weight loss to ensure hydration 4-6 hours after exercise.

Drink 450 to 675 mL (16 to 24 oz) of fluid for every pound of body weight lost during exercise.

If an athlete is participating in multiple workouts in 1 day, then 80% of fluid loss must be replaced before the next workout.

#### Electrolyte Replacement

Sodium: 0.5 to 0.7 g/L in activity longer than 1 hour to enhance palatability and the drive to drink and to reduce the risk of hyponatremia and minimize risk of muscle cramps.

Data from Murray R: Fluid, electrolytes, and exercise. In Danford M, editor: Sports nutrition: a practice manual for professionals, ed 4, Washington, DC, 2006, American Dietetic Association.

## Potassium

As the major electrolyte inside the body's cells, potassium works in close association with sodium and chloride in maintaining body fluids, as well as generating electrical impulses in the nerves, muscles, and heart. Potassium balance is regulated by aldosterone and regulation is precise. Although aldosterone acts on sweat glands to increase the resorption

of sodium, potassium secretion is unaffected. Loss of potassium from skeletal muscle has been implicated in fatigue during athletic events. There is little loss of potassium through sweat; loss of 32 to 48 mEq/day does not appear to be significant and is easily replaced by diet.

### Fluid Absorption

The speed at which fluid is absorbed depends on a number of different factors, including the amount, type, temperature, and osmolality of the fluid consumed and the rate of gastric emptying. Because glucose is actively absorbed in the intestines, it can markedly increase both sodium and water absorption. A carbohydrate-electrolyte solution enhances exercise capacity by elevating blood sugar, maintaining high rates of carbohydrate oxidation, preventing central fatigue, and reducing perceived exertion (Byrne et al., 2005).

Early studies indicate that water absorption is maximized when luminal glucose concentrations range from 1% to 3% (55 to 140 mM); however, most sports drinks contain two to three times this quantity without causing adverse GI symptoms. To determine the concentration of carbohydrate in a sports drink, the grams of carbohydrate or sugar in a serving are divided by the weight of a serving of the drink, which is usually 240 g, the approximate weight of 1 cup of water. A 6% carbohydrate drink contains 14 to 16 g of carbohydrate per 8 oz (1 cup).

Cold water is preferable to warm water because it attenuates changes in core temperature and peripheral blood flow, decreases sweat rate, speeds up gastric emptying, and is absorbed more quickly.

### Children

Because young children are likely to participate in physical activities less than 60 minutes in duration there is often little attention to their hydration. Children do not drink enough when offered fluids freely during exercise in hot and humid climates. But children differ from adults in that, for any given level of dehydration, their core temperatures rise faster than those of adults, putting them at far greater risk for heat stress. Children who participate in sports activities must be taught to prevent dehydration by drinking above and beyond thirst and at frequent intervals, such as every 20 minutes.

A rule of thumb is that a child 10 years of age or younger should drink until he or she does not feel thirsty and then should drink an additional half a glass ( $\frac{1}{3}$  to  $\frac{1}{2}$  cup). Older children and adolescents should follow the same guidelines; however, they should consume an additional cup of fluid (8 oz). When relevant, regulations for competition should be modified to allow children to leave the playing field periodically to drink. One of the hurdles to getting children to consume fluids is to provide fluids they like. Providing a sports drink that will maintain the drive to drink and rehydrate them is the key.

### Older Athletes

Older, mature, or masters-level athletes are also at risk for dehydration and need to take precautions when exercising

or staying fit. **Hypohydration** (water loss exceeding water intake with a body water deficit) in older individuals can affect circulatory and thermoregulatory function to a greater extent and may be caused by the lower skin blood flow, causing core temperature to rise. Because the thirst drive is reduced in older adults, they need to drink adequately before exercise, well before they become thirsty. Women athletes need to drink more than men during interval exercise in the heat. Fluid balance is maintained better when palatable carbohydrate and electrolyte solutions are offered (Baker et al., 2005).

### Hydration at High Altitudes

Unacclimated individuals undergo a plasma volume contraction when acutely exposed to moderately high altitude. This is the result of increased renal sodium and water excretion and decreased voluntary sodium and water intake. Respiratory losses are increased by high ventilatory rates and typically dry air. The result is an increase in serum hematocrit and hemoglobin, which increases the oxygen-carrying capacity of the blood, but at the cost of reduced blood volume, stroke volume, and cardiac output. Fluid requirements increase as a result. With acclimation, red blood cell production increases and plasma and blood volume return to pre-high altitude levels.

## OTHER CONSIDERATIONS

### Alcohol

Alcohol is a central nervous system depressant. Pure alcohol supplies 7 kcal/g and is a source of energy that is metabolized more like fat. For alcohol to be used by muscle, it must first be metabolized in the liver. Alcohol consumption immediately before or during exercise has a detrimental effect on athletic performance, even though, by reducing feelings of insecurity, tension, and discomfort, it may cause the athlete to believe that he or she is performing better. Some athletes incorrectly believe that because alcohol contains carbohydrates, they can load up on beer to improve their performance. Perceptual motor performance, gross motor skills, balance, and coordination are affected by alcohol consumption.

Alcohol may cause reduced glucose secretion from the liver, which may lead to hypoglycemia and early fatigue during endurance exercise. Alcohol may also be a contributing factor to hypothermia if consumed during exercise in cold weather. Alcohol should not be used to replace fluids immediately after exercise because of its diuretic effect and adverse effects on blood glucose and glycogen levels. Chronic alcohol use causes the loss of many nutrients important for performance and health, including thiamin, vitamin B<sub>6</sub>, and calcium.

### Caffeine

Caffeine contributes to endurance performance, apparently because of its ability to enhance mobilization of fatty acids and thus conserve glycogen stores. Caffeine may also directly

affect muscle contractility, possibly by facilitating calcium transport. It could reduce fatigue as well by reducing plasma potassium accumulation, which contributes to fatigue. Probably some ergogenic effects occur at doses of 6.5 mg/kg of body weight when taken before endurance exercise, however, caffeine does not seem to offer any benefits before high-intensity exercise.

Because of this potential ergogenic effect, caffeine is banned by the International Olympic Committee (IOC), although the banned level is much higher than that needed to enhance performance. An energy-enhancing effect is seen with only 1.5 to 3 mg of caffeine per pound (3.3 to 6.6 mg/kg). For a 150-lb man this is equivalent to only one 10-oz cup of coffee. As fluid-replacement beverages, tea, iced tea, coffee, cola, caffeinated water, and some of the new caffeine-containing energy drinks are poor choices because of their diuretic effect and variable carbohydrate content. The diuretic action of caffeine could have negative consequences for athletes with excessive water needs or for those participating in long-distance events who do not want to have to urinate during the event. As a restricted drug by the IOC, caffeine is considered a doping agent if the intake results in urine caffeine concentrations of more than 12 mg/L.

## ERGOGENIC AIDS

**Ergogenic aids** include any training technique, mechanical device, nutrition practice, pharmacologic method, or physiologic technique that can improve exercise performance capacity and training adaptations. The use of ergogenic aids in the form of dietary supplements is widespread in all sports. Many athletes, whether recreational, elite, or professional, use some form of dietary supplementation (e.g., substances obtainable by prescription or by illegal means or others marked as supplements, vitamins, or minerals) to improve athletic performance or to assist with weight loss (Dhar et al., 2005). Research suggests that 50% to 98.6% of university athletes use some form of supplements as ergogenic aids (Kristiansen et al., 2005; Neiper, 2005).

Reasons for supplement use differ between genders. Women athletes reported taking supplements for their health or to overcome an inadequate diet, whereas men may take supplements to improve speed, agility, strength, and power. Health reasons (45%), immune system enhancement (40%), and performance improvement (25%) have also been cited as reasons for supplement use (Neiper, 2005). Performance enhancement supplements are pills, drinks, bars, or gels that improve speed, strength, or performance, or minimize or delay fatigue (Bishop, 2010). Supplements used to help build body mass and reduce weight or excess body fat may also enhance exercise performance. The most common supplements used by athletes are described in Tables 24-2 and 24-3.

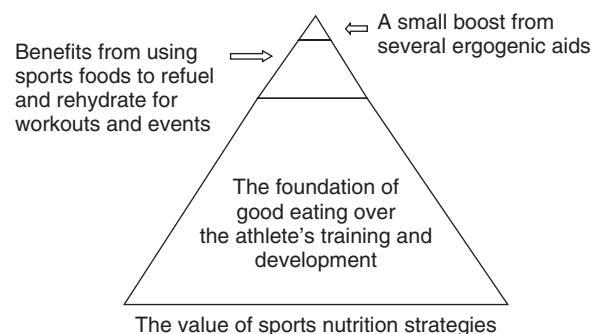

Athletes are bombarded with advertisements and testimonials from other athletes and coaches about the effects of dietary supplements on performance. The Dietary Supplement Health and Education Act (DSHEA) protects

dietary supplements from being required to demonstrate proof of efficacy or safety (see Chapter 13). Under this act the Food and Drug Administration no longer has regulatory control of supplements and they are now classified as foods. Manufacturers are allowed to publish limited information about the benefits of dietary supplements in the form of statements of support, as well as so-called structure and function claims. This results in a great deal of printed material that can be confusing to athletes at the point of sale of nutritional products.

Research suggests that the Internet, family members, friends, physicians, or pharmacists guide supplement choices for women athletes; whereas the store nutritionist, fellow athletes, friends, or coaches, advise on supplement decisions for men athletes (Kristiansen et al., 2005). Many believe that ergogenic aids will improve their performance and assist in recovery. As in the past and probably in the future, many of these ergogenic aids are not supported by scientific studies. In fact, many act only as placebos (Figure 24-6).

Many of these supplements confer no performance or health benefit, and some may actually be detrimental to both performance and health when taken for prolonged periods. They may contain excessive doses of potentially toxic ingredients or contain significant amounts of ingredients not approved by the IOC, the World Anti-Doping Agency, the National Collegiate Athletic Association (NCAA), Major League Baseball, and the National Football League (NFL) (Maughan, 2005).

Sports nutritionists need to know how to evaluate the scientific merit of articles and advertisements about exercise and nutrition products so they can separate marketing hype from scientifically based training and nutrition practices. Performance-enhancing substances such as anabolic-androgenic steroids, tetrahydrogestrinone, and androstenedione (andro); stimulants such as ephedra; and nonsteroidal agents such as recombinant human erythropoietin (EPO), human growth hormone (HGH), creatine, and  $\beta$ -hydroxy- $\beta$ -methylbutyrate (HMB) may cause serious side effects, including adverse cardiovascular changes and sudden death (Dhar et al., 2005).

**FIGURE 24-6** The value of sports nutrition strategies versus sports drinks and ergogenic aids. (From Australia Sports. Accessed 14 July 2010 at <http://fulltext.ausport.gov.au/fulltext/2001/ascpub/images/FactSupp2.gif>)

**TABLE 24-2****Recommendations for Use of Sport Foods and Drinks**

<b>Sport Food</b>	<b>Characteristics</b>	<b>Guidelines for Consumption in Exercise</b>		
		<b>Before</b>	<b>During</b>	<b>After</b>
Sports drink	CHO: 5%-7% by volume (approximately 14 g/8 oz) Sodium: 20-30 mEq/L (110-165 mg/8 oz) Multiple carbohydrates with high glycemic indices	0.5 L (16 oz) 1 hr before exercise	150-300 mL every 15-20 min (20-40 oz/hr)	24 oz/lb of body weight lost
High CHO energy drink	CHO: >13% by volume (more than 50 g/8 oz) Optional B vitamins: thiamin, niacin, and riboflavin at 10%-40% of RDA	0.5 L (16 oz) 2-5 hr before exercise	Typically not advised for use during the event	Immediately after and at 1-hr intervals to deliver 1 g CHO/kg of body weight
Sports bar	CHO: >70% of total kcal High glycemic index Fat: low (1-2 g/bar) or absent Vitamins and minerals not critical component	One bar 2 hr before exercise	Usually not advised except for those desiring solid foods during long-duration events	One to two bars immediately after exercise and with daily meals as desired
Sports shake	CHO: >65% of total kcal (>18 g/100 mL) High glycemic index Fat: not to exceed 25% of total kcal Protein: 15%-20% of total kcal Vitamins and minerals: optional at low levels (10%-40% of RDA)	0.5 L (16 oz) 2-5 hr before exercise	Not recommended	Immediately after exercise to deliver 1 g CHO/kg body weight and as a supplement to daily meals
Energy gel	CHO: >50% by volume (>50 g/100 mL or 15 g/oz) Vitamins and minerals: trace or absent	1 packet before exercise; consume adequate fluid to promote absorption	If overall fluid intake is adequate, enough to supply 30-60 g CHO/hr	Immediately after exercise and at 1-hr intervals to deliver 1 g CHO/kg body weight
Shot bloks	Avoid those with herbs Organic electrolyte chew Gelatin consistency CHO: 24 g/1 oz 3 bloks = 100 cal plus electrolytes	Not applicable	3-6 bloks every hour with water	Not applicable
Sports beans	CHO: 25 g/1 oz 14 beans = 100 cal 10% DV of vitamins B <sub>1</sub> , B <sub>2</sub> , B <sub>3</sub> 20% DV of vitamins C and E	Not applicable	Up to 14 pieces per hour for energy	Not applicable

Modified from Gatorade Sports Science Institute.

CHO, Carbohydrate; DV, daily value; RDA, recommended dietary allowance.

**Muscle-Building Supplements**

Muscle-building supplements include amino acids, HMB, creatine, prohormones, glutamine, protein, high-calorie powders, protein-fortified beverages and bars, and other compounds listed in Table 24-2.

**Amino Acids**

Protein or amino acid supplementation in the form of powders or pills is not necessary and should be discouraged.

Taking large amounts of protein or amino acid supplements can lead to dehydration, hypercalciuria, weight gain, and stress on the kidney and liver. Taking single amino acids or in combination, such as arginine and lysine, may interfere with the absorption of certain other essential amino acids. An additional concern is that substituting amino acid supplements for food may cause deficiencies of other nutrients found in protein-rich foods such as iron, zinc, niacin, and thiamin. Athletes and coaches need to realize that amino

**TABLE 24-3**

<b>Ergogenic Aids</b>				
<b>Ergogenic Aid</b>	<b>Reported Action/Claim</b>	<b>Research on Ergogenic Effects</b>	<b>Side Effects</b>	<b>Legality</b>
α-Ketoglutarate	Intermediate in Krebs cycle.	Some evidence as anticatabolic after surgery; unclear in training.	None	Legal
ALA	Enzyme found in mitochondria involved in energy production.	No studies of use in humans for sport; used in Europe with persons with diabetes to treat insulin resistance and neuropathy.	None	Legal
<b>Amino Acids</b>				
Arginine	Protein synthesis; precursor to creatine and potential to increase GH; precursor to NO.	Little evidence; some rationale for athletic improvement may be the result of role as precursor to NO; some improvement in cardiac patients on protocol of 1.5 g/10 kg of body weight for 7 days.	None	Legal
Branched-chain amino acids	Decreases mental fatigue. Decreases exercise-induced protein degradation and muscle enzyme release.	Some evidence that decreased fatigue may occur at higher altitudes.	Mild	Legal
EAAs		Limited; suggests 3–6 g of EAAs before exercise; stimulates protein synthesis.	Same as protein	Legal
Glutamine	Boosts immunity; stimulates protein and glycogen synthesis.	May boost immunity with branched-chain amino acids and enriched whey.	None	Legal
HMB	Anticatabolic; enhances recovery by stimulating protein and glycogen synthesis.	Minimum gains in strength and lean body mass in untrained athletes and the elderly; possibly catabolic with prolonged exercise; mixed reports in trained subjects.	None with short-term use	Legal
Chokeberry juice	Enhances endogenous antioxidant defense system.	Limits exercise-induced oxidative damage to red blood cells.	None reported	Legal
Chitosan	Inhibits fat absorption; lowers cholesterol.	No evidence in humans.	None reported	Legal
<i>Citrus aurantium</i> , bitter orange, synephrine	Increases metabolism.	No evidence of weight-reducing properties.	None reported	Legal
Ciwujia aka Siberian ginseng E.S.	Improves CF, FAM, and EP.	Mixed; limited research shows improvement in CF, FAM, EP, although studies flawed	None reported	Legal
Chondroitin sulfate	Builds and grows cartilage.	No studies that it is effective in treating arthritis or joint damage or helps torn ligaments or cartilage.	None	Legal

*Continued*

**TABLE 24-3****Ergogenic Aids—cont'd**

<b>Ergogenic Aid</b>	<b>Reported Action/Claim</b>	<b>Research on Ergogenic Effects</b>	<b>Side Effects</b>	<b>Legality</b>
Ephedrine, other sympathomimetics Pseudoephedrine, ma huang	Stimulates central nervous system; increases energy.	With caffeine, increases energy, time to exhaustion; increases metabolism without exercise; without caffeine, no benefits.	Restlessness, nervousness, tachycardia, arrhythmias, hypertension, death	Banned by NFL, NCAA, and IOC
Glucosamine	Serves as nonsteroidal antimflammatory drug alternative.	Readily absorbed; benefit in reducing pain and need for medication.	None reported	Legal
Green tea extract	Antioxidant; increases energy expenditure.	Limited; may increase energy expenditure.	Same as caffeine	Legal
Human growth hormone MSM	Anabolic effect on muscle growth; increases fat metabolism.	Limited ergogenic benefits.	Significant and dangerous	Illegal
	Metabolite of dimethylsulfoxide, a solvent used topically for analgesic and antiinflammatory properties.	Little evidence of effectiveness for pain control in humans.	None	Legal
NO	Promotes a “muscle pump,” signals muscle growth and speeds recovery.	No evidence that NO promotes muscle growth synthesis or improves muscle strength.	None	Legal
Ornithine- $\alpha$ -ketoglutarate	Anabolic/catabolic	Limited; may improve protein balance, gains in bench press, but no significant gains in muscle mass, GH, squat strength, or training capacity.	None reported	Legal
Oxygenated beverages	Increases aerobic metabolism, decreases lactic acid, improves endurance.	Performance hydration and blood oxygenation unaffected by oxygenated water.	None	Legal
Ribose	3-Carbon carbohydrate; involved in synthesis of adenosine triphosphate.	Limited; can increase exercise capacity in heart patients; no effect on exercise capacity in trained or untrained subjects.	None reported	Legal
Sodium bicarbonate	Buffers lactic acid production; delays fatigue.	Increases body's ability to buffer lactic acid during sub max exercise for events lasting 1–7 min.	Stomach distress; bloating, diarrhea; dangerous in high doses; alklosis	Legal
Sodium phosphate	Buffer	Some; increases $V_{O_2\text{max}}$ and anaerobic threshold by 5%–10%; improves endurance.	Stomach distress	Legal
<i>Tribulus terrestris</i>	Increases endogenous steroid production; promotes skeletal hypertrophy.	Mixed; no effect on strength or change in body composition.	Potentially dangerous at high doses	Legal
Vanadyl sulfate (Vanadium)	Trace mineral; may affect protein and glucose metabolism.	No effect on strength training or muscle mass during training.	None reported	Legal

*ALA*,  $\alpha$ -Lipoic acid; *CF*, cardiorespiratory fitness; *EAA*, essential amino acid; *EP*, endurance performance; *ES*, *Eleutherococcus senticosus*; *FAM*, fat metabolism; *GH*, growth hormone; *HMB*,  $\beta$ -hydroxy- $\beta$ -methylbutyrate; *IOC*, International Olympic Committee; *MSM*, methylsulfonylmethane; *NCAAD*, National Collegiate Athletic Association; *NFL*, National Football League; *NO*, nitric oxide.

acid supplements taken in large doses have not been tested in human subjects, and no margin of safety is available. It is important for the health professional to develop a strategy to approach and discuss this supplement use effectively with both athletes and coaches.

### Branched-chain amino acids

The BCAAs include leucine, isoleucine, and valine and they make up 35% to 40% of the essential amino acids (EAAs) in the body's protein and 14% of the total AAs in muscle. In order to get energy, the body can break down muscle to get the BCAAs. During times of stress, BCAAs are required more than any other EAA.

BCAAs consumed before and after training have been shown to increase protein synthesis and muscle gains beyond normal adaptation. They have been reported to decrease exercise-induced protein breakdown and muscle enzyme release, which is a sign of muscle damage. Some research suggests that 14 grams of BCAAs during eight weeks of weight training can produce a significantly greater weight gain in lean mass.

Dairy products and red meat contain the greatest amounts of BCAAs. Whey protein and egg protein supplements are also good sources.

Branched-chain amino acid	Food sources
Leucine	meats, dairy, nuts, beans, brown rice, soy, and whole wheat
Isoleucine	meats, chicken, eggs, fish, almonds, chickpeas, soy protein, and most seeds
Valine	meat, dairy, soy protein, grains, peanuts, and mushrooms

Leucine is the most readily oxidized BCAA and is most effective at causing insulin secretion from the pancreas. It lowers elevated blood sugar levels and aids in growth hormone production. Leucine works in conjunction with isoleucine and valine to protect muscle and act as fuel for the body. Doses of up to 2 grams (2000 mg) post workout have been suggested by some experts for accelerating muscle repair and recovery.

### $\beta$ -Hydroxy- $\beta$ -Methylbutyrate

HMB is an important compound made in the body and a metabolite of the essential amino acid leucine. In humans oral administration of HMB has been associated with increased body mass across the young, elderly, untrained, trained, and clinically cachexic (Wilson JM et al., 2009). The effects of HMB supplementation in trained athletes is not clear, with most studies reporting nonsignificant gains in muscle mass (Palisin and Stacy, 2005). Regarding HMB supplementation and exercise recovery, several studies have found that subjects supplemented with HMB may have less stress-induced muscle protein breakdown. Recent research

suggests that both acute and chronic administration of HMB are associated with less exercise-induced muscle damage and soreness (Wilson JM et al., 2009). Additional research is necessary to determine the effectiveness of this supplement both as an ergogenic and recovery aid for athletes.

### Creatine

Creatine is an amino acid normally produced in the body from arginine, glycine, and methionine. Most dietary creatine comes from meat, but half is manufactured in the liver and kidneys. For meat eaters, dietary intake of creatine is approximately 1 g daily. The body also synthesizes approximately 1 g of creatine per day, for a total production of approximately 2 g daily.

In normal healthy persons approximately 40% of muscle creatine exists as free creatine; the remainder combines with phosphate to form CP. Approximately 2% of the body's creatine is broken down daily to creatinine before excretion by the kidneys. The normal daily excretion of creatinine is approximately 2 g for most persons. Those with lower levels of intramuscular creatine such as vegetarians may respond to creatine supplementation (Williams, 2006).

Creatine is one of the most researched and popular sports supplements. It supplies most of the energy for short-term, maximum exercise such as weight lifting, running a 100-m sprint, swinging a bat, or punting a football. Supplementation elevates muscle creatine levels and facilitates the regeneration of CP, which helps to regenerate ATP. When creatine stores in the muscles are depleted, ATP synthesis is prevented and energy can no longer be supplied at the rate required by the working muscle. Improved athletic performance has been attributed to this ATP resynthesis.

Creatine supplementation increases body mass or muscle mass during training; short-term gains may be primarily water, whereas long-term gains along with resistance training are muscle mass (Williams, 2006). Studies suggest that creatine does not enhance exercise and events lasting more than 90 seconds (Astorino et al., 2005). However, creatine supplementation may improve submaximal exercise performance for HIIT, which promotes fitness similar to endurance training (Graef et al., 2009).

Creatine absorption appears to be stimulated by insulin. Therefore ingesting creatine supplements in combination with carbohydrate, amino acid, or protein can increase muscle creatine concentrations (Buford TW, 2007). Once creatine is taken up by the muscles, it is trapped within the muscle tissue. It is estimated that muscle creatine stores decline slowly and will still be elevated 2 to 3 months after ingestion of 20 g of creatine for 5 days.

Current thought is to consume creatine at a dose of 2 to 5 g daily. Human muscle appears to have an upper limit of creatine storage; thus excess creatine presumably will be of little benefit. Few data exist on the long-term benefits and risks of creatine supplementation. There have been anecdotal descriptions of athletes who have had muscle strains and tears, dehydration, and kidney damage (Rodriquez et al., 2009). Thus the American College of

Sports Medicine advises against taking creatine for youth 18 years old and younger.

### Peptide Hormones

**Erythropoietin.** EPO is commonly used to keep up the body's production of red blood cells in patients with bone marrow suppression such as patients with leukemia, those who are receiving chemotherapy, or those with renal failure (see Chapter 36). In athletes, injections increase the serum hematocrit and oxygen-carrying capacity of the blood and thus enhance  $V_{O_2\text{max}}$  and endurance. EPO use as an ergogenic aid is difficult to detect because it is a hormone produced by the kidneys, although newer blood tests can detect its use. Typically, athletes with elevated hematocrit have been banned from endurance sports for suspected EPO misuse; however, despite its ban by the IOC, it is still commonly abused. Drastically high hematocrit combined with exercise-induced dehydration can lead to thick or viscous blood, which can lead to coronary or cerebral vascular occlusions, heart attack, or stroke. EPO can also cause elevated blood pressure or elevated potassium levels.

**Human growth hormone (HGH)** has many functions in the body, and it is produced naturally throughout life. It stimulates protein synthesis, enhances carbohydrate and fat metabolism, helps to maintain sodium balance, and stimulates bone and connective tissue turnover. HGH production decreases with age after the peak growth years. The amount secreted is affected by diet, stress, exercise, nutrition, and medications. HGH is banned by the IOC; however, it continues to be abused by athletes. Potential side effects can include skin changes, darkening of moles, an adverse effect on glucose metabolism and on the lipid profile, and growth of bones as evidenced by a protruding jaw and boxy forehead.

### Prohormones and Steroids

Prohormones are popular among bodybuilders, many of whom believe that these prohormones are natural boosters of anabolic hormones. Androstenedione, 4-androstenediol, 19-nor-4-androstenedione, 19-nor-4-androstenediol, 7-keto dehydroepiandrosterone (DHEA) and 7-keto DHEA are naturally derived precursors to testosterone and other anabolic steroids. Androstenedione is an anabolic androgenic steroid used to increase blood testosterone levels for the purpose of increasing strength and lean body mass, although there is no research that it has that effect in humans. Although theoretically prohormones may increase testosterone levels, there is no evidence that these compounds affect training adaptations in younger men with normal hormone levels. They may even increase estrogen levels and low-density lipoprotein cholesterol levels and reduce high-density lipoprotein (HDL) cholesterol.

**Androstenedione.** Androstenedione (andro) is a pre-hormone, an inactive precursor to both female estrogen and male testosterone. It has about one seventh of the activity of testosterone and is a precursor that directly converts to testosterone by a single reaction. It is naturally produced in the body from either DHEA or 17- $\alpha$ -hydroxyprogesterone.

Some researchers have found that taking andro elevates testosterone more than DHEA does; however, the induced increase lasts only several hours and remains at peak levels for just a few minutes. Acute or long-term administration of testosterone precursors does not effectively increase serum testosterone levels and fails to produce any significant changes in lean body mass, muscle strength, or performance improvement (Smurawa and Congeni, 2007).

Adverse reactions occur in male and female athletes, including muscle tightness and cramps, increased body weight, acne, GI problems, changes in libido, amenorrhea, liver damage, and stunted growth in adolescents. Consumption of a prohormone supplement can alter a patient's hypothalamic-pituitary-gonadal axis. Andro-related hormones may abnormally elevate estrogen-related hormones and alter elevations of serum estrogen, which is thought to increase the risk for developing prostate or pancreatic cancers. A significant decline in HDLs occur, leading to an increased cardiovascular disease risk (Dhar et al., 2005). Therefore taking androstenedione may be irresponsible because of the potential risks associated with long-term use. Until there is scientific support for its use, andro should not be sold under the assumption that it is either an effective or a safe athletic ergogenic aid. Clearly adolescents and women of childbearing age should not use it. In 1998 andro was added to the list of banned substances by the IOC and several amateur and professional organizations, including the NFL and the NCAA.

**Dehydroepiandrosterone (DHEA)** is a weak androgen and product of dehydroandrosterone-3-sulfate (DHEA-S) and is used to elevate testosterone levels. It is a precursor to more potent testosterone and dihydrotestosterone. Although DHEA-S is the most abundant circulating adrenal hormone in humans, its physiologic role is poorly understood. DHEA has been labeled the "fountain of youth" hormone because its levels peak during early adulthood. The decline with aging has been associated with increased fat accumulation and risk of heart disease. Several studies have suggested a positive correlation between increased plasma levels of DHEA and improved vigor, health, and well-being in persons who range in age from 40 to 80 years. By decreasing cortisol output from the liver by 50%, DHEA could have an anabolic effect. If this were to occur in muscle tissue as well, the anabolic effect would be comparable to that of anabolic steroids; however, no proof of this currently exists.

DHEA supplementation does not increase testosterone levels or increase strength in men, but it may increase testosterone levels in women with a virilizing effect. Because DHEA can take several different hormonal pathways, the one that it follows depends on several factors, including existing levels of other hormones. It can take several routes in the body and interact with certain enzymes along the sex-steroid pathway. Thus it can turn into less desirable byproducts of testosterone, including dihydrotestosterone, which is associated with male-pattern baldness, prostate enlargement, and acne.

Until recently DHEA was a prescription drug, but it is now sold over the counter. Analysis of DHEA products on

the market shows a dramatic difference between the amount stated on the label and the actual amount in the product.

The benefits of taking DHEA for sports performance have not been clearly established, and the effects of chronic DHEA ingestion are not known. Long-term safety has not been established, and there are concerns that chronic use in men may worsen prostate hyperplasia or even promote prostate cancer. DHEA is not recommended for athletic use because it can alter the testosterone-epitestosterone ratio so that it exceeds the 6:1 limit set by the IOC, the U.S. Olympic Committee, the NFL, and the NCAA.

**Steroids.** Androgenic-anabolic steroids (AASs) categorize all male sex steroid hormones, their synthetic derivatives, and their active metabolites used to enhance athletic performance and appearance (DiLuigi et al., 2005). AAS use was reported in the 1950 Olympics and was banned in 1976. Steroids may be used in oral or intramuscular preparations.

The legal and illegal use of these drugs is increasing as a result of society's preoccupation with increasing muscle strength, size, and libido. Originally designed for therapeutic uses to provide enhanced anabolic potency, nontherapeutic use of AAS is increasing among adolescents and females (DiLuigi et al., 2005). Anecdotal evidence suggests widespread use of anabolic steroids among athletes (20% to 90%), especially at the professional and elite amateur levels. Use among high school boys is approximately 5% to 10%; rates among college athletes are slightly higher. Use of multiple steroids simultaneously in excess of therapeutic doses by 10-fold to 100-fold is known as "stacking" (Trenton and Currier, 2005). See Box 24-3 for a list of commonly abused steroids.

Short-term administration of these drugs by athletes can increase strength and body weight. **Anabolic effects**

include increased muscle mass; increased bone mineral density; increased blood cell production; decreased body fat; increased heart, liver, and kidney size; vocal cord changes; and increased libido. Anabolic steroids increase protein synthesis in skeletal muscles and reverse catabolic processes; however, increased muscle mass and strength are observed only in athletes who maintain a high-protein, high-calorie diet during steroid administration. **Androgenic effects** are the development of secondary sexual characteristics in men, changes in genital size and function, and growth of auxiliary pubic and facial hair (Trenton and Currier, 2005). Some adverse effects associated with steroid use are irreversible, especially in women (Table 24-4).

### BOX 24-3

#### Commonly Abused Steroids

##### Oral

oxymetholone (Anadrol)  
oxandrolone (Oxandrin)  
methandrostenolone (Dianabol)  
stanozolol (Winstrol)

##### Injectable Steroids

stanozolol (Sanobolic)  
nandrolone decanoate (Deca Durabolin)  
nandrolone phenylpropionate (Durabolin)  
testosterone cypionate (Depo-Testosterone)  
boldenone undecylenate (Equipoise)

**TABLE 24-4**

#### Effects of Androgenic Anabolic Steroids in Athletes

Children	Premature closing of growth plates
Males	Increase sex drive, acne vulgaris, enlarged breasts, testicular hypotrophy, infertility
Females	Clitoris enlargement, excessive body hair
Athletic performance	Increased strength and lean body mass; no increase in endurance performance
Cardiovascular system	Increased blood pressure, depression of HDL, HDL2, and HDL3 cholesterol
Hormonal changes	Disturbance in endocrine and immune function
Hepatic system	Peliosis (purpura), hepatitis, increased liver enzymes, jaundice, cancer
Immune compromised—those with HIV, AIDS, hepatitis	Infections from injectable forms
Mental health	Increase in aggressive behavior, mood disturbances (e.g., depression, hypomania, psychosis, homicidal rage, mania, delusions)
Metabolic changes	Changes in hemostatic system and urogenital tract, altered glucose metabolism, immune system suppression, low thyroid hormone levels
Physical	Short stature, tendon rupture
Skin	Acne, cysts, oily scalp

*AIDS*, Acquired immune deficiency syndrome; *HDL*, high-density lipoprotein; *HIV*, human immunodeficiency virus.

## CLINICAL SCENARIO

**B**en is a 21-year-old active college student who is interested in building muscle mass and losing body fat. His height is 5 ft 8 in, and his weight is 160 lb. Ben says that, although he is very disciplined, he has weekend splurges of a pizza and a six-pack of beer, as well as chips, ribs, and nuts during football, basketball, and baseball season. He does not work out on the weekends. He cannot understand why he is not losing body fat because he works out twice a day, includes resistance training and cardiovascular exercise, and eats the following:

### Before Breakfast

1 protein bar with 45 g of protein and 300 calories

### After Workout

1 protein drink with 30 g of protein

### Breakfast

1 protein smoothie with berries and 60 g of protein  
1 oatmeal with 1 whey protein scoop (25 g of protein)

### Snack

3 oz bologna or ham

### Lunch

1 turkey sandwich with 6-9 oz of protein, lettuce, and tomato

### Before Afternoon Workout

1 protein bar with 60 g of protein

### After Workout

Protein drink with 45 g of protein

### Dinner

½ chicken, string beans, and a lettuce salad with olive oil

### Nutrition Diagnostic Statement

Excessive protein intake related to frequent intake of protein bars and supplemental beverages, as evidenced by an intake of 265 g of protein per day from these products compared with a recommended dietary allowance (RDA) of 55 to 75 g/day for normal growth and development.

### Nutrition Care Questions

- How many grams of protein is Ben consuming? What is his protein per kilogram of body weight consumption? Can this be a contributing factor to his difficulty with losing body fat?
- What level of protein intake would you recommend for him? Is this different from the RDA for normal growth and development? Are there healthier sources of protein that he can consume?
- What is the calorie cost of his weekend splurges? Are they in excess of his calorie needs? And if so, by how much? What type of recovery beverages and protein dosages may be more suitable for Ben to consume? What additional questions would you ask Ben about his bars and supplements?
- What nutrients are in deficient amounts in Ben's diet? Including what foods in his diet would be beneficial?
- What are other changes Ben can make on the weekends? What foods and exercise will help him reduce his body fat and manage his weight better?

RD, LDN

# Nutrition and Bone Health

### KEY TERMS

25-hydroxy vitamin D (calcidiol)  
1,25-dihydroxy vitamin D<sub>3</sub> (calcitriol)  
age-related primary osteoporosis  
bisphosphonates  
bone densitometry  
bone mineral content (BMC)  
bone mineral density (BMD)  
bone modeling  
bone remodeling  
calcium homeostasis  
calcitonin  
cancellous bone  
cortical bone  
estrogen-androgen deficient osteoporosis  
estrogen receptor (ER)

estrogen replacement therapy (ERT)  
hydroxyapatite  
intermittent parathyroid hormone (PTH) therapy  
osteoid  
osteoblast  
osteocalcin  
osteoclast  
osteocyte  
osteomalacia  
osteopenia  
osteoporosis  
parathyroid hormone (PTH)  
peak bone mass (PBM)  
secondary osteoporosis  
selective estrogen receptor modulator (SERM)  
trabecular bone

Adequate nutrition is essential for the development and maintenance of the skeleton (i.e., bone health). Although diseases of the bone such as osteoporosis and **osteomalacia** (a condition of impaired mineralization caused by vitamin D and calcium deficiency) have complex causes, the development of these diseases can be minimized by providing adequate amounts of nutrients throughout the life cycle. Of these diseases, osteoporosis is the most common and destructive of productivity and quality of life.

The number of people older than 65 years in the United States is projected to reach almost 25% of the population by 2020. The average life expectancy in the United States

is almost 81 years for women and 74 for men. As a result of the increasing numbers of older adults, osteoporosis with resulting hip fractures has become more significant in cost, morbidity, and mortality in the United States. Although the use of bone-building nutrients is necessary after the onset of osteoporosis, the benefits of adequate intakes (AIs) of bone-building nutrients during adolescence and adulthood are significant.

### BONE STRUCTURE AND BONE PHYSIOLOGY

*Bone* is a term used to mean both an organ, such as the femur, and a tissue, such as trabecular bone tissue. Each

Sections of this chapter were written by John J.B. Anderson, PhD for the previous edition of this text.

bone contains bone tissues of two major types, trabecular and cortical. These tissues undergo bone modeling during growth (height gain) and bone remodeling after growth ceases.

## Composition of Bone

Bone consists of an organic matrix or **osteoid**, primarily collagen fibers, in which salts of calcium and phosphate are deposited in combination with hydroxyl ions in crystals of **hydroxyapatite**. The cablelike tensile strength of collagen and the hardness of hydroxyapatite combine to give bone its great strength. Other components of the bone matrix include osteocalcin, osteopontin, and several other matrix proteins.

## Types of Bone Tissue

Approximately 80% of the skeleton consists of compact or cortical bone tissue. Shafts of the long bones contain primarily **cortical bone**, which consists of osteons or Haversian systems that undergo continuous but slow remodeling, and both contain an outer periosteal layer of compact circumferential lamellae and an inner endosteal layer of trabecular tissue. The remaining 20% of the skeleton is **trabecular** or **cancellous bone** tissue, which exists in the knobby ends of the long bones, the iliac crest of the pelvis, the wrists, scapulas, vertebrae, and the regions of bones that line the marrow. Trabecular bone is less dense than cortical bone as a result of an open structure of interconnecting bony spicules that resemble a sponge in appearance; thus trabecular bone is also called *spongy bone* or *spongiosa*.

The elaborate interconnecting components (columns and struts) of trabecular bone tissue add support to the cortical bone shell of the long bones and provide a large surface area that is exposed to circulating fluids from the marrow, and is lined by a disproportionately larger number of cells than cortical bone tissue. Therefore trabecular bone tissue is much more responsive to estrogens or the lack of estrogens than cortical bone tissue (Figure 25-1). The loss of trabecular bone tissue late in life is largely responsible for the occurrence of fractures, especially those of the spine.

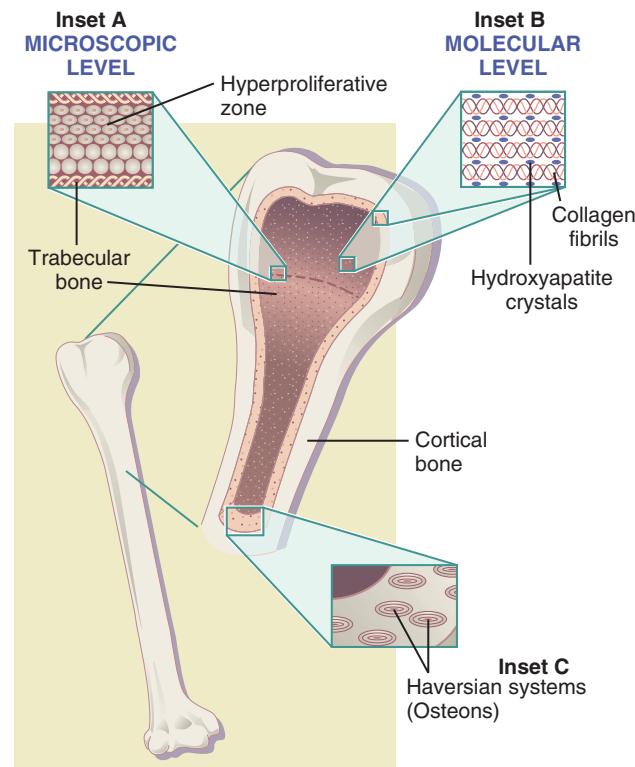

## Bone Cells

**Osteoblasts** are responsible for the formation or production of bone tissue, and **osteoclasts** govern the resorption or breakdown of bone (also see “Bone Modeling and Bone Remodeling” later in this chapter). The functions of these two cell types are listed in Table 25-1.

Two other important cell types also exist in bone tissue, **osteocytes** and bone-lining cells (inactive osteoblasts), both of which are derived from osteoblasts. The origin of the osteoblasts and osteoclasts is from primitive precursor cells found in bone marrow, now known to be stimulated by hormones and growth factors as part of their differentiation to become mature, functional bone cells.

## Cartilage

In the embryo, cartilage forms the first temporary skeleton, until it develops into a mature bone matrix. In the adult,

**FIGURE 25-1** Schematic diagram of the structure of a long bone (hemisection of a long bone, such as the tibia).

The ends of the long bones contain high percentages of trabecular (cancellous) bone tissue, whereas the shaft contains predominately cortical bone tissue. *Inset A* includes an enlarged section (approximately 100-fold) of the growth plate (epiphysis) and the subjacent hyperproliferative zone containing cartilage cells stacked like coins. *Inset B* includes a section of collagen molecules (triple helices) surrounded by mineralized deposits (dark spheroids) at a magnification of approximately 1,000,000-fold. These collagen-mineral complexes exist in both trabecular and cortical bone tissues. *Inset C* shows the cross-section of half of the mid-shaft of a long bone (magnification 10-fold). This section of cortical bone tissue contains vertical Haversian systems (osteons) that run parallel with the shaft axis; many are required to extend this system from one end of the shaft to the other. At the center of each osteon is a canal that contains an artery that supplies bone tissues with nutrients and oxygen, a vein for removing wastes, and a nerve for returning afferent relays to the brain. (*Copyright John J. B. Anderson and Sanford C. Garner.*)

cartilage is found as flexible supports in areas such as the nose and ear. Cartilage is not bone, and is neither vascularized nor calcified.

## Calcium Homeostasis

Bone tissue serves as a reservoir of calcium and other minerals that are used by other tissues of the body. **Calcium homeostasis** is the process of maintenance of a constant serum calcium concentration. The body is almost totally

**TABLE 25-1****Functions of Osteoblasts and Osteoclasts**

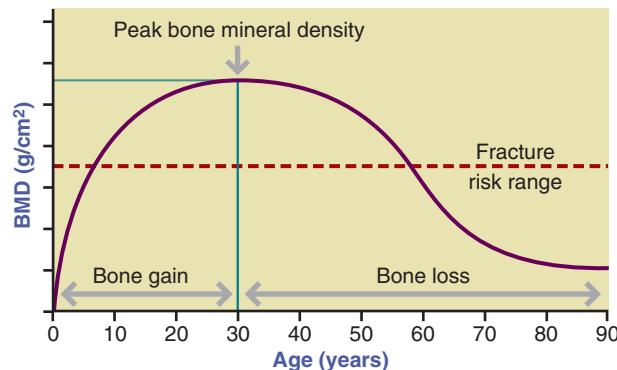

Osteoblasts	Osteoclasts
Bone Formation	Bone Resorption
Synthesis of matrix proteins: Collagen type 1 (90%); Osteocalcin and others (10%)	Degradation of bone tissue via enzymes and acid ( $H^+$ ) secretion
Mineralization	Communication: Secretion of cytokines that act on osteoblasts

reliant on this bone tissue source of calcium when the diet is inadequate. Bone tissue is also dynamic, because it undergoes bone turnover via both modeling early in life and remodeling after skeletal growth (height gain) ceases.

Although 99% of the body calcium is found in the skeleton, the remaining 1% is critical to a great variety of indispensable life processes. The concentration of calcium in blood and other extracellular fluids is regulated by complex mechanisms that balance calcium intake and excretion with bodily needs. When calcium intake is not adequate, homeostasis is maintained by drawing on mineral from the bone to keep the serum calcium ion concentration at its set level (approximately 10 mg/dL). Depending on the amount of calcium required, homeostasis can be accomplished by drawing from two major skeletal sources: readily mobilizable calcium ions in the bone fluid, or through osteoclastic resorption from the bone tissue itself. The daily turnover of skeletal calcium ions (transfers in and out of bone) is surprisingly high, which supports the dynamic activity of bone tissue in calcium homeostasis.

Blood calcium concentration is regulated by two calcium-regulating hormones -**parathyroid hormone (PTH)** and **1,25 dihydroxy vitamin D<sub>3</sub> (calcitriol)**. Through direct actions on the skeleton and kidney and indirect actions in the gut, PTH contributes to overall calcium homeostasis. **Intermittent parathyroid hormone (PTH) therapy** contributes to bone formation by prolonging the life of osteoblasts. However, high continuous levels of PTH contribute to bone loss (Kousteni and Bilezikian, 2008).

Active vitamin D, as calcitriol, also plays a role by increasing the efficiency of intestinal calcium absorption in the upper half of the small bowel. Vitamin D works in concert with PTH, enhancing bone release of calcium to maintain blood values. Vitamin D primarily is obtained from sunlight's interaction with precursors in the skin and secondarily from the diet. Calcitriol also has a direct effect on osteoblasts to increase the formation of several bone matrix proteins and other local factors needed for new bone formation and the suppression of bone degradation. The optimal

**FIGURE 25-2** The early gain and later loss of bone in females. Peak bone mineral density (BMD) is typically achieved by age 30. Menopause occurs at approximately age 50 or within a few years. Postmenopausal women typically enter the fracture risk range after age 60. Men have a more gradual decline in BMD, which starts at 50 years. (Copyright John J. B. Anderson and Sanford C. Garner.)

intake and blood values for vitamin D remain under study. (see Chapter 3 and Chapter 8).

**Bone Modeling**

**Bone modeling** is the term applied to the growth of the skeleton until mature height is achieved. For example, during bone modeling long bones elongate and widen by undergoing great internal changes as well as external expansions in their structures. In modeling, the formation of new bone tissue occurs first and is followed by the resorption of old tissue. In long bones growth occurs both at terminal epiphyses (growth plates that undergo hyperproliferation) and circumferentially in lamellae; at each location cells undergo division and contribute to the formation of new bone tissue (see Figure 25-1).

Bone modeling is typically completed in females by ages 16 to 18 and in males by ages 18 to 20. After growth (height gain) ceases, gains in bone tissue may continue by the process known as *bone consolidation*. The major event of the skeleton in early life is growth, whereas there is an inevitable decline of bone mass in later stages of life (Figure 25-2).

**Bone Remodeling**

After skeletal growth is completed, bone continuously undergoes change in response to strains on the skeleton. Bone adapts to changes in lifestyle factors and dietary intakes, maintains calcium concentration in extracellular fluids, and repairs microscopic fractures that occur over time. **Bone remodeling** is a process in which bone is continuously resorbed through the action of the osteoclasts and reformed through the action of the osteoblasts. A greater proportion occurs in the trabecular bone, especially at those sites located in areas subject to the greatest weight-bearing strains. In normal young adults the resorption and formation phases are tightly coupled, and bone mass is maintained

at zero balance. In seniors bone loss involves an uncoupling of the phases of bone remodeling with an increase of resorption over formation and thus bone loss. Trabecular bone declines the most following menopause because of unopposed osteoclastic activity.

The remodeling process is initiated by the *activation* of preosteoclast cells in the bone marrow. Interleukin (IL)-1 and other cytokines released from bone-lining cells act as the triggers in the activation of precursor stem cells in bone marrow. The preosteoclast cells from the bone marrow migrate to the surfaces of bone while differentiating into mature osteoclasts. The osteoclasts then cover a specific area of trabecular or cortical bone tissue. Acids and proteolytic enzymes released by the osteoclasts form small cavities on bone surfaces and *resorb* both bone mineral and matrix on the surface of trabecular bone or cortical bone. The resorptive process is rapid, and it is completed within a few days, whereas the refilling of these cavities by osteoblasts is slow (i.e., on the order of 3 to 6 months or even as long as a year or more in older adults).

The *rebuilding* or *formation* stage involves secretion of collagen and other matrix proteins by the osteoblasts, also derived from precursor stem cells in bone marrow. Collagen polymerizes to form mature triple-stranded fibers, and other matrix proteins are secreted. Within a few days salts of calcium and phosphate begin to precipitate on the collagen fibers, developing into crystals of hydroxyapatite. Approximately 4% of the total bone surface is involved in remodeling at any given time as new bone is renewed continually throughout the skeleton. Even in the mature skeleton, bone remains a dynamic tissue. Normal bone turnover is illustrated in Figure 25-3.

When the resorption and formation phases are in balance, the same amount of bone tissue exists at the completion of the formation phase as at the beginning of the resorption phase. The benefit to the skeleton of this remodeling is

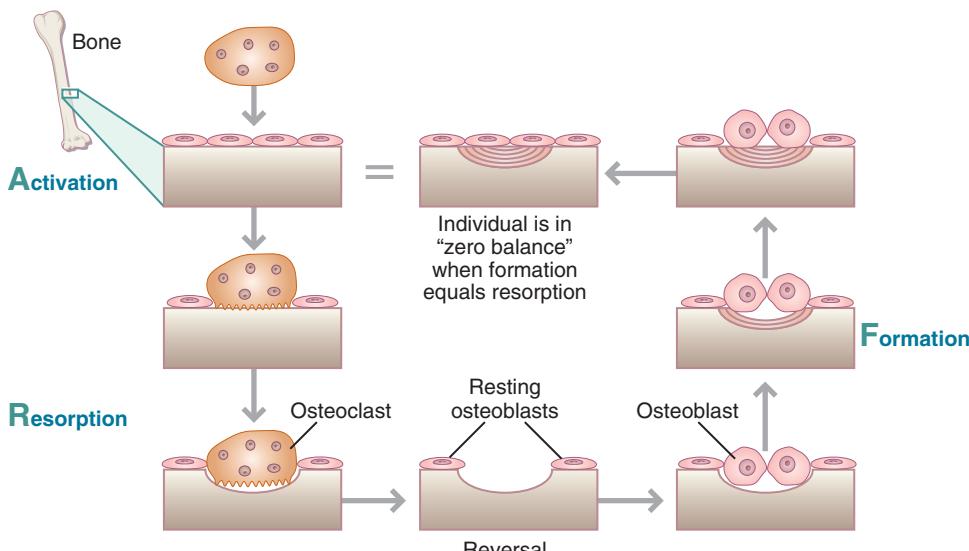

the renewal of bone without any microfractures. However, when dietary calcium is low, osteoclastic resorption becomes relatively greater than formation by osteoblasts because of a persistently elevated PTH concentration in blood (Figure 25-4). Then large amounts of bone tissue are removed and typically not fully replaced. The net result is a decrease in both bone mineral content (BMC) and bone mineral density (BMD).

The action of PTH in promoting activity of the osteoclasts is countered by estrogen, which reduces the response of osteoblasts to PTH. PTH acts directly on osteoblasts, which increase the production of IL-6 and other cytokines that in turn stimulate osteoclasts to resorb bone. Estrogen helps to block the production of PTH-stimulated cytokines. See Fig. 25-5. **Calcitonin**, a vestigial hormone, may directly inhibit osteoclast activity (resorption), but the significance of its physiologic role in human subjects is not clear.

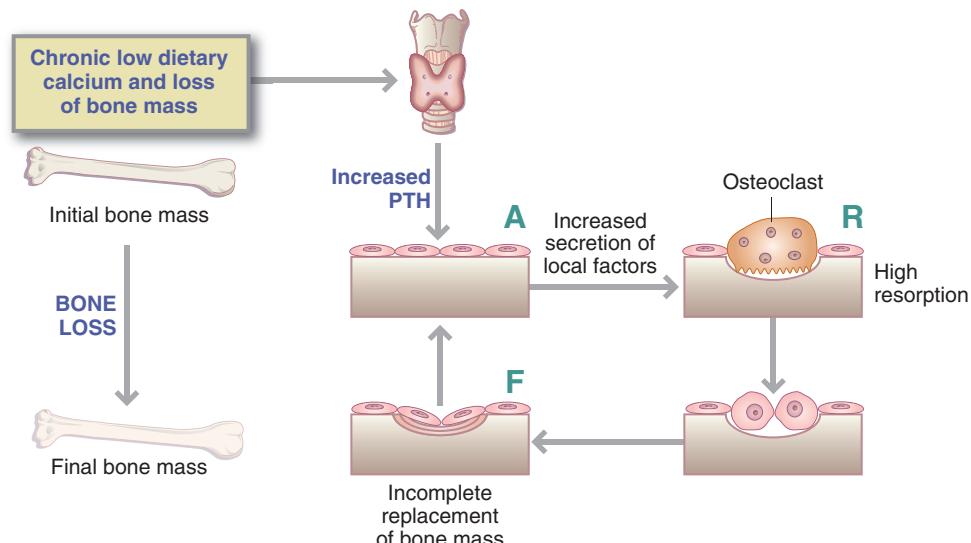

### Osteocalcin and Bone Markers

**Osteocalcin** is a protein derived from osteoblasts. In bone matrix, osteocalcin assists in the mineralization process, perhaps acting to stop the formation of crystals and to prevent overmineralization. Interpretation of its level in blood is complicated by the fact that it is involved in both formation and resorption, which typically occur simultaneously at several different skeletal sites. There is difficulty in using it as a marker for predicting future fracture risk. Some osteocalcin is secreted by osteoblasts directly into the circulating blood, with a reciprocal relationship between bones and energy metabolism. Leptin influences osteoblast functions and, in turn, osteocalcin influences energy metabolism through increased insulin secretion and sensitivity, increased energy expenditure, and fat mass reduction (Hinoi et al., 2009).

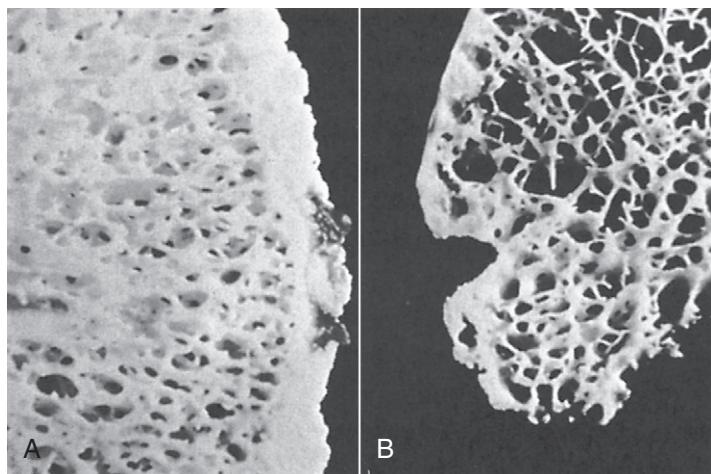

Bone markers are used for research and for monitoring the effectiveness of medication on bone turnover. Plasma

**FIGURE 25-3** Normal bone turnover in healthy adults. (Copyright John J. B. Anderson and Sanford C. Garner.)

**FIGURE 25-4** Effects of persistently elevated serum concentration of parathyroid hormone (PTH) on bone mass; this incorporates the effect of estradiol, counteracting the effect of PTH. (*Copyright John J. B. Anderson and Sanford C. Garner.*)

**FIGURE 25-5** Difference between normal bone (A) and osteoporotic bone (B). (*From Maher AB et al: Orthopaedic nursing, Philadelphia, 1994, Saunders.*)

bone-specific alkaline phosphatase is a marker of bone formation, although total plasma alkaline phosphatase may also be used. Other markers of bone resorption include plasma crosslinked collagen telopeptides, urinary N-telopeptides, and plasma tartrate-resistant acid phosphatase.

## BONE MASS

**Bone mass** is a generic term that refers to BMC but not to BMD. **Bone mineral content (BMC)** is more appropriately used in assessing the amount of bone accumulated before the cessation of growth (height gain), whereas **bone mineral density (BMD)** is better used to describe bone after the developmental period is completed. These measurements are often used interchangeably, but BMD is more useful for monitoring bone changes in adults. However, neither BMC nor BMD provides information on the microarchitectural

(three-dimensional) structural quality of bone tissue (i.e., index of risk of fracture).

### Accumulation of Bone Mass

During the growth periods of childhood, puberty, and early adulthood, formation exceeds the resorption of bone. **Peak bone mass (PBM)** is reached by 30 years of age or so (see Figure 25-2). The long bones stop growing in length by approximately age 18 in females and age 20 in males, but bone mass continues to accumulate for a few more years by a process known as consolidation (i.e., filling-in of osteons in the shafts of long bones). The age when BMD acquisition ceases varies, depending not only on diet but also on physical activity.

### Peak Bone Mass

PBM is greater in men than in women because of men's larger frame size. BMC, but not necessarily BMD, is

typically lower in women. Both the lean and fat components of body composition contribute to these differences in bone mass. BMD is also greater in blacks and Hispanics than in whites and Asians, related to larger muscle mass, differences in body weight, lifestyle factors, and dietary intake (Pothiwala et al., 2006). Hereditary factors also contribute to the extent of accumulation of PBM.

PBM is related to appropriate intake of calories, protein, calcium, phosphorus, and vitamins D and K. Because bone formation begins in the embryo, more attention is being focused on maternal nutrition and health as a predictor of the child's future PBM (Prentice et al., 2011). Physical activity also plays a role. Children's activities should include ground-force reactions, such as running, skipping, or jumping, as these activities are site-specific to the bone. The importance of strengthening exercise continues to be investigated. The optimal time to begin physical activity to enhance PBM is not exact.

Body weight is positively associated with BMD, probably attributable to both adipose and lean mass (Reid, 2008). PBM is diminished in cases of anorexia nervosa (Misra and Klibanski, 2006), as well as in chronic diseases.

### Loss of Bone Mass

Age is an important determinant of BMD. At approximately age 40, BMD begins to diminish gradually in both sexes, but bone loss increases greatly in women after age 50 or after menopause. A continuous loss thereafter in postmenopausal women occurs at rate of 1% to 2% per year during the next decade. Men continue to have bone loss, but at a much lower rate than women of the same age until age 70, when the loss rates are about the same for both genders. Loss of bone mass is the result of changes in the hormone-directed mechanisms that govern bone remodeling.

Cortical bone tissue and trabecular bone tissue undergo different patterns of aging. Loss of cortical bone eventually plateaus and may even cease late in life. Trabecular bone loss begins in both sexes as early as 40 years of age. Premenopausal loss of trabecular bone in women is much greater than that of cortical bone. Loss of both kinds of bone accelerates in women after menopause, although trabecular bone is also lost at a much higher rate than cortical bone. Differences between normal and osteoporotic bone—both trabecular and cortical tissues—are shown in Figure 25-6.

The accelerated bone loss rate of 2% to 3% per year continues for between 5 and 10 years after menopause, and then the rate declines gradually to 0.5% to 1% per year thereafter. Some postmenopausal women lose bone at an even faster rate (Figure 25-7). If the age of a woman is known, her vertebral bone mass may be predicted (see *Clinical Insight: Postmenopausal Women at High Risk for Hip Fracture*).

The normal bone loss that occurs with aging in both sexes is related to the decline of osteoblastic function such as the reduced production of collagen, osteocalcin, osteopontin, and other matrix proteins. As a result of the uncoupling of the remodeling process, osteoclastic resorption

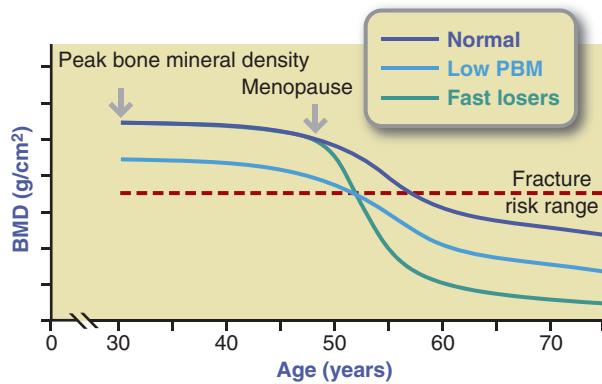

### CLINICAL INSIGHT

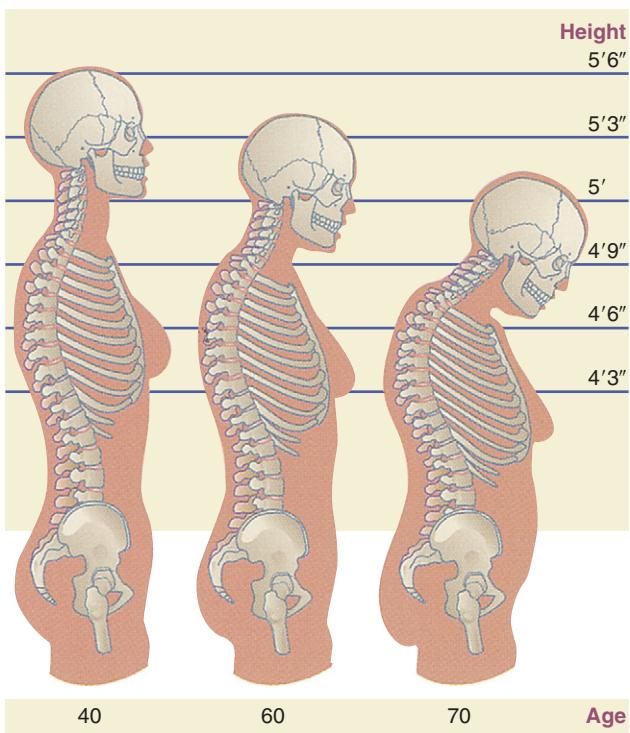

## Postmenopausal Women at High Risk for Hip Fracture

It is important to identify women who are at risk of developing osteoporosis as early as possible so that measures can be taken to monitor bone status and to prevent further bone loss. Because low bone mineral density (BMD) is a major risk factor for osteoporosis, its assessment is clinically useful. Assessment of bone status based on the existence of one or more risk factors such as age, height, weight, smoking status, alcohol consumption, drug use, calcium intake, exercise, frame size, and selected bone markers is not sufficiently accurate. BMD as measured by bone densitometry is more clinically useful. Typically total body BMD and the regional sites such as the proximal femur and lumbar vertebrae are measured by dual-energy x-ray absorptiometry.

A BMD measurement of an at-risk woman entering menopause (before becoming estrogen deficient) serves as a baseline for subsequent measurements as the individual becomes increasingly estrogen deficient and loses bone mass. This information helps physicians and patients make decisions about the need for and use of drug therapy such as bisphosphonates, parathyroid hormone drugs, and selective estrogen receptor modulators. For men or women on long-term glucocorticosteroid therapy, a BMD measurement may indicate the need for treatment with a bone-preserving medication or calcitonin.

**FIGURE 25-6** Variable patterns of bone loss of women following the onset of menopause at approximately 50 years of age. The rapid loss of bone mineral density (BMD) in some women referred to as *fast losers* is contrasted to the loss of *slow losers*. Women who develop low peak BMD have less bone mass than women with normal BMD, but they also can lose BMD either as slow or fast losers. (Copyright John J. B. Anderson and Sanford C. Garner.)

**FIGURE 25-7** Normal spine at age 40 and osteoporotic changes at ages 60 and 70. These changes can cause a loss of as much as 6 to 9 inches in height and result in the dowager's hump (*far right*) in the upper thoracic vertebrae. (From Ignatavicius D, Workman M: *Medical-surgical nursing: critical thinking for collaborative care*, ed 5, Philadelphia, 2006, Saunders.)

exceeds formation with an increasing differential. Bone loss in men accelerates in later years, typically in ages 60 through 79. The reason for bone loss in men is very similar to that in women, being either age-related, idiopathic, or secondary to an underlying disease or medication. The prevalence of low bone mass and osteoporosis in men is increasing as more men are being screened or diagnosed using dual-energy x-ray absorptiometry (DEXA). It has been estimated that 39% of osteoporotic fractures are in men (Khosla, 2010.)

### Measurement of Bone Mineral Content and Bone Mineral Density

**Bone densitometry** measures bone mass on the basis of tissue absorption of photons produced by one or two monoenergetic x-ray tubes. DEXA (see Chapter 6 and Fig. 6-10) is available in most hospitals and many clinics for the measurement of the total body and regional skeletal sites such as the lumbar vertebrae and the proximal femur (hip). Results of DEXA measurements are commonly expressed as T-scores.

### Ultrasound Measurements of Bone

Quantitative ultrasound measurements of the heel bone (calcaneus) and the kneecap are becoming popular.

Ultrasound instruments measure the velocity of sound waves transmitted through bone and broadband ultrasound attenuation (BUA). Measurements at the calcaneus correlate well with BMD measurements at this same skeletal site, meaning that low values by DEXA are typically mirrored by low values of BUA. However, ultrasound measurements are considered screening tools, whereas DEXA measurements are considered diagnostic.

### Fracture Risk Assessment

The World Health Organization (WHO) developed an algorithm to predict fracture by using femoral head BMD and clinical indicators of low bone mass. This uses economic modeling to guide the most cost-effective instances to begin medications. Vertebral fractures that are confirmed by x-rays are a strong predictor of future vertebral fractures, as well as fractures at other sites (National Osteoporosis Foundation [NOF], 2010). DEXA scans can also identify vertebral fractures.

## NUTRITION AND BONE

Calcium, phosphate, and vitamin D are essential for normal bone structure and function. Protein, calories, and other micronutrients also help develop and maintain bone (Tucker, 2009).

### Protein

Both protein and calcium are important components of PBM, especially before puberty (Rizzoli, 2008). Adequate protein intake, with adequate calcium intake, is needed for optimal bone health. A meta-analysis of studies concerned with protein intake and indicators of bone health found a slight positive effect on BMD, but it did not influence the risk of fracture over the long-term for total protein, animal protein, or vegetable protein (Darling et al., 2009;) unfortunately, this analysis did not consider calcium intake.

The negative effects of either too high or too low an intake of protein is more pronounced with inadequate calcium intake, especially in seniors (Tucker, 2009). The theory that higher protein intakes produce a higher acidic load, which increases calcium urinary excretion, has not been verified.

Very low protein intake may theoretically negatively affect bone turnover and development. In cases of negative nitrogen balance, such as with fracture or surgery, higher protein intake may be advised.

### Minerals

#### Calcium from Foods

Calcium intake in the primary prevention of osteoporosis has received much attention. The Institute of Medicine Dietary Reference Intakes (DRIs) for calcium and vitamin D, are given as RDAs. The RDA for calcium from pre-adolescence (age 9 years) through adolescence (up to 19 years) was increased to 1300 mg/day for both genders (IOM, 2011). The RDAs for calcium adults, pregnant and

lactating women and children, are listed on the inside front cover).

People older than 11 years, particularly females, typically do not receive the recommended amount of calcium. According to the [National Health and Nutrition Examination Survey \(2007\)](#), teen and adult women consume considerably less than the current RDAs. Males are more likely to consume somewhat greater amounts than females, but after 50 years of age they also do not meet the recommended levels. These deficits translate, on average, into the need for an additional 500 mg/day for teenage girls and adult women.

Food sources are recommended first for supplying calcium needs because of the coingestion of other essential nutrients. In the United States, the primary source of calcium is dairy foods, and this intake is higher in white than in black women ([Plawecki et al., 2009](#)). However, calcium fortification of nondairy foods such as nondairy milks and other beverages, juices, breakfast cereals, bread, and some crackers is common.

Calcium bioavailability from foods is generally good, and the amount of calcium in the food is more important than its bioavailability. However, the order of concern relative to calcium absorption efficiency is first the individual's need for calcium, second the amount consumed because absorption efficiency is inversely related to amount consumed, and third the intake of absorption enhancers or inhibitors. For example, absorption from foods high in oxalic and phytic acid (certain vegetables and legumes) is lower than from dairy products.

The amount of calcium in foods varies with the brand, serving size, and whether it has been fortified. Read the Nutrition Facts label to determine the amount of calcium per serving. Multiply the daily value (DV) percentage by 10 to determine the milligrams of calcium. For example, a 20% DV equals 200 mg of calcium (see [Chapter 12](#)). Labeling for "excellent" (>200 mg/serving) and "good" (100-200 mg/serving) sources of calcium are regulated by the Food and Drug Administration (FDA).

### Calcium from Supplements

Reaching RDA levels of calcium from foods should be the first goal, but if insufficient amounts of calcium from foods are consumed, supplements of calcium should then be ingested to reach the age-specific RDA. The upper limit of safety for calcium intake is 2500 mg for everyone older than 1 year except for youth age 9-18 years and pregnant or lactating women when it is 3000 mg/day. [Box 25-1](#) lists the potential risks associated with excessive calcium intake.

An increasing percentage of the population is taking calcium supplements. Persons who should take supplements include those not meeting the RDA on most days, those taking corticosteroids, those with low bone mass or osteoporosis, women who are perimenopausal or postmenopausal, and those who are lactose intolerant. Calcium carbonate is the most common form of calcium supplement. It should be

### BOX 25-1

#### Potential Risks Associated with Excessive Calcium Supplementation

- Contamination of bone meal or dolomite supplements with cadmium, mercury, arsenic, or lead
- Urinary tract or renal stones in susceptible individuals
- Hypercalcemia or milk alkali syndrome from extremely high intakes (>4000 mg/day)
- Deficiency of iron and other mineral divalent cations resulting from decreased absorption
- Constipation

taken with food because an acidic environment enhances absorption. For those with achlorhydria, which often occurs in seniors, calcium citrate may be more appropriate because it does not require an acidic environment for absorption and does not further reduce the acidity of the stomach ([Straub, 2007](#)).

Calcium supplementation absorption is optimal when taken as individual doses of 500 mg or less. Many formulations include vitamin D, because the likelihood of needing vitamin D is high if calcium supplementation is needed. Choosing a supplement that has the United States Pharmacopeia designation increases the likelihood that the supplement quantity is consistent with the label, and that good manufacturing practices are used.

### Phosphate

Phosphate salts are available in practically all foods either naturally or because of processing. In healthy adults, the urinary phosphorus excretion approximately equals intake.. The regulation of phosphorus levels in the blood is tightly controlled by an interaction between vitamin D from the kidney, PTH from the parathyroid glands, and fibroblast growth factor 23 from bone. Both calcium and phosphate ions in a ratio of approximately 1:1 are needed for the mineralization of bone.

Excessive phosphorus intake as phosphates can greatly alter the calcium/phosphate ratio, especially if calcium intakes are low. Too much phosphate compared with calcium lowers the serum calcium ion concentration, which then stimulates PTH; if this pattern of intake becomes chronic, bone loss is thought to follow.

Soft drinks are poor in nutrient value but high in phosphate content. However, studies have found that the soft drink primarily displaces milk as a beverage, so the negative effect is from lower calcium intake rather than higher phosphate intake. Some studies have found a negative correlation between soft drink intake and BMD in women but not in men. Those at high risk and those who have osteoporosis may want to avoid these beverages because an effect is theoretically possible ([Tucker, 2009](#)).

## Magnesium

Magnesium dietary deficits seem to have little effect on bone tissue, but one report suggests that meeting the RDIs for magnesium improve BMD (Ryder et al., 2005). However, diets deficient in magnesium are likely deficient in other nutrients that are needed for healthy bone growth and maintenance. Nevertheless, magnesium deficiency may affect the quality of bone by decreasing bone formation, preventing the optimal crystal formation, and having a negative effect on PTH (Rude et al., 2009).

## Trace Minerals

Few studies are available about the effects of trace elements on bone. Iron, zinc, copper, manganese, and boron may function in bone cells, but their specific roles in preventing bone loss are not well established. In one study, supplementation of copper, fluoride, manganese, and zinc along with calcium for 1 year resulted in a reduced loss of lumbar BMD compared with the greater loss in a group receiving only calcium supplementation (Nieves, 2005).

### Boron

Boron is used by osteoblasts for bone formation. It is required to convert estrogen to its most active form, 17-betaestradiol, and estrogen is involved in bone metabolism. However, it is not known whether, or how much boron is required for optimal bone health. (Hakki et al., 2010; Nielsen, 2008).

### Copper

Copper is needed for the enzyme that increases the crosslinking of collagen and elastin molecules, and it may have roles in other enzymes of bone cells. Because of the changes induced in the two matrix proteins by low copper intakes, bone mineralization may also be reduced, especially in seniors.

### Fluoride

Fluoride ions enter the hydroxyapatite crystals of bone as substitutes for hydroxyl ions. Water containing 1 ppm of fluoride does not help bone in the same way that it helps tooth surfaces. Within narrow limits of safety (less than 2 ppm), fluoride ions have little effect on increasing the hardness of bone mineral. At intakes of 2 ppm or greater, fluoride may produce bone that is subject to increased microfractures because of the change in the properties of the hydroxyapatite crystals.

### Iron

Iron serves as a catalytic cofactor for the vitamin C-dependent hydroxylations of proline and lysine in collagen maturation. Iron also has other roles in osteoblasts and osteoclasts in mitochondrial oxidative-phosphorylation, as well as in other heme- and nonheme-containing enzymes, similar to the needs of other cells in the body.

## Manganese

Manganese is required for the biosynthesis of mucopolysaccharides in bone matrix formation, and it also acts as a cofactor in energy-generating reactions.

### Zinc

Zinc is essential for several critical enzymes in osteoblasts that are essential for collagen synthesis and other products. In addition, alkaline phosphatase requires zinc for its activity in the osteoblasts.

## Vitamins

### Vitamin D

An individual's vitamin D status depends mostly on sunlight exposure, and secondarily on dietary intake of vitamin D. The synthesis of vitamin D by skin exposed to sunlight varies considerably as a result of many factors, including skin tone, sunscreen use, environmental latitude, and age (McCarty, 2008). The skin of older individuals is less efficient at producing vitamin D following exposure to ultraviolet (UV) light because the skin is thinner and it contains fewer cells that can synthesize vitamin D. In addition, older adults living in nursing homes and similar institutions typically have little exposure to sunlight. Those who live at northern latitudes in the United States and Canada are at increased risk of osteoporosis because of limited UV light during winter months.

The few foods that naturally contain vitamin D are egg yolks, fatty fish such as salmon, mackerel, catfish, tuna, and sardines, cod liver oil, and mushrooms (see Appendix 51). The vitamin D content of fish varies, as does the content in UV-exposed mushrooms. Fluid milk in the United States is fortified with vitamin D at a standardized level of 400 IU per quart, whereas other foods, including juices, cereals, yogurt, and margarines, may be fortified in varying amounts. The RDAs for vitamin D across the life cycle are shown inside the front cover. The upper limit is 100 µg (4000 IU) for everyone older than 8 years, and lower levels for younger children (see inside front cover). From any source, vitamin D must be hydroxylated in the kidney before becoming the physiologically active calcitriol.

To prevent rickets, the American Academy of Pediatrics recommends that all infants who are exclusively breastfed be supplemented with 400 IU of vitamin D. Infants who are both formula and breastfed should also be supplemented until they are consistently taking 1 liter (1 quart) of formula a day. They further recommend continuing the supplementation until 1 year of age, when children begin drinking vitamin D-fortified milk (Wagner and Greer, 2008).

The older adult is at increased risk for vitamin D deficiency. Risks are from decreased synthesis of vitamin D by the skin because of changes in the skin and decreased exposure to sunlight; increased body fat; decreased renal function that decreases the hydroxylation of vitamin D to its active form; and decreased levels of insulin-like growth

factor 1, calcitonin, and estrogen, which affect hydroxylase activity. In general, seniors may benefit from daily vitamin D supplementation of 10–20 mcg (400 IU–800 IU) to reach serum **25-hydroxy vitamin D (calcidiol)** levels of at least 30 ng/mL (75 nmol/L). Older adults who are frail or institutionalized may need up to 50 mcg (2000 IU)/day. Mobility, skin tone, body weight, and dietary habits may modify these recommendations (Oudshoorn et al., 2009). The most common blood test for vitamin D status is serum 25-hydroxyvitamin D level, although other tests may also be used.

## Vitamin K

Vitamin K is an essential micronutrient for bone health. Its role in posttranslational modification of several matrix proteins, including osteocalcin, is well established. Following bone resorption, osteocalcin is released and enters the blood. In this way, osteocalcin serves as a serum bone marker for predicting the risk of a fracture (see Appendix 30). Many older adults have inadequate intakes of vitamin K, primarily because their consumption of dark-green leafy vegetables is so low. Most of the vitamin K intake in the United States is from green leafy vegetables, with about one third from fats and oils. Although menaquinones, a form of vitamin K, are formed in the gut by bacteria, the influence of this source on vitamin K status appears to be weak. It is important to consider the vitamin K intake in older persons who may also be taking blood-thinning medications (vitamin K antagonists). Rather than having these patients avoid vitamin K in foods and thus jeopardize their bone status, it is better to have the vitamin K daily intake be consistent and regulate the vitamin K antagonist medication. In fact, it has been shown that therapeutic international normalized ratio (INR) ranges from blood thinning medication can be achieved with vitamin K in low-dose supplementation, and when fluctuations are few (Ford and Moll, 2008).

## Vitamin A (Retinol)

Vitamin A consumption is generally considered to be beneficial to bone growth and maintenance. Lycopene may be protective against oxidative stress; more research is suggested (MacKinnon et al., 2011).

Excessive retinol intake (but not carotenoids) may contribute to risk for hip fractures. However, there is not complete understanding, and many still question the effect on bone of excessive retinol intake (Ribaya-Mercado and Blumberg, 2007). Nevertheless, concern remains that the combined intakes of supplemental vitamin A and vitamin A from fortified foods may be too high in the United States, especially in health-conscious postmenopausal white women. The window of safe consumption of vitamin A is fairly narrow, but it may be even narrower for seniors.

## Other Dietary Components

Several other dietary factors have been associated with bone health but their relative quantitative importance is not clear.

## Alcohol

Moderate consumption of wine and beer may be beneficial to bone in men and postmenopausal women. Non-alcoholic constituents, such as silicon in beer, need further investigation.

In men, high liquor intakes (>2 drinks/d) are associated with significantly lower BMD (Kanis et al., 2005; Tucker et al., 2009). Heavy alcohol consumption also may be accompanied by poor dietary intake, cigarette smoking, poor balance, and an increased risk of falls.

## Caffeine and Soft Drinks

The relationship of moderate consumption of caffeine to osteoporosis has not been clearly established. Excessive caffeine intake may have a deleterious effect on BMD (Ruffing et al., 2006). Intake of colas is also associated with lower BMD. Although the primary issue may be displacement of dairy beverages, there is also a potential direct effect (Tucker, 2009). Rapid metabolizers of caffeine may be a high risk group for bone loss (Hallström et al., 2010).

## Dietary Fiber

Excessive dietary fiber intake may interfere with calcium absorption, but any interference is considered extremely small in the typical low-fiber diet. Vegans who may consume as much as 50 g of fiber a day are most likely to have a significant depression in intestinal calcium absorption, but this is often offset by adequate calcium intake.

## Isoflavones

The isoflavones in soybeans function both as estrogen agonists and antioxidants in bone cells. They inhibit bone resorption in female animal models without ovaries, but not in young adult females with normal estrogen status. Some but not all studies show modest skeletal benefits.

## Potassium bicarbonate

The skeleton serves as a buffer to help regulate acid-base balance, and a high-acid diet may contribute to the progressive decline in bone mass and osteoporosis (Sebastian, 2005).

In postmenopausal women, an oral dose of potassium bicarbonate sufficient to neutralize endogenous acid improves calcium balance and bone. Decreased bone resorption and an increased rate of bone formation can result. See *Clinical Insight: Urine pH—How Does Diet Affect It?* in Chapter 36.

## Sodium

A high sodium intake may contribute to osteoporosis because of increased calcium excretion (Massey, 2005). While the calciuric effect of sodium has been speculated, there seem to be no adverse effects with adequate calcium and vitamin D intake (Ilich et al., 2010).

## Vegetarian Diets

Though research is inconclusive, vegetarian diets may be more beneficial for bone than animal-based diets. They may

provide less calcium than animal diets but animal proteins contribute to urine acidity. In general, fruits and vegetables in the diet promote an alkaline urine and less need for neutralizing calcium. In addition they are high in potassium, which is considered a bone-protective nutrient. See *Clinical Insight: Urine pH—How Does Diet Affect It?* in Chapter 36. Polyphenols and other antioxidants in plant foods support optimal functioning and health of bone cells and provide many bone-healthy nutrients.

## OSTEOPENIA AND OSTEOPOROSIS

Osteoporosis may have its origin in early life during the period of skeletal growth and PBM accumulation. The WHO defines osteoporosis in terms of decline in BMD.

### Definitions

When BMD falls sufficiently below healthy values (1 standard deviation [SD] according to WHO standards) low bone mass or **osteopenia** exists. **Osteoporosis** occurs when the BMD becomes so low (greater than 2.5 SDs below healthy values) that the skeleton is unable to sustain ordinary strains. However, the National Osteoporosis Foundation (2010) states that the WHO BMD diagnostic classification should not be applied to premenopausal women, men younger than 50 years of age, or children. Clinical assessment and ethnically adjusted Z-scores are thought to be more reflective of the norms in other groups.

### Prevalence

It is estimated that 8 million women and 2 million men in the United States are classified as osteoporotic. More than 2 million osteoporotic fractures were estimated to occur in 2005, which represents a cost of billions of dollars in health care and rehabilitation services. One fourth of these osteoporosis-related fractures involve the vertebrae; 297,000 are fractures of the hip, which typically result in incapacitation, long-term nursing care, and significant mortality.

### Types of Osteoporosis

Osteoporosis is considered to have a broad spectrum of variant forms. There are two types of primary osteoporosis, distinguished in general by sex, the age at which fractures occur, and the kinds of bone involved. **Secondary osteoporosis** results when an identifiable drug or disease process causes loss of bone tissue (Box 25-2).

**Estrogen-androgen deficient osteoporosis** occurs in women within a few years of menopause from loss of trabecular bone tissue and cessation of ovarian production of estrogens. BMC and BMD measurements of the lumbar spine of women with postmenopausal osteoporosis may be as much as 25% to 40% lower than in age-matched nonosteoporotic control women of the same age range. Other bone sites with a preponderance of trabecular bone such as the pelvis, ribs, and proximal femur also display low BMD. Rarely, men may develop androgen-deficient

### BOX 25-2

#### Medical Conditions That Deplete Calcium and Promote Risk of Osteoporosis

- Chronic diarrhea or intestinal malabsorption
- Chronic obstructive lung disease
- Chronic renal disease
- Diabetes
- Hemiplegia
- Hyperparathyroid disease
- Hyperthyroidism
- Scurvy
- Subtotal gastrectomy

osteoporosis if they have a significant decline in androgen production. This osteoporosis is characterized by fractures of the distal radius (Colles fractures) and “crush” fractures of the lumbar vertebrae that are often painful and deforming.

**Age-related primary osteoporosis** occurs at approximately age 70 and beyond. Both cortical and trabecular bone tissues undergo remodeling, but more remodeling occurs in trabecular tissue. In seniors, the processes of bone resorption and bone formation become uncoupled. Many women lose several inches in height between 50 and 80 years of age. Although age-associated osteoporosis affects both sexes, women are more severely affected because they have a smaller skeletal mass than men and they live longer.

Fractures may occur during ordinary activities, such as lifting a sack of groceries or stepping over a shower opening, but more hip fractures result from a fall. Hip fractures affect nearly 20% of postmenopausal women up to age 80 and almost 50% of those beyond that age, and the hip fracture numbers are steadily increasing in men. A dramatic increase in hip fractures occurs late in life, and almost all women beyond 80 years of age are at risk of hip fracture. Although fractures of the hips characterize this osteoporosis, vertebral fractures also increase with age. Wedge fractures of vertebrae typically lead to back pain, loss of height, spinal deformity, and kyphosis or “dowager’s hump.”

### Causes and Risk Factors

Osteoporosis is a complex heterogeneous disorder and many risk factors contribute during a lifetime. Low BMD is common to all types of osteoporosis, but an imbalance between bone resorption and formation results from an array of factors characteristic of each form of this disease. Loss of bone mass to a degree that produces fractures can result from (1) an excessive acceleration of resorption, especially after menopause; or (2) a suboptimal peak bone mass that results in bone after menopause (or later in life in men) that becomes fragile and susceptible to fracture. Risk factors for osteoporosis include age, race, gender, and factors noted in Box 25-3.

**BOX 25-3****Risk Factors for Developing Osteoporosis**

- Age, especially older than age 60
- Amenorrhea in women as a result of excessive exercise
- Androgen depletion with hypogonadism in men
- Cigarette smoking
- Estrogen depletion from menopause or early oophorectomy
- Ethnicity: white or Asian
- Excessive intake of alcohol, caffeine, fiber
- Female gender
- Family history of osteoporosis
- Inadequate calcium or vitamin D intake
- Lack of exercise
- Prolonged use of certain medications (see Box 25-4)
- Sarcopenia
- Underweight, low body mass index, low body fatness

**Alcohol and Cigarettes**

Cigarette smoking and excessive alcohol consumption are risk factors for developing osteoporosis, probably because of toxic effects on osteoblasts. Moderate alcohol intake has no detrimental effect on bone, and some studies show a modest positive effect in postmenopausal women. Three or more drinks per day is associated with increased risk of falling and may pose other threats to bone health. The risk appears significant even after adjusting for BMD when comparing smokers versus nonsmokers (North America Menopause Society, 2010). Excessive consumption (more than three drinks a day) for an extended period may result in bone loss. The combination of smoking and alcohol, common among young women and men, places them at increased risk for osteoporosis.

**Body Weight**

Body weight is a principal determinant of bone density and fracture risk; adipose tissue mass is a major contributor (Reid, 2010). The greater the body mass, the greater the BMD. Fat and bone are linked by pathways involving adiponectin; insulin, amylin, and preptin; and leptin and adipocytic estrogens, which ultimately serve the function of providing a skeleton appropriate to the mass of adipose tissue it is carrying (Reid, 2010).

The lower the body mass, the lower the BMD. Young girls who are typically premenarcheal may incur fractures with minimum trauma because of low BMC and BMD related to rapid growth in height that is not accompanied with a proportionate increase in weight (Goulding et al., 2005). Young, overweight males with low bone mass may also suffer fractures (Goulding et al., 2005). Weight loss from dieting, bariatric surgery, or sarcopenia are also associated with bone loss. Thus being overweight is protective against osteoporosis and underweight is a risk factor for fractures (Reid, 2010).

**Ethnicity**

Whites and Asians suffer more osteoporotic fractures than blacks and Hispanics, who usually have a greater bone density. However, hypovitaminosis D with secondary hyperparathyroidism occurs more often in the black population. Thin women, particularly of northern European ancestry, have the highest risk of osteoporosis.

**Lactation**

A striking but transient bone loss occurs in women who breast-feed for 6 months or longer, especially from the femoral neck and lumbar spine. Sufficient calcium and vitamin D intake are essential during this time for the mother to replete her own serum and storage levels, but repletion typically does not occur until several months after peak lactation. Several successive pregnancies and lactations over a relatively few years may contribute to significant bone loss by the end of the period of childbearing if nutrition is inadequate.

**Limited Weight-Bearing Exercise**

Maintenance of healthy bone requires exposure to weight-bearing pressures. A good diet plus exercise from roughly ages 10 to 20 years is particularly important for skeletal growth, accrual of bone mass, and increased femoral bone dimensions (Iuliano-Burns et al., 2005). Physical activity, especially upper body activities, is thought to contribute to an increase in bone mass or density (Chubak et al., 2006). Lack of exercise and a sedentary mode of living may also contribute to bone loss, although the most important influence is probably an inadequate accumulation of bone mass.

Exercise is beneficial for reducing skeletal inflammatory markers in frail older individuals (Lambert et al., 2008). Stresses from muscle contraction and maintaining the body in an upright position against the pull of gravity stimulate osteoblast function. Bones not subjected to normal use rapidly lose mass.

Immobility in varying degrees is well recognized as a cause of bone loss. Invalids confined to bed or persons unable to move freely are commonly affected. Astronauts living in conditions of zero gravity for only a few days experience bone loss, especially in the lower extremities; appropriate exercise is a feature of their daily routines.

**Loss of Menses**

Loss of menses at any age is a major determinant of osteoporosis risk in women. Acceleration of bone loss coincides with menopause, either natural or surgical, at which time the ovaries stop producing estrogen. Estrogen replacement therapies have been shown to conserve BMD and reduce fracture risk within the first few years following menopause, at least in short-term studies.

Any interruption of menstruation for an extended period results in bone loss. The amenorrhea that accompanies excessive weight loss seen in patients with anorexia nervosa or in individuals who participate in high-intensity sports,

dance, or other forms of exercise has the same adverse effect on bones as menopause. BMD in amenorrheic athletes has been measured at levels 25% to 40% below normal. Young women with the “female athlete triad” of disordered eating, amenorrhea, and low BMD are at increased risk for having fractures. These young women may benefit from the use of oral contraceptive agents plus calcium and vitamin D supplements.

## Nutrients

Many nutrients and several nonnutrients have been implicated as causal risk factors for osteoporosis and have been discussed in previous paragraphs. Frank vitamin D deficiency has been widely reported at northerly latitudes in North America and Europe. Vitamin D insufficiency is now considered more common at latitudes closer to the equator than previously thought because of reduced exposure to sunlight during the year (Hypponen and Power, 2007).

## Medications

A number of medications contribute adversely to osteoporosis, either by interfering with calcium absorption or by actively promoting calcium loss from bone (Box 25-4). For example, corticosteroids affect vitamin D metabolism and can lead to bone loss. Excessive amounts of exogenous thyroid hormone can promote loss of bone mass over time.

## Prevention of Osteoporosis and Fractures

The increasing longevity of the population emphasizes the need for prevention of osteoporosis. Universal guidelines apply to everyone. Consuming adequate amounts of calcium and vitamin D, lifelong muscle strengthening and weight-bearing exercise, avoidance of tobacco, moderate or no intake of alcohol, and steps to avoid falls are all part of the holistic approach to a lifestyle that promotes bone health (NAMS, 2010).

### BOX 25-4

#### Medications That Increase Calcium Loss and Promote Risk of Osteoporosis

- Aluminum-containing antacids
- Corticosteroids
- Cyclosporine
- Heparin
- Lasix and thiazide diuretics
- Lithium
- Methotrexate
- Phenobarbital
- Phenothiazine derivatives
- Phenytoin (Dilantin)
- Thyroid hormone
- Tetracycline

## Exercise

To preserve bone health through adulthood, the American Academy of Sports Medicine recommends weight-bearing activity three to five times per week and resistance exercise two to three times per week with moderate to high bone-loading force for a combination of 30 to 60 minutes per week. Regular walking and swimming appear to have minor benefits in older individuals. More active participation (such as weight-bearing exercises and intensive walking) has positive effects on BMD.

## Medical Nutrition Therapy

Calcium (1000 mg/day) and vitamin D (800 to 1000 units/day) are typically recommended as supplements for patients being treated with one of the bone drugs, either antiresorptive or anabolic. These amounts are considered both safe and sufficient for bone formation. The efficacy of calcium or calcium plus vitamin D supplementation continues to be investigated. Several studies report a reduction in fracture risk for postmenopausal women when supplements with calcium and vitamin D are used (Stránský and Rysavá, 2009). In a meta-analysis of 15 publications of nursing home residents, supplementation with calcium (1200 mg) and vitamin D (800 IU) reduced fracture risk and improved BMD (Parikh et al., 2009). Several studies also report the efficacy of calcium and vitamin D supplementation in older adults who live at home.

Interventions with children also show the benefits of calcium supplementation on PBM (Lanham-New, 2008). Reports are not consistent, however, possibly because of the variation in calcium and vitamin D status or environmental factors. Thus, because of the range of nutrients involved in bone health, a healthy diet emphasizing the key nutrients seems most promising in achieving an intake for optimal bone health (Tucker, 2009).

## FDA-Approved Drug Treatments

**Estrogen replacement therapy (ERT)** is hormone-replacement therapy approved by the FDA as treatment for the prevention of osteoporosis. Because of potential side effects, nonestrogen treatment for prevention is recommended, especially if menopausal symptom relief is not a goal.

**Bisphosphonates** act as antiresorbers on osteoclasts to reduce their bone-degradative activities. They have been shown to be effective in reducing the incidence of new fractures (Epstein, 2006). The bisphosphonates act by inhibiting osteoclast-mediated bone resorption. Examples include alendronate, risedronate, ibandronate, and zoledronic acid. Side effects include gastrointestinal problems and rare cases of jaw necrosis.

Calcitonin, the hormone, is used to inhibit osteoclastic bone resorption by blocking the stimulatory effects of PTH on these cells. Calcitonin can be administered by nasal spray. It improves BMD, especially of the lumbar spine, and it may reduce the recurrence of fractures in

patients with osteoporosis. Calcitonin is approved by the FDA for postmenopausal treatment of osteoporosis, but it is recommended that the women be at least five years' postmenopausal.

PTH therapy is approved by the FDA for the treatment of postmenopausal women and men at high risk for fracture, and for those on long-term glucocorticoid therapy. PTH works by increasing osteoblast number and function (Kousteni and Bilezikian, 2008). PTH increases spine, hip, and total body BMD. PTH is often prescribed first, followed by bisphosphonates, so that an increase in bone mass is followed by antiresorptive therapy (Cosman, 2008).

**Selective estrogen receptor modulators (SERMs)** are able to stimulate **estrogen receptors (ER)** in bone tissue and yet have very little effect on the ERs of the breast or uterus. Another term for SERMs is *estrogen agonist* or *antagonist* because they act as weak estrogen agonists at times and as weak estrogen antagonists at others. Two examples of these drugs are tamoxifen and raloxifene. The most common side effect is hot flashes.

### Drug Treatments Not Yet Approved By the FDA

Calcitriol is 1,25-dihydroxy vitamin D<sub>3</sub>, and has had little use in the treatment of osteoporosis because of its potential toxicity. Calcium plus calcitriol may be useful, however, in patients who are taking high-dose corticosteroid therapy, during which vertebral fractures are common.

Growth hormone and insulin-like growth factors may improve bone through anabolic effects, but more research is needed.

Osteoprotegerin (OPG) is a natural cytokine secreted by osteoblasts as well as other cell types. OPG can be detected in human serum and inactivates another cytokine that affects osteoclasts, thereby inhibiting osteoclast activation and bone resorption. Final results from clinical trials are anticipated.

PTH 1-84 is an intact human recombinant form of PTH undergoing clinical trials.

Sodium fluoride treatment increases bone mass, especially in trabecular bone. However, the quality of the bone typically is not normal. Fluoride ions become incorporated at the surfaces of hydroxyapatite crystals; the size and structure of the crystals become so altered that the mechanical competence of the bone declines. Fluoride therapy is not likely ever to be approved by the FDA.

Strontium ranelate is the mechanism supporting the reduction in spine and nonspine fractures; yet, the use of strontium is not clear.

### Prevention of Falls

Fractures of the humerus, wrist, pelvis, and hip are often age related, resulting from a combination of osteoporosis and falling. Although only a small percentage of falls result in fractures, preventing falls through education and attention to the living environment of older adults is an important measure. Wearing girdles with built-in pads to protect the hips during a fall has been demonstrated in some, but not all, studies to significantly reduce the rate of fractures in a well-controlled investigation. A physical therapist can often evaluate the home to provide advice on reducing the likelihood of falls.

### CLINICAL SCENARIO

Annie B., a 70-year-old white woman of Northern European ancestry, developed lactose intolerance during her early 50s when she had a serious gastrointestinal infection. She currently is retired, lives alone, and stays indoors most of each day watching television. Approximately 3 years ago at age 67, she had dual-energy x-ray absorptiometry (DEXA) measurements that showed that she had low bone mineral density (BMD) values of her proximal femur and lumbar vertebrae (both values are classified as osteoporotic according to World Health Organization definitions). Her physician recommended that she start taking supplements of calcium (1000 mg/day) and vitamin D (800 units/day) because of her lactose intolerance and her lack of consumption of all dairy products.

Annie took the supplements regularly for a year when a second set of DEXA measurements revealed that she had practically maintained her BMD values of 1 year earlier, with only a small decline in BMD. However, her continuing low measurements concerned her physician, and he ordered

laboratory tests of calcium-regulatory hormones to see if she had any hormonal complications. These tests showed that her parathyroid hormone and 25-hydroxy vitamin D concentrations fell in the upper half of the normal range for each variable. Other routine measurements such as serum calcium and phosphate were normal. After discussion of her high risk of an osteoporotic fracture, her physician decided to place Annie on a bisphosphonate drug in addition to calcium and vitamin D.

After 1 year on the new therapy and continuation of the calcium and vitamin D, her BMD values (her third set of DEXA measurements) actually increased a few percentage points, even though they remained within the classification of osteoporosis. She was then instructed by her physician to continue indefinitely on this therapeutic regimen.

### Nutrition Diagnostic Statement

Inadequate calcium and vitamin D intake related to avoidance of dairy products as evidenced by diet history revealing less

## CLINICAL SCENARIO—cont'd

than 20% of estimated requirements. Note: This may be resolved once she starts taking supplements.

### Nutrition Care Questions

- How would you classify Annie's calcium intake at the initial visit with her physician (who did not take a diet history or estimate her calcium intake)? Her vitamin D intake? Her exposure to sunlight?
- What would you have recommended to improve her calcium intake from foods so that she could reduce her supplemental calcium to 500 mg/day? Why would you

recommend foods to provide calcium rather than supplements? Could you make similar recommendations for improving her intake of vitamin D from foods?

- Design a set (3 days minimum) of daily menus that provide approximately 800 mg of calcium from foods alone, which, coupled with a 500-mg supplement, would provide a total of 1300 mg, the current adequate intake for calcium. Similarly, design these same meals to include 400 units of vitamin D, with another 400 units coming from supplements.

## CHAPTER 26

Diane Rigassio Radler, PhD, RD

# Nutrition for Oral and Dental Health

### KEY TERMS

anticariogenic  
calculus  
candidiasis  
cariogenic  
cariogenicity  
cariostatic  
demineralization  
dental caries  
dental erosion  
dentin  
**early childhood caries (ECC)**  
edentulism  
enamel

fermentable carbohydrate  
fluoroapatite  
fluorosis  
gingiva  
gingival sulcus  
hydroxyapatite  
lingual caries  
periodontal disease  
plaque  
remineralization  
root caries  
stomatitis  
***Streptococcus mutans***  
xerostomia

Diet and nutrition play key roles in tooth development, integrity of the **gingiva** (gums) and mucosa, bone strength, and the prevention and management of diseases of the oral cavity. Diet has a local effect on tooth integrity; the type, form, and frequency of foods and beverages consumed have a direct effect on the oral pH and microbial activity, which may promote dental decay. Nutrition systemically affects the development, maintenance, and repair of teeth and oral tissues.

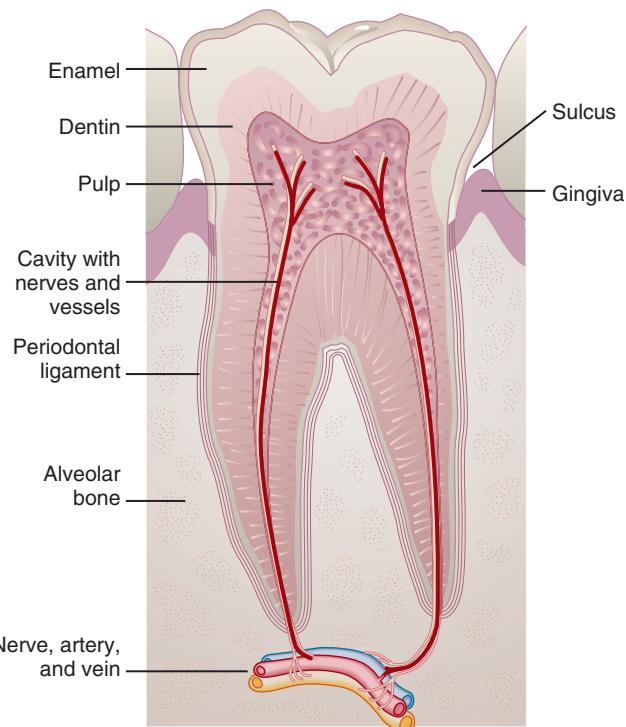

Nutrition and diet affect the oral cavity, but the reverse is also true; that is, the status of the oral cavity may affect one's ability to consume an adequate diet and achieve nutritional balance. Indeed, there is a lifelong synergy between

nutrition and the integrity of the oral cavity in health and disease related to the known roles of diet and nutrients in the growth, development, and maintenance of the oral cavity structure, bones, and tissues (Touger-Decker et al., 2007).

### NUTRITION FOR TOOTH DEVELOPMENT

Primary tooth development begins at 2 to 3 months' gestation. Mineralization begins at approximately 4 months' gestation and continues through the preteen years. Therefore maternal nutrition must supply the preeruptive teeth with the appropriate building materials. Inadequate maternal nutrition consequently affects tooth development.

Sections of this chapter were written by Riva Touger-Decker, PhD, RD, FADA for the previous edition of this text.

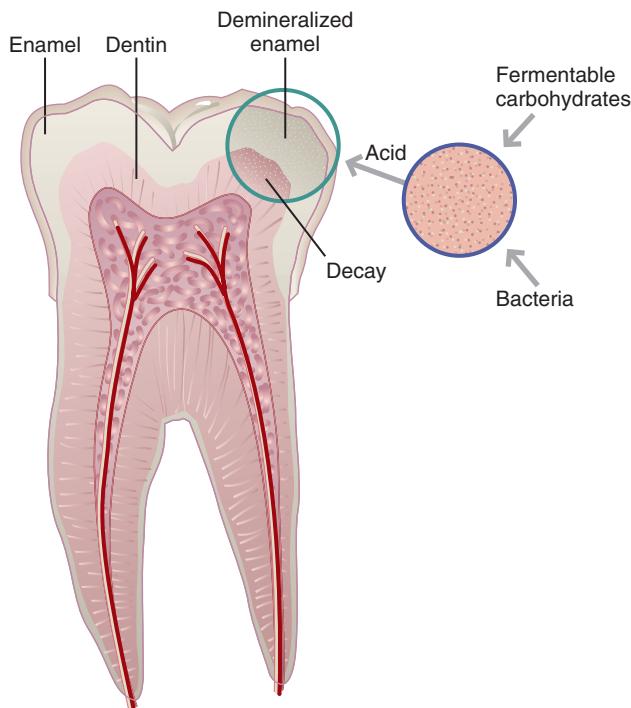

**FIGURE 26-1** Anatomy of a tooth.

Teeth are formed by the mineralization of a protein matrix. In **dentin**, protein is present as collagen, which depends on vitamin C for normal synthesis. Vitamin D is essential to the process by which calcium and phosphorus are deposited in crystals of **hydroxyapatite**, a naturally occurring form of calcium and phosphorus that is the mineral component of **enamel** and dentin. Fluoride added to the hydroxyapatite provides unique caries-resistant properties to teeth in both prenatal and postnatal developmental periods.

Diet and nutrition are important in all phases of tooth development, eruption, and maintenance (Figure 26-1). Posteruption, diet and nutrient intake continue to affect tooth development and mineralization, enamel development and strength, and eruption patterns of the remaining teeth. The local effects of diet, particularly fermentable carbohydrates and eating frequency, affect the production of organic acids by oral bacteria and the rate of tooth decay as described later in this chapter.

## DENTAL CARIES

Dental caries is one of the most common infectious diseases. According to a Surgeon General's report on oral health in 2000, dental caries is seven times more common than hay fever and five times more common than asthma. Unfortunately, differences are evident in caries prevalence; approximately 20% to 25% of U.S. children have 80% of the dental caries. Trends in dental caries have demonstrated that children who come from homes in which parents have at least a college education have fewer caries than children

**FIGURE 26-2** Formation of dental caries.

from homes in which parents have less than a college education (Centers for Disease Control and Prevention [CDC], 2010). These differences, or health disparities, may happen as a result of lack of access to care, cost of care not reimbursed by third-party payors (e.g., insurance, Medicaid), lack of knowledge of preventive dental care, or a combination of factors.

## Pathophysiology

**Dental caries** is an oral infectious disease in which organic acid metabolites lead to gradual **demineralization** of tooth enamel, followed by rapid proteolytic destruction of the tooth structure. Caries can occur on any tooth surface. The cause of dental caries involves many factors. Four factors must be present simultaneously: (1) a susceptible host or tooth surface; (2) microorganisms such as *Streptococcus* or *Lactobacillus* in the dental plaque or oral cavity; (3) fermentable carbohydrates in the diet, which serve as the substrate for bacteria; and (4) time (duration) in the mouth for bacteria to metabolize the fermentable carbohydrates, produce acids, and cause a drop in salivary pH to less than 5.5. Once the pH is acidic, which can occur within minutes, oral bacteria can initiate the demineralization process. Figure 26-2 shows the formation of dental caries.

## Susceptible Tooth

The development of dental caries requires the presence of a tooth that is vulnerable to attack. The composition of enamel and dentin, the location of teeth, the quality and quantity of saliva, and the presence and extent of pits and fissures in the tooth crown are some of the factors that

**BOX 26-1****Factors Affecting Cariogenicity of Foods**

- Frequency of consumption
- Food form (liquid or solid, slowly dissolving)
- Sequence of eating certain foods and beverages
- Combination of foods
- Nutrient composition of foods and beverages
- Duration of exposure of teeth

govern susceptibility. Alkaline saliva may have a protective effect, whereas acidic saliva increases susceptibility to decay.

**Microorganisms**

Bacteria are an essential part of the decay process. *Streptococcus mutans* is the most prevalent, followed by *Lactobacillus casein* and *Streptococcus sanguis*. All three contribute to the process because they metabolize carbohydrates in the mouth, producing acid as a byproduct, which is sufficient to cause decay. Genetic variations of the type and quantity of bacteria present in the oral cavity may put someone at an increased risk for caries and periodontal disease, but the quantity and quality of oral hygiene contributes directly to the risk of oral infectious disease.

**Substrate**

**Fermentable carbohydrates**, those carbohydrates susceptible to the actions of salivary amylase, are the ideal substrate for bacterial metabolism. The acids produced by their metabolism cause a drop in salivary pH to less than 5.5, creating the environment for decay. Bacteria are always present and begin to reduce pH when they have exposure to fermentable carbohydrates.

Although both the Dietary Guidelines for Americans and the MyPlate Food Guidance system support a diet high in carbohydrates, it is important to be aware of the cariogenicity of foods. **Cariogenicity** refers to the caries-promoting properties of a diet or food. The cariogenicity of a food varies, depending on the form in which it occurs, its nutrient composition, when it is eaten in relation to other foods and fluids, the duration of its exposure to the tooth, and the frequency with which it is eaten (Box 26-1).

Individuals should be aware of the form of food consumed and the frequency of intake to integrate positive diet and oral hygiene habits to reduce risk of oral disease.

Fermentable carbohydrates are found in three of the five MyPlate food groups: (1) grains, (2) fruits, and (3) dairy. Although some vegetables may contain fermentable carbohydrates, little has been reported about the cariogenicity, or caries-promoting properties, of vegetables. Examples of grains and starches that are cariogenic by nature of their fermentable carbohydrate composition include crackers, chips, pretzels, hot and cold cereals, and breads.

All fruits (fresh, dried, and canned) and fruit juices may be cariogenic. Fruits with high water content, such as melons, have a lower cariogenicity than others such as bananas and

dried fruits. Fruit drinks, sodas, ice teas, and other sugar-sweetened beverages; desserts; cookies; candies; and cake products may be cariogenic. Dairy products sweetened with fructose, sucrose, or other sugars can also be cariogenic because of the added sugars; however, dairy products are rich in calcium, and their alkaline nature may have a positive influence, reducing the cariogenic potential of the food.

Like other sugars (glucose, fructose, maltose, and lactose), sucrose stimulates bacterial activity. The causal relationship between sucrose and dental caries has been established (Marshall, 2007; Moynihan, 2005). All dietary forms of sugar, including honey, molasses, brown sugar, and corn syrup solids, have cariogenic potential and can be used by bacteria to produce organic acid.

**Caries Promotion by Individual Foods**

It is important to differentiate between cariogenic, cariostatic, and anticariogenic foods. **Cariogenic** foods are those that contain fermentable carbohydrates, which, when in contact with microorganisms in the mouth, can cause a drop in salivary pH to 5.5 or less and stimulate the caries process.

**Cariostatic** foods do not contribute to decay, are not metabolized by microorganisms, and do not cause a drop in salivary pH to 5.5 or less within 30 minutes. Examples of cariostatic foods are protein foods such as eggs, fish, meat, and poultry; most vegetables; fats; and sugarless gums. Sugarless gum may help to reduce decay potential because of its ability to increase saliva flow and because it uses noncarbohydrate sweeteners (Deshpande, 2008; Splieth, 2009).

**Anticariogenic** foods are those that, when eaten before an acidogenic food, prevent plaque from recognizing the acidogenic food. Examples are aged cheddar, Monterey Jack, and Swiss because of the casein, calcium, and phosphate in the cheese. The five-carbon sugar alcohol, xylitol, is considered anticariogenic because bacteria cannot metabolize five-carbon sugars in the same way as six-carbon sugars like glucose, sucrose, and fructose. It is not broken down by salivary amylase and is not subject to bacterial degradation. Salivary stimulation leads to increased buffering activity of the saliva and subsequent increased clearance of fermentable carbohydrates from tooth surfaces. Another anticariogenic mechanism of xylitol gum is that it replaces fermentable carbohydrates in the diet. *S. mutans* cannot metabolize xylitol and is inhibited by it. Both the antimicrobial activity against *S. mutans* and the effect of gum chewing on salivary stimulation are protective. Brands of chewing gum that include xylitol are Arm and Hammer Advance White, Dentyne Ice, Spry, and Trident.

**Remineralization** is mineral restoration of the hydroxyapatite in dental enamel. Casein phosphopeptide-amorphous calcium phosphate (CPP-ACP; Recaldent) is a substance that promotes remineralization of enamel surfaces. It is currently available as an ingredient in Trident White brand chewing gums (Ramalingam, 2005). CPP-ACP has also exhibited anticariogenic activity in randomized, controlled clinical trials of sugar-free gum and a tooth cream (Walker et al., 2010). Its use for that purpose is not suggested at this time.

## Factors Affecting Cariogenicity of Food

Cariogenicity also is influenced by the volume and quality of saliva; the sequence, consistency, and nutrient composition of the foods eaten; dental plaque buildup; and the genetic predisposition of the host to decay.

### Form and Consistency

The form and consistency of a food have a significant effect on its cariogenic potential and pH-reducing or buffering capacity. Food form determines the duration of exposure or retention time of a food in the mouth, which, in turn, affects how long the decrease in pH or the acid-producing activity will last. Liquids are rapidly cleared from the mouth and have low adherence (or retentiveness) capabilities. Solid foods such as crackers, chips, pretzels, dry cereals, and cookies can stick between the teeth (referred to as the *interproximal spaces*) and have high adherence (or retention) capability.

Consistency also affects adherence. Chewy foods such as gum drops and marshmallows, although high in sugar content, stimulate saliva production and have a lower adherence potential than solid, sticky foods such as pretzels, bagels, or bananas. High-fiber foods with few or no fermentable carbohydrates, such as popcorn and raw vegetables, are cariostatic.

### Exposure

The duration of exposure may be best explained with starchy foods, which are fermentable carbohydrates subject to the action of salivary amylase. The longer starches are retained in the mouth, the greater their cariogenicity (Fontana, 2006). Given sufficient time, such as when food particles become lodged between the teeth, salivary amylase makes additional substrate available as it hydrolyzes starch to simple sugars. Processing techniques, either by partial hydrolysis or by reducing particle size, make some starches rapidly fermentable by increasing their availability for enzyme action.

Sugar-containing candies rapidly increase the amount of sugar available in the oral cavity to be hydrolyzed by bacteria. Sucking on hard candies such as lollipops or sugared breath mints results in prolonged sugar exposure in the mouth. Simple carbohydrate-based snacks and dessert foods (e.g., potato chips, pretzels, cookies, cakes, and doughnuts) provide gradually increasing oral sugar concentrations for a longer duration because these foods often adhere to the tooth surfaces and are retained for longer periods than candies (Fontana, 2006).

### Nutrient Composition

Nutrient composition contributes to the ability of a substrate to produce acid and to the duration of acid exposure. Dairy products, by virtue of their calcium- and phosphorus-buffering potential, are considered to have low cariogenic potential. Evidence suggests that cheese and milk, when consumed with cariogenic foods, help to buffer the acid pH produced by the cariogenic foods. Because of the anticariogenic properties of cheese, eating cheese with a fermentable

carbohydrate, such as dessert at the end of a meal, may decrease the cariogenicity of the meal and dessert (Moynihan, 2005).

Nuts, which do not contain a significant amount of fermentable carbohydrates and are high in fat and dietary fiber, are cariostatic. Protein foods such as seafood, meats, eggs, and poultry, along with other fats such as oils, margarine, butter, and seeds, are also cariostatic.

### Sequence and Frequency of Eating

Eating sequence and combination of foods also affect the caries potential of the substrate. Bananas, which are cariogenic because of their fermentable carbohydrate content and adherence capability, have less potential to contribute to decay when eaten with cereal and milk than when eaten alone as a snack. Milk, as a liquid, reduces the adherence capability of the fruit. Crackers eaten with cheese are less cariogenic than when eaten alone.

The frequency with which a cariogenic food or beverage is consumed determines the number of opportunities for acid production. Every time a fermentable carbohydrate is consumed, a decline in pH is initiated within 5 to 15 minutes, causing caries-promoting activity. Small, frequent meals and snacks, often high in fermentable carbohydrate, increase the cariogenicity of a diet more than a diet consisting of three meals and minimal snacks. Eating several cookies at once, followed by brushing the teeth or rinsing the mouth with water, is less cariogenic than eating a cookie several times throughout a day. Table 26-1 lists messages that can be given to children to prevent caries.

### The Decay Process

The carious process begins with the production of acids as a by-product of bacterial metabolism taking place in the dental plaque. Decalcification of the surface enamel continues until the buffering action of the saliva is able to raise the pH above the critical level. See Box 26-2 for prevention guidelines.

**Plaque** is a sticky, colorless mass of microorganisms and polysaccharides that forms around the tooth and adheres to teeth and gums. It harbors acid-forming bacteria and keeps the organic products of their metabolism in close contact with the enamel surface. As a cavity develops, the plaque blocks the tooth, to some extent, from the buffering and remineralization action of the saliva. In time the plaque combines with calcium and hardens to form **calculus**.

An acidic pH is also required for plaque formation. Soft drinks (diet and regular), sports beverages, citrus juices and “ades,” and vitamin C supplements have high acid content. Research using National Health and Nutrition Examination Survey III data reported significantly more dental caries in children (ages 2 to 10 years) who consumed large amounts of carbonated soft drinks or juices when compared with children who had high consumption of water or milk (Sohn, 2006). Other beverages and foods contribute to **dental erosion**, a loss of minerals from tooth surfaces by a chemical process in the presence of acid (Wongkhantee, 2006).

**TABLE 26-1****Nutrition Messages Related to Oral Health for 3- to 10-Year-Old Children and Their Caregivers**

<b>Message</b>	<b>Rationale</b>
Starchy, sticky, or sugary foods should be eaten with nonsugary foods.	The pH will rise if a nonsugary item that stimulates saliva is eaten immediately before, during, or after a challenge.
Combine dairy products with a meal or snack.	Dairy products (nonfat milk, yogurt) enhance remineralization and contain calcium.
Combine chewy foods such as fresh fruits and vegetables with fermentable carbohydrates.	Chewy, fibrous foods induce saliva production and buffering capacity.
Space eating occasions at least 2 hours apart and limit snack time to 15–30 minutes.	Fermentable carbohydrates eaten sequentially one after another promote demineralization.
Limit bedtime snacks.	Saliva production declines during sleep.
Limit consumption of acidic foods such as sports drinks, juices, and sodas.	Acidic foods promote tooth erosion that increases risk for caries.
Combine proteins with carbohydrates in snacks: Examples: tuna and crackers, apples and cheese	Proteins act as buffers and are cariostatic.
Combine raw and cooked or processed foods in a snack.	Raw foods encourage mastication and saliva production, whereas cooked or processed foods may be more available for bacterial metabolism if eaten alone.
Encourage use of xylitol- or sorbitol-based chewing gum and candies immediately following a meal or snack.*	Five minutes of exposure is effective in increasing saliva production and dental plaque pH.
Sugar-free chewable vitamin and mineral supplements and syrup-based medication should be recommended.	Sugar-free varieties are available and should be suggested for high-caries risk groups.
Encourage children with pediatric GERD to adhere to dietary guidelines.	GERD increases risk for dental erosion and thus increases risk for caries.

Modified from Mobley C. Frequent dietary intake and oral health in children 3 to 10 years of age, *Building Blocks* 25(1):17-20, 2001.

*GERD*, Gastroesophageal reflux disease.

\*Gum is not recommended for children younger than 6 years old.

**BOX 26-2****Caries Prevention Guidelines**

- Brush at least twice daily, preferably after meals.
- Rinse mouth after meals and snacks.
- Chew sugarless gum for 15 to 20 min after meals and snacks.
- Floss twice daily.
- Use fluoridated toothpastes.
- Pair cariogenic foods with cariostatic foods.
- Snack on cariostatic and anticariogenic foods such as cheese, nuts, popcorn, and vegetables.
- Limit between-meal eating and drinking of fermentable carbohydrates.

For example, diet soft drinks, which may not contain sugar, also are acidic by nature and therefore cause a drop in pH. Chewable vitamin C supplements provide an acidic substance that directly contacts tooth surfaces and causes a drop in pH of the oral cavity, making teeth susceptible to erosion.

**Roles of Saliva**

Salivary flow clears food from around the teeth. By means of the bicarbonate-carbonic acid and phosphate buffer system, it also provides buffering action to neutralize bacterial acid metabolism. Chewing promotes saliva production and may account for the reduced cariogenicity of fermentable carbohydrates consumed with a meal.

Saliva is supersaturated with calcium and phosphorus. Once buffering action has restored pH above the critical point, remineralization can occur. If fluoride is present in the saliva, the minerals are deposited in the form of **fluoroapatite**, which is resistant to erosion. It should be noted that salivary production decreases as a result of diseases affecting salivary gland function (e.g., Sjögren's syndrome); as a side-effect of fasting; as a result of radiation therapy to the head and neck involving the parotid gland; normally during sleep; with the use of medications associated with reduced salivary flow; or with **xerostomia**, dry mouth caused by inadequate saliva production. There are estimates that between 400 and 500 medications currently available by prescription or over the counter may cause dry mouth. The degree of xerostomia may vary but may be caused by medications such as those to treat depression, hypertension, anxiety, human immunodeficiency virus (HIV), and allergies, to name a few.

## Caries Patterns

Caries patterns describe the location and surfaces of the teeth affected. Coronal caries affect the crown of the tooth, the part of the tooth visible above the gum line, and may occur on any tooth surface. Although the overall incidence of decay in the United States has declined, as many as 17% of children between 2 and 4 years of age have tooth decay. According to the National Oral Health Surveillance System, many states report 40% to 70% of children having some decay by age 8.

**Root caries**, occurring on the root surfaces of teeth secondary to gingival recession, affect a large portion of the older population. Root caries is a dental infection that is increasing in older adults, partly because this population is retaining their natural teeth longer. The gums recede in older age, exposing the root surface. Other factors related to the increased incidence of this decay pattern are lack of fluoridated water, poor oral hygiene practices, decreased saliva, frequent eating of fermentable carbohydrates, and dementia (Chalmers, 2008). Management of root caries includes dental restoration and nutrition counseling. Poor oral health from caries, pain, or edentulism may adversely affect dietary intake and nutritional status in the older adult (Quandt, 2009).

**Lingual caries**, or caries on the lingual side (surface next to or toward the tongue) of the anterior teeth, are seen in persons with gastrointestinal reflux, bulimia, or anorexia-bulimia (see Chapter 23). Frequent intake of fermentable carbohydrates, combined with regurgitation or induced vomiting of acidic stomach contents, results in a constant influx of acid into the oral cavity. The caries are the end result of tooth erosion characterized by erosion of the palatal and buccal surfaces of the maxillary anterior teeth and the

lingual surfaces of the palatal surface of the maxillary posterior teeth (Holbrook, 2009).

## Fluoride

Fluoride is a primary anticaries agent. Used systemically and locally, it is a safe, effective public health measure to reduce the incidence and prevalence of dental caries (Palmer and Wolfe, 2005). Water fluoridation began in 1940; by 1999 the Centers for Disease Control and Prevention listed water fluoridation as one of the top 10 greatest public health achievements of the 20th century because of its influence on decreasing the rate of dental caries (CDC, 2006). The effect of fluoride on caries prevention continues with water fluoridation, fluoridated toothpastes, oral rinses, and dentifrices, as well as beverages made with fluoridated water. Optimal water fluoridation concentrations (0.7 to 1.2 ppm) can provide protection against caries development without causing tooth staining (Palmer and Wolfe, 2005). See *Focus On: Water Fluoridation*.

## Mechanism of Action

There are four primary mechanisms of fluoride action on teeth: (1) when incorporated into enamel and dentin along with calcium and phosphorus, it forms fluoroapatite, a compound more resistant to acid challenge than hydroxyapatite; (2) it promotes repair and remineralization of tooth surfaces with early signs of decay (incipient carious lesions); (3) it helps to reverse the decay process while promoting the development of a tooth surface that has increased resistance to decay; and (4) helps to deter the harmful effects of bacteria in the oral cavity by interfering with the formation and function of microorganisms.

## © FOCUS ON

### Water Fluoridation

Fluoride supplementation has been endorsed as a public health measure by the American Dental Association and American Dietetic Association (American Dental Association, 2005; Palmer and Wolfe, 2005). The American Academy of Pediatrics, American Dental Association, and the American Academy of Pediatric Dentistry have developed a dosing schedule for fluoride supplementation that is aimed at providing adequate fluoride while preventing fluorosis.

1. All possible sources of fluoride must be taken into account. These include:
  - Knowing the fluoride content of the child's primary drinking water source and all other sources of water for the child (eg, other home, child care, school, relative or caregiver's house, bottled water).

- Other sources of fluoride, such as prescriptions from the dentist, fluoride mouthrinse in school, or fluoride varnish.
- 2. If it is determined that fluoride access is limited, then supplementation should be written.
- 3. No child younger than 6 months of age and no child older than 16 years of age should be supplemented.
- 4. No child who has adequate access to (and is drinking) appropriately fluoridated community water should be supplemented.

The American Dental Association published a new guideline in 2010, recommending fluoride supplements be prescribed only to children determined to be high risk for the development of caries.

[http://www.aap.org/oralhealth/pact/ch6\\_sect3b.cfm](http://www.aap.org/oralhealth/pact/ch6_sect3b.cfm) accessed 11 Mar 2011

## Food Sources

Most foods, unless prepared with fluoridated water, contain minimal amounts of fluoride, except for brewed tea, which has approximately 1.4 ppm (Morin, 2006). Fluoride may be unintentionally added to the diet in a number of ways, including through the use of fluoridated water in the processing of foods and beverages. Fruit juices and drinks, particularly white grape juice produced in cities with fluoridated water, may have increased fluoride content; however, because of the wide variation in fluoride content, it is difficult to estimate amounts consumed.

## Supplementation

It is prudent for health professionals to consider a child's fluid intake as well as food sources and the availability of fluoridated water in the community before prescribing fluoride supplements. Because bones are repositories of fluoride, bone meal, fish meal, and gelatin made from bones are potent sources of the mineral. In communities without fluoridated water, dietary fluoride supplements may be recommended for children ages 6 months to 16 years.

Fluoride can be used topically and systemically. When consumed in food and drink, it enters the systemic circulation and is deposited in bones and teeth. Systemic sources have a topical benefit as well by providing fluoride to the saliva. A small amount of fluoride enters the soft tissues; the remainder is excreted. The primary source of systemic fluoride is fluoridated water; food and beverages supply a smaller amount. *Table 26-2* contains a schedule of fluoride supplementation for the public through age 16.

Fluoride supplements are not recommended for formula-fed infants or for breast-fed infants living in fluoridated communities if these infants receive drinking water between feedings. If the infant does not drink water between feedings or drinks bottled water when on a diet of only breast milk, he or she should be supplemented according to the fluoride supplement guidelines. Fluoride supplements must be prescribed by the child's doctor; they are not available as over-the-counter supplements (American Dental Association, 2005).

Topical fluoride sources include toothpastes, gels, and rinses used by consumers daily, along with more concentrated forms applied by dental professionals in the form of gels, foams, and rinses. Frequent fluoride exposure via topical fluorides, fluoridated toothpastes, rinses, and fluoridated water is important in maintaining an optimal concentration of fluoride, but excess intake should be avoided. (See Chapter 3.)

## Excess Fluoride

**Fluorosis** occurs when too much fluoride is provided during tooth development and can range from mild to severe and present on teeth from unnoticeable to very apparent dark spots on teeth (Alvarez, 2009). Causes of mild fluorosis from excessive fluoride intake include misuse of dietary fluoride supplements, ingestion of fluoridated toothpastes and rinses, or excessive fluoride intake secondary to fluoride in foods and beverages processed in fluoridated areas and transported to other areas (Palmer and Wolfe, 2005). Topical fluorides, available as fluoridated toothpaste and mouthwashes, are effective sources of fluoride that can be used in the home, school, or dental office. Caries prevention efforts in preschool children include diet modification, water fluoridation or supplements in nonfluoridated areas, and supervised toothbrushing with fluoridated toothpaste (Alvarez, 2009).

Children younger than 6 years of age should not use fluoridated mouthwashes, and older children should be instructed to rinse, but not swallow, mouthwash. No more than a pea-size amount of toothpaste should be placed on a child's toothbrush to reduce the risk of accidental fluoride ingestion. Topical fluorides may be administered in the dental office.

Fluoride gels often are prescribed for adults and older adults. Such gels are effective in reducing the risk of coronal and root decay and tooth loss (Weintraub, 2006). Fluoride is most effective when given from birth through ages 12 to 13, the period when mineralization of unerupted permanent teeth occurs.

## EARLY CHILDHOOD CARIES

**Early childhood caries (ECC)**, often called "baby-bottle tooth decay," describes a caries pattern in the maxillary anterior teeth of infants and young children. Characteristics include rapidly developing carious lesions in the primary anterior teeth and the presence of lesions on tooth surfaces not usually associated with a high caries risk. Because tooth decay remains a common oral disease of childhood, caries are a primary marker for a child's oral health. Good behavioral habits and child nutrition patterns must be encouraged, beginning in infancy.

## Pathophysiology and Incidence

Often ECC follows prolonged bottle-feeding, especially at night, of juice, milk, formula, or other sweetened beverages. The extended contact time with the fermentable carbohydrate-containing beverages, coupled with the position of the tongue against the nipple, which causes pooling

**TABLE 26-2**

### Dietary Fluoride Supplement Schedule

Fluoride Ion Level In Drinking Water (ppm)*			
Age	<0.3 ppm	0.3-0.6 ppm	>0.6 ppm
Birth-6 mo	None	None	None
6 mo-3 yr	0.25 mg/day <sup>†</sup>	None	None
3-6 yr	0.50 mg/day	0.25 mg/day	None
6-16 yr	1.0 mg/day	0.50 mg/day	None

Approved by The American Dental Association, The American Academy of Pediatrics, and The American Academy of Pediatric Dentistry, 1994.

\*1 ppm = 1 mg/L.

<sup>†</sup>2.2 mg of sodium fluoride contains 1 mg of fluoride ion.

**FIGURE 26-3** Early childhood caries. (From Swartz MH: Textbook of physical diagnosis, history, and examination, ed 5, Philadelphia, 2006, Saunders.)

of the liquid around the maxillary incisors, particularly during sleep, contributes to the decay process. The mandibular anterior teeth are usually spared (Figure 26-3) because of the protective position of the lip and tongue and the presence of a salivary duct in the floor of the mouth. In general, children from low-income families and minority populations experience the greatest amount of oral disease, the most extensive disease, and the most frequent use of dental services for pain relief; yet these children have the fewest overall dental visits (CDC, 2010).

### Nutrition Care

Management of ECC includes diet and oral hygiene education for parents, guardians, and caregivers (Zero, 2010). Messages should be targeted to counter the health habits that contribute to this problem: poor oral hygiene, failure to brush a child's teeth at least daily, frequent use of bottles filled with sweetened beverages, and lack of fluoridated water. Dietary guidelines include removal of the bedtime bottle and modification of the frequency and content of the daytime bottles. Bottle contents should be limited to water, formula, or milk. Infants and young children should not be put to bed with a bottle. Teeth and gums should be cleaned with a gauze pad or washcloth after all bottle feedings. All efforts should be made to wean children from a bottle by 1 year of age. Educational efforts should be positive and simple, focusing on oral hygiene habits and promotion of a balanced, healthy diet. Between-meal snacks should include cariostatic foods. When foods are cariogenic, they should be followed by tooth brushing or rinsing the mouth. Parents and caregivers need to understand the causes and consequences of ECC and how they can be avoided.

### CARIES PREVENTION

Caries prevention programs focus on a balanced diet, modification of the sources and quantities of fermentable carbohydrates, and the integration of oral hygiene practices into individual lifestyles (Zero, 2010). Meals and snacks should be followed with brushing, rinsing the mouth vigorously with water, or chewing sugarless gum for 15 to 20 minutes, preferably gum that contains xylitol (Splieh, 2009). Positive habits should be encouraged, including snacking on anticariogenic or cariostatic foods, chewing sugarless gum after

**FIGURE 26-4** A balanced diet plan with low cariogenic risk.

eating or drinking cariogenic items, and having sweets with meals rather than as snacks. Despite the potential for a diet that is based on the dietary guidelines to be cariogenic, with proper planning and good oral hygiene a balanced diet low in cariogenic risk can be planned. See Figure 26-4 for a sample diet.

Practices to avoid include sipping carbonated beverages for extended periods; frequent snacking; and harboring candy, sugared breath mints, or hard candies in the mouth for extended periods. Over-the-counter chewable or liquid medications and vitamin preparations, such as chewable vitamin C or liquid cough syrup, may contain sugar and contribute to caries risk.

Fermentable carbohydrates such as candy, crackers, cookies, pastries, pretzels, snack crackers, chips, and even fruits should be eaten with meals. Notably, “fat-free” snack and dessert items and “baked” chips and snack crackers tend to have a higher simple sugar concentration than their higher fat-containing counterparts.

### TOOTH LOSS AND DENTURES

Tooth loss (**edentulism**) and removable prostheses (dentures) can have a significant effect on dietary habits, masticatory function, olfaction, and nutritional adequacy. As

dentition status declines, masticatory performance is compromised. Compromised masticatory function, from partial or complete edentulism or complete dentures, may have a negative effect on food choices, resulting in decreased intake of whole grains, fruits, and vegetables (Tsakos, 2010). This problem is more pronounced in older adults, whose appetite and intake may be compromised further by chronic disease, social isolation, and the use of multiple medications (see Chapter 9).

Dentures need to be checked periodically by a dental professional for appropriate fit. Changes in body weight or changes in alveolar bone over time possibly may alter the fit of the dentures. Counseling on appropriate food choices and textures is advocated.

### Nutrition Care

Full dentures replace missing teeth but are not a perfect substitute for natural dentition. Both before and after denture placement, many individuals may experience difficulty biting and chewing, even after denture insertion. The foods found to cause the greatest difficulty for persons with complete dentures include fresh whole fruits and vegetables (e.g., apples and carrots), hard-crusted breads, and steak. Therefore dietary assessment and counseling related to oral health should be provided to the denture wearer. Simple guidelines should be provided for cutting and preparing fruits and vegetables to minimize the need for biting and reduce the amount of chewing. The importance of positive eating habits needs to be stressed as a component of total health. Overall, guidelines that reinforce the importance of a balanced diet should be part of the routine counseling given to all patients.

## OTHER ORAL DISORDERS

Oral diseases extend beyond dental caries. Deficiencies of several vitamins (riboflavin, folate, B<sub>12</sub>, and C) and minerals (iron and zinc) may be first detected in the oral cavity because of the rapid tissue turnover of the oral mucosa (see Appendix 30). Periodontal disease is a local and systemic disease. Select nutrients play a role, including vitamins A, C, E; folate; β-carotene; and the minerals calcium, phosphorus, and zinc. Oral cancer, often a result of tobacco and alcohol abuse, can have a significant effect on eating ability and nutritional status. This problem is compounded by the increased caloric and nutrient needs of persons with oral carcinomas. In addition, surgery, radiation therapy, and chemotherapy are modalities used to treat oral cancer that also can affect dietary intake, appetite, and the integrity of the oral cavity. Some but not all problems affecting the oral cavity are discussed here.

## PERIODONTAL DISEASE

### Pathophysiology

**Periodontal disease** is an inflammation of the gingiva with infection caused by oral bacteria and subsequent destruction

of the tooth attachment apparatus. Untreated disease results in a gradual loss of tooth attachment to the bone. Progression is influenced by the overall health of the host and the integrity of the immune system. The primary causal factor in the development of periodontal disease is plaque. Plaque in the **gingival sulcus**, a shallow, V-shaped space around the tooth, produces toxins that destroy tissue and permit loosening of the teeth. Important factors in the defense of the gingiva to bacterial invasion are (1) oral hygiene, (2) integrity of the immune system, and (3) optimal nutrition. The defense mechanisms of the gingival tissue, epithelial barrier, and saliva are affected by nutritional intake and status. Healthy epithelial tissue prevents the penetration of bacterial endotoxins into subgingival tissue.

### Nutritional Care

Deficiencies of vitamin C, folate, and zinc increase the permeability of the gingival barrier at the gingival sulcus, increasing susceptibility to periodontal disease. Severe deterioration of the gingiva is seen in individuals with scurvy or vitamin C deficiency. Although other nutrients, including vitamins A, E, β-carotene, and protein, have a role in maintaining gingival and immune system integrity, there are no scientific data to support supplemental uses of any of these nutrients to treat periodontal disease.

Although optimal nutrition may play a role in positive outcomes of periodontal treatment, nutrients alone are not a cure for the disease (Schifferle, 2005). In societies in which malnutrition and periodontal disease are prevalent, poor oral hygiene is also usually evident. In such instances it is difficult to determine whether malnutrition is the cause of the disease or one of many contributing factors, including poor oral hygiene, heavy plaque buildup, insufficient saliva, or coexisting illness.

The roles of calcium and vitamin D relate to the link between osteoporosis and periodontal disease, in which bone loss is the common denominator. The association between periodontal disease and systemic osteopenia and osteoporosis has been documented (Jeffcoat, 2005) (see Chapter 25). Because dairy foods are a rich source of calcium and vitamin D, researchers documented an inverse relationship between increased dairy food intake and decreased incidence of periodontal disease (Al-Zahrani, 2006). Although causal relationships have not been determined, the association of calcium and dairy foods with periodontal disease warrants advocating a sufficient intake of dairy foods in those who tolerate them. Management strategies for the patient or client with periodontal disease follow many of the same guidelines as for caries prevention listed in Box 26-2.

Severe periodontal disease may be treated surgically. Diet adequacy is particularly important both before and after periodontal surgery, when adequate nutrients are needed to regenerate tissue and support immunity to prevent infection. Adequacy of calories, protein, and micronutrients should be ensured. If the ability to consume one's regular diet is altered, a diet modified in consistency can be individually designed. Oral supplements can be used when necessary to attain adequate nutrient intake.

## ORAL MANIFESTATIONS OF SYSTEMIC DISEASE

Acute systemic diseases such as cancer and infections, as well as chronic diseases such as diabetes mellitus, autoimmune diseases, and chronic kidney disease, are characterized by oral manifestations that may alter the diet and nutritional status. Cancer therapies, including irradiation of the head and neck region, chemotherapy, and surgeries to the oral cavity, have a significant effect on the integrity of the oral cavity and on an individual's eating ability, which may consequently affect nutrition status (see [Chapter 37](#)).

If the condition of the mouth adversely affects one's food choices, the person with chronic disease may not be able to follow the optimal diet for medical nutrition therapy. For example, poorly controlled diabetes may manifest in xerostomia or candidiasis, which may then affect the ability to consume a diet to appropriately control blood sugar, further deteriorating glucose control.

In addition, many medications alter the integrity of the oral mucosa, taste sensation, or salivary production (see [Chapter 9](#)). Phenytoin (Dilantin) may cause severe gingivitis. Many of the protease inhibitor drugs used to treat HIV and acquired immune deficiency syndrome (AIDS) are associated with altered taste and dry mouth. Care should be taken to assess the effects of medication on the oral cavity and minimize these effects using alterations in diet or drug therapy.

### Diabetes Mellitus

Diabetes is associated with several oral manifestations, many of which occur only in periods of poor glucose control. These include burning mouth syndrome, periodontal disease, candidiasis, dental caries, and xerostomia ([Lamster, 2008](#)). The microangiopathic conditions seen in diabetes, along with altered responses to infection, contribute to risk of periodontal disease in affected persons. Tooth infection, more common in those with diabetes, leads to deterioration of diabetes control ([Bender and Bender, 2003](#)). Besides blood glucose control, dietary management for people with diabetes after any oral surgery procedures or placement of dentures should include modifications in the consistency, temperature, and texture of food to increase eating comfort, reduce oral pain, and prevent infections or decay while managing glucose control (see [Chapter 31](#)).

### Fungal Infections

Oropharyngeal fungal infections may cause a burning, painful mouth and dysphagia. The ulcers that accompany viral infections such as herpes simplex and cytomegalovirus cause pain and can lead to reduced oral intake. Very hot and cold foods or beverages, spices, and sour or tart foods also may cause pain and should be avoided. Consumption of temperate, moist foods without added spices should be encouraged. Small, frequent meals followed by rinsing with lukewarm water or brushing to reduce the risk of dental caries are helpful. Once the type and extent of oral manifestations are identified, a nutrition care plan can be developed.

Oral high calorie-high protein supplements in liquid or pudding form may be needed to meet nutrient needs and optimize healing.

### Head and Neck Cancers

Head, neck, and oral cancers can alter eating ability and nutrition status because of the surgeries and therapies used to treat these cancers. Surgery, depending on the location and extent, may alter eating or swallowing ability, as well as the capacity to produce saliva. Radiation therapy of the head and neck area and chemotherapeutic agents can affect the quantity and quality of saliva and the integrity of the oral mucosa. Thick, ropey saliva is often the result of radiation therapy to the head and neck area, causing xerostomia. Dietary management focuses on the recommendations described earlier for xerostomia, along with modifications in food consistency following surgery (see [Chapter 37](#)).

### HIV Infection and AIDS

Viral and fungal infections, stomatitis, xerostomia, periodontal disease, and Kaposi sarcoma are oral manifestations of HIV that can cause limitations in nutrient intake and result in weight loss and compromised nutrition status. These infections often are compounded by a compromised immune response, preexisting malnutrition, and gastrointestinal consequences of HIV infection (see [Chapter 38](#)). Viral diseases, including herpes simplex and cytomegalovirus, result in painful ulcerations of the mucosa.

**Stomatitis**, or inflammation of the oral mucosa, causes severe pain and ulceration of the gingiva, oral mucosa, and palate, which makes eating painful. **Candidiasis** on the tongue, palate, or esophagus can make chewing, sucking, and swallowing painful (odynophagia), thus compromising intake. [Table 26-3](#) outlines the effects of associated oral infections.

### Xerostomia

Xerostomia (dry mouth) is seen in poorly controlled diabetes mellitus, Sjögren's syndrome, other autoimmune diseases, and as a consequence of radiation therapy and certain medications ([Box 26-3](#)). Xerostomia from radiation therapy

### BOX 26-3

#### Medications That May Cause Xerostomia

- Antianxiety agents
- Anticonvulsants
- Antidepressants
- Antihistamines
- Antihypertensives
- Diuretics
- Narcotics
- Sedatives
- Serotonin reuptake inhibitors
- Tranquilizers

**TABLE 26-3****Effects of Oral Infections**

<b>Location</b>	<b>Problem</b>	<b>Effect</b>	<b>Diet Management</b>
Oral cavity	Candidiasis, KS, herpes, stomatitis	Pain, infection, lesions, altered ability to eat, dysgeusia	Increase kilocalorie and protein intake; administer oral supplements; provide caries risk reduction education
	Xerostomia	Increased caries risk, pain, no moistening power, tendency of food to stick, dysgeusia	Moist, soft, nonspicy foods; “smooth” cool or warm foods and fluids; caries risk reduction education
Esophagus	Candidiasis, herpes, KS, cryptosporidiosis	Dysphagia, odynophagia	Try oral supplementation first; if that is unsuccessful, initiate NG feedings using silastic feeding tube or PEG
	CMV, with or without ulceration	Dysphagia, food accumulation	PEG

*CMV*, Cytomegalovirus; *KS*, Kaposi's sarcoma; *NG*, nasogastric; *PEG*, percutaneous endoscopic gastrostomy.

**CLINICAL SCENARIO**

**G**ina is a 74-year-old woman with a history of type 2 diabetes, hypertension, and arthritis. She complains of dry mouth and difficulty chewing; is partially edentulous; and states that she tends to choose soft, “mushy” foods. She states that her dentist told her she has periodontal disease and will need multiple tooth extractions and a full maxillary and partial mandibular denture. She takes glyburide, amlodipine (Norvasc), and celecoxib (Celebrex), and glucosamine and chondroitin. She is 5'1" and weighs 176 lb. She lives alone, but receives assistance with food shopping and cooking from her family and friends. She claims to brush her teeth daily but rarely flosses because of her arthritic hands. She occasionally conducts self-monitoring fasting glucose fingersticks and states that her usual reading is 150 mg/dL.

**Nutrition Diagnostic Statements**

- Chewing difficulty secondary to poor dentition and xerostomia as evidenced by patient report and choice of soft foods.

- Altered nutrition-related laboratory value (glucose) secondary to diabetes and possibly food choices as evidenced by inadequate blood glucose control.

**Nutrition Care Questions**

- What are the cultural, educational, and environmental influences affecting dental and nutritional health?
- What are the diet counseling recommendations for the dental conditions?
- What are the nutritional and dietary risk factors?
- What are appropriate diet counseling recommendations for this patient?

may be more permanent than that from other causes (Kielbassa et al., 2006). Radiation therapy procedures to spare the parotid gland should be implemented when possible to reduce the damage to the salivary gland. Efforts to stimulate saliva production using pilocarpine and citrus-flavored, sugar-free candies may ease eating difficulty.

Individuals without any saliva at all have the most difficulty eating; artificial salivary agents may not offer sufficient relief. Lack of saliva impedes all aspects of eating, including chewing, forming a bolus, swallowing, and sensing taste; causes pain; and increases the risk of dental caries and infections. Dietary guidelines focus on the use of moist

foods without added spices, increased fluid consumption with and between all meals and snacks, and judicious food choices.

Problems with chewy (steak), crumbly (cake, crackers, rice), dry (chips, crackers), and sticky (peanut butter) foods are common in persons with severe xerostomia. Alternatives should be suggested, or the foods should be avoided to avert dysphagia risk. Drinking water with a lemon or lime twist or citrus-flavored seltzers or sucking on frozen tart grapes, berries, or sugar-free candies may help. Good oral hygiene habits are important in reducing the risk of tooth decay and should be practiced after all meals and snacks. Flavored

gums and mints containing xylitol may help to reduce the risk of associated decay.

# Medical Nutrition Therapy

The chapters in this section reflect the evolution of nutritional science, from the identification of nutrient requirements and the practical application of this knowledge, to the concepts that relate nutrition to the prevention of chronic and degenerative diseases and optimization of health. The role of nutrition in reducing inflammation, now recognized as a contributor to chronic disease, supports the awareness of diet in disease prevention and management.

Medical nutrition therapy (MNT) includes the assessment, nutrition diagnosis, interventions, monitoring, and evaluation for established disease. In some cases, medical nutrition therapy is a powerful preventive measure. The list of diseases amenable to nutrition intervention continues to increase, especially because hundreds of conditions are now known to have a genetic component and a connection with the nutrient-gene expression pathway.

Sophisticated feeding and nourishment procedures place an increased responsibility on those who provide nutrition care. The nutrition-related disorders included here can be managed by changes in dietary practices based on current knowledge. The goal in all cases is to move the individual along the continuum of disease management toward better nutritional health and overall well-being.

## CHAPTER 27

Kathie Madonna Swift, MS, RD, LDN

# Medical Nutrition Therapy for Adverse Reactions to Food: Food Allergies and Intolerances

### KEY TERMS

adverse reaction to food (ARF)  
allergen  
anaphylaxis  
antibodies  
antigen  
antigen presenting cell (APC)  
atopic dermatitis (eczema)  
atopy  
basophils  
B cells  
CAP-fluorescein-enzyme immunoassay (FEIA)  
cell-mediated immunity  
conformational epitopes  
cross reactivity  
cytokine  
double-blind, placebo-controlled food challenge (DBPCFC)  
dysbiosis  
elimination diet  
eosinophilic esophagitis (EE)  
eosinophilic gastroenteritis (EGE)  
epitope  
food allergen-specific serum IgE testing  
food allergy  
food and symptom diary  
food challenge  
food immunotherapy vaccine  
food intolerance  
food protein-induced enterocolitis syndromes (FPIES)

food sensitivity  
granulocyte  
gut-associated lymphoid tissue (GALT)  
hapten  
histamine  
hypersensitivity  
immunoglobulin (Ig)  
IgE-mediated food allergy  
immunoglobulin G (IgG)  
leaky gut  
lymphocyte  
macrophage  
mast cells  
monocytes  
nonallergic food sensitivities  
oral allergy syndrome (OAS)  
oral mucosal tolerance  
pollen-food syndrome (PFS)  
probiotics  
profilins  
radioallergosorbent test (RAST)  
sensitivity related illness  
sensitization  
skin-prick test  
specific oral tolerance induction (SOTI)  
T cells  
Th cells  
Th1 cells  
Th2 cells

Sections of this chapter were written by Sherry Hubbard, RD, for the previous edition of this text.

There is growing evidence that adverse reactions to food (ARFs) are more prevalent than in the past, with a defined increase in severity and scope. Changes in the modern diet and environmental influences interacting with genetic predisposition have been implicated in the escalation of ARFs and the parallel rise in other chronic disorders such as asthma and autoimmune diseases. Estimates suggest that 20% of the population alters their diet because of perceived ARFs (Sicherer and Sampson, 2010). ARFs are implicated in many conditions as a result of the involvement of major organ systems, including the digestive tract, the respiratory system, and the skin. The management of ARFs is complex because of the diverse response by which the body reacts to food constituents and the multifaceted nature of the mechanisms involved. The clinical relevance of ARFs should be carefully assessed and evaluated in the nutrition care process, because this can greatly affect a person's quality of life.

## DEFINITIONS

It is important to comprehend the language of ARFs because it can be a source of confusion and misunderstanding. The following definitions are used in this chapter. **Adverse reactions to food (ARFs)** encompass both food allergies and food intolerances, both of which can result in distressing symptoms and adversely affect health.

**Food allergy** or **hypersensitivity** is an adverse immune mediated reaction to a food, usually a food protein or **hapten** (a small molecule that can elicit an immune response only when attached to a large carrier protein). The symptoms are caused by the individual's unique response to the food, not by the food itself. For example, a person who is allergic to a food such as peanuts can develop life-threatening **anaphylaxis** after consuming a very small amount of peanuts, whereas other individuals have no adverse response to eating peanuts. Furthermore, the symptoms of the allergy in one individual can differ greatly from those in another in response to the same food. It has been estimated that food allergy affects up to 4% of the population, with a greater prevalence in childhood that is estimated at almost 8% (Chafen et al., 2010; National Institute of Allergy and Infectious Diseases [NIAID], 2010). Symptoms of food allergy are noted in Box 27-1.

**Food intolerance** is an adverse reaction to a food that does not involve the immune system and occurs because of the way the body processes the food or components in the food. It may be caused by a toxic, pharmacologic, metabolic, digestive, psychologic, or idiopathic reaction to a food or chemical substances in that food. For example, an individual can be intolerant of milk not because of an allergy to milk protein, but because of an inability to digest lactose; see Chapter 29 for discussion of lactose intolerance).

**Food sensitivity** refers to an ARF or component of the food when it is not clear whether the reaction is due to food allergy or intolerance. The umbrella term food sensitivity has been used interchangeably with food allergy and food intolerance, but does not give any indication as to the cause of the person's symptoms (Joneja, 2003). An

## BOX 27-1

### Symptoms of Food Allergy

#### Gastrointestinal

- Abdominal pain
- Nausea
- Vomiting
- Diarrhea
- Gastrointestinal bleeding
- Protein-losing enteropathy
- Oral and pharyngeal pruritus

#### Cutaneous

- Urticaria (hives)
- Angioedema
- Eczema
- Erythema (skin inflammation)
- Itching
- Flushing

#### Respiratory

- Rhinitis
- Asthma
- Cough
- Laryngeal edema
- Milk-induced syndrome with respiratory disease (Heiner syndrome)
- Airway tightening

#### Systemic

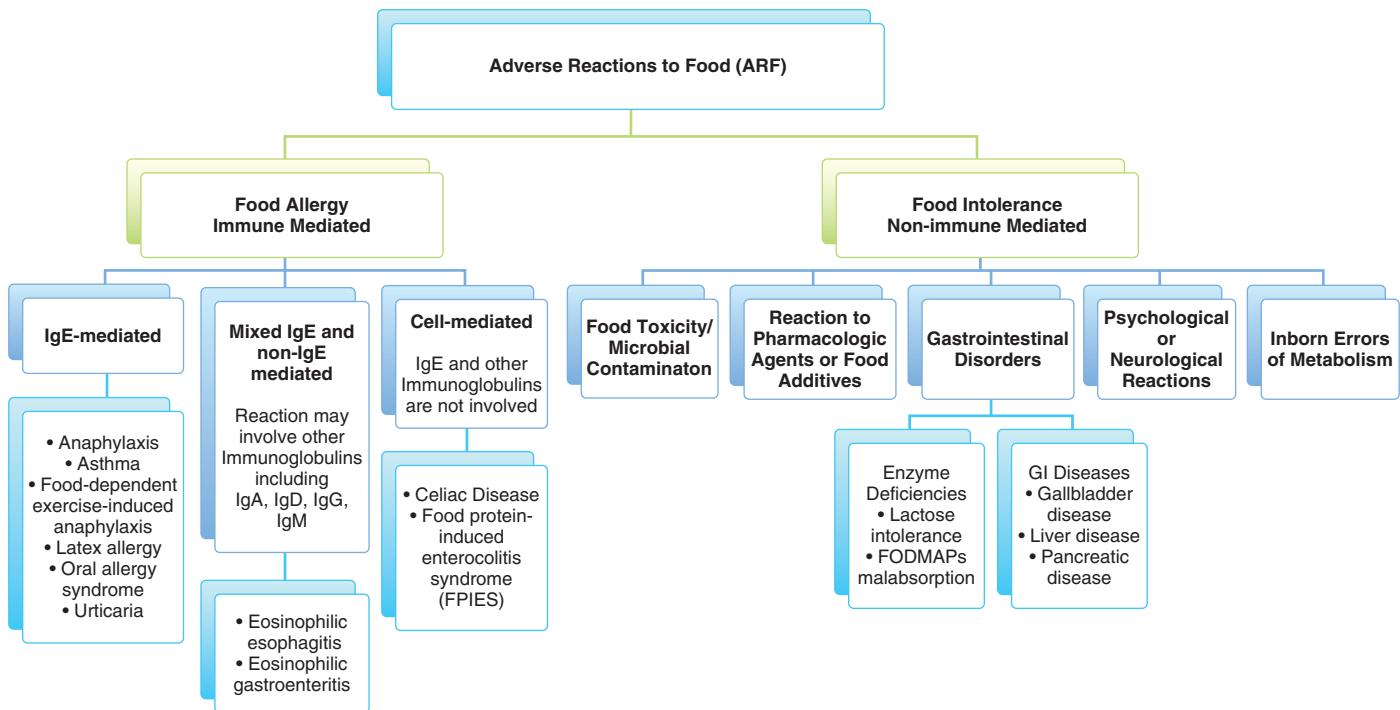

- Anaphylaxis
- Hypotension
- Dysrhythmias

#### Conditions with Possible Allergy Component

- Irritable bowel syndrome
- Chronic-fatigue syndrome
- Attention-deficit and hyperactivity disorders
- Otitis media
- Psychiatric disorders
- Neurologic disorders
- Fibromyalgia
- Migraine headache

emerging hypothesis called **sensitivity-related illness** poses that an individual who is exposed to some type of toxicant or insult may then become sensitive to food, inhalants, or chemicals (Genuis, 2010).

ARFs illustrate the critical importance of appreciating “biochemical uniqueness” as a core clinical concept in an integrative nutrition assessment. Numerous factors, including genetics, intestinal barrier integrity, resident intestinal microflora, stress, psychological factors, and environmental and physiological influences, affect an individual's unique

**FIGURE 27-1** Adverse reactions to food.

response to food or a component of food and its ultimate interpretation by the body as either “friend” or “foe” (Figure 27-1).

The immune system functions to clear the body of foreign substances or **antigens** such as viruses, bacteria, cancer cells, and other pathogens and disease-causing agents. Normally, when food antigens interact with cells of the immune system, they are dispelled from the body without an adverse reaction, unlike when a pathogenic virus or bacterium is expelled and there is a noticeable inflammatory reaction from microbial infection. Food comes from foreign material, either plant or animal, that our immune systems typically perceive as “foreign but safe” as a result of a process of **oral mucosal tolerance** that occurs when we digest and absorb food. Tolerance indicates that an individual is clinically and immunologically tolerant of the food (NIAID and NIH, 2010).

## ETIOLOGY

### Heredity

Food allergy has a hereditary component that it is not yet clearly defined. **Atopy** is a condition of genetic predisposition to produce excessive immunoglobulin (Ig) E antibodies in response to an **allergen**. Atopic individuals, usually identified in infancy, and confirmed by positive skin-prick test, are characterized by severe IgE-mediated reactions to dander, pollens, food, or other environmental factors, which present as food allergy, **atopic dermatitis (eczema)**, atopic conjunctivitis, atopic rhinitis, or asthma. A study of Finnish children

showed that up to the age of 4 years, children with two parents reporting any type of allergic reactions were three times as likely to have a food allergy as were children with allergy-free parents. Children with one allergic parent were twice as likely to have a food allergy (Pyrhönen et al., 2010). However, genetic susceptibility alone does not completely explain the prevalence of food allergy; other environmental influences (external, maternal, and gastrointestinal [GI] environment) and interactions between the host and the environment need to be considered.

### Antigen Exposure

Exposure to food antigens in the digestive tract, followed by immune regulation or suppression, is a prerequisite for the development of tolerance to the food, or oral tolerance (Burks et al., 2008). Food allergy is believed to occur when oral tolerance fails. Ongoing research is focused on how oral tolerance develops and is maintained (Brandtzaeg, 2010). The amount of antigen and environmental factors also influence the development of food allergy. The effects of food antigens and other antigens may be additive. Clinical symptoms of food allergy may increase when inhalant allergies are exacerbated by seasonal or environmental changes. Similarly, the effects of environmental factors, such as early exposure to microbes, toxins, tobacco smoke, stress, exercise, and cold may exacerbate the clinical symptoms of food allergy.

### Maternal Diet and Early Infant Feeding

The initial exposure to an antigen may occur during pregnancy or lactation or in early infancy. The food does not

have to be ingested by the infant directly. Postnatal sensitization may occur with exposure to food allergens by inhalation, skin contact, or ingestion. In fact, there is increasing evidence that many allergic reactions to food are initiated by exposure to food antigens through routes other than the digestive tract. (Lack, 2008). Food allergen sensitization can be a result of exposure to a food antigen through breast milk. More likely, it occurs from environmental exposure (skin or air) causing initial sensitization that is followed by continued exposure to antigens from the mother's milk.

### Gastrointestinal Microbiota

GI permeability and microbiota are critical influences in allergic disease. Both increased intestinal permeability; also referred to as “**leaky gut**” and the presence of excessive amounts of abnormal bacteria or “**dysbiosis**” influence gut immune function. This gut immune function is in the **gut-associated lymphoid tissue (GALT)**, the largest mass of lymphoid tissue in the body. GI permeability is thought to be greatest in early infancy and to decline with intestinal maturation. A leaky gut with altered permeability and possibly dysbiosis allows antigen penetration and presentation to the GALT lymphocytes and sensitization (Groschwitz and Hogan, 2009). Other conditions such as GI disease, malnutrition, prematurity, and immunodeficiency may also be associated with increased gut permeability and risk of development of food allergy. See Fig. 39-3 in Chapter 39.

## PATOPHYSIOLOGY

In allergy, the immune system unleashes defensive chemicals (inflammatory mediators) in response to something (in this case, food) that should not cause a response. The immune system mistakenly identifies food as a threat and mounts an attack against it. **Sensitization** occurs on the first exposure of the immune cells to the allergen and there are no symptoms of reaction. Thereafter, whenever that same foreign material enters the body, the immune system responds to this threat in the same manner. Because individuals can develop immunologic sensitization as evidenced by the production of allergen-specific IgE without having clinical symptoms upon exposure to those foods, a **IgE-mediated food allergy** requires both the presence of sensitization and the development of specific signs and symptoms on exposure to the food. Sensitization alone is not sufficient to define food allergy (NIAID and NIH, 2010; Boyce et al., 2011; Vickery et al., 2011) (Figure 27-2).

The combination of an allergen with allergen-specific IgE fixed to tissue mast cells or circulating **basophils** causes the release of chemical mediators, including **histamine**, enzymes, lipid-derived prostaglandins, interleukins, and others. When released, these inflammatory mediators can cause itching, pain, reddening, tissue swelling, contraction of smooth muscle, vasodilation, and fluid secretions. Manifestations, which are most often systemic, may involve

multiple organs and systems (see *Pathophysiology and Care Management Algorithm: Food Allergies*).

### Immune System Cells

**Lymphocytes** are the “command and control” cells of the immune system and include two important groups: **B cells**, arising from stem cells in the bone marrow, and **T cells**. T cells also originate from stem cells, but are later transported to the thymus gland where they mature. These two types of cells function as the basis for the humoral immune response and for cell-mediated immunity

**Monocytes** and **macrophages** are primarily phagocytes that engulf foreign material, break it apart, and display specific molecules of the material on their surfaces, making them **antigen-presenting cells (APC)**. The antigenic component displayed on the surface is an **epitope**, and is recognized by T cells. T cells respond by generating a cytokine message that stimulates their differentiation.

T cells, often called T “helper” cells (**Th cells**) differentiate into Th-1 cells or Th-2 cells which have different roles in the immune response under different circumstances, and secrete different sets of cytokines. **Th1 cells** regulate the activities of the B cells to produce antibodies and direct damage to target cells, resulting in the destruction of antigens. This function is useful in defending against bacteria, viruses, and other pathogenic cells. **Th2 cells** mediate the allergic response by regulating the production by B cells of IgE sensitized to food allergens.

These allergen-specific antibodies attach themselves to **mast cells** (in the lungs, skin, tongue and linings of the nose and intestinal tract) or basophils (in circulation). On second exposure to the allergen, the sensitized IgE antibodies and the allergen form antibody-antigen complexes that activate granulocytes

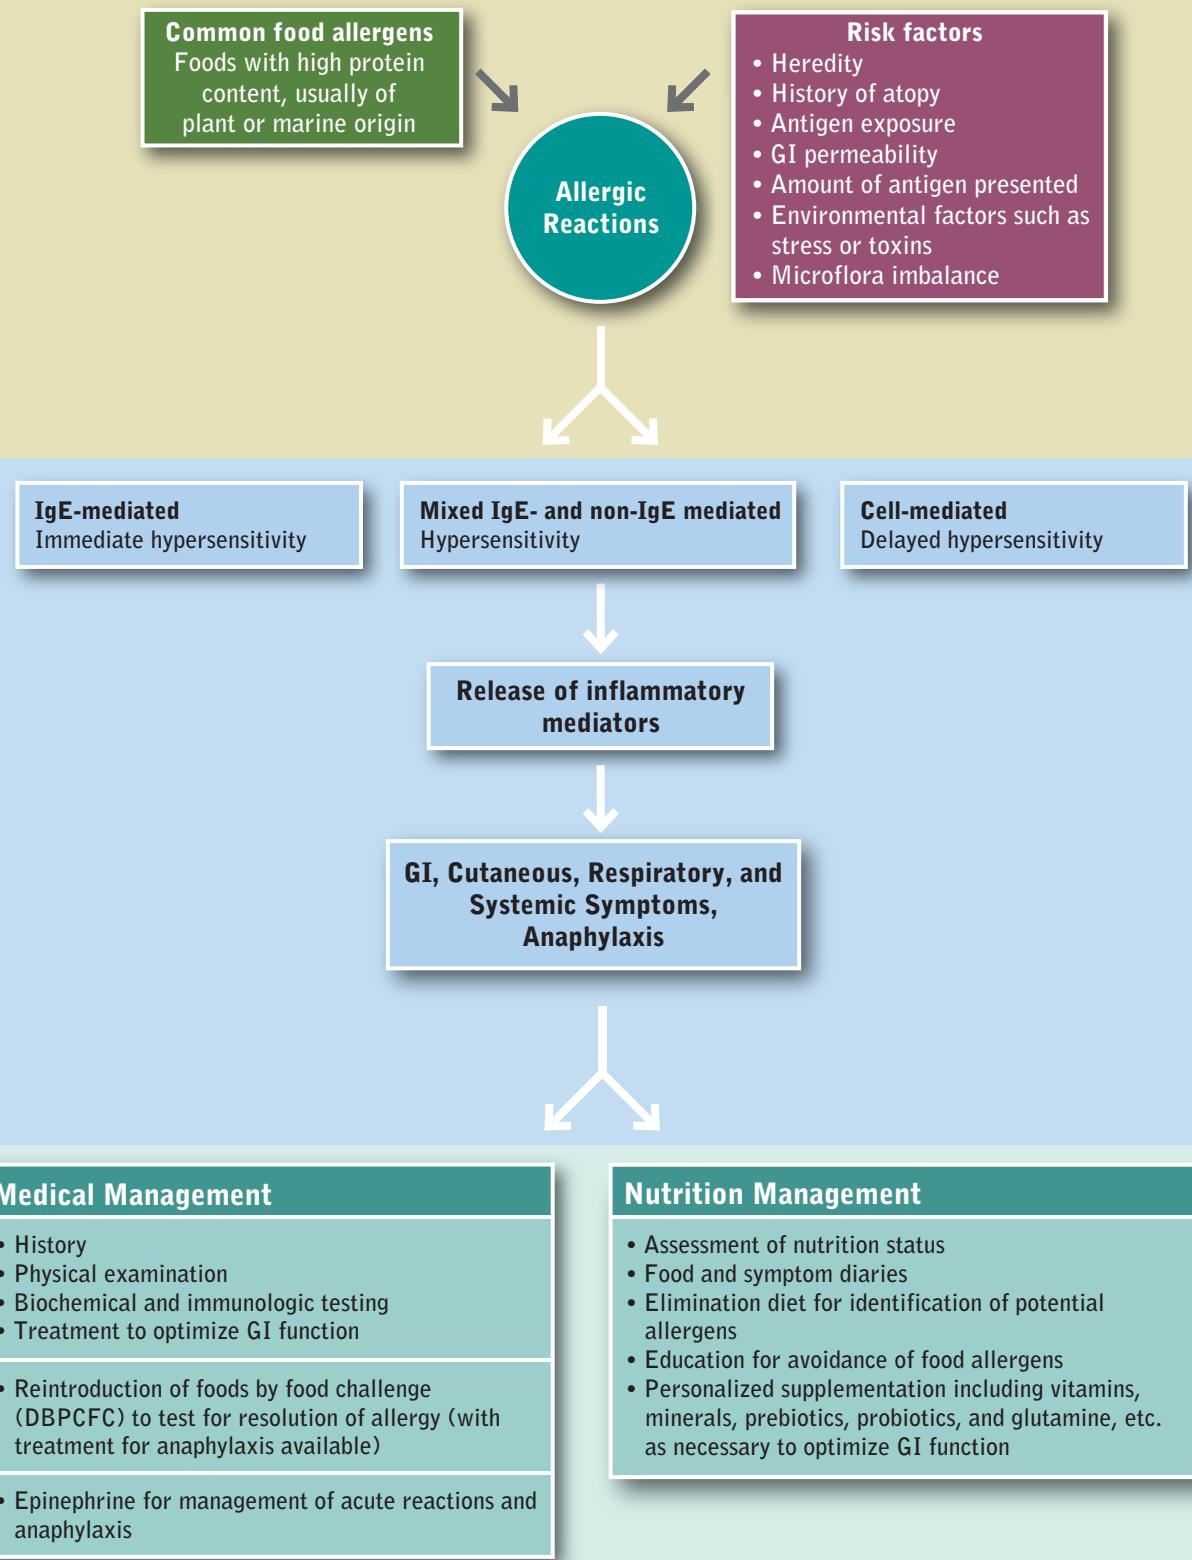

**Granulocytes** contain intracellular granules, or small vessels that are storage depots for defense chemicals or inflammatory mediators that protect the body from invading pathogens. When these granulocytes are activated, they degranulate and release these inflammatory mediators such as histamine, prostaglandins, leukotrienes, and cytokines. Each of the mediators has a specific effect on local tissues and at distant sites, resulting in the symptoms of allergy. Degranulation of other granulocytes such as neutrophils and eosinophils attracted to the reaction site by mediators such as chemokines causes release of additional inflammatory chemicals, which further enhance the allergic response, resulting in increased symptom severity.

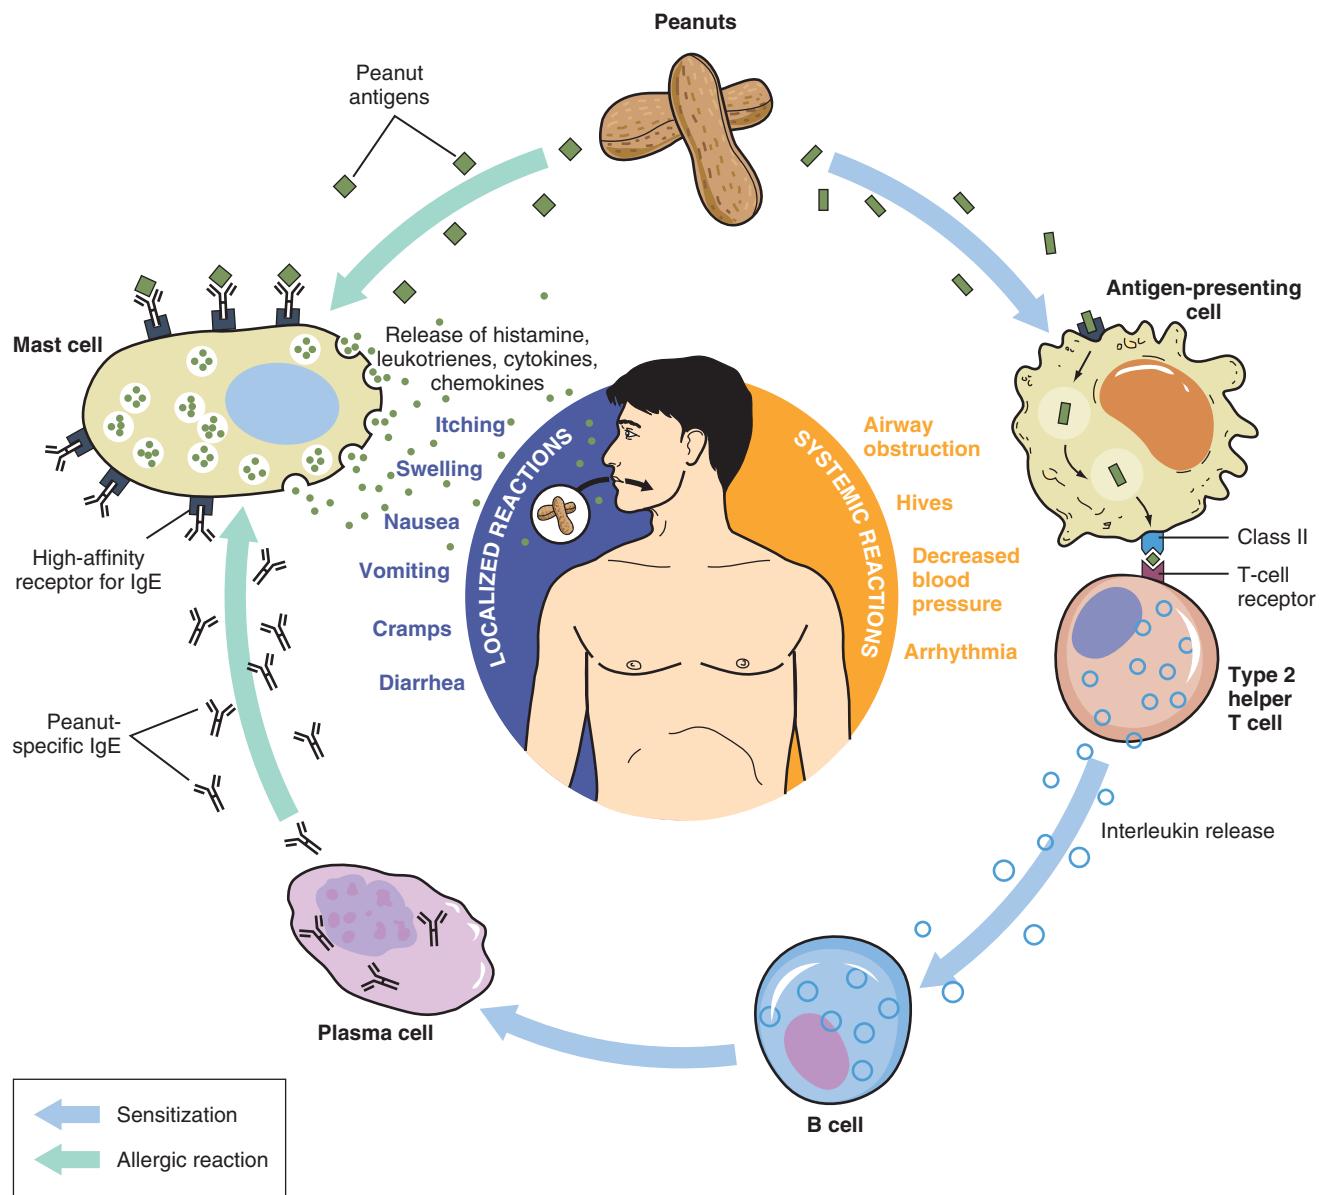

The humoral immune response is mediated by **antibodies** and has a major role in food allergy. Antigen-specific antibodies are produced by the B lymphocytes (B cells) in response to the antigen presented. The union of an antigen and antibody results in the degranulation of mast cells or basophils and the release of chemical inflammatory mediators, or direct cellular damage, which in turn causes symptoms. Each antibody contains a globulin protein; because of their association with the immune system, they are referred to as **immunoglobulins (Ig)**. Five distinct classes of

## PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

### Food Allergies

**FIGURE 27-2** Sensitization process and IgE-mediated allergic reaction.

antibodies have been identified: IgA, IgD, IgE, IgG, and IgM. Each Ig has a specific function in immunity reactions (Box 27-2).

## IgE-MEDIATED REACTIONS

IgE-mediated food allergic reactions usually are rapid in onset, occurring within minutes to a few hours of exposure. The methods of exposure include inhalation, skin contact and ingestion. A wide range of symptoms has been attributed to this type of food allergy; and frequently involve the GI, cutaneous, or respiratory systems, and can range from mild hives to life-threatening anaphylaxis Table 27-1).

A few foods account for the vast majority of IgE-mediated allergic reactions: milk, eggs, peanuts, tree nuts,

soy, wheat, fish, and shellfish. However, any food is capable of eliciting an IgE-mediated reaction after a person has been sensitized to it. Food-induced anaphylaxis, oral allergy syndrome (OAS), immediate GI hypersensitivity, latex-food allergy syndrome, and exercise-induced anaphylaxis are IgE-mediated immune reactions.

### Food-Induced Anaphylaxis

Food-induced anaphylaxis is an acute, often severe, and sometimes fatal immune response that usually occurs within a limited period following exposure to an antigen. Multiple organ systems are affected. Symptoms can include respiratory distress, abdominal pain, nausea, vomiting, cyanosis, arrhythmia, hypotension, angioedema, urticaria, diarrhea, shock, cardiac arrest, and death. The vast majority of fatal anaphylactic reactions to foods in adults in North America

**BOX 27-2****The Immunoglobulins****IgM**

The largest antibody; a first line defender that can mop up many antigens at one time.

**IgA**

Found in two forms—serum IgA and secretory IgA (sIgA). The latter is present in mucus secretions in the mouth, respiratory and gastrointestinal tracts, vagina, and colostrum in mammalian milk. It is the “first-line” defense immunoglobulin, which encounters any antigen entering from the external environment. Serum IgA is in the second highest amount in circulation, exceeded only by IgG.

**IgG**

Defends against pathogens and persists long after the threat is over; it may be responsible for some non-IgE mediated hypersensitivity reactions. Four subtypes include IgG1,

IgG2, IgG3, and IgG4. IgG4 has been implicated in some types of adverse reactions to food. Food protein-specific IgG antibodies tend to rise in the first few months after the introduction of a food and then decrease even though the food may continue to be consumed. People with inflammatory bowel disorders such as celiac disease or ulcerative colitis often have high levels of IgG and IgM (Stapel et al., 2008).

**IgE**

The classic allergy antibody of hay fever, asthma, eczema, and food-induced anaphylaxis, oral allergy syndrome, and immediate gastrointestinal hypersensitivity reactions. Immediate allergic reactions usually involve IgE and are the most clearly understood mechanisms.

**IgD**

Involved in immunoglobulin class switching and its role in allergy is not well defined.

**TABLE 27-1****Types of Allergic Reactions**

<b>Reaction/ Classification</b>	<b>IgE-Mediated</b>	<b>Mixed IgE- and Non-IgE-Mediated</b>	<b>Cell-Mediated</b>
Mechanism	The allergen binds with sensitized IgE antibodies on mast cells or basophils. Upon binding, chemical inflammatory mediators are released from the cell.	Both antibodies and T-cells are associated with triggering inflammatory mediators and the development of symptoms.	T-cells interact directly with antigen and release inflammatory mediators.
Timing	Immediate hypersensitivity; minutes to 1 hour	Delayed onset >2 hr; chronic, relapsing	Delayed onset >2 hr; chronic, relapsing
Symptomology			
Systemic	Anaphylactic shock; food-dependent, exercised-induced anaphylaxis		
Cutaneous	Acute contact urticaria, angioedema, flushing, morbilliform rash, pruritus, urticaria	Atopic dermatitis	Contact dermatitis, dermatitis herpetiformis
Gastrointestinal	Immediate gastrointestinal food allergy, oral allergy syndrome	Eosinophilic esophagitis (EE), eosinophilic gastroenteritis (EGE)	Allergic proctitis, celiac disease, FPIES, infantile colic
Respiratory	Acute rhinoconjunctivitis, asthma	Asthma	Pulmonary hemosiderosis (Heiner syndrome)

FPIES, Food protein-induced enterocolitis syndrome; Ig, immunoglobulin.

involve peanuts or tree nuts; in children anaphylaxis to other foods such as egg and milk are reported more frequently. People with known anaphylactic reactions to food allergens should carry and be prepared to use injected epinephrine via an injectable adrenaline at all times. Epinephrine is the drug of choice to reverse an allergic reaction, even with asthma (Franchini et al, 2010). Delayed use of epinephrine has been associated with an increased risk of biphasic reactions in which a recurrence of symptoms 4 to 12 hours after the initial anaphylactic reaction may be fatal.

### Oral Allergy Syndrome

The **oral allergy syndrome (OAS)**, or **pollen-food syndrome (PFS)**, results from direct contact with food allergens and is confined almost exclusively to the oropharynx and rarely involves other target organs (Hoffmann and Burks, 2008). Sensitization occurs through the respiratory system or skin (Fernandez-Rivas et al., 2006). The reaction to foods occurs as a result of the presence of an antigen within the food with a structure similar to that of the pollen. The primary sensitization is to the pollen, not the food. Symptoms are rapid and appear within minutes upon ingestion of the offending food. They include itching and irritation of oral tissues along with swelling and sometimes blisters, and most often subside within 30 minutes. OAS is most commonly seen in individuals with coexisting seasonal allergic rhinitis to birch, ragweed, or grass pollens following ingestion of specific fruits, vegetables, and some nuts. (Geroldinger-Simic et al, 2011.) The cooked fruit or vegetable is often tolerated because the reactions are caused by predominately heat-labile proteins cross-reacting with pollen proteins. However, this is not always the case and a careful history and questioning about the food is important (Kondo and Urisu, 2009). Box 27-3 lists the foods and pollens most commonly linked with OAS.

### Immediate Gastrointestinal Hypersensitivity

A range of GI symptoms can develop within minutes to 2 hours after ingestion of an offending food and may include nausea, vomiting, diarrhea, and abdominal pain. More than half of patients with food allergy have GI reactions that are mediated by IgE-dependent and independent mechanisms involving mast cells, eosinophils, and other immune cells (Bischoff and Crowe, 2005). The GI manifestations can involve eosinophilic esophagitis, or may occur in conjunction with allergic symptoms outside the digestive tract such as respiratory (wheezing) or skin symptoms (urticaria) (Sicherer and Sampson, 2010).

### Profilins and Allergy to Latex

Allergy to latex or natural rubber is common. Up to 50% of latex-sensitive individuals can respond with allergic symptoms when exposed to cross-reactive food allergens (Blanco, 2003). In the pollen-food-latex syndrome, **cross reactivity** occurs between the food antigen and various latex antigens found in many items such as latex gloves, clothing, children's toys, and other articles in the immediate environment.

### BOX 27-3

#### Foods and Pollens Involved in Oral Allergy Syndrome

Almonds	B
Apple	B
Apricot	B
Banana	R
Carrot	B
Celery	B
Chamomile	R
Cherry	B
Cucumber	R
Echinacea	R
Fennel	B
Fig	B, G

Peach	B
Pear	B
Plum	B
Potato	B
Prune	B
Pumpkin seed	B
Tomato	G
Walnut	B
Zucchini	R

B = birch pollen; R = ragweed pollen; G = grass pollen.

**Profilins** are proteins, present in all eukaryotic cells, that form allergens from pollen, latex, and plant foods (Santos and Van Ree, 2011). As a food allergen, profilin usually elicits mild oral allergy syndrome, is not modified by processing, but may be linked with allergy to melons, banana, tomato, and many of the OAS foods (see Box 27-3) (Santos and Van Ree, 2011; Condemi, 2002). Potential therapies such as curcumin may help control the allergic response (Kurup et al., 2007).

### Food-Dependent, Exercise-Induced Anaphylaxis

Food-dependent, exercise-induced anaphylaxis (FDEIA) is a distinct form of physical allergy in which an offending food triggers an anaphylactic reaction only when the individual exercises within 2 to 4 hours after eating (DuToit, 2007). The food may not be problematic in the absence of exercise. It appears to be more common in adolescent girls and young women. Celery, seafood, a gliadin component in wheat, and other foods have been reported as offending agents (Morita et al., 2009). In FDEIA, the combination

of a sensitizing food and exercise precipitates symptoms, possibly related to increased GI permeability, blood-flow redistribution, and increased osmolality (Robson-Ansley and Toit, 2010). The prevalence and causative agents and effective methods of diagnosis in FDEIA continue to be explored.

## NON-IgE-MEDIATED OR MIXED ANTIBODY REACTIONS

The contribution of non-IgE-mediated immunologic reactions to food hypersensitivity continues to be investigated. It has been postulated that non-IgE antigen-antibody complexes may play a role in food-related inflammatory diseases. These include various forms of colitis, enteritis with bleeding, malabsorptive disorders, ulceration, and chronic pneumonitis (Heiner syndrome). Non-IgE-mediated antibody reactions may also be involved in celiac disease, protein-losing enteropathies, **eosinophilic esophagitis (EE)**, **eosinophilic gastroenteritis (EGE)**, and ulcerative colitis. Multiple components of the immune system are likely to be involved with different underlying mechanisms.

### Eosinophilic Esophagitis and Eosinophilic Gastroenteritis

EE and EGE are characterized by eosinophilic infiltration of the esophagus, stomach, or intestines with peripheral eosinophilia. Both conditions can have serious consequences and distinction is important because it may influence therapy (Rothenberg, 2004). Many studies have indicated that food allergies are responsible, and almost half of the patients who present with EGE have atopic features (Eroglu et al., 2009; Roy-Ghanta et al., 2008). Identification of specific offending allergens is not always possible. A comprehensive elimination diet may improve symptoms of EE (Kagalwalla et al., 2006; Spergel et al., 2005). EGE can occur at any age and symptoms can easily be mistaken for functional GI disorders. Nutrition assessment is important with either condition because the implementation of an elimination diet aimed at identifying and excluding food antagonists can be most helpful.

## CELL-MEDIATED REACTIONS

**Cell-mediated immunity** is non-IgE-mediated and acts in response to viruses, fungi, tumor cells, and other foreign cells through its production of the controller T lymphocytes (T helper or Th cells.) Th cells are involved in most aspects of the immune response, from directing other immune cells, to responding to the recognition of a foreign antigen. However they have no cytotoxic or phagocytotic activity themselves.

When an antigen stimulates a T-cell response, the T cells produce **cytokines** which cause them to differentiate into Th-1 cells or Th-2 cells. Specific cytokines secreted by allergen-driven Th2 cells may induce B cells to produce IgE antibodies. The IgE antibodies attach to specific receptors on the surface of mast cells or basophils. Coupling of the

specific antigen with the IgE on the mast cell or basophil surface starts a series of reactions that result in the release of the inflammatory mediators stored within the mast cell and basophil granules.

Manipulating the Th1 and Th2 immune response for allergy prevention and possible protection against Th1 type autoimmune disease and Th2-mediated atopic disease is a current area of investigation. The model of Th1 and Th2 immunity will continue to evolve, moving beyond the simplistic interpretation of protective versus allergic response in view of more recent evidence on the complexities of T helper cells and cytokine production (Durrant and Metzger, 2010).

### Food Protein-Induced Enterocolitis Syndromes (FPIES)

An example of a cell-mediated reaction is **food protein-induced enterocolitis syndrome (FPIES)** which is most commonly seen in formula-fed infants, and is typically provoked by cow's milk or soy protein-based formula (Mehr et al., 2009). A response to sheep or goat's milk is less common but can also occur (Järvinen and Chatchatee, 2009.)

Occasionally FPIES is seen in breast-fed infants, presumably caused by milk proteins from the mother's diet crossing into her milk. The infant reacts with emesis, diarrhea, poor growth, and lethargy. In protein-induced proctocolitis, bloody and mucus-laden stools are also seen. Food-specific IgE antibodies have no value in this diagnosis; confirmation of FPIES is challenging because it mimics other GI inflammatory disorders. Infants should be switched to an extensively hydrolyzed casein formula. If they do not tolerate that, they may require an elemental formula. Breast-fed infants should remain on the breast, and the mother should eliminate cow's milk from her diet. FPIES is usually transient and resolves after a few weeks to months.

## FOOD INTOLERANCES

Food intolerances (**nonallergic food sensitivities**) are ARFs caused by nonimmunologic mechanisms including toxic, pharmacologic, metabolic, or idiosyncratic reactions. Food intolerances are much more common than food allergies. Clinically, it is important to distinguish food intolerance from immune-mediated food allergy. Symptoms caused by food intolerances are often similar to food allergy and include GI, cutaneous, and respiratory manifestations. See Table 27-2.

### Lactose Intolerance

Intolerance to the disaccharide lactose is the most common ARF, and most cases result from a genetically influenced reduction of intestinal lactase. Half of the world's population has hypolactasia (Jarvela et al., 2009). Abdominal bloating and cramping, flatulence, and diarrhea occur usually several hours following lactose ingestion. Because the symptoms are similar, lactose intolerance is often confused with allergy to cow's milk; however, some individuals who are allergic to cow's milk can also have respiratory or

**TABLE 27-2****Examples of Food Intolerances**

Cause	Associated Food(s)	Symptoms
<b>Gastrointestinal Disorders</b>		
<b>Enzyme Deficiencies</b>		
Lactase	Foods containing lactose and mammalian milk	Bloating, flatulence, diarrhea, abdominal pain
Glucose-6 phosphate dehydrogenase	Fava or broad beans	Hemolytic anemia
Fructase	Foods containing sucrose or fructose	Bloating, flatulence, diarrhea, abdominal pain
<b>Diseases</b>		
Cystic fibrosis	Symptoms may be precipitated by many foods, especially high-fat foods or certain proteins	Bloating, loose stools, abdominal pain, malabsorption
Gallbladder disease	Symptoms may be precipitated by high-fat foods	Abdominal pain after eating
Pancreatic disease	Symptoms may be precipitated by eating	Anorexia, nausea, dysgeusia, and other gastrointestinal symptoms
<b>Inborn Errors of Metabolism</b>		
Phenylketonuria	Foods containing phenylalanine	Elevated serum phenylalanine levels, mental retardation
Galactosemia	Foods containing lactose or galactose	Vomiting, lethargy, failure to thrive
<b>Psychological or Neurologic Reactions</b>		
	Symptoms may be precipitated by any food	Wide variety of symptoms involving any system
<b>Reactions to Pharmacologic Agents in Foods</b>		
<b>Vasoactive Amines</b>		
Phenylethylamine	Chocolate, aged cheeses, red wine	Migraine headaches
Tyramine	Aged cheeses, brewer's yeast, Chianti wine, canned fish, bananas, eggplant, tomatoes, raspberries, plums	Migraine headaches, cutaneous erythema, urticaria and hypertensive crisis in patients taking monoamine oxidase inhibitors
Histamine	Aged cheeses, fermented foods (e.g., tofu, sauerkraut), many processed meats (e.g., sausage), canned fish, beer, red wine, champagne, ketchup	Erythema, headaches, decreased blood pressure
Histamine-releasing agents	Shellfish, egg whites, chocolate, strawberries, bananas, pineapple, tomatoes, spinach, nuts, peanuts	Urticaria, eczema, pruritus
<b>Reactions to Food Additives</b>		
Tartrazine or FD&C yellow no. 5	Artificially colored yellow or yellow-orange foods, soft drinks, some medicines	Hives, rash, asthma
Benzoic acid or sodium benzoate; BHA; BHT; nitrates	Soft drinks and some cheeses, some margarines, and many processed food products and foods with preservatives	Hives, rash, asthma
Monosodium glutamate (MSG)	Asian food and foods with MSG added as a flavor enhancer	Headaches, nausea, asthma, flushing, abdominal pain

*Continued*

**TABLE 27-2****Examples of Food Intolerances—cont'd**

Cause	Associated Food(s)	Symptoms	
<b>Sulfites</b>	Sodium sulfite, potassium sulfite, sodium metabisulfite, potassium metabisulfite, sodium bisulfite, potassium bisulfite, sulfur dioxide	Shrimp, avocado, instant potatoes, dried fruits and vegetables, and fresh fruits and vegetables treated with sulfites to prevent browning, acidic juices, wine, beer, and many processed foods	Acute asthma and anaphylaxis, loss of consciousness
<b>Reactions to Microbial Contamination or Toxins in Foods</b>	Proteus, klebsiella or Escherichia coli bacteria cause histidine to break down to a histamine	Unrefrigerated scombroid fish (tuna, bonita, mackerel); heat-stable toxin produced	Scombroid fish poisoning (itching, rash, vomiting, diarrhea); anaphylactic type reaction
<i>BHA</i> , Butylated hydroxyanisole; <i>BHT</i> , butylated hydroxytoluene.			

anaphylactic reactions. Deficiencies of lactase and other carbohydrate-digesting enzymes and their management are discussed further in Chapter 29.

### Carbohydrate Intolerances

Carbohydrates, sugars, starches, and polysaccharides are complex in structure and must be broken down by enzymes for optimal digestion, absorption, and assimilation. Adverse reactions can occur if there is a deficiency of enzymes responsible for the breakdown of carbohydrates, especially disaccharides.

Maldigestion and malabsorption of the fructo-, oligo-, di-, and monosaccharides and polyols (FODMAPs) may also occur (Gibson and Shepherd, 2010). Included are the sugars and the polyols sorbitol, maltitol, and others. Intolerances lead to diarrhea, cramping, and flatulence. They appear to be more common in individuals who have an underlying functional GI disorder, such as irritable bowel syndrome. GI symptoms reported after the ingestion of fruit juice may be related to fructose intolerance, a problem from widespread use of high-fructose corn syrups in food manufacturing and processing (see Chapter 29 for discussion of the FODMAPs diet.) Tools are available for assessment of FODMAPs intake (Barrett and Gibson, 2010.)

### Food Additives or Pharmacologic Reactions

An adverse reaction may be to a food additive or pharmacologically active component in that food. Research should clarify nutritional concerns, including underlying mechanisms, genetic susceptibilities, risks from medications, food processing techniques, and food labeling. A wide range of allergic-like symptoms can result from ingestion of biogenic amines such as histamine and tyramine; salicylates; carmine (cochineal extracts); artificial food dyes and colorings such as FD & C #5; and preservatives such as benzoic acid, sodium benzoate, butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), nitrates, sulfites, and monosodium glutamate (MSG) (Joneja, 2003).

Ingestion of foods with a high histamine content, including fermented foods such as tofu and sauerkraut, aged cheeses, processed meats and fish, alcoholic beverages (champagne and red wine), and old food, may result in symptoms indistinguishable from food allergy, because histamine is an important mediator responsible for IgE-mediated hypersensitivity reactions. Foods such as strawberries, egg whites, shellfish, and some food additives (e.g., tartrazine) and preservatives (e.g., benzoates) stimulate histamine release from mast cells. Histamine intolerance or sensitivity may be suspected when an allergic cause has been ruled out (Maintz and Novak, 2007). A deficiency of the enzymes diamine oxidase or histamine-N-methyltransferase and a genetic defect in histamine metabolism have been implicated (Maintz and Novak, 2007).

Tyramine is formed from the amino acid tyrosine and can cause adverse reactions in individuals who are taking monoamine oxidase inhibitors (MAOIs), which inhibit the breakdown of tyramine. This is an example of a potentially serious ARF caused by a drug-food interaction. Fortunately, the MAOIs are used infrequently today. Tyramine is found in some fermented foods such as aged cheeses, wines, vinegars, and naturally in bananas, eggplant, raspberries, plums, and tomatoes. Ingestion may cause migraine headaches or chronic hives in tyramine-sensitive individuals, with the response being dose-dependent (Joneja, 2003). See Box 9-3 in Chapter 9 and Chapter 41.

Reactions to sulfites are most common in asthmatics and result in a range of symptoms in sulfite-sensitive individuals. These can include dermatitis, urticaria, hypotension, abdominal pain, diarrhea, and life-threatening asthmatic and anaphylactic reactions. Chronic respiratory and skin problems can also be due to sulfite sensitivity (Vally et al., 2009). The mechanisms remain unclear.

Adverse reactions to MSG were originally reported as the “Chinese restaurant syndrome” because of its use in Chinese cooking. Complaints of headache, nausea, flushing, abdominal pain, and asthma occurred after ingestion.

Glutamates are found naturally in tomatoes, Parmesan cheese, mushrooms, and other foods. Results from double-blind, placebo-controlled food challenges (DBPCFC) found symptoms from MSG to be neither persistent, clear, consistent, nor serious (Geha et al., 2000; Williams and Woessner, 2009). Considering the debate about this common flavoring agent, dietetic practitioners should be aware of MSG sensitivity.

### Food Toxins and Microbial Contaminants

Other causes of food intolerance can be mistaken for food allergy. Food toxicity or food poisoning results from microbial contamination of food and can cause nausea, vomiting, diarrhea, abdominal pain, headache, and fever. Most episodes are self-limiting and should be distinguished from food allergy through a thorough history. Pseudoallergic or anaphylactoid reactions to food can result from ingredients that mimic the effects of mast cell degranulation, but do not involve the production of antibodies (Reese et al., 2009). Some adverse reactions are triggered by physiologic reactions to foods that result from a heightened sensory response to foods.

### Unclear Adverse Reactions

The role of food allergy or intolerance in behavioral disorders (anxiety, depression, and mood disorders), neurologic disorders (migraine headache), musculoskeletal disorders (fibromyalgia, chronic fatigue syndrome), irritable bowel syndrome, and many other clinical conditions is emerging. Even if a food-symptom relationship is not proven but food avoidance is perceived as helpful because of personal experience, appropriate therapy can optimize nutritional status (Hepworth, 2010). Psychological ARFs exist and are often prevalent in individuals with underlying psychiatric disorders (Kelsay, 2003).

## ASSESSMENT

Diagnosis of ARFs requires identification of the suspected food or food ingredient, proof that the food causes an adverse response, and verification of immune- or nonimmune-mediated response. The first diagnostic tool is the detailed clinical history, followed by appropriate testing. Biochemical tests can rule out nonallergenic causes of symptoms. Tests that may be useful include a complete blood count and differential; stool tests for reducing substances, ova, parasites, or occult blood; breath hydrogen tests; intestinal permeability tests; genetic tests for celiac disease and gluten sensitivity profiles; tests for small intestinal bacterial overgrowth (SIBO); and a sweat chloride test for cystic fibrosis (see Chapters 8, 28, 29 and 35). Tests to diagnose adverse reactions to food and identify the immune response should not be used alone, but rather in conjunction with history, physical, and nutrition assessment. See Table 27-3 for a complete description of tests.

## Immunologic Testing

### Skin-Prick Test

In **skin-prick tests**, the skin is pricked and a food allergen is placed under the skin in contact with allergen-specific IgE (bound to the surface of cutaneous mast cells). These tests are the most economic immunologic tests, providing results within 15 to 30 minutes. Comparison with the positive control (histamine) and the negative control (usually the solute used for the antigen or saline) provide parameters necessary for accurate readings (see Figure 27-3). All skin-prick tests are compared with the control wheal. Test wheals that are 3 mm greater than the negative control usually indicate a positive result. Negative skin-prick tests have good negative predictive accuracy and suggest the absence of an IgE-mediated reaction. Positive skin-prick test results, however, indicate only the possibility of food allergy. In the patient with a suspected food allergy, the skin-prick test is useful in supporting the diagnosis. For children younger than 2 years of age, the skin test is reserved to confirm immunologic mechanisms after symptoms have been confirmed by a positive test result from a food challenge or when the history of the reaction is impressive.

In children with atopic dermatitis, skin-prick testing for food allergens is contraindicated because of the high reactivity of the skin, leading to false-positive reactions and the real danger of sensitization to the allergen through inflamed skin (Lack, 2008) (Figure 27-4).

All foods that test positive must correlate with a strong exposure history or be proven to cause allergic reactions through food challenges before they can be considered

**FIGURE 27-3** A skin-prick test showing the wheal and flare of the reaction to the allergen as compared with the reaction to the histamine control at the bottom.

**TABLE 27-3****Tests Used in the Assessment of Adverse Reactions to Foods**

<b>Skin Tests</b>	
Skin testing (scratch, prick, or puncture)	A drop of antigen is placed on the skin, and the skin is then scratched or punctured to allow penetration; assesses IgE-mediated sensitization.
Atopy patch test	Small pads soaked with allergen are applied to unbroken skin for 48 hours and read at 72 hours.
Intradermal testing also called skin endpoint titration (SET)	In a clinical setting, a small amount of allergen is injected directly into subcutaneous layer of skin.
Applied kinesiology also called muscle strength testing	Subject's arm is extended and foods to be tested are placed in the hand; test is considered to yield positive results if the arm moves more easily after the food has been placed in hand.
Sublingual testing	Drops of allergen extract are placed under the tongue and symptoms are recorded.
Provocation testing and neutralization	Subcutaneous injection of allergen extract elicits symptoms; this is then followed by injection of a weaker or stronger preparation to neutralize symptom.
<b>Blood Tests</b>	
CAP-FEIA	Serum is mixed with food on a paper disk and then washed with radioactively labeled IgE. Compared with RAST, this test binds more allergen; best for assessing IgE-mediated reactions.
RAST	Being replaced with CAP-FEIA test; assesses IgE-mediated sensitization.
ELISA	Much like RAST, except that no radioactive material is used; being replaced with CAP-FEIA; assesses IgE-mediated sensitization.
ALCAT	Indirect measurement of the presence of prostaglandins, cytokines, and leukotrienes released from degranulation of leukocytes in presence of allergen; measures change of leukocyte via automated computer analysis.
MRT	Indirect measurement of the presence of prostaglandins, cytokines and leukotrienes released from degranulation of leukocytes in presence of allergen; measures volume change of leukocyte via automated computer analysis.

**TABLE 27-3****Tests Used in the Assessment of Adverse Reactions to Foods—cont'd**

<b>Food Challenges</b>		
DBPCFC	Allergen is disguised and given orally and patient monitored for reaction; patient and physician blinded; also tested with placebo.	“Gold standard” for food allergy testing.
Single-blind food challenge	Suspect food is disguised from patient and orally given by physician in a clinical setting.	Less time-consuming than DBPCFC; may be used in instances in which patient experiences symptoms secondary to fear or aversion to suspect food.
Open oral food challenge	Suspect food is orally given to patient in undisguised, natural form in gradual doses under medical supervision.	Less time-consuming than DBPCFC; should not be used in instances in which patient experiences symptoms secondary to fear or aversion to suspect food.
Food elimination diets	Suspect foods are eliminated from the diet for a set period to identify foods responsible for ARF. During gradual reintroduction symptoms are carefully observed.	May help identify foods responsible for ARF; strict, long-term elimination diets may require monitoring to ensure nutritional adequacy.

*ALCAT, Antigen leukocyte cellular antibody test; BAT, basophil activation test; CAP-FEIA, CAP-fluorescein-enzyme immunoassay; CRD, component-resolved diagnostics; DBPCFC, double-blind, placebo-controlled food challenge; ELISA, enzyme-linked immunosorbent assay; Ig, immunoglobulin; MD, medical doctor; MRT, mediator release test; RAST, radioallergosorbent test; sIg, secretory immunoglobulin.*

allergenic. The most common food allergens (milk, egg, peanut, soy, wheat, shellfish, fish, and tree nuts) account for most of the positive food skin-prick tests (Nowak-Wegrzyn and Sampson, 2006).

### Serum Antibody Tests

**Food allergen-specific serum IgE testing** is used to identify foods that may be causing the allergic response. The **radioallergosorbent test (RAST)** and the enzyme-linked immunosorbent assay (ELISA), both IgE tests, are being replaced by the **CAP-fluorescein-enzyme immunoassay (FEIA)**. The

CAP-FEIA is a blood test that provides a quantitative assessment of allergen-specific IgE antibodies; higher levels of antibodies are predictors of clinical symptoms. The CAP-FEIA test has been approved for only six foods: egg, milk, peanut, fish, wheat, and soy (soy is still not as predictive) (Sampson, 2004). It is fairly effective as shown by testing known food-allergic children whose food allergies had been previously proven with DBPCFCs. Test results should be followed with either food elimination and challenge or DBPCFCs to complete the diagnostic process (Sampson, 2004). It should be noted that CAP-FEIA or skin testing

**FIGURE 27-4** Atopic eczema: An immunoglobulin E-mediated skin reaction to a food allergen. Commonly seen on the back of knees and the inside of elbows.

results for IgE sensitization may remain positive even after the child has “outgrown” the allergy, and the food can be eaten without symptoms.

### Other Tests

Many attempts have been made to suggest that **immuno-globulin G (IgG)** is an indicator of allergy, especially measured by the IgG4 fraction of the immunoglobulin. However, a positive IgG4 response to foods only indicates repeated exposure to components that are recognized as foreign proteins by the immune system; thus the clinical usefulness of IgG4 testing is questionable (Stapel et al., 2008).

Some tests indirectly measure the amount of cytokines released by lymphocytes and granulocytes upon degranulation in response to food antigen exposure. Examples of these tests are the antigen leukocyte cellular antibody test (ALCAT) and the mediator release test (MRT). These tests do not measure IgE-mediated responses. They may be useful in identifying problematic foods in cell-mediated or delayed reactions, but should be followed up with appropriate food elimination and clinical observation of the patient. (NIAID and NIH, 2010).

## MEDICAL NUTRITION THERAPY

A nutrition-focused physical examination and a complete nutrition assessment (see Chapters 4, 6, 8 and Appendices 29 and 30) should be performed. Gathered information should include the time of food ingestion relative to the onset of symptoms, a description of the most recent symptoms, a list of suspected foods, and an estimate of the quantity of food required to cause a reaction. Prenatal history, early feeding practices, and exposure is also important in a thorough history.

Measurements for infants and children should be plotted on a growth chart and evaluated in relationship to earlier measurements. Because decreased weight-for-height measurements may be related to malabsorption or food allergy

or intolerance, patterns of growth and their relationship to the onset of symptoms should be explored. Clinical signs of malnutrition should be assessed, including the evaluation of fat and muscle stores.

### Food and Symptom Diary

A 7- to 14-day **food and symptom diary** is a very useful tool for uncovering ARFs (Figure 27-5). This diary can also be used to identify possible nutrient insufficiencies and deficiencies. The food and symptom diary should include the time the food is eaten, the quantity and type of food, all food ingredients if possible, the time symptoms appear relative to the time of food ingestion, and any supplements or medications taken before or after the onset of symptoms. Other influences such as stress, physical exercise, elimination and sleep patterns can provide valuable information in piecing together the factors that affect ARFs.

The location where the reaction occurred can even be informative, providing unexpected insights into possible food sources of allergen exposure. Or the information obtained can indicate something other than a food reaction. A reaction that appears to be caused by a food when the food allergen cannot be found may actually be caused by a pet or a chemical or other environmental factor. The more information obtained about the adverse reaction, the more useful the diary. The 1- to 2-week food and symptom diary also can serve as a baseline for future interventions.

### Food-Elimination Diets

Food elimination is a useful tool in the diagnosis and management of ARFs when used in conjunction with a thorough history and nutrition assessment. With a standard **elimination diet**, suspect foods are eliminated from the diet for a specified period, usually 4 to 12 weeks, followed by a reintroduction and food-challenge phase. All forms (i.e., cooked, raw, and protein derivatives) of a suspected food are removed from the diet, and a food and symptom record is kept during the elimination phase. This record is used to ensure that all forms of suspected foods have been eliminated from the diet and to evaluate the nutritional adequacy of the diet. Elimination diets should be personalized, and may entail eliminating only one or two suspect foods at a time to see if there is improvement in symptoms. If multiple foods are suspected, a variation of the “strict” elimination diet shown in Table 27-4 could be used. Any food on the list that is suspect should be substituted with a food that is not likely to cause a reaction.

Elemental formulas, medical foods or hypoallergenic formulas can also be used for additional nutrition support with the elimination diet. An elemental formula provides high-quality calories in an easily digestible form and helps to optimize nutritional status. Because of low palatability and high cost, this should be reserved for the most restrictive cases.

After the designated elimination phase, foods are systematically reintroduced into the diet one at a time to determine any adverse reactions while the person is carefully monitored. If symptoms persist with careful avoidance of suspect

**FIGURE 27-5** Food and symptom diary.

foods, other causes for the symptoms should be considered. If a positive result has been obtained on a skin test or allergen-specific IgE blood test and symptoms improve unequivocally with the elimination of the food, that food should be eliminated from the diet until an oral food challenge is appropriate. The oral food challenge will prove or disprove a food symptom relationship. If symptoms improve with only the elimination of multiple foods, multiple food challenges are necessary.

### Oral Food Challenge

An oral **food challenge** is conducted in a supervised medical setting once symptoms have resolved and when the person is not taking any antihistamines. Foods are challenged one at a time on different days while the person is carefully observed in a medical setting for the recurrence of symptoms, thus eliminating confusion. The three types of food challenges are an open food challenge, which allows the food to be given openly; a single-blind, placebo-controlled food challenge, in which the food is hidden from the patient with at least one placebo; and a **double-blind, placebo-controlled food challenge (DBPCFC)**, in which the food is hidden from the patient and the clinician and is presented with at least one to three placebos. Increasing amounts of the offending food should be given every 15 to 60 minutes until there is a convincing, but not life-threatening, response.

The goal is to ingest 6 to 10 g of dry food or 80 mL of liquid food mixed in a masking food the patient tolerates (Nowak-Wegrzyn and Sampson, 2006). A person with a positive challenge response must be given appropriate medications to stop symptoms and be observed for an additional 1 to 2 hours. Those who are observed to have a negative challenge response should also be observed for an additional 1 to 2 hours because a reaction may occasionally occur later than expected. The amount of food tolerated under observation can then be offered at home.

The DBPCFC provides objective results by eliminating outside influences; it is the standard when attempting to establish a food and symptom relationship and to confirm a food allergy. Each DBPCFC must be personalized. Single foods (e.g., applesauce, grape juice) or tolerated food combinations can “hide” a suspect food. The product must mask any hint of the flavor, color, or texture of the suspect food or allergen. The patient should not be able to detect the differences between the “reactive” food and the placebo food. Because severe reactions can occur during a challenge, a physician must be in attendance with emergency supplies measured and ready to be administered.

After a negative DBPCFC, an open challenge should be given. In this challenge the patient is given a serving of the suspect food. Interestingly, reactions have occurred during the open challenge that did not occur in the blind challenge.

**TABLE 27-4****Guidelines for Elimination Diets**

- These guidelines emphasize foods that are naturally nutrient-rich.
- Guidelines should be personalized according to the patient's history and should eliminate other foods that are known allergens or foods that aggravate symptoms.
- Refer to label reading guidelines to avoid ingredients to be eliminated. See Boxes 27-4 through 27-10.
- Amounts should be individually tailored to energy needs.
- Suggest limiting number of spices to five to minimize dietary variables.

	<b>Foods Allowed</b>	<b>Foods To Avoid</b>
<b>Elimination Diet Level I: Milk-, egg-, and wheat-free</b>		
Animal proteins	Fish, shellfish, turkey, chicken, beef, pork	Eggs, egg substitutes containing egg whites and all products containing eggs (see Box 27-4)
Plant proteins	Beans, lentils, split peas, organic soybeans, and soy products	Nonorganic soy
Dairy alternatives	Nondairy beverage alternatives including soy beverages	Milk (cow, goat, sheep) and all products containing milk ingredients (see Box 27-5)
Grains	Amaranth, barley, buckwheat, corn, millet, oats, quinoa, rice, rye	Wheat, all forms of wheat (see Box 27-6)
Vegetables	All vegetables and starchy vegetables	Vegetable dishes containing milk, egg, or wheat (e.g., tempura, breaded, etc.)
Fruits	All fruits and 100% fruit juices	Fruit pies, pastries, cookies, etc., that contain milk, egg, or wheat
Fats and oils	Coconut oil, organic canola oil, grapeseed oil, olive oil, flaxseed oil, sesame oil, safflower oil, milk-free organic (nonhydrogenated) margarines	Butter, margarine, hydrogenated oils, shortening
Peanuts, nuts, and seeds	Peanuts, nuts, and natural nut butters, seeds and natural seed butters	Any peanut, nut, or seed product containing milk, egg, wheat (e.g., milk chocolate candy with nuts)
Beverages	Tea, herbal tea, coffee, decaffeinated tea, and coffee	Beverages containing milk (cow, goat, sheep)
Sweeteners	Cane or beet sugar, honey, maple syrup, blackstrap molasses	Artificial sweeteners
Other	Salt, pepper, herbs, and spices	Egg-, milk-, or wheat-containing condiments; all artificial ingredients, salad dressing, mayonnaise, spreads containing milk, egg, wheat
<b>Elimination Diet Level 2: More Limited</b>		
Eliminates top eight allergens (milk, egg, wheat, fish, shellfish, soybeans, peanuts, tree nuts) and corn, gluten, chocolate, sesame, coffee, tea, alcohol, and artificial ingredients		
Animal protein sources	Turkey, chicken, lean cuts beef, lamb, pork	Fish, shellfish, eggs, sausages, deli meats
Plant protein sources	Beans, lentils, split peas	Soybeans and soy products, peanuts, tree nuts
Dairy alternatives	Nondairy, soy-free, nut-free beverage alternatives (rice beverage, hempseed beverage)	Milk and all dairy alternative beverages containing soy, or tree nuts
Grains	Amaranth, buckwheat, millet, quinoa, rice, teff, tapioca, wild rice, gluten-free oat	Wheat, regular oats, barley, rye, corn, spelt, kamut, triticale
Vegetables	Most vegetables and starchy vegetables	Corn; vegetable dishes containing ingredients to avoid such as breaded, creamed, etc.
Fruits	Most fruits and 100% fruit juices	Fruit pies, pastries, cookies, etc., that contain ingredients to avoid

**TABLE 27-4****Guidelines for Elimination Diets—cont'd**

	<b>Foods Allowed</b>	<b>Foods To Avoid</b>
Fats and oils	Olive oil, coconut oil, flaxseed oil, grapeseed oil, organic canola oil, safflower oil, sunflower oil	Butter, margarine, vegetable oil, soy oil, corn oil, peanut oil, shortening, processed oils, sesame oil
Peanuts, nuts, and seeds	Seeds and seed butters	Peanuts and peanut-containing products, tree nuts and tree nut-containing products
Beverages	Herbal tea, 100% unsweetened fruit or vegetable juice, water, nondairy soy-free beverages	Coffee, caffeinated tea, other caffeinated beverages, alcoholic beverages, soft drinks
Sweeteners	Cane or beet sugar, honey, maple syrup, blackstrap molasses	Artificial sweeteners
Other	Salt, pepper, all spices	Chocolate, condiments containing any eliminated ingredient, all artificial ingredients, salad dressing, mayonnaise, spreads

**Elimination Diet Level 3: Very few foods/Limited ingredients**

Intended to be used in the short-term only.

- Animal proteins: Chicken, turkey, lamb
- Grains: Rice in any form including rice cakes and rice cereal
- Vegetables: Sautéed or steamed leafy green vegetables including spinach, kale, bok choy, collard greens, green beans, squash, sweet potatoes, potatoes
- Fruits: Pear
- Oils: Extra virgin olive oil
- Beverages: Water, herbal tea, vegetable broths (gluten-free)
- Sweeteners: Maple syrup

Occasionally symptoms may accompany the last presentation if the threshold is greater than indicated by the history. Most allergic reactions occur within 2 hours of the challenge. Non-IgE-mediated reactions may occur more than 24 hours after challenge. Monitoring of the patient should continue during this time.

If there is a clear history of a life-threatening anaphylactic reaction after eating a specific food, that food should not be challenged unless there is sufficient evidence that the person is no longer reacting to the allergen and skin test or allergen-specific IgE blood test results are negative, and then only in a controlled medical setting where epinephrine is available. Because of the risk of severe reactions and the lack of standardization of the testing procedure, many clinicians are questioning the use of the DBPCFC to document a food allergy reaction (Mullin et al., 2010).

### Avoidance of Unsafe Food

Although many food intolerances may allow some ingestion of the offending food, food allergies usually do not. Total avoidance of the unsafe food (food allergen) is the only proven treatment for food allergy. **Food immunotherapy vaccine** is a possible future treatment meant to complement food allergen avoidance, but these vaccines are still experimental (Sicherer and Sampson, 2010).

Recent research has produced encouraging evidence that **specific oral tolerance induction (SOTI)** can be achieved by

introducing the culprit food via the digestive tract in minute then increasing quantities for an extended period (Clark et al., 2009; Zapatero et al., 2008). Allergic individuals and their families need guidelines and suggestions for avoiding allergenic foods and ingredients, substituting permissible foods for restricted foods in meal planning and preparation, and selecting nutritionally adequate replacement foods (Joneja, 2007).

Additional food characteristics may be relevant. For example, recent studies suggest that 70% to 80% of young children allergic to milk or eggs can tolerate baked (heat-denatured) forms of the protein, but not the unbaked form. It is suggested that these children make IgE antibodies primarily to **conformational epitopes** (antigenic determinants on the surface of the food proteins that are recognized by the immune system) and represent those children who will naturally outgrow their food allergies (Sicherer and Sampson, 2010).

To help identify and avoid offending foods, allergy-specific lists that describe foods to avoid, state key words for ingredient identification, and present acceptable substitutes are useful and necessary in counseling (Boxes 27-4 through 27-8). Caretakers and school personnel working with the food-allergic child should be cautioned to read labels carefully before purchasing or serving food. The Food Allergy and Anaphylaxis Network, a nonprofit organization

Data from Bahna SL: Hypoallergenic formulas: optimal choices for treatment versus prevention, *Ann Allergy Asthma Immunol* 101:5, 2008; Greer FR et al: Effects of early nutritional interventions on the development of atopic disease in infants and children: the role of maternal dietary restriction, breastfeeding, timing of introduction of complementary foods, and hydrolyzed formulas, *Pediatrics* 121:183, 2008; Kneepkens CM, Meijer Y: Clinical practice: diagnosis and treatment of cow's milk allergy, *Eur J Pediatr* 168:891, 2009.

\*Individuals who must avoid all cow's milk sources frequently need a calcium supplement.

<sup>‡</sup>Goat's milk protein is similar to cow's milk protein. Those with cow's milk allergy may experience similar symptoms with goat's milk ingestion (Pessler and Nejat, 2004). Goat's milk is not recommended as a cow's milk substitute, especially in infants, because it has a high renal solute load and is very low in folic acid compared with cow's milk.

<sup>§</sup>Partially hydrolyzed: Nonhypoallergenic; contains partially digested proteins that have a molecular weight greater than extensively hydrolyzed formula protein chains. May cause a reaction in one third to one half of individuals with a cow's milk protein allergy.

<sup>¶</sup>Extensively hydrolyzed: Hypoallergenic; contains extensively digested casein or whey proteins that have a molecular weight less than partially hydrolyzed formula protein chains. Tolerated without an allergic reaction in 90% of individuals with a cow's milk protein allergy.

<sup>¶</sup>Free amino acid-based infant formula: Hypoallergenic; peptide-free formula that contains essential and nonessential amino acids. Usually tolerated by those allergic to extensively hydrolyzed formulas.

<sup>¶</sup>Soy formula: Should not be used in infants younger than 6 months old with food allergies.

\*There is a high risk of cross-contamination when eating out, especially dining at Asian restaurants.

<sup>†</sup>Several studies indicate that soybean lecithin and soy oil are frequently tolerated by individuals who are soy allergic.

<sup>‡</sup>Partially hydrolyzed: Nonhypoallergenic; contains partially digested cow's milk proteins that have a molecular weight greater than extensively hydrolyzed formula protein chains.

<sup>§</sup>Extensively hydrolyzed: Hypoallergenic; contains extensively digested casein or whey proteins that have a molecular weight less than partially hydrolyzed formula protein chains.

<sup>¶</sup>Free amino-acid-based infant formula: Hypoallergenic; peptide-free formula that contains essential and nonessential amino acids. Usually tolerated by those allergic to extensively hydrolyzed formulas.

created to support the food-allergic child, has worked with board-certified allergists and dietitians to develop an excellent education program for day-care or school programs. Food substitutions can be challenging when working within school food program guidelines and special help may be necessary.

Food ingredients to be avoided may be hidden in the diet in unfamiliar forms. When a food-sensitive person ingests a hidden allergen, the most common reason is that the "safe" food was contaminated. This may happen as a result of using common serving utensils such as at an ice cream parlor, salad bar, or deli (where the meat slicer may be used to slice both meat and cheese). Manufacturing plants or restaurants may use the same equipment to produce two different products (e.g., peanut butter and almond butter); despite cleaning, traces of an allergen may remain on the equipment between uses. Alternatively, a restaurant may use the same oil to fry both potatoes and fish (Box 27-9).

In addition, the food may have been genetically modified, changing its allergenicity. Here again, label reading is essential. See *Focus On: Genetically Modified (GM) Foods*.

Another situation that may lead to the unknowing ingestion of an allergenic food occurs when one product is used to make a second product, and only the ingredients of the second product are listed on the food label. An example is the listing of mayonnaise as an ingredient in a salad dressing without specifically listing egg as an ingredient of the mayonnaise. Labels must be read often to ensure that ingredients have not changed in the processing of the food (Box 27-10).

**BOX 27-9****Reasons Why Allergens May Contaminate a Food**

- Common serving utensils used to serve different foods
- Manufacture of two different food products using the same equipment without proper cleaning in between
- Misleading or inaccurate labels (e.g., nondairy creamers that contain sodium caseinate)
- Ingredients added for a specific purpose are listed on the label only in general terms of their purpose rather than as a specific ingredient (e.g., egg white that is simply listed as an "emulsifier")
- Addition of an allergenic product to a second product that bears a label listing only the ingredients of the second product (e.g., mayonnaise, without noting eggs)
- Switching of ingredients by food manufacturers (e.g., a shortage of one vegetable oil prompting substitution with another)
- An ingredient that is present in a food but in such a low percentage that it does not have to be listed on a label

## Genetically Modified (GM) Foods

**G**enetic engineering or modification (GM) is the process whereby a protein from one plant can be transferred to another. GM foods have been in the U.S. food supply for at least 15 years. Plants can be made to tolerate herbicides and thus be more insect resistant with changed taste, texture, and appearance. In addition GM can affect the allergenicity of the modified food in two ways: (1) by introducing allergens, or (2) by changing the level or nature of intrinsic allergens. Once a protein has been transferred, the allergenicity potential must be evaluated (Zolla, 2008). For example, GM soy and GM corn contain new transgenic proteins with allergenic properties; GM soy has up to seven times more of a known soy allergen than its non-GM counterpart (Pusztai and Bardocz, 2005). The safety evaluation of a GM food should include the gene source, how closely the new protein resembles known allergens, and how persons with known allergy to the protein transferred might react if exposed. The lack of evidence that GM food is unsafe cannot be interpreted as proof that it is safe.

There are also long-term concerns beyond those related to the presence of unknown protein allergens. A long-term study of both weaning and old mice consuming either GM corn or non-GM corn found that the mice consuming the GM corn had an increased presence of several cytokines that are specifically involved in inflammatory and allergic responses, and alterations in the numbers of B cells and T cells, indicating an abnormal response to the genetically altered corn (Finamore et al., 2008). Furthermore, it has been argued that GM foods should be subjected to the same testing and approval procedures as medicines (i.e., clinical trials) to ensure that any possibility of an adverse effect on human health from a GM food can be detected (Dona and Arvanitoyannis, 2009). Because using GM foods can complicate the elimination diet or, as already mentioned, aggravate an immune-mediated response, it may be prudent to advise those with documented food allergies to eat only organic forms of corn, soybeans, canola, and other foods for which there are GM versions in the food supply.

### BOX 27-10

#### Allergen Labeling of Foods

Since January 1, 2006 the updated **Food Allergen Labeling and Consumer Protection Act (FALCPA)** requires the top allergens to be clearly listed by manufacturers as an ingredient or following the ingredient list on food labels. This includes ingredients in any amount and also mandates specific ingredients to be listed such as the type of nut or seafood.

#### The Food Allergen Labeling and Consumer Protection Act of 2004 (FALCPA) Effective January, 2006

##### Requirements of the Law

- **Top 8 allergens must be clearly listed** by manufacturers as an ingredient or following the ingredient list on food labels of any food product containing allergens
- Applies to all packaged foods sold in the United States
- Does not apply to USDA regulated products including meat, poultry products, and some egg products
- Does not list sources of possible contamination
- Does not apply to prescription medication or alcoholic beverages

- Does not apply to foods packaged or wrapped after being ordered by the consumer

##### Top Allergens

- Any ingredient containing or derived from the top 8 allergens—milk, eggs, fish, shellfish, tree nuts, peanuts, wheat, or soybeans
- For tree nuts, fish, and shellfish the specific type must be listed (example: walnut, pecan, shrimp, tuna)

##### Reading the Food Label

- Ingredients may be included within the food's ingredient list directly or in parentheses following the name, if an ingredient does not clearly identify the allergen
- Following the list of ingredients all food allergens may be listed in a “**Contains**” statement
- Manufacturers may voluntarily list potential unintended allergens that may be present due to cross contamination in a clear way that does not interfere with the required food ingredient list

When foods are removed from the diet, alternative nutrient sources must be provided. Table 27-5 defines the levels of nutritional risk based on the types of food removed from the diet. For example, when eggs are omitted, other foods must provide choline, vitamin D, protein, and energy.

## Healing the Gut and Restoring Immune Balance

Because 70% of immune cells are located in the gut-associated lymphatic tissue (GALT), efforts to restore gut health should improve immune function and modulate allergic responses. Besides eliminating problematic foods, other

measures include optimizing stomach acidity and enzyme function; identifying and treating intestinal pathogens such as bacteria, yeasts, and parasites; restoring intestinal barrier function; and repleting nutritional stores (see Chapters 28 and 29). Sometimes after the gut is healed it is possible to institute a rotation diet where foods identified as causing allergic reactions can be consumed on a planned “rotating” basis without symptoms developing. There is some preliminary research to suggest that rotation diets in combination with probiotics may be useful in the management of food intolerances in patients with diarrhea-dominant irritable bowel syndrome (Drisko, et al, 2006). See *Clinical Insight: Rotation Diets—Where’s the Science? Are they Clinically Useful?*

## CLINICAL INSIGHT

### Rotation Diets—Where’s the Science? Are they Clinically Useful?

By Janice V Joneja, PhD, CDR

#### *With Ig-E Mediated Allergy*

There is no published evidence-based research on the use of rotation diets in the management of Ig-E mediated food allergy. Available material on the subject relies on anecdotal reports, testimonials, and directives from practitioners based on theory and perception, but no science (Teuber and Porch-Curren, 2003).

There are numerous websites claiming relief from multiple allergies with a variety of diagnostic procedures and rotation diets. There is no evidence-based research to support their claims, but the description of the management strategy and testimonials from clients is very convincing. It is critical that dietitians be aware of these claims and the enormous incentive

for the patient suffering sometimes debilitating symptoms, to believe them and follow their directives.

#### *With Non-IgE mediated allergy and food sensitivities*

Non- IgE immunologically-mediated food hypersensitivities may be dose-related. A rotation diet that restricts the number and quantity of foods known to contain the culprit component is often beneficial (Joneja, 2003). However, when the diet is used, there is no scientific basis for a 4, 5, 7 or even 30 day rotation of foods. All have been used clinically. Such diets need to be formulated on an individual basis to ensure that the dose of the reactive component is reduced to a minimum, while nutrients equivalent to those eliminated are supplied by alternative foods.

**TABLE 27-5**

### Nutritional Risk in food Allergy Management

Level of Risk	Food Characteristics/Examples
Low risk	Any food that can easily be eliminated with minimum or no nutritional risk to the patient; protein, calorie, and nutrient consumption is adequate. <i>Example:</i> Avoidance of a specific fruit or vegetable
Moderate risk	Any food that may be encountered frequently throughout the food supply yet the elimination of which does not significantly limit food choices or vital nutrient sources; questionable adequacy of protein, calorie, and nutrient consumption. <i>Example:</i> Avoidance of fish, crustaceans, or tree nuts
Complex risk	Any food that permeates the food supply, providing a significant source of specific nutrients that are not readily available through other foods that are a part of the normal diet, the elimination of which results in a significant lifestyle and dietary change because of the difficulty of avoiding that food and products containing that food; adequate protein, calorie, and nutrient consumption unlikely. <i>Example:</i> Avoidance of wheat, soy, egg, milk, peanuts, or multiple foods

## Nutritional Adequacy

The nutritional adequacy of the diet should be monitored on a regular basis by conducting an ongoing evaluation of the patient's growth, nutrition status, and food records. The omission of foods from the diet on the basis of proper or improper diagnosis can and has threatened the nutritional status of the allergic individual (Noimark and Cox, 2008). Malnutrition and poor growth may occur in children who consume inadequate elimination diets. Vitamin and mineral supplementation may be needed to prevent this, especially when multiple foods are omitted. Nutrition assessment needs to be done regularly. Because food is an important part of a person's culture, the social aspects of eating can make adherence to an elimination diet difficult. Continued support from health care providers is needed to minimize the effect of dietary changes on family and social life. The strategies listed in **Box 27-11** can help families and individuals cope with food allergies.

It was previously thought that most children would "outgrow" their food allergies by 3 years of age; however, it is becoming apparent that this is not the case. Only 11% of egg-allergic and 19% of milk-allergic children resolved their allergies by 4 years of age. However, almost 80% resolved these allergies by age 16 (Savage et al., 2007; Skripak et al., 2007).

This is not true for peanut allergy, which is considered a persistent allergy lasting a lifetime for most children (Sicherer and Sampson, 2010). Sensitization procedures show some promise (Stahl and Rans, 2011.) While about 20% of children with peanut allergy will outgrow their early allergy to peanut, it appears that, once outgrown, frequent peanut ingestion is recommended to maintain the tolerance (NIAID, 2010.)

## PREVENTING FOOD ALLERGY

Intensive research is being focused on the pathogenesis and prevention of allergic disease, including the role of genetics and environmental factors such as early dietary exposures and feeding practices. Allergy prevention guidelines have gradually shifted away from allergen avoidance to examination of the role of specific dietary factors in the development and prevention of allergic disease (Jennings and Prescott, 2010).

## Pregnancy and Infancy

### Allergen Exposure

The traditional approach for dietary allergy prevention has been avoidance of food allergens in the maternal diet and early postnatal period. However, there is a lack of evidence that maternal dietary restrictions during pregnancy help prevent atopic disease in infants. Food restriction to avoid antigen exposure while breast-feeding does not appear to prevent atopic disease, with the possible exception of atopic eczema (Greer et al., 2008). However, recent research indicates that exposure to food antigens in the "safe"

## BOX 27-11

### Strategies for Coping with Food Allergy

#### Food Substitutions

Try to substitute item-for-item at meals. For example, if the family is eating pasta for dinner, substitution of a gluten free pasta may be better accepted for the gluten sensitive person than a dissimilar item.

#### Dining Out and Eating Away from Home

Eating meals away from home can be risky for individuals with food allergies. Whether at a fancy restaurant or a fast-food establishment, inadvertent exposure to an allergen can occur, even among the most knowledgeable individuals. Here are some precautions to take:

- Bring "safe" foods along to make eating out easier. For breakfast, bring along soy milk if others will be having cereal with milk.
- Alert the wait staff to the potential severity of the food allergy or allergies.
- Question the wait staff carefully about ingredients.
- Always carry medications.

#### Special Occasions

Call the host family in advance to determine what foods will be served. Offer to provide an acceptable dish that all can enjoy.

#### Grocery Shopping

Be informed about what foods are acceptable, and read labels carefully. Product ingredients change over time; continue to read the labels on foods, even if they were previously determined to be "safe" foods. Allow for the fact that shopping will take extra time.

#### Label Reading

Labeling legislation makes it easier for individuals with food allergies to identify certain potential allergens from the ingredient list on food labels. For example, when food manufacturers use protein hydrolysates or hydrolyzed vegetable protein, they must now specify the source of protein used (e.g., hydrolyzed soy or hydrolyzed corn). Although reactions to food colors or food dyes are rare, individuals who suspect an intolerance will find them listed separately on the food label, rather than categorized simply as "food color."

environment of pregnancy and in breast milk is more likely to lead to tolerance rather than sensitization to those foods in the infant. Current trials on infant feeding are attempting to elucidate the concept of oral tolerance and define the effect that delayed introduction of solids and allergenic foods has on development of allergic disease.

## Breastfeeding

Breast milk contains a host of immunologically active compounds such as transforming growth factor-beta, lactoferrin, lysozymes, long-chain fatty acids, antioxidants, and secretory IgA (sIgA), all of which have an effect on immune development, including oral tolerance, and help to reinforce the gut-epithelial barrier (Brandtzaeg, 2009; Jennings and Prescott, 2010). Breastfeeding without any maternal dietary restrictions is strongly encouraged, although the exact role of breastfeeding in allergy prevention is unclear. There is evidence that exclusive breastfeeding for at least 3 months protects against wheezing in early life (Greer et al., 2008). For infants at high risk of developing atopic disease (infants with a first-degree relative with allergy) exclusive breastfeeding for at least 4 months is recommended (Host et al., 2008). Continuation of breastfeeding through the time when solid foods are introduced is believed to help prevent the development of food allergy (Greer et al., 2008).

Sensitivity to breast milk is rare but has been reported. Allergens in the mother's diet such as cow's milk, eggs, and peanuts can pass into the breast milk and cause sensitization and then an allergic reaction in the exclusively breast-fed infant. Food challenges to each food will determine food symptom relationships. The mother eats a suspect food before nursing, and the infant is observed for symptoms for up to 24 hours after nursing. If a food is judged to yield a positive test result through challenge, that food is eliminated from the mother's diet and she is encouraged to continue breastfeeding. The nutritional adequacy of the mother's diet should be monitored when food groups are omitted from her diet.

## Choice of Infant Formula

In infants at high risk of developing atopic disease who are not exclusively breastfed for 4 to 6 months, a partially hydrolyzed or extensively hydrolyzed formula to replace a cow's milk formula is recommended. Extensively hydrolyzed formulas may be more protective than partially hydrolyzed formulas in prevention of atopic disease (Greer et al., 2008). Soy-based infant formulas offer no advantage for the purpose of allergy prevention and some infants may react adversely to these formulas. Amino acid-based formulas may be used in allergy, but have not been adequately studied for atopy prevention. See Boxes 27-5 and 27-8.

## Solid Food Introduction

It is recommended that solid foods or complementary foods other than breastmilk or formula should not be introduced until 4 to 6 months of age. There is no convincing evidence that delaying introduction beyond this time prevents the development of atopic disease, and this also pertains to the introduction of foods that are considered to be highly allergenic such as peanuts, eggs, and fish (Greer et al., 2008; Jennings and Prescott, 2010). Although early exposure to some food antigens, such as wheat and gluten, is being promoted as a method of encouraging oral tolerance to them, this technique has not been proven to be effective (Poole et al., 2006).

## Early Diet and Immunomodulatory Factors

Dietary factors in early life may influence asthma and allergic disease development. The immunoregulatory network in newborns is orchestrated not only by microbial products but also by dietary constituents such as vitamin A, vitamin D,  $\omega$ -3 fatty acids, folate, and other micronutrients (Brandtzaeg, 2010).

## Antioxidants

Diets high in antioxidants such as  $\beta$ -carotene, vitamin C, vitamin E, zinc, and selenium may prevent the development of food allergies. There have been positive associations found between maternal antioxidant status in pregnancy and cord blood immune responses (West et al., 2010). Higher maternal intake of green and yellow vegetables, citrus fruit, and  $\beta$ -carotene during pregnancy was significantly associated with a reduced risk of eczema, but not wheezing, in the infants. Maternal vitamin E consumption was inversely related to the risk of infantile wheeze, but not eczema (Miyake et al., 2010). Thus optimizing food sources of antioxidants from fruit and vegetable intake during pregnancy may be an effective effort for allergy risk reduction.

## Folate

Folate deficiency has been associated with several disorders characterized by enhanced activation of the cellular, Th1-type immune response (Husemoen et al., 2006). An intriguing development has been the recognition of epigenetic effects of dietary folate in the development of asthma (Jennings and Prescott, 2010). Impaired folate metabolism may be related to the development of atopy, although the significance is not clear, because one study demonstrated that prenatal folate supplementation was associated with increased childhood wheezing (Miller, 2008), whereas another found the opposite (Matsui and Matsui, 2009).

## Pre- and Probiotics

Prebiotics include the nondigestible, fermentable oligosaccharides that stimulate the growth and activity of bacteria in the colon, whereas **probiotics** are live microorganisms that impart health benefits to the host. Their role in allergy prevention has not been thoroughly studied and should elucidate the effect of the individual strain, timing, dose, and environmental factors that affect colonization and host genetic factors. By supplementing during pregnancy 1 month before delivery, or providing the infant with 6 months' treatment of probiotic therapy either from the nursing mother or with direct supplementation, the incidence of infant food allergy-related atopic eczema may be reduced (Rautava et al., 2005). However, administration of probiotics to infant feeds for prevention of allergic disease requires further investigation and studies have not yielded consistent results (Osborn and Sinn, 2007).

## Polyunsaturated Fatty Acids (PUFA)

The role of polyunsaturated fatty acids ( $\omega$ -3 and  $\omega$ -6 PUFAs) in allergy development has been the subject of investigation

## CLINICAL SCENARIO

Sally is 18 months old. At birth she was unable to tolerate cow's milk-based formulas. Each feeding resulted in diarrhea and vomiting. The pediatrician recommended that her mother switch to a partially hydrolyzed casein infant formula, which Sally tolerated well. Within 2 months she developed eczema that was treated with steroid creams. Cow's milk was introduced when Sally was 12 months of age. Skin symptoms increased remarkably. When eggs and later peanut butter were introduced, she experienced immediate wheezing; watery, swelling eyes; hives; increased itchiness; and diarrhea. Sally's parents are unaware of how to look for egg or peanut sources; thus Sally has experienced several trips to the emergency room. The last reaction was much more intense. Her family physician suspects egg and peanut allergies and has sent her to see a board-certified allergist and a registered dietitian.

### Nutrition Diagnostic Statements

1. Food and nutrition-related knowledge deficit by parents related to food sources of eggs and peanuts as evidenced

by serious reactions in their daughter following ingestion.

2. Intake of unsafe foods related to ingestion of egg- and peanut-containing foods as evidenced by serious reactions to foods.

### Nutrition Care Questions

1. How many food allergen suspects are there, and what are they? Why?
2. What measures will her parents need to take if Sally is to lose sensitivity to any of the food allergens?
3. What other circumstances may arise that may warrant special instructions to caregivers?
4. How often should Sally be checked for sensitivity changes?
5. What would you tell Sally's parents to look for on food labels?
6. What nutrient substitutions must be considered?

because PUFAs have effects on immune function and inflammation. Some studies have suggested that maternal consumption of fish oil in pregnancy protects against the development of asthma, eczema, and allergic sensitization. However, a recent systematic review indicated that supplementation with  $\omega$ -3 and  $\omega$ -6 oils is unlikely to play an important role for the primary prevention of sensitization or allergic disease (Anandan et al., 2009). Further studies are needed to elucidate the role of fatty acids in allergy prevention and their role in the inflammatory cascade. In the meantime, inclusion of both plant (flaxseeds, hempseeds, chia seeds, purslane, organic soybeans, walnuts) and animal food sources (safe wild fish) of  $\omega$ -3 PUFAs in the maternal diet can be encouraged.

### Vitamin D

It has been proposed that the increase in the development of food allergy in children may be due to an increased prevalence of vitamin D deficiency. Deficiency of this vitamin in a developmentally critical period increases susceptibility to colonization of the gut with abnormal intestinal microbial flora and GI infections, contributing to an abnormally porous gut and inappropriate exposure of the immune system to dietary allergens. Vitamin D helps promote immunoregulation through T-cell differentiation and has been found to be associated with a reduced risk of infant wheezing (Jennings and Prescott, 2010). Preliminary studies suggest that early correction of vitamin D deficiency might promote mucosal immunity, healthy microbial ecology, and allergen tolerance, and may prevent food allergy development (Vassallo and Camargo, 2010).

# Medical Nutrition Therapy for Upper Gastrointestinal Tract Disorders

### KEY TERMS

achalasia  
achlorhydria  
achylia gastrica  
atrophic gastritis  
**Barrett's esophagus (BE)**  
bezoar  
**Billroth I**  
**Billroth II**  
dumping syndrome  
duodenal ulcer  
dyspepsia  
endoscopy  
**esophagogastroduodenoscopy (EGD)**  
epigastric  
esophagitis  
functional dyspepsia  
fundoplication  
gastrectomy

gastric ulcer  
gastritis  
**gastroesophageal reflux disease (GERD)**  
gastroparesis  
heartburn  
*Helicobacter pylori*  
hiatal hernia  
**lower esophageal sphincter (LES)**  
melena  
odynophagia  
parietal cells  
parietal cell vagotomy  
peptic ulcer  
pyloroplasty  
reactive hypoglycemia  
Roux-en-Y  
stress ulcer  
truncal vagotomy  
vagus nerve

Digestive disorders are among the most common problems in health care. More than 50 million visits are made annually to ambulatory care facilities for symptoms related to the digestive system. More than 10 million endoscopies and surgical procedures involving the gastrointestinal tract (GIT) are performed each year (Cherry et al., 2008). Dietary habits and specific food types can play an important role in the onset, treatment, and prevention of many GI disorders. Nutrition therapy is vital in prevention and treatment of malnutrition, deficiencies, and conditions that can develop from GIT disease, such as secondary osteoporosis or anemia.

Additionally, diet and lifestyle modifications can improve nutritional well being and quality of life by decreasing symptoms, health care visits, and associated costs. Table 28-1 describes disorders of the upper GIT, their typical symptoms, and nutritional consequences.

### ASSESSMENT PARAMETERS

Nutritional screening and careful evaluation of patients with upper GI disorders guide the patient's overall plan of care. Unintentional weight loss over time is the single most useful

**TABLE 28-1****Upper Gastrointestinal Disorders and Nutritional Consequences**

Gastrointestinal Condition	Common Symptoms	Possible Nutritional Consequences
Achalasia	Aperistalsis; delayed or incomplete relaxation of the lower esophageal sphincter in response to swallowing; dysphagia	Decreased nutritional intake leading to malnutrition, weight loss, nutrient deficiencies; considered a premalignant disorder
Cancer of the oral cavity, esophagus, or stomach	Asymptomatic, or difficulty chewing, swallowing, epigastric discomfort, delayed gastric emptying	Anorexia, decreased variety of foods, weight loss, change in food textures; may require surgery, radiation, chemotherapy, enteral feeding
Dumping syndrome after gastrectomy, pyloroplasty, fundoplication, Roux-en-Y gastric bypass surgery	Early satiety, bloating, nausea; weak, lightheaded, sweaty; later symptoms such as reactive hypoglycemia and possible cramping, diarrhea	Decreased intake, malabsorption of nutrients, weight loss, nutrient deficiencies
Duodenal ulcer	Pain several hours after meals; may be relieved by eating	Perceived food intolerances, increased or decreased food intake
Dyspepsia	Upper abdominal discomfort, bloating, especially after meals	Possible decreased intake of food variety or energy intake, gastric acid suppression may lead to nutrient malabsorption and deficiencies.
Esophageal stricture or tumor	Asymptomatic, or difficulty swallowing foods; solids may especially cause discomfort	Reduced energy and nutrient intake, weight loss.
Gastric ulcer	Vague epigastric discomfort associated with eating	Decreased intake in general, or of selected foods
GERD	Acid taste, increased belching, hoarseness, dry cough, burning sensation in upper middle of chest, sometimes spasm, difficulty swallowing, bloating	Reduced quality and quantity of dietary intake, gastric acid suppression may lead to nutrient malabsorption and deficiencies
Gastroparesis	Abdominal bloating, decreased appetite/anorexia, nausea and vomiting, fullness, early satiety, halitosis, and postprandial hypoglycemia	Reduced energy and nutrient intake, decreased nutrient use resulting from hyperglycemia, dehydration Severe cases may benefit from feeding-tube placement.

GERD, Gastroesophageal reflux disease.

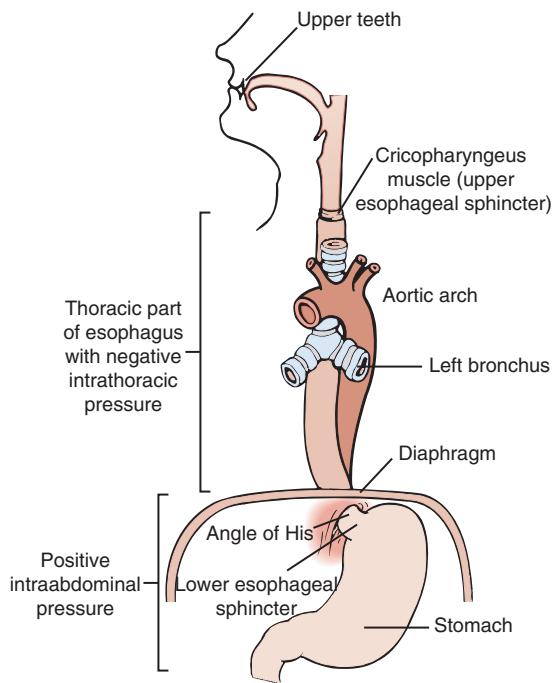

parameter, with severe malnutrition indicated by a loss of 2% or more of usual body weight in 1 week, 5% or more during 1 month, or 10% or more during 6 months. Other assessments of nutritional risk include percent of ideal body weight and body mass index. Patients who have severe weight loss benefit from beginning nutritional support early, sometimes prior to or during other medical treatments.

During the initial assessment, the clinician should also obtain an assessment of the patient's weight history, changes in appetite, nausea, vomiting, diarrhea, problems with chewing or swallowing, typical daily dietary intake, use of supplemental nutrition (oral, enteral, or parenteral), food allergies or intolerances, use of supplements (vitamins, minerals, herbs, probiotics, or protein powders), use of stool-bulking agents or laxatives, and medications. Intolerance to various foods, inadequate intake, and malabsorption can lead to nutrient deficiencies and increased morbidity.

Common laboratory values, such as B<sub>12</sub>, folate, ferritin, and 25-hydroxy vitamin D, may be useful in the initial assessment and monitoring. Other laboratory values may be useful, particularly when malabsorption or insufficient intake of certain nutrients is suspected. Patients with gastric surgeries or gastric acid suppression are at higher risk for nutrient deficiencies, such as iron or B<sub>12</sub>. In patients with gastric surgeries, deficiencies may manifest early or develop over time.

## THE ESOPHAGUS

The esophagus is a tubular organ, approximately 25 cm long, that is lined with both tubular and striated muscles. Swallowing triggers peristalsis—waves of coordinated muscles contractions. As a bolus of food is moved voluntarily from the mouth to the pharynx, the upper sphincter

**FIGURE 28-1** Normal esophagus. (Modified from Price SA, Wilson LM: *Pathophysiology: clinical concepts of disease processes*, ed 6, St Louis, 2003, Mosby.)

relaxes, the food moves into the esophagus, and peristaltic waves move the bolus down the esophagus; the **lower esophageal sphincter (LES)** relaxes to allow the food bolus to pass into the stomach (Figure 28-1). From start to finish, this process generally takes 5 seconds when in an upright position, and up to 30 seconds when in a supine position (Cordova-Fraga, 2008).

The normal esophagus has a multitiered defense system that prevents tissue damage from exposure to gastric contents, including LES contraction, normal gastric motility, esophageal mucus, tight cellular junctions, and cellular pH regulators. Dysphagia (difficulty in swallowing) may be by obstruction, inflammation, or abnormal upper esophageal sphincter function that causes derangement of the swallowing mechanism. Skeletomuscular disorders and motility disorders may result in dysphagia. For example, **achalasia** is characterized by a failure of esophageal neurons, resulting in loss of ability to relax the LES and normal peristalsis. **Odynophagia** (painful swallowing) may interfere with nutritional intake in some patients with oral or esophageal cancers.

### Gastroesophageal Reflux and Esophagitis

Regurgitation occurs in approximately half of infants in the first few months of life; most cases resolve after the first year. Reflux of gastric contents into the esophagus is a normal physiologic event that occurs daily in healthy individuals (Orlando, 2008). In **gastroesophageal reflux disease (GERD)** episodes of reflux overwhelm esophageal protective mechanisms and result in symptoms such as **heartburn**, a burning

sensation in the esophagus, or inflammation with erosion of the lining of the esophagus. Approximately 7% to 8% of the U.S. population experiences heartburn daily, and 20% to 40% of adults report symptoms of GERD at least once weekly. The prevalence of GERD in children may range from approximately 2% to 20% (Gold, 2006).

The types of GERD can be distinguished by **esophagogastroduodenoscopy (EGD)**, which uses a fiberoptic endoscope to directly visualize the esophagus, stomach, and duodenum. EGD can be useful in determining the success of treatment in erosive GERD (Yuan and Hunt, 2009). Erosive GERD is generally associated with more severe and prolonged symptoms, compared with the nonerosive esophageal reflux disease (Orlando, 2008). Some people experience GERD symptoms primarily in the evening (nocturnal GERD), which may occur as a result of decreased salivary secretions and swallowing, decreased GI motility, prolonged exposure to acid, and being in the supine position (Gerson and Fass, 2009).

### Pathophysiology

The pathophysiology of GERD is complex. The most common underlying mechanisms are thought to be reduced LES pressure, inadequate esophageal tissue defense, direct mucosal irritants, decreased gastric motility, and increased intraabdominal pressure. LES pressure decreases during pregnancy (heartburn affects up to 80% of women in their third trimester), in women taking progesterone-containing oral contraceptives, and even in the late stage of a normal menstrual cycle (Dowswell and Neilson, 2008).

The pressure of the LES may be influenced by other conditions, including hiatal hernia, scleroderma (a disease that involves hardening and tightening of skin and connective tissues), and hypersecretory diseases such as Zollinger-Ellison syndrome. Transient LES relaxations, which are induced by distension of the proximal stomach (the same stimulus for belching) are common in GERD. Patients with chronic respiratory disorders, such as chronic obstructive pulmonary disease, are at risk for GERD because of frequent increases in intraabdominal pressure. Muscle relaxants and nonsteroidal antiinflammatory drugs (NSAIDs) are the primary offending medications implicated in GERD.

The presentation of GERD symptoms varies, but may include reflux of gastric secretions, heartburn, substernal pain, belching, and esophageal spasm. In children, vomiting, dysphagia, refusal to eat, or complaints of abdominal pain may be present (Hassall, 2005). Manifestations such as pharyngeal irritation, frequent throat clearing, hoarseness, and worsening of asthmatic symptoms may also occur. The frequency and severity of symptoms do not always predict the severity or complications of the disease, and may not correlate with endoscopic findings. Some patients have few overt symptoms and relatively significant disease; others may have considerable discomfort without erosive, long-standing consequences.

Prolonged acid exposure can result in **esophagitis** (inflammation of the esophagus), esophageal erosions, ulceration, scarring, stricture, and in some cases dysphagia (see

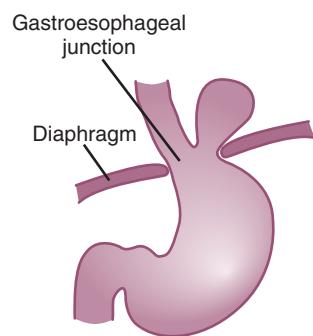

**Pathophysiology and Care Management Algorithm:** Esophagitis. Acute esophagitis may be caused by reflux, ingestion of a corrosive agent, viral or bacterial infection, intubation, radiation, or eosinophilic infiltration. Eosinophilic esophagitis is characterized by an isolated, severe eosinophilic infiltration of the esophagus manifested by GERD-like symptoms that may be caused by an immune response. See Chapter 27. Irritants such as smoking and large doses or chronic use of aspirin or NSAIDs can increase the risk of esophagitis (Pera et al., 2005).

The severity of the esophagitis resulting from gastroesophageal reflux is influenced by the composition, frequency, and volume of the gastric reflux; length of exposure of the esophagus to the gastric reflux; the health of the mucosal barrier; and the rate of gastric emptying. Symptoms of esophagitis and GERD may impair the ability to consume an adequate diet, and interfere with sleep, work, social events, and the overall quality of life.

A common contributor to gastroesophageal reflux and esophagitis is **hiatal hernia**. The presence of hiatal hernia is not synonymous with reflux, but it increases the likelihood of symptoms and complications. The esophagus passes through the diaphragm by way of the esophageal hiatus or ring. The attachment of the esophagus to the hiatal ring may become compromised, allowing a portion of the upper stomach to move above the diaphragm. The most common type of hiatal hernia is the sliding hernia, and the less common form is the paraesophageal hernia (Figure 28-2).

When acid reflux occurs with a hiatal hernia, the gastric contents remain above the hiatus longer than normal. The prolonged acid exposure increases the risk of developing more serious esophagitis (Orlando, 2008). Because increases in intragastric pressure force acidic stomach contents up into the esophagus, persons with hiatal hernia may experience difficulty when lying down or bending over. **Epigastric** pain occurs in the upper middle region of the abdomen after large, energy-dense meals. Weight reduction and decreasing meal size decreases the negative consequences of hiatal hernia.

**Barrett's esophagus (BE)** is a precancerous condition in which the normal squamous epithelium of the distal esophagus is replaced by an abnormal columnar epithelium

**FIGURE 28-2** Hiatal hernia. (Modified from Price SA, Wilson LM: Pathophysiology: clinical concepts of disease processes, ed 6, St Louis, 2003, Mosby.)

known as *specialized intestinal metaplasia*. Certain risk factors may prompt physicians to consider testing for BE, including prolonged history of GERD symptoms (>5 years), white race, male sex, older age (>50 years), and family history of BE or adenocarcinoma of the esophagus. It is estimated that 5% to 15% of persons with GERD have BE (Lichtenstein et al., 2007; Pera et al., 2005). Both GERD and BE increase a patient's risk for adenocarcinoma of the esophagus. The incidence of adenocarcinoma of the esophagus is rising at a rate exceeding all other cancers in the US—4% to 10% annually (Okoro and Wang, 2010).

### Medical and Surgical Management

The primary medical treatment of esophageal reflux is suppression of acid secretion. Proton pump inhibitors (PPIs), which decrease acid production by the gastric parietal cell, are most effective (Rohof et al., 2009), but milder forms of reflux are sometimes managed by H<sub>2</sub> receptor (a type of histamine receptor on the parietal cell) antagonists and antacids. The aim in acid-suppression therapy is to raise the gastric pH above 4 during periods when reflux is most likely to occur. (See “*Gastritis and Peptic Ulcers*” later in this chapter for side effects.) Prokinetic agents, which increase propulsive contractions of the stomach, may be used in persons who have delayed gastric emptying. Refer to Table 28-2 for medications commonly used in upper GI disorders.

Raising the head of the bed by 6 to 8 inches can reduce likelihood of nocturnal reflux. Frequent bending over should be avoided. Obesity is a contributing factor to GERD and hiatal hernia because it increases intragastric pressure, and weight loss may reduce acid contact time in the esophagus, leading to decreased reflux symptoms. Box 28-1 lists modifications that are aimed at enhancing esophageal acid

### BOX 28-1

#### Nutrition Care Guidelines for Reducing Gastroesophageal Reflux and Esophagitis

1. Avoid large, high-fat meals.
2. Avoid eating at least 3 to 4 hours before lying down.
3. Avoid smoking.
4. Avoid alcoholic beverages.
5. Avoid caffeine-containing foods and beverages.
6. Stay upright and avoid vigorous activity soon after eating.
7. Avoid tight-fitting clothing, especially after a meal.
8. Consume a healthy, nutritionally complete diet with adequate fiber.
9. Avoid acidic and highly spiced foods when inflammation exists.
10. Lose weight if overweight.

Data from National Digestive Diseases Information Clearinghouse. Accessed 17 February 2010 from <http://digestive.niddk.nih.gov/>.

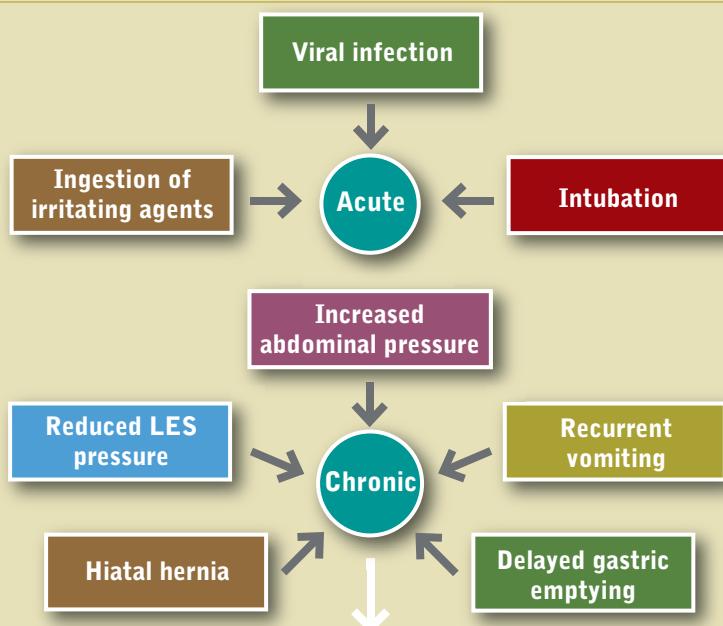

## PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

### Esophagitis

**Etiology**

**Pathophysiology**

**Management**

Reflux of gastric acid and/or intestinal contents through the lower esophageal sphincter (LES) and into the esophagus

#### Behavioral Modification

**Avoid:**

- Eating within 3-4 hours of retiring
- Lying down after meals
- Tight-fitting garments
- Cigarette smoking

#### Nutrition Management

**Goal:**

Decrease exposure of esophagus to gastric contents

**Avoid:**

- Large meals
- Dietary fat
- Alcohol

**Goal:**

Decrease acidity of gastric secretions

**Avoid:**

- Coffee
- Fermented alcoholic beverages

**Goal:**

Prevent pain and irritation

**Avoid:**

- Any food that the patient feels exacerbates his/her symptoms

#### Medical/Surgical Management

- Proton pump inhibitors
- Histamine-2 receptor antagonists
- Antacids
- Prokinetic agents
- Fundoplication

clearance, minimizing the occurrence of reflux, or both. Lifestyle interventions alone are unlikely to suffice, except in mild cases of GERD.

Of patients with severe GERD, 5% to 10% do not respond to medical therapy. They may be treated surgically with **fundoplication**, a procedure in which the fundus of the stomach is wrapped around the lower esophagus to limit reflux. Use of tobacco products is contraindicated with reflux. Smoking tobacco products decreases LES pressure

and prolongs acid clearance by decreasing salivation. Smoking also compromises GIT integrity and increases the risk of esophageal and other cancers (see *Clinical Insight: Smoking and Gastrointestinal Function*).

### Medical Nutrition Therapy

Certain diet and lifestyle changes may relieve symptoms in some patients with GERD. The main factors are caffeine, alcohol, tobacco, and stress. Other dietary factors include

### CLINICAL INSIGHT

## Smoking and Gastrointestinal Function

The gastrointestinal effects of smoking include the reduction of lower esophageal and pyloric sphincter pressure, increased reflux, alteration of the nature of the gastric contents, inhibition of pancreatic bicarbonate secretion, accelerated gastric emptying of liquids, and lower duodenal pH. The acid secretory response to gastrin or acetylcholine is increased considerably. Smoking also impairs the ability of cimetidine and other drugs to lower the overnight acid secretion that is thought to play a key role in ulcerogenesis. Nicotine is responsible for many of the effects of tobacco use; but increased exposure to hydrocarbons, oxygen radicals, and

a number of other substances is thought to also contribute to the overall effects. Finally, smoking impairs spontaneous healing and increases the risk and rapidity of ulcer recurrence, as well as the likelihood that the ulcer will perforate and require surgery.

Tobacco exposure may play a role in the development of inflammatory bowel disease (IBD). Smoking impairs the formation of granulomas in Crohn's disease (Leong et al., 2006). Passive and active smoking exposure in childhood (by age 10 to 15) seems to be associated with the development of IBD (Mahid et al., 2006).

**TABLE 28-2**

### Some Common Medications Used in the Treatment of Upper Gastrointestinal Tract Disorders

Type of Medication	Common Names	Medication Function
Proton pump inhibitor	Omeprazole Lansoprazole Esomeprazole Pantoprazole Dexlansoprazole Rabeprazole	Inhibits acid secretion
H <sub>2</sub> blocker	Cimetidine Ranitidine Famotidine Nizatidine	Blocks the action of histamine on parietal cells, decreasing the production of acid
Prokinetic	Erythromycin Metoclopramide Domperidone	Increases contractility of the stomach and shortens gastric emptying time
Antisecretory	Octreotide (somatostatin analogue) Somatostatin	Inhibits release of insulin and other gut hormones. Slows rate of gastric emptying and small intestine transit time; increases intestinal water and sodium absorption
Antidumping	Acarbose	Delays carbohydrate digestion by inhibiting alpha-glycoside hydrolase, which interferes with conversion of starch to monosaccharides
Antigas agent	Simethicone	Lowers surface tension of gas bubbles
Antacids	Magnesium, calcium, or aluminum bound to carbonate or phosphate	Buffers gastric acid

dietary fat, chocolate, coffee, onions, peppermint, spices, citrus foods, wine, and carbonated beverages.

The role of spices in the pathologic conditions related to upper GI disorders is not clear. In patients with GI lesions, foods highly seasoned with chili powder and pepper may cause discomfort. The type of chili and amount of capsaicin consumed make the difference (Milke et al., 2006). Foods such as carminatives (peppermint and spearmint) may lower LES pressure. While fermented alcoholic beverages (such as beer and wine) stimulate the secretion of gastric acid and should be limited, coffee may be used in small amounts.

Limiting or avoiding aggravating foods may improve symptoms in some individuals. There is no need to eliminate foods if they do not affect symptoms (El-Serag et al., 2005). Chewing gum has been shown to increase salivary secretions, which help to raise esophageal pH, but no studies prove efficacy when compared with other lifestyle changes.

For patients with severe esophagitis, a low-fat, liquid diet initially minimizes esophageal distention, passes more easily through any strictured areas, and empties readily from the stomach. Foods with an acidic pH including citrus juices, tomatoes, and soft drinks cause pain when the esophagus is already inflamed and should be avoided.

Identification and treatment of the main mechanism underlying the GERD is the first line of therapy. Large, high-fat meals delay gastric emptying and prolong acid secretion; avoiding those conditions prior to going to bed is often useful. Lifestyle modifications, including change in dietary practices, weight loss, smoking cessation, and elevation of the head of the bed, can reduce symptoms (see Box 28-1).

## Oral Cancer and Surgeries

### Pathophysiology

The patient diagnosed with cancer of the oral cavity, pharynx, or esophagus may present with existing nutritional problems and dysphagia or odynophagia secondary to the tumor mass, obstruction, oral infection, or ulceration. Nutritional deficits may be compounded by the treatment, which commonly involves surgical resection, radiation, or chemotherapy. Chemotherapy may produce nausea, vomiting, and anorexia (see Chapter 37). Chewing, swallowing, salivation, and taste acuity are often altered. Extensive dental decay, osteoradionecrosis, and infections may also occur.

### Surgery of the Mouth or Esophagus

Surgery of the mouth or esophagus may be necessary to remove tumors. Thus it may be necessary to provide nutrition using liquid supplements. Patients who are unable to take adequate nutrition orally for an extended time, such as those with extensive disease or those requiring major surgery, are likely to benefit from a gastrostomy tube placement. The enteral route of nutrition is preferred; however, if the GIT is not functional, parenteral nutrition can be provided (see Chapter 14).

**Tonsillectomy.** Tonsils are lymphatic tissue. Mild inflammation of the tonsils is considered a natural part of the

efforts of the immune system to fight infection. Rarely, the physician may remove the tonsils if they are too large and obstruct the ability to breathe, or for the purpose of reducing the number and frequency of ear infections, tonsillitis, and sinusitis. Cold, mild-flavored, soft, moist foods bring the most comfort to the patient and offer the most protection against unexpected bleeding from the surgical area. The patient can typically consume a normal diet within 3 to 5 days.

### Medical Nutrition Therapy

When the patient is unable to meet energy and protein needs orally for prolonged periods, tube feeding should be considered. Gastrostomy feedings can be total or supplemental; many nutritionally complete formulas are available (see Appendix 32). Enteral tube feedings are most commonly provided as ready-to-feed formulas, which are convenient and nutritionally complete. To add variety to the diet, ordinary foods such as fruits can be puréed and mixed with water until liquefied. Table foods may be prepared in a blender, but maintaining nutritional adequacy, sanitation, and a viscosity that will not clog feeding tubes is too labor-intensive to be practical for most patients or their families.

Fluid intake, artificial saliva solutions, and saline rinses may be used to prevent dry mouth. Topical anesthetics can be used to relieve pain. Because narcotic pain medications delay gastric emptying and constipation, extra fluids and a bowel regimen (stool softeners, laxatives) may be necessary.

## THE STOMACH

The mucosa of the stomach and duodenum is protected from the proteolytic actions of gastric acid and pepsin by a coating of mucus secreted by glands in the epithelial walls from the lower esophagus to the upper duodenum. The mucosa is also protected from bacterial invasion by the digestive actions of pepsin and hydrochloric acid (HCl) and the mucus secretions. HCl is secreted by the parietal cells in response to stimuli by gastrin, acetylcholine, and histamine. The mucus contains acid-neutralizing bicarbonate, and additional bicarbonate is provided by the pancreatic juice secreted into the intestinal lumen. Production of mucus is stimulated by the action of prostaglandins.

### Dyspepsia

#### Pathophysiology

**Dyspepsia** (indigestion) refers to nonspecific, persistent upper-abdominal discomfort or pain. The discomfort may be related to organic causes such as esophageal reflux, gastritis, peptic ulcer, gallbladder disease, or other identifiable pathologic conditions. Because of the variety of presentations and symptoms, dyspepsia may overlap with other problems such as GERD or irritable bowel syndrome, anxiety, and depression. Diet, stress, and other lifestyle factors may contribute to the symptoms.

**Functional dyspepsia** (nonulcer dyspepsia) describes persistent or recurrent upper GI discomfort, without underlying pathologic conditions. Symptoms of functional dyspepsia are reported in approximately 15% to 20% of adults per year and may include vague abdominal discomfort, bloating, early satiety, nausea, and belching. Underlying mechanisms are not entirely clear; visceral hypersensitivity to acid or distention, impaired gastric accommodation, altered brain-gut axis, and abnormal gastric motility and emptying have all been considered (Fajardo et al., 2005).

### Medical Nutrition Therapy

Dietary and lifestyle management is the same as for GERD. Excessive volumes of food or high intake of fat, sugar, caffeine, spices, or alcohol are commonly implicated but have not been confirmed in all cases. Delayed emptying and increased sensation of fullness are common features. Reduction of dietary fat intake, use of smaller meals, diets of low caloric density, and achieving a healthy weight may be helpful (Pilichiewicz et al., 2009). Because alcoholic beverages may alter GI functions in a number of ways, limiting intake is recommended. Mild exercise enhances movement of foodstuffs through the GIT and increases one's sense of well being. Because periods of persistent stress may contribute to functional GI disorders, behavioral management and emotional support may also help. If symptoms persist, further evaluation should be pursued to identify the underlying cause.

## Gastritis and Peptic Ulcers

### Pathophysiology

**Gastritis** and peptic ulcers result when infectious, chemical, or neural abnormalities disrupt mucosal integrity of the stomach. The most common cause is *Helicobacter pylori* infection, a gram-negative bacteria that is somewhat resistant to the acidic medium of the stomach. *H. pylori* infection induces inflammation from both innate and systemic immune response. Olfactomedin 4 is a glycoprotein that has been found to be up-regulated in *H. pylori*-infected patients, leading to expression of proinflammatory cytokines or chemokines through Nod1- and Nod2-mediated nuclear factor (NF)- $\kappa$ B activation; this inhibits host immune response and contributes to persistence of *H. pylori* colonization (Liu et al., 2010).

The prevalence of *H. pylori* infection generally correlates with geography and the socioeconomic status of the population. It ranges from approximately 10% in developed countries to 80% to 90% in developing countries. Although gastritis is a characteristic observation, only 10% to 15% of those infected by the organism develop symptomatic ulceration, and approximately 1% develop gastric cancer (Ernst et al., 2006; Fennerty, 2005).

*H. pylori* infection is responsible for most cases of chronic inflammation of the gastric mucosa and peptic ulcer, gastric cancer, and **atrophic gastritis** (chronic inflammation with deterioration of the mucous membrane and glands) resulting in achlorhydria and loss of intrinsic factor (Israel and

Peek, 2006; Selgrad et al., 2008). The infection does not resolve spontaneously, and risks of complications increase with duration of the infection. Other factors affect the risk of pathologic consequences, including the patient's age at onset of the initial infection, the specific strain and concentration of the organism, genetic factors related to the host, and the lifestyle and overall health of the patient. The infection is typically confined to the mucosa of the stomach. Treatment of *H. pylori* typically involves the use of two or three antibiotics and acid-suppressing medications. Doing so ameliorates the gastritis, reduces the conditions that favor carcinogenesis, and may improve digestive function (Bytzer and O'Morain, 2005; Guzzo et al., 2005) (see *Focus On: The Changing Face of Helicobacter pylori and Gastric Cancer*).

### FOCUS ON

## The Changing Face of *Helicobacter pylori* and Gastric Cancer

Traditionally, gastric cancer was considered a single disease. However, scientists now classify gastric cancer by its location in either the top inch of the stomach near the esophagus (gastric cardia) or the rest of the stomach (non-cardia). This new classification of gastric cancers was adopted in part because of the role of *Helicobacter pylori*.

*H. pylori* appears to be a strong risk factor for noncardia gastric cancer; however, the role of *H. pylori* in the development of gastric cardia cancer remains controversial. A study of patients in Finland investigated *H. pylori* infection in patients from blood obtained at the time of enrollment, before the patients actually developed cancer (Kamangar et al., 2006). When patients who developed cancer were compared with age-matched controls who did not develop cancer, *H. pylori* infection resulted in an eightfold increase in the incidence of noncardia gastric cancer but a 60% decrease in the incidence of cardia gastric cancer.

The decrease in gastric cardia cancer with *H. pylori* infection was an unexpected finding because previous studies had not shown this. One reason that older studies may have had misleading results was that researchers did not check for the presence of *H. pylori* until after the diagnosis of gastric cancer, and *H. pylori* does not flourish on precancerous or malignant cells.

Population studies support the protective effect of *H. pylori* on gastric cardia cancer (Whiteman et al., 2010). Developed countries have seen a decrease in this infection in recent years because of increased information, testing, and effective treatment. Concomitantly, there has been a decreased incidence of noncardia gastric cancer, but an increase in the incidence of gastric cardia and esophageal cancers in these countries. The revelation that treating *H. pylori* infection decreases the risk for some cancers but may increase the risk of other cancers is prompting more research.

## Other Forms of Gastritis

Chronic use of aspirin or other NSAIDs, steroids, alcohol, erosive substances, tobacco, or any combination of these factors may compromise mucosal integrity and increase the chance for acquiring acute or chronic gastritis. Eosinophilic gastritis may also contribute to some cases of gastritis (Whittingham and Mackay, 2005). See Chapter 27. Poor nutrition and general poor health may contribute to the onset and severity of the symptoms and can delay the healing process.

Acute gastritis refers to rapid onset of inflammation and symptoms. Chronic gastritis may occur over a period of months to decades, with waxing and waning of symptoms. Gastritis may manifest by a number of symptoms, including nausea, vomiting, malaise, anorexia, hemorrhage, and epigastric pain. Prolonged gastritis may result in atrophy and loss of stomach parietal cells, with a loss of secretion of HCl (**achlorhydria**) and intrinsic factor, resulting in pernicious anemia.

Recent studies emphasize the importance of considering side effects of chronic acid suppression either from disease or chronic use of acid-suppressing medication such as PPIs (Katz, 2010). These include reduction of gastric secretion of HCl, which has been shown to reduce absorption of nutrients such as B<sub>12</sub>, calcium, and nonheme iron, which rely on intragastric proteolysis to make them bioavailable (McColl, 2009). Acid suppression may increase incidence of some bone fractures (Gray et al., 2010), as well as increase

risk for intestinal infection, as gastric acidity is a front-line barrier to microbial invasion (Ali et al., 2009; Linsky et al., 2010).

## Medical Treatment

**Endoscopy** is a common diagnostic tool (see *Focus On: Endoscopy and Capsules*). Treatment of gastritis includes the eradication of pathogenic organisms (e.g., *H. pylori*) and withdrawal of any provoking agents. Antibiotics and PPIs are the primary medical treatments.

## Peptic Ulcers

### Pathophysiology

Normal gastric and duodenal mucosa is protected from the digestive actions of acid and pepsin by the secretion of mucus, the production of bicarbonate, the removal of excess acid by normal blood flow, and the rapid renewal and repair of epithelial cell injury. **Peptic ulcer** refers to an ulcer that occurs as a result of the breakdown of these normal defense and repair mechanisms. Typically more than one of the mechanisms must be malfunctioning for symptomatic peptic ulcers to develop. Peptic ulcers typically show evidence of chronic inflammation and repair processes surrounding the lesion.

The primary causes of peptic ulcers are *H. pylori* infection, gastritis, the use of aspirin, other NSAIDs and corticosteroids, and severe illness (see “**Stress Ulcers**” later in this chapter) (see *Pathophysiology and Care Management*

## FOCUS ON

### Endoscopy and Capsules

The mucosa of the upper gastrointestinal (GI) tract can be viewed, photographed, and biopsied by means of endoscopy, a procedure that involves passing a flexible tube into the esophagus that has a light and camera on the distal end. It can be passed through the esophagus and into the stomach or upper small bowel. This procedure is called esophagogastroduodenoscopy (EGD). Inflammation, erosions, ulcerations, changes in the blood vessels, and destruction of surface cells can be identified. These changes can then be correlated with chemical, histologic, and clinical findings to formulate a diagnosis. This may be useful when physicians suspect certain conditions, such as complicated GERD (strictures, BE, esophageal varices, or gastroduodenal ulcers.) EGD can also be used for a number of therapeutic purposes such as cauterization at ulcer sites, dilation or deployment of stents in areas of stricture, and placement of percutaneous feeding tubes.

Endoscopy may be used in long-term monitoring of patients with chronic esophagitis and gastritis because of the possibility that they will develop premalignant lesions or carcinoma (Wong et al., 2010). Recently, capsules containing a

miniaturized video camera, light, and radio transmitter that can be swallowed and the signal transmitted to a receiver worn on the waist of the patient, allow wireless capsule endoscopy. Capsule endoscopy can be used to view segments of the GIT that are not accessible by standard EGD, to screen for abnormalities or bleeding, check pH, and measure the time it takes to pass through different segments of the GIT.

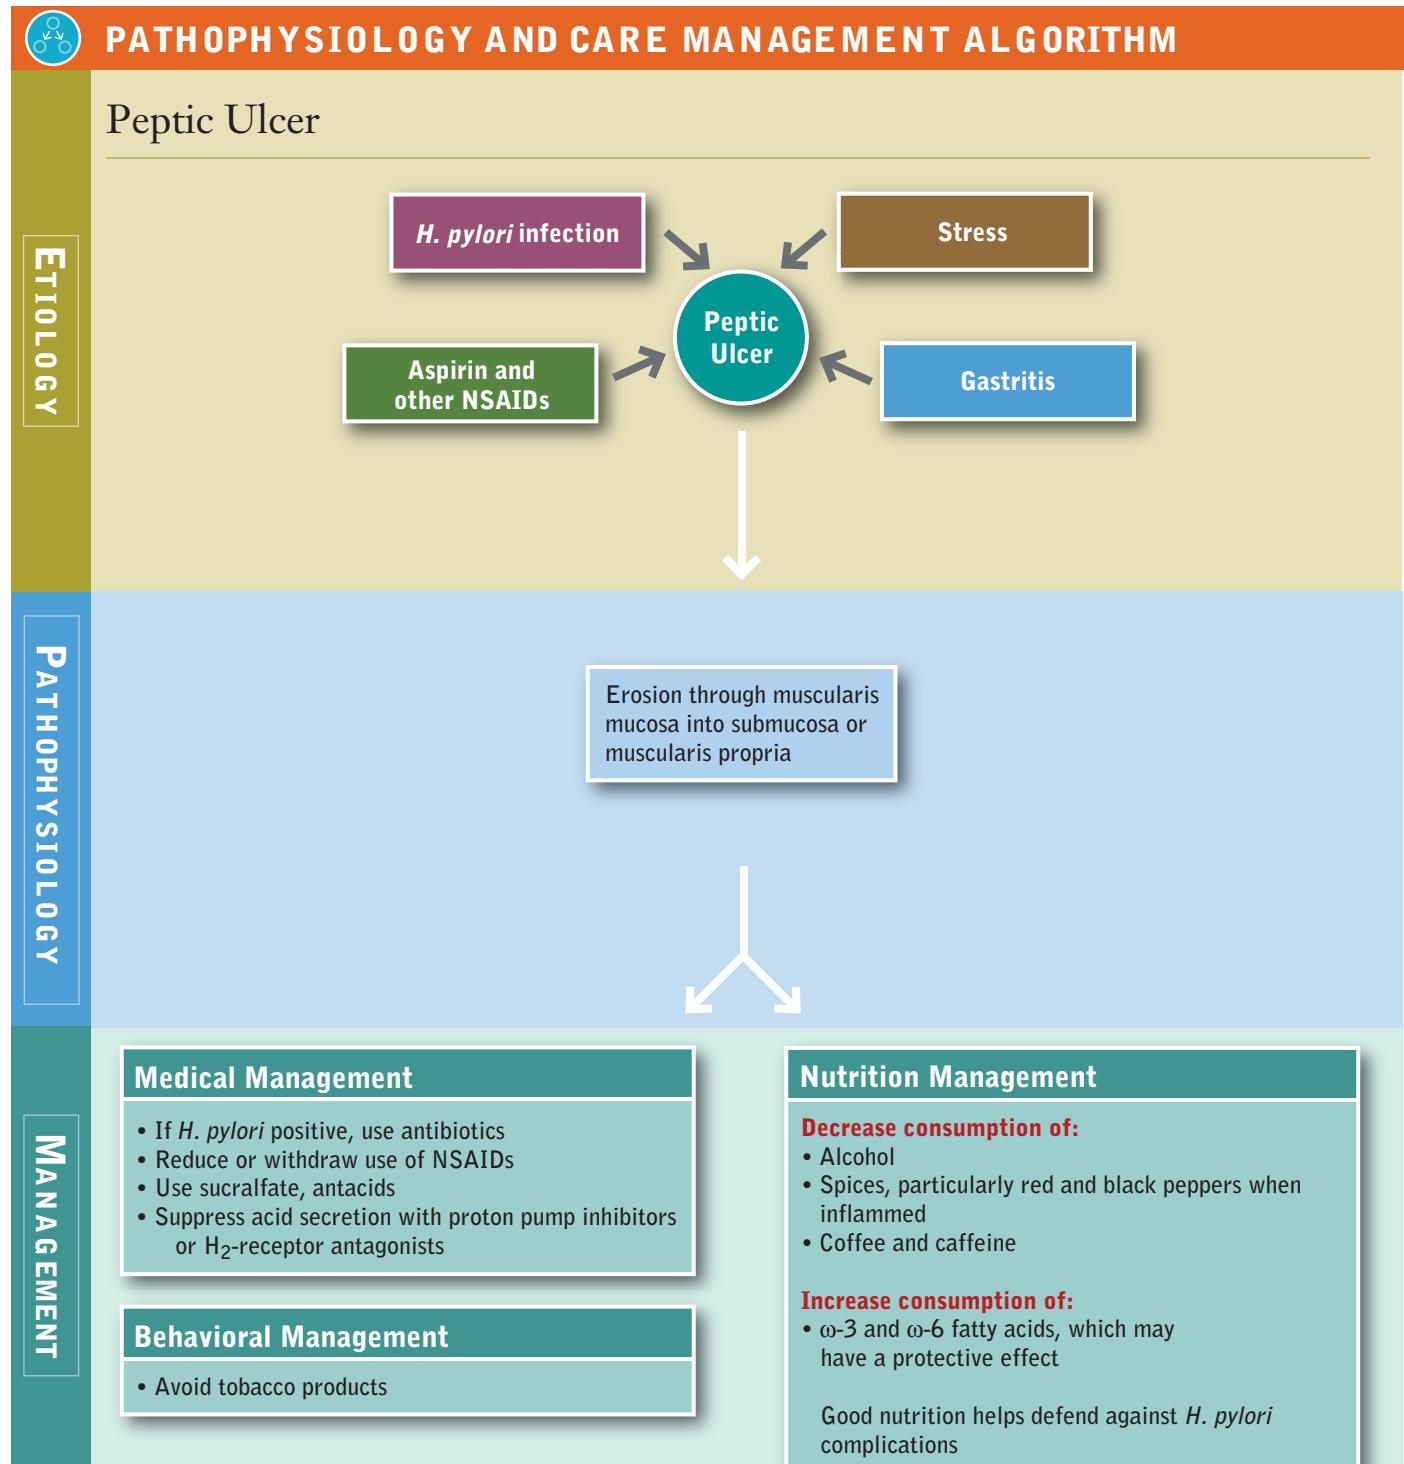

The procedure is less invasive than normal endoscopy and provides the advantage of being able to observe, record, and measure GI function as the patient is ambulatory. However, the images from capsule endoscopy can be blurred by rapid intestinal transit or limited in number after battery failure in cases of slow transit. Additionally, reviewing the thousands of images obtained after each capsule endoscopy can be very time consuming.

Prototypes of the newest generation of capsule endoscopy allow the physician to magnetically guide the capsule to a specific location by having the patient lie on a special table. Future generations of capsule endoscopy are on the drawing boards to hopefully allow therapeutic measures to be accomplished in the small bowel via capsule endoscopy.

**Algorithm:** Peptic Ulcer) (Israel and Peek, 2006). Life stress may lead to behaviors that increase peptic ulcer risk. Excessive use of concentrated forms of ethanol can damage gastric mucosa, worsen symptoms of peptic ulcers, and interfere with ulcer healing. However, modest doses of alcoholic beverages in otherwise healthy persons do not appear to cause peptic ulcers. Consumption of beer and wine increases gastric secretions, whereas low concentrations of

alcohol may not. Use of tobacco products decreases bicarbonate secretion, decreases mucosal blood flow, exacerbates inflammation, and is associated with additional complications of *H. pylori* infection. Other risk factors include gastrinoma and Zollinger-Ellison syndrome (see Chapter 30).

As a result of earlier screening for *H. pylori* and early recognition of the symptoms and risk factors associated with peptic ulcers, their incidence and prevalence and the number

of surgical procedures related to them have decreased markedly in the last three decades.

Peptic ulcers normally involve two major regions: gastric and duodenal. Uncomplicated peptic ulcers in either region may present with signs similar to those associated with dyspepsia and gastritis. Abdominal pain or discomfort is characteristic of both gastric and duodenal ulcers, although anorexia, weight loss, nausea and vomiting, and heartburn may occur slightly more often in persons with gastric ulcers. In some patients peptic ulcers are asymptomatic.

Complications of hemorrhage and perforation contribute significantly to the morbidity and mortality of peptic ulcers. Ulcers can perforate into the peritoneal cavity or penetrate into an adjacent organ (usually the pancreas), or they may erode an artery and cause massive hemorrhage. **Melena** refers to black, tarry stools that are common in peptic ulcer disease, especially in older adults. Melena may suggest either acute or chronic upper GI bleeding.

## Gastric versus Duodenal Ulcers

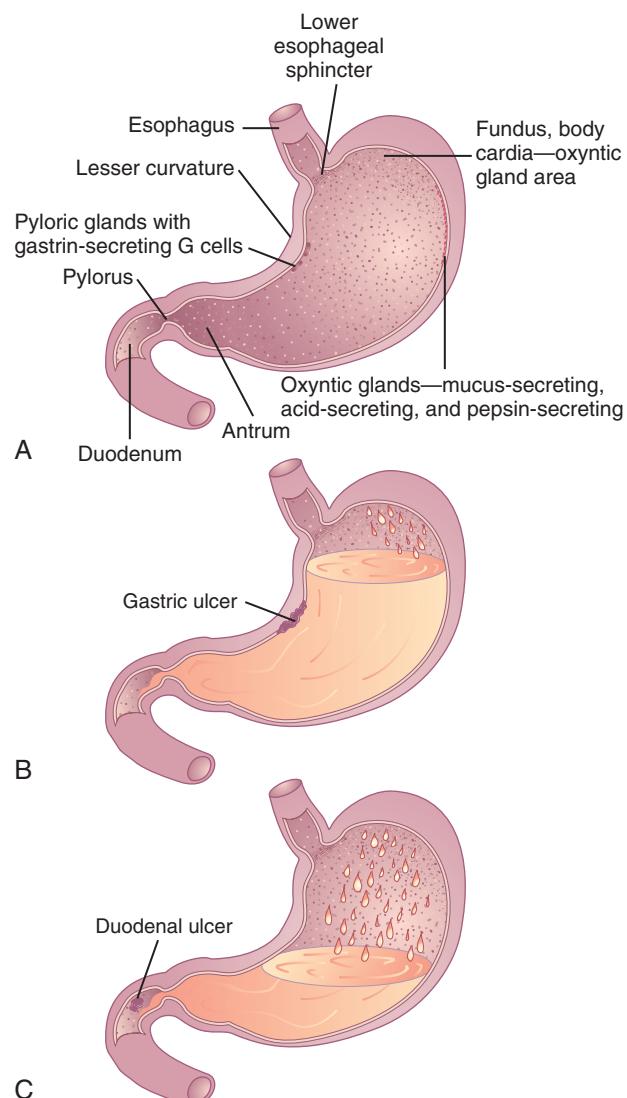

### Pathophysiology

Although **gastric ulcers** can occur anywhere in the stomach, most occur along the lesser curvature of the stomach (Figure 28-3). Gastric ulcers typically are associated with widespread gastritis, inflammatory involvement of parietal (acid-producing) cells, and atrophy of acid- and pepsin-producing cells with advancing age. In some cases gastric ulceration develops despite relatively low acid output. Antral hypomotility, gastric stasis, and increased duodenal reflux are common in gastric ulcer and, when present, may increase the severity of the gastric injury. With a gastric ulcer, hemorrhage and overall mortality are higher than with a duodenal ulcer.

A **duodenal ulcer** is characterized by increased acid secretion, nocturnal acid secretion, and decreased bicarbonate secretion. Most duodenal ulcers occur within the first few centimeters of the duodenal bulb, in an area immediately below the pylorus. Gastric outlet obstruction occurs more commonly with duodenal ulcers than with gastric ulcers, and gastric metaplasia (i.e., replacement of duodenal villous cells with gastric-type mucosal cells) may occur with duodenal ulcer related to *H. pylori*.

### Medical and Surgical Management of Ulcers

**Peptic Ulcers.** The primary cause of gastritis and peptic ulcers is *H. pylori* infection; therefore the primary focus of treatment in most cases is the eradication of this organism with the appropriate antibiotic and acid suppressive regimen. As a result of the ability to recognize and eradicate *H. pylori*, surgical intervention for peptic ulcer management is less frequent, although emergent and elective surgeries are still needed for complications. Interventions may include endoscopic, open, and laparoscopic procedures to treat individual lesions, to partial gastrectomy and selective vagotomies. One measure includes regular use of protective foods that contain phenolic antioxidants such as cranberries or ginger extracts (*Zingiber officinale*), which may have the capacity to

**FIGURE 28-3** Diagram showing A, the normal stomach and duodenum; B, a gastric ulcer; and C, a duodenal ulcer.

help eradicate *H. pylori* (Siddaraju and Dharmesh, 2007; Vattem et al., 2005).

**Stress Ulcers.** **Stress ulcers** may occur as a complication of severe burns, trauma, surgery, shock, renal failure, or radiation therapy. A primary concern with stress ulceration is the potential for significant hemorrhage. Gastric ischemia with GI hypoperfusion, oxidative injury, reflux of bile salts and pancreatic enzymes, microbial colonization, and mucosal barrier changes have also been implicated. The true mechanisms are not completely understood, but the use of antioxidant compounds shows promise (Zhu and Kaunitz, 2008).

Stress ulcers that bleed can be a significant cause of morbidity in critically ill patients, but knowledge of effective prevention and treatment is still incomplete. Sucralfate, acid suppressives, and antibiotics as necessary are used for prophylaxis and therapy (Kallet and Quinn, 2005; Stollman and Metz, 2005). Efforts to prevent gastric ulcers in stressed patients have focused on preventing or limiting conditions

leading to hypotension and ischemia and coagulopathies. Avoiding NSAIDs and large doses of corticosteroids is also beneficial. Providing oral or enteral feeding (when possible) increases GI vascular perfusion and stimulates secretion and motility.

### Medical Nutrition Therapy

In persons with atrophic gastritis, vitamin B<sub>12</sub> status should be evaluated because a lack of intrinsic factor and acid results in malabsorption of this vitamin (see *Chapters 3 and 33*). Low acid states result in reduced absorption of iron, calcium, and other nutrients because of the role of gastric acid in increasing their bioavailability. In the case of iron-deficiency anemia, other causes may be the presence of *H. pylori* and gastritis. Eradication of *H. pylori* has resulted in improved absorption of iron and increased ferritin levels (Hershko and Ronson, 2009).

For several decades dietary factors have gained or lost favor as a significant component in the cause and treatment of dyspepsia, gastritis, and peptic ulcer disease. There is little evidence that specific dietary factors cause or exacerbate gastritis or peptic ulcer disease. Protein foods temporarily buffer gastric secretions, but they also stimulate secretion of gastrin, acid, and pepsin. Milk or cream, which in the early days of peptic ulcer management was considered important in coating the stomach, is no longer considered medicinal.

The pH of a food has little therapeutic importance, except for patients with existing lesions of the mouth or the esophagus. Most foods are considerably less acidic than the normal gastric pH of 1 to 3. The pH of orange juice and grapefruit is 3.2 to 3.6, and the pH of commonly used soft drinks ranges from approximately 2.8 to 3.5. On the basis of their intrinsic acidity and amount consumed, fruit juices and soft drinks are not likely to cause peptic ulcers or appreciably interfere with healing. Some patients express discomfort with ingestion of acidic foods, but the response is not consistent among patients, and in some, symptoms may be related to heartburn.

Consumption of large amounts of alcohol may cause at least superficial mucosal damage and may worsen existing disease or interfere with treatment of the peptic ulcer. Modest consumption of alcohol does not appear to be pathogenic for peptic ulcers unless coexisting risk factors are also present. On the other hand, beers and wines significantly increase gastric secretions and should be avoided in symptomatic disease.

Both coffee and caffeine stimulate acid secretion and may also decrease LES pressure; however, neither has been strongly implicated as a cause of peptic ulcers outside of the increased acid secretion and discomfort associated with their consumption.

When very large doses of certain spices are fed orally or placed intragastrically without other foods, they increase acid secretion and cause small, transient superficial erosions, inflammation of the mucosal lining, and altered GI permeability or motility. Most often incriminated are chili, cayenne,

and black peppers (Milke et al., 2006). Small amounts of chili pepper or its pungent ingredient, capsaicum, may serve to increase mucosal protection by increasing production of mucus; but large amounts may cause superficial mucosal damage, especially when consumed with alcohol. Interestingly, another spice, curcumin, through its antiinflammatory activity that inhibits NF-κB pathway activation may be a chemopreventive candidate against *H. pylori*-related cancer (Zaidi et al., 2009).

The synergy of food combinations may inhibit the growth of *H. pylori*. Food provides an interesting alternative to therapies that include antibiotics, PPIs, and bismuth salts (Kennan et al., 2010). Studies suggest that green tea, broccoli sprouts, black currant oil, and kimchi (fermented cabbage) help with *H. pylori* eradication. Probiotics containing *lactobacillus* and *bifidobacterium* have also been studied for prevention, management, and eradication of *H. pylori* (Lionetti et al., 2010; Sachdeva and Nagpal, 2009). More controlled studies with different foods and combinations of probiotics would be beneficial.

Omega-3 and omega-6 fatty acids are involved in inflammatory, immune, and cytoprotective physiologic conditions of the GI mucosa, but they have not yet been found to be effective for treatment. Long-term clinical trials have not been performed. Overall, a high-quality diet without nutrient deficiencies may offer some protection and may promote healing. Persons being treated for gastritis and peptic ulcer disease should be advised to avoid foods that exacerbate their symptoms, and to consume a nutritionally complete diet with adequate dietary fiber from fruits and vegetables.

### Carcinoma of the Stomach

#### Pathophysiology

Because symptoms are slow to manifest themselves and the growth of the tumor is rapid, carcinoma of the stomach is frequently overlooked until it is too late for a cure. Loss of appetite, strength, and weight frequently precede other symptoms. In some cases **achylia gastrica** (absence of HCl and pepsin) or achlorhydria (absence of HCl in gastric secretions) may exist for years before the onset of gastric carcinoma.

Consumption of fruits, vegetables, and selenium appears to have a modest role in the prevention of GI cancers, whereas alcohol consumption and overweight increase the risk (van den Brandt and Goldbohm, 2006). Other factors that may increase the risk of gastric cancer include chronic infection with *H. pylori*, smoking, intake of highly salted or pickled foods, or inadequate amounts of micronutrients (Lynch et al., 2005).

Malignant neoplasms of the stomach can lead to malnutrition as a result of excessive blood and protein losses or, more commonly, because of obstruction and mechanical interference with food intake. Most cancers of the stomach are treated by surgical resection; thus part of the nutritional considerations includes partial or total resection of the stomach, a **gastrectomy**.

## Medical Nutrition Therapy

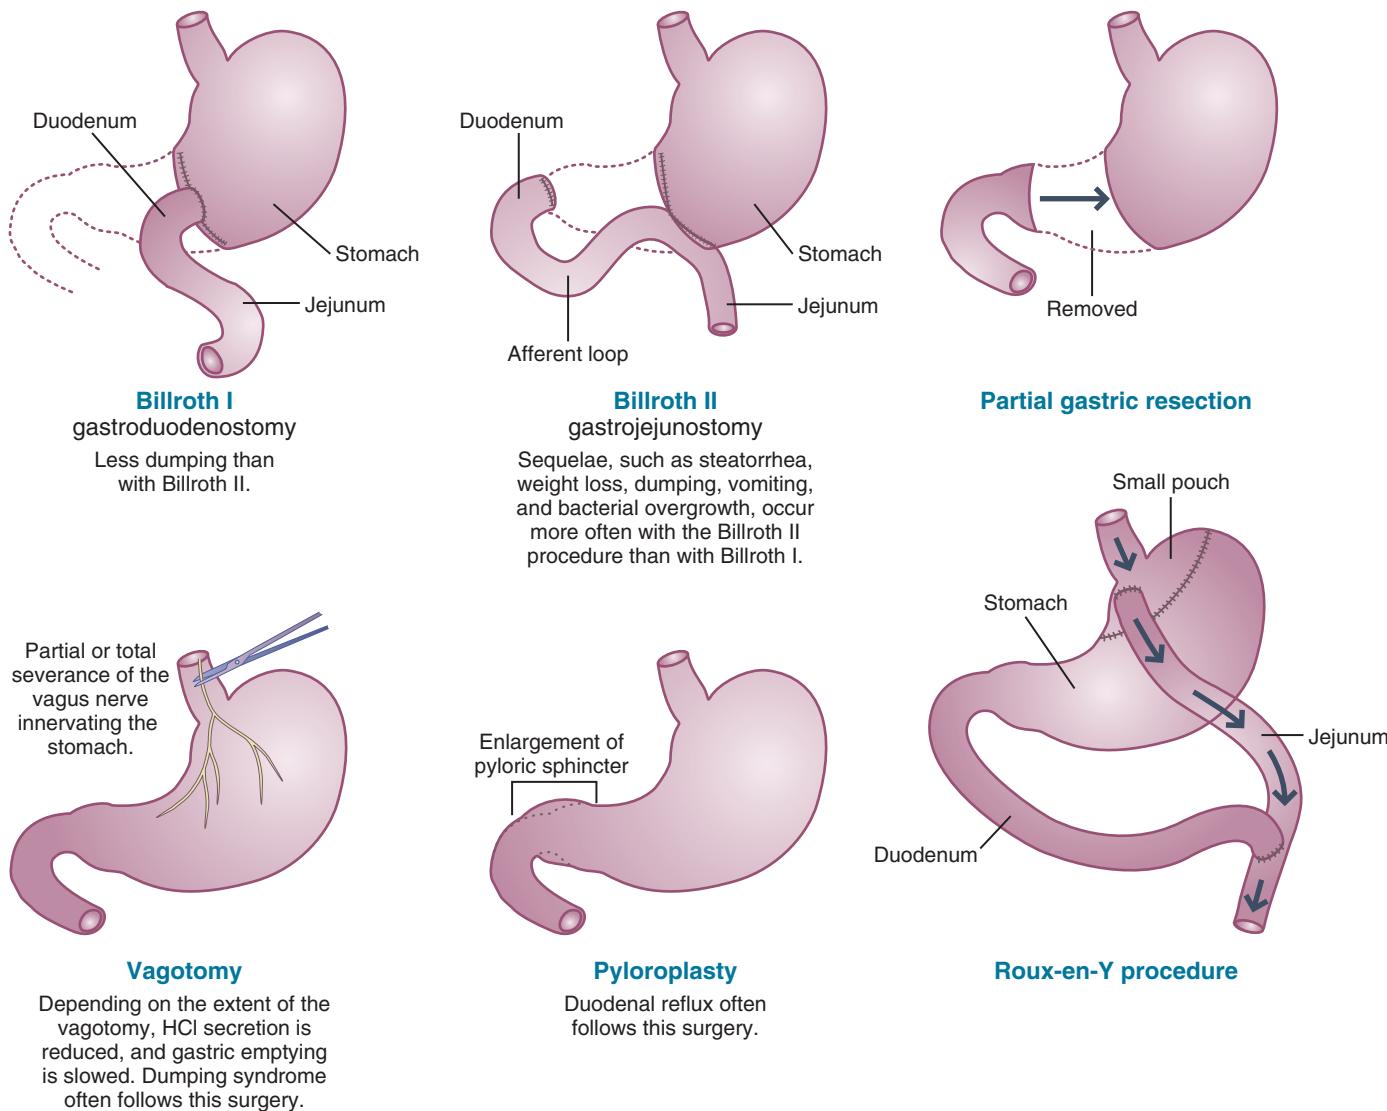

The dietary regimen for carcinoma of the stomach is determined by the location of the cancer, the nature of the functional disturbance, and the stage of the disease. Gastrectomy is one of the possible therapies, and some patients may experience difficulties with nutrition after surgery. The patient with advanced, inoperable cancer should receive a diet that is adjusted to his or her tolerances, preferences, and comfort. Anorexia is almost always present from the early stages. In the later stages of the disease, the patient may tolerate only a liquid diet. If a patient is unable to tolerate oral feeding, consideration should be given to using an alternate route, such as a gastric or intestinal feeding tube, or in the case of the inability to feed enterally, parenteral nutrition. The nutritional support for the patient should be in line with the patient's goals of care.

## Gastric Surgeries

Gastric surgeries are performed less frequently today, because of increased recognition and improved treatment of *H. pylori* and acid secretion. However, partial or total gastrectomy may still be necessary for patients with ulcer disease that does not respond to therapy, or with malignancy (Figure 28-4). Gastric surgeries performed for weight loss, or bariatric surgeries, are becoming increasingly common. These surgeries, such as Roux-en-Y, gastric bypass, gastric banding, vertical banding gastroplasty, and jejunointestinal bypass, are designed to induce malnutrition through volume restriction, malabsorption, or both (see Chapter 22).

### Types of Surgeries

A partial gastrectomy involves removal of the gastrin-secreting antrum, as much as 75% of the distal stomach.

**FIGURE 28-4** Gastric surgical procedures.

During surgery, the remnant stomach may be reattached to the duodenum, a **Billroth I**, or to the side of the jejunum, a **Billroth II**. In a Billroth II, the duodenal stump is preserved, allowing for the continued flow of bile and pancreatic enzymes into the intestines.

Vagotomy, with or without gastric resection, was developed after it was demonstrated that the **vagus nerve** was not only responsible for motility of the stomach but also stimulated the parietal cells in the proximal stomach to secrete acid. **Truncal vagotomy**, complete severing of the vagus nerve on the distal esophagus, decreases acid secretion by **parietal cells** in the stomach and decreases their response to gastrin, but it also creates poor gastric emptying. When truncal vagotomy is performed, a drainage procedure such as **pyloroplasty** is performed to allow better gastric emptying of solids. A **parietal cell vagotomy** (partial or selective) divides and severs only the vagus nerve branches that affect the proximal stomach where gastric acid secretion occurs, whereas the antrum and pylorus remain innervated, and gastric emptying can proceed more normally.

Total gastrectomy is performed for malignancies that affect the middle or upper stomach. The entire stomach is removed and usually reconstructed with the Roux-en-Y method. The total gastrectomy, by definition, involves a functional vagotomy, eliminating acid production.

### Postoperative Medical Nutrition Therapy

After most types of gastric surgery, oral intake of foods and fluids is initiated as soon as it is determined that the patient's GIT is functioning. Small, frequent feedings of ice or water are initiated, followed by liquids and easily digested solid foods, after which the patient can progress to a regular diet. If the surgery requires an extended period for healing, or the patient is unable to tolerate an oral diet, the patient may be fed through a feeding tube, such as a jejunostomy (see Chapter 14).

Understanding the surgery performed and patient's resulting anatomy is paramount to providing proper nutritional care. Nutritional complications after gastric surgeries are varied. Complications such as obstruction, dumping, abdominal discomfort, diarrhea, and weight loss may occur, depending on the nature and extent of the disease and surgical interventions (see Figure 28-4). Patients may have difficulty regaining normal preoperative weight because of inadequate food intake related to (1) early satiety, (2) symptoms of dumping syndrome (see later in this chapter), or (3) malabsorption of nutrients.

Patients with certain gastric surgeries, such as Roux-en-Y, are set up for impaired digestion and absorption caused by a mismatch in timing of entry of food into the small intestine and the release of bile and pancreatic enzymes. Patients who were lactose tolerant before gastric surgery may experience relative lactase deficiency, either because food enters the small intestine further downstream or because the rate of transit through the proximal small intestine is increased. Because of the complications of reflux or dumping syndrome associated with traditional

gastrectomies, other procedures are used, including truncal, selective, or parietal cell vagotomy, pyloromyotomy, antrectomy, Roux-en-Y esophagojejunostomy, loop esophagojejunostomy, and pouches or reservoirs made from jejunal or ileocecal segments (Tomita, 2005).

Over the long term, anemia, osteoporosis, and select vitamin and mineral deficiencies may occur as a result of malabsorption or limited dietary intake. Iron deficiency may be attributable to loss of acid secretion. Gastric acid normally facilitates the reduction of iron compounds, allowing their absorption. Rapid transit and diminished contact of dietary iron with sites of iron absorption can also lead to iron-deficiency anemia.

Vitamin B<sub>12</sub> deficiency may cause a megaloblastic anemia. If the amount of gastric mucosa is reduced, intrinsic factor may not be produced in quantities adequate to allow for complete vitamin B<sub>12</sub> absorption, and pernicious anemia may result. Bacterial overgrowth in the proximal small bowel or in the afferent loop contributes to vitamin B<sub>12</sub> depletion because bacteria compete with the host for use of the vitamin. Therefore after gastrectomy patients should receive prophylactic vitamin B<sub>12</sub> supplementation (injections) or take synthetic oral supplementation.

### Dumping Syndrome

#### Pathophysiology

The **dumping syndrome** is a complex GI and vasomotor response to the presence of larger-than-normal quantities of hypertonic foods and liquids in the proximal small intestine. Dumping syndrome usually occurs as a result of surgical procedures that allow excessive amounts of liquid or solid foods to enter the small intestine in a concentrated form. Milder forms of dumping may occur to varying degrees in persons without surgical procedures, and most of the symptoms can be reproduced in normal individuals by infusing a loading dose of glucose into the jejunum (Ukleja, 2005). Dumping may occur as a result of total or partial gastrectomy, manipulation of the pylorus, after fundoplication, vagotomy, and after some gastric bypass procedures for obesity (Ukleja, 2005). As a result of better medical management of peptic ulcers, use of selective vagotomies, and newer surgical procedures to avoid complications, classic dumping is less frequently encountered in clinical practice.

Symptoms can be divided into early, mid, and late stages of dumping of foods and beverages into the small intestine. Early dumping is characterized by both GI and vasomotor symptoms, whereas late dumping is predominantly characterized by vascular symptoms. Characteristics and severity of symptoms vary between patients. In early dumping, patients may experience abdominal fullness and nausea within 10-30 minutes of eating a meal. These symptoms are attributed to accelerated gastric emptying of hyperosmolar solution into the small bowel, and resultant fluid shifts from the circulation into the bowel. It is thought that patients with these early dumping symptoms are experiencing a decrease in peripheral vascular resistance and perhaps visceral pooling of blood.

In the intermediate stage, from 20 minutes to more than 1 hour after eating, patients may experience abdominal bloating, increased flatulence, crampy abdominal pain, and explosive diarrhea. These symptoms are likely related to the malabsorption of carbohydrates and other foodstuffs and the subsequent fermentation of the substrates entering the colon (see Chapter 29).

Late dumping, occurring from 1 to 3 hours after a meal, is characterized by vascular symptoms, related to **reactive hypoglycemia**. Rapid delivery, as well as hydrolysis and absorption of carbohydrates, produces an exaggerated rise in insulin level with a subsequent decline in blood glucose level (see Chapter 31). Patients may experience flushing, rapid heartbeat, faintness, and sweating, and feel the need to sit or lie down. They may feel anxious, weak, shaky, or hungry, and have difficulty concentrating. The rapid changes in blood glucose and the secretion of gut peptides, glucose insulinotropic polypeptide, and glucagon-like polypeptide-1 appear to be at least partly responsible for the late symptoms (Ukleja, 2005).

### Medical Management

Medical intervention typically involves dietary changes as the initial treatment, and they are usually effective. In 3% to 5% of patients, severe dumping persists despite dietary change. In these patients, medications may be used to slow gastric emptying and delay transit of food through the GIT. Some, such as acarbose, inhibit alpha glycoside hydrolase and interfere with carbohydrate absorption, and octreotide, a somatostatin analogue, inhibits insulin release. See Table 28-2 for common medications. Rarely, surgical intervention is used to treat dumping syndrome.

### Medical Nutrition Therapy

Patients with dumping syndrome may experience weight loss and malnutrition caused by inadequate intake, malabsorption or a combination of both. The prime objective of nutrition therapy is to restore nutrition status and quality of life. Proteins and fats are better tolerated than carbohydrates because they are hydrolyzed more slowly into osmotically active substances. Simple carbohydrates such as lactose, sucrose, and dextrose are hydrolyzed rapidly; thus quantities should be limited, but complex carbohydrates (starches) can be included in the diet. Liquids enter the jejunum rapidly; thus some patients may have problems tolerating liquids with meals. Patients with severe dumping may benefit from limiting the amount of liquids taken with meals, and taking liquids between meals, without solid food. Lying down immediately after meals may also decrease the severity of symptoms.

The use of fiber supplements, particularly pectin or gums (e.g., guar) can be beneficial in managing dumping syndrome because of their ability to form gels with carbohydrates and delay GI transit. Patients may need to be taught true portion sizes of foods, especially carbohydrate foods such as juices, soft drinks, desserts, and milk. The exchange lists given in Appendix 34 can be used to calculate carbohydrate intake and teach the patient about carbohydrate control.

### BOX 28-2

#### Basic Guidelines for Dumping Syndrome

- Small, more frequent meals
- Less solid, more crushed foods
- Limited fluids during meals
- Fewer simple sugars
- More complex carbohydrates
- More soluble fiber
- Increased amounts of fat in the diet
- Lactose-free foods if needed

Postgastrectomy patients often do not tolerate lactose, but small amounts (e.g., 6 g or less per meal) may be tolerated at one time. Patients typically do better with cheeses or unsweetened yogurt than with fluid milk. Nondairy milks are also useful. Vitamin D and calcium supplements may be needed when intake is inadequate. Commercial lactase products are available for those with significant lactose malabsorption (see Chapter 29).

When steatorrhea (greater than 7% of dietary fat excreted in stool) exists, reduced fat formulas or pancreatic enzymes may be beneficial. Box 28-2 provides general nutrition guidelines for patients with dumping syndrome after gastric surgery; however, each diet must be adjusted based on a careful dietary and social history from the patient.

### Gastroparesis

#### Pathophysiology

**Gastroparesis**, or delayed gastric emptying, is a complex and potentially debilitating condition. The nature of gastroparesis is complex in part because gastric motility is orchestrated by a variety of chemical and neurologic factors. Viral infection, diabetes, and surgeries are the most common causes for gastroparesis; however, more than 30% of cases are idiopathic. Numerous classes of clinical conditions are associated with gastroparesis, including mechanical obstructions, metabolic or endocrine disorders, acid-peptic diseases, gastritis, postgastric surgery, disorders of gastric smooth muscle, psychogenic disorders, and neuropathic disorders. Clinical symptoms may include abdominal bloating, decreased appetite and anorexia, nausea and vomiting, fullness, early satiety, halitosis, and postprandial hypoglycemia.

#### Diagnosis and Medical Management

The gold-standard measure of gastric emptying rate is scintigraphy, a nuclear test of gastric emptying. This consists of the patient ingesting a radionucleotide-labeled meal (such as an egg labeled with  $^{99m}$ technetium), and scintigraphic images are taken over time (generally 4 hours) to assess the rate of gastric emptying.

Numerous symptoms of gastroparesis can affect oral intake, and the management of these symptoms generally improves nutritional status. Treatment of nausea and

vomiting is perhaps the most vital, and prokinetics and antiemetics are the primary medical therapies (see Table 28-2). Metoclopramide and erythromycin are medications that may be used to promote gastric motility. Small bowel bacterial overgrowth, ileal brake (the slowing effect on intestinal transit and appetite of undigested nutrients, often fat, reaching the ileum), or formation of a bezoar (concentration of undigested material in the stomach) are other factors that may affect nutritional status.

**Bezoar** formation may be related to undigested food such as cellulose, hemicellulose, lignin and fruit tannins (phytobezoars), or medications (pharmacobezoars) such as cholestyramine, sucralfate, enteric coated aspirin, aluminum-containing antacids, and bulk-forming laxatives. Treatment of bezoars includes enzyme therapy (such as papain or cellulose), lavage, and sometimes endoscopic therapy to mechanically break up the bezoar. Most patients respond to some combination of medication and dietary intervention; however, unresponsive and more severe cases may benefit from placement of an enteral tube, such as a percutaneous endoscopic gastrostomy (PEG) with jejunal extension or a PEG and percutaneous endoscopic jejunostomy (Parrish and Yoshida, 2005). These tube combinations allow nutrition to bypass the stomach while providing an alternative route for venting of gastric secretions, which may relieve nausea and vomiting.

### Medical Nutrition Therapy

The primary dietary factors that affect gastric emptying (in order of clinical importance) are volume, liquids versus solids, hyperglycemia, fiber, fat, and osmolality (Maljaars et al., 2007). Larger volumes of food that create stomach distension (approximately 600 mL) have been shown to

delay gastric emptying and increase satiety (Oesch et al., 2006). Generally, patients benefit from smaller, more frequent meals. Patients with gastroparesis often have preserved emptying of liquids, as they empty, in part, by gravity and do not require antral contraction. Shifting the diet to more pureed and liquefied foods is often useful. A number of medications (such as narcotics and anticholinergics) slow gastric emptying. Moderate to severe hyperglycemia (serum blood glucose >200 mg/dL) may acutely slow gastric motility, with long-term detrimental effects on gastric nerves and motility. Laboratory data considered in initial assessment include glycosylated hemoglobin A1c (if diabetes is present), ferritin, vitamin B<sub>12</sub>, and 25-OH vitamin D.

Fiber, particularly pectin, can slow gastric emptying and increase risk of bezoar formation in patients who are susceptible. It is prudent to advise patients to avoid high-fiber foods and fiber supplements. The size of the fibrous particles, not the amount of fiber, is more important in bezoar risk (e.g., potato skins versus bran). This and the resistance to chewing are factors in bezoar formation. Examination of the patient's dentition is very important because patients who have missing teeth, a poor bite, or are edentulous are at greater risk. People even with good dentition have swallowed and passed food particles up to 5–6 cm in diameter (potato skins, seeds, tomato skins, peanuts).

Fat is a powerful inhibitor of stomach emptying primarily mediated by cholecystokinin (Goetze et al., 2007); however, many patients tolerate fat well in liquid form. Fat should not be restricted in patients who are struggling to meet their daily caloric needs. Studies have demonstrated a slowing effect of highly osmotic foods on gastric emptying, but, compared with other interventions, dietary manipulation of osmolarity is not clinically effective (Parrish, 2007).

### CLINICAL SCENARIO 1

Jim, a 45-year-old man, is an executive who travels extensively in his work. He recently visited his doctor complaining about upper gastrointestinal (GI) distress. He reports frequent bouts of heartburn in the middle of the night, and he has lost 15 lb during the last year without intentionally dieting. Jim also occasionally experiences heartburn soon after consumption of specific meals and foods. Jim's doctor diagnosed esophageal reflux, and x-ray studies revealed a hiatal hernia.

Jim has received a good deal of advice regarding specific foods and diets from a variety of sources, but he is confused about what he should eat. Jim is coming to you to discuss nutrition therapies.

#### Nutrition Diagnostic Statements

- Involuntary weight loss related to heartburn and GI pain after some meals and foods as evidenced by 15-lb weight loss in the absence of dieting.

- Food- and nutrition-related knowledge deficit related to appropriate foods for reflux as evidenced by confusion related to multiple sources of information.

#### Nutrition Care Questions

- What is heartburn? Does hiatal hernia have anything to do with it?
- Why might Jim experience heartburn in the middle of the night?
- Why might Jim experience burning after consumption of certain foods or meals?
- Why do you suppose Jim lost weight?
- Do you recommend that he regain the weight?
- What recommendations would you give for reducing Jim's symptoms?
- Write a progress note using ADIME language.

**CLINICAL SCENARIO 2**

**M**r. Smith had his stomach removed 3 months ago as a result of gastric cancer. He is having difficulty with bloating, nausea, and light-headedness soon after meals. Later, after the meal, he often experiences lower abdominal cramping and diarrhea.

### Nutrition Diagnostic Statement

Altered gastrointestinal function related to dumping symptoms following meals as evidenced by history of gastric carcinoma requiring resection of stomach.

### Nutrition Care Questions

1. What do you think could be responsible for the different symptoms Mr. Smith is experiencing?
2. What additional information should you gather about Mr. Smith in your nutritional assessment?
3. Should you recommend laboratory work to check any vitamin or mineral levels?
4. Are there measures you can recommend to prevent his postprandial symptoms?

S-pouch

steatorrhea

synbiotic

tropical sprue

ulcerative colitis (UC)

W-pouch

Dietary interventions for many diseases of the intestinal tract are primarily designed to alleviate symptoms and to correct nutrient deficiencies. However, nutrition interventions play a preventative and therapeutic role in several conditions, such as diverticular disease and treatment of some types of constipation. Celiac disease (CD) is the only gastrointestinal (GI) condition for which dietary

modification is the primary treatment. Careful assessment of the nature and severity of the primary GI problem is necessary to identify the nutrition diagnosis and appropriate interventions. Assessment may include evaluating the frequency and amount of nutrients consumed, medical and surgical history, medications used, subjective experiences with foods, and depth of understanding of the relationship

between diet and the GI problem. The GI assessment should include information on the duration and severity of the disorder; its effect on digestion, secretion, and absorption of nutrients; and its effect on symptoms and complications. Meal consistency, frequency, and size, as well as other characteristics of the diet, may then be altered to fit the patient's needs.

## COMMON INTESTINAL PROBLEMS

It is important to understand some of the common GI processes and symptoms that occur in healthy people prior to discussing the nutrition issues relating to lower GI tract (GIT) disorders. The interaction of diet with intestinal gas, flatulence, constipation, and diarrhea provides insight when considering the more serious disorders.

### Intestinal Gas and Flatulence

#### Pathophysiology

Air is commonly swallowed (**aerophagia**), and other gasses are produced within the GIT by digestive processes and bacteria. These gases are either expelled through belching (eructation) or passed rectally (**flatus**). Intestinal gases include nitrogen ( $N_2$ ), oxygen ( $O_2$ ), carbon dioxide ( $CO_2$ ), hydrogen ( $H_2$ ), and in some persons methane ( $CH_4$ ). Some of these gasses are absorbed into the circulation and then exhaled from the lungs.

Approximately 200 mL of gas is present in the healthy GIT. Humans excrete an average of 700 mL of gas each day, but are capable of moving considerably more through the GIT. The amount of intestinal gas varies greatly among individuals and from one day to the next. When patients complain about "excessive gas," or **flatulence**, they may be referring to increased volume or frequency of belching or passage of rectal gas. They may also complain of abdominal distention or cramping associated with the accumulation of gases in the upper or lower GIT. However, the perception of gas and the degree of symptoms experienced by an individual do not necessarily correlate with the amount of gas that is actually in the GIT (Azpiroz, 2005; Morken et al., 2007). Inactivity, decreased GI motility, aerophagia, dietary components, and certain GI disorders can alter the amount of intestinal gas and individual symptoms. Aerophagia can be avoided to some degree by eating slowly, chewing with the mouth closed, limiting gum chewing, and refraining from drinking through straws. Movement of gas through the GIT may be enhanced with upright stance, mild exercise, or abdominal massage.

Gas production occurs in the stomach and small intestine from bacterial fermentation of carbohydrates, and can result in abdominal discomfort and distention. The colonies of bacteria in the small bowel are normally present in limited numbers, but various conditions can lead to overgrowth of bacteria, potentially causing diarrhea, bloating, distention, or other symptoms. Because the small intestine is less tolerant of gas than the colon, this distention may cause pain. The movement of gas into the small intestine and beyond

is slowed by high-calorie, high-fat meals. Slowed excretion or retained gas may contribute to the perception of distention or bloating with large meals in normal circumstances and with the abdominal discomfort that is experienced in **functional GI disorders**, such as irritable bowel syndrome (IBS) (Azpiroz, 2005; Harder et al., 2006). Functional GI disorders present symptoms that are not explained by a known structural, infectious, or metabolic cause.

Increased amounts of  $H_2$  and  $CO_2$ —and sometimes  $CH_4$ —in rectal gas can lower the fecal pH, causing excessive colonic bacterial fermentation and malabsorption of fermentable substrate. The amounts and types of gases produced may depend on the mix of microorganisms in the individual's colon. Consumption of large amounts of dietary fiber (especially soluble fiber), resistant starches, lactose in persons who are lactase deficient, or modest amounts of fructose or sugar alcohols (such as sorbitol) may result in increased gas production in the colon and increased flatulence (Beyer et al., 2005). In the United States consumption of fruit juices, fruit drinks, and high-fructose corn syrup (HFCS) in soft drinks and confections has increased significantly in recent years. Fructose is normally well absorbed when consumed in the form of sucrose or as small amounts of HFCS, but not so well when consumed as the only or predominant sugar in the diet (see Chapter 1). In children 10–20 g of fructose, or 25 g in adults, is sufficient to result in malabsorption.

#### Medical Nutrition Therapy

When assessing a patient it is important to differentiate between increased production of gas and gas that is not being passed. Likewise, it is important to consider why a patient may have new or increased symptoms. A thorough review of the patient's medical history considers predisposing factors and treatment of underlying conditions before implementing nutrition therapy.

One of the direct nutrition considerations is development of lactose intolerance. Recent viral or GI infection may provoke temporary or even permanent impairment in the ability to digest lactose, and appropriate diet modifications can improve symptoms. A dramatic change in diet, such as adoption of a high-fiber diet, can also alter gas production. Foods that contain raffinose (a complex sugar resistant to digestion), such as beans, cabbage, Brussels sprouts, broccoli, asparagus and some whole grains, can increase gas production.

Altered bowel flora occur over time after an increase in dietary fiber. Although there are no randomized studies regarding the best way to implement high-fiber diets, a gradual introduction of fiber with adequate fluid consumption appears to reduce complaints of gas. Inactivity, dysmotility, constipation, or partial obstruction may be contributing to the inability to move normal amounts of gas as produced. Increased physical activity or exercise may help, if an underlying obstruction or dysmotility is not present.

### Constipation

**Constipation**, commonly defined as difficult or infrequent passage of stool (Cook et al., 2009), is one of the most

common intestinal maladies in Western societies, and may occur in 5% to 25% of the population or more (Müller-Lissner, 2009). Prevalence of constipation has been reported in as high as 50% to 80% of patients taking opioids daily for chronic pain, and may occur despite laxative use (Bell et al., 2009; Tuteja et al., 2010).

Although several definitions for constipation are based on frequency, difficulty, or consistency of stool, the sensation of “feeling constipated” may be enough to warrant intervention. Often, patients are troubled more by the physical discomfort of straining, hard stools, or incomplete evacuation than by the infrequency of bowel movements. In adults, normal stool weight is approximately 100 to 200 g daily, and normal frequency may range from one stool every 3 days to three times per day. Normal transit time through the GIT ranges from approximately 18 to 48 hours.

Children normally have more frequent stools, ranging from an average of two to three stools daily for the first few months of life to approximately one and a half bowel movements daily by age 3. As many as one third of children from ages 6 to 12 years complain of constipation in any given year (Biggs and Dery, 2006). Children may exhibit vomiting, abdominal pain, anorexia, or **encopresis** (involuntary passage of stool or fecal soiling).

## Pathophysiology

Constipation may be caused by lifestyle factors (inadequate hydration, lack of exercise) or other medical conditions. Treatments differ based on the cause of constipation. **Box 29-1** outlines numerous factors that may contribute to constipation.

The most common causes of constipation in otherwise healthy persons include repeatedly ignoring the urge to defecate, lack of fiber in the diet, insufficient fluid intake, inactivity, or use of certain medications. Individuals who believe that it is necessary to have scheduled and frequent bowel movements, yet ignore dietary and other recommendations for maintaining laxation, may be at risk for overuse of medications. When the desired stool frequency or timing of defecation does not occur, they may try to compensate with the use of medications and enemas. Chronic use of stimulant laxatives may damage the structure and innervation of the colon. Opioid medications bind to motility receptors in the gut, and chronic use may lead to constipation, delayed gastric emptying, nausea, and abdominal pain (Holzer, 2009).

## Medical Treatment for Adults

It is important to first rule out serious neurologic, GI, or endocrine disorders, or constipation caused by medications. After this is done, the first approach to treat mild and functional constipation is to ensure adequate dietary fiber, exercise, and heeding the urge to defecate. Patients who depend on laxatives are usually encouraged to use milder products, reducing the dose until withdrawal is complete.

When constipation persists despite lifestyle interventions, medications that promote regular bowel movements may be prescribed (Emmanuel et al., 2009). Anionic

## BOX 29-1

### Causes of Constipation

#### Lifestyle

- Lack of exercise or mobility
- Ignoring the urge to defecate
- Inadequate fiber
- Laxative abuse

#### Dysmotility Disorders

- Chronic intestinal pseudoobstruction
- Hypothyroidism
- Colonic inertia
- Gastroparesis
- Hirschprung's disease
- Metabolic and endocrine abnormalities such as diabetes

#### Neuromuscular Disorders (Particularly in Immobile or Wheelchair-Bound Patients)

- Amyotrophic lateral sclerosis
- Multiple sclerosis
- Muscular dystrophy
- Friedreich ataxia
- Scleroderma involving the gut
- Cerebral palsy
- Para- or quadriplegia

#### Chronic Use of Opiates

- Oncology patients
- Chronic pain patients
- Narcotic bowel syndrome

#### Pelvic Floor Disorders

- Pregnancy

#### Other Gastrointestinal Disorders

- Diseases of the upper gastrointestinal tract
- Diseases of the large bowel resulting in:
  - Failure of propulsion along the colon (colonic inertia)
  - Anorectal malformations or outlet obstruction
  - Irritable bowel syndrome (IBS)
  - Anal fissure or hemorrhoid

Data from DeLillo AR, Rose S: Functional bowel disorders in the geriatric patient: constipation, fecal impaction and fecal incontinence, Am J Coll Gastroenterol 95:901, 2000; Schiller, LR: Nutrients and constipation: cause or cure? Pract Gastroenterol 32:4,2008; Siddiqui MA, Castell DO: Gastrointestinal disorders in the elderly, Comp Ther 23:349, 1997.

surfactants such as docusate sodium or docusate potassium are used as stool softeners to make bowel movements easier to pass. Osmotic agents such as magnesium hydroxide, sorbitol, and lactulose draw fluid into the bowel. Polyethylene glycol is an isosmotic agent that treats constipation by keeping the water it is taken within the gut rather than it being absorbed. Bisacodyl and senna compounds have stimulant activity on bowel motility and also act to prevent water

absorption. Lubiprostone is a prostaglandin E1 derivative that increases fluid secretion by the epithelial cells of the GIT (Ramkumar and Rao, 2005). Impactions of stool require evacuation and a more stringent preventive and maintenance program, including combinations of medications, fluids, activity, or enemas.

### Medical Treatment for Infants and Children

Approximately 3% to 5% of all pediatric outpatient visits are related to chronic constipation. In the most severe cases of functional constipation with frequent stool retention, the rectum becomes insensitive to distention, and encopresis may result. After disease is ruled out, treatment includes laxatives, lubricants, adequate dietary fiber, and fluid. A careful history and physical examination followed by parent and child education, behavioral intervention, and appropriate use of laxatives often leads to dramatic improvement (Biggs and Dery, 2006) (see Chapter 18).

### Medical Nutrition Therapy

Primary nutrition therapy for constipation in otherwise healthy people is consumption of adequate amounts of dietary fiber, both soluble and insoluble, as well as fluids. Fiber increases colonic fecal fluid, microbial mass (which accounts for 60% to 70% of stool weight), stool weight and frequency, and the rate of colonic transit. With adequate fluid, fiber may soften stools and make them easier to pass. Unfortunately, most adults and children in the United States chronically consume only about half the amount of fiber recommended by the Institute of Medicine (14 g/1000 kcal). Adult women should consume approximately 25 g of fiber daily, men approximately 38 g, and children from 19 to 25 g daily.

**Dietary fiber** refers to edible plant materials not digested by the enzymes in the GIT. It consists of cellulose, hemicelluloses, pectins, gums, lignin, starchy materials, and oligosaccharides that are partially resistant to digestive enzymes. Fiber can be provided in the form of whole grains, fruits, vegetables, legumes, seeds, and nuts. These foods are also high in **prebiotics**, substances that are not digested by humans and fuel colonic microflora. Appendix 41 lists the fiber content of foods.

Different from fiber, **residue** refers to the end result of digestive, secretory, absorptive, and fermentative processes. Increasing dietary fiber may result in increased fecal output, but increasing dietary lactose (a fiber-free food) in a person who is a lactose malabsorber also increases fecal weight (residue).

Every 10 g of carbohydrate reaching the colon may be fermented into as much as 1000 mL of gas. Thus transition to a diet pattern that meets guidelines for fiber often requires substantial change. A high-fiber therapeutic diet may need to exceed 25 to 38 g/day. The **high-fiber diet** in Box 29-2 provides more than the amount of fiber recommended. Amounts greater than 50 g/day are not necessary and may increase abdominal distention and excessive flatulence.

Bran and powdered fiber supplements may be helpful in persons who cannot or will not eat sufficient amounts of

### BOX 29-2

#### Guidelines for High-Fiber Diets

1. Increase consumption of whole-grain breads, cereals, and other products to 6-11 servings daily.
2. Increase consumption of vegetables, legumes, fruits, nuts, and edible seeds to 5-8 servings daily.
3. Consume high-fiber cereals, granolas, and legumes to bring fiber intake to 25 g in women or 38 g in men or more daily.
4. Increase consumption of fluids to at least 2 L (or approximately 2 qt) daily.

Note: Following these guidelines may cause an increase in stool weight, fecal water, and gas. The amount that causes clinical symptoms varies among individuals, depending on age and presence of gastrointestinal (GI) disease, malnutrition, or resection of the GI tract.

fibrous foods. Several of these concentrates are palatable and can be added to cereals, yogurts, fruit sauces, juices, or soups. Cooking does not destroy fiber, although the structure may change. Consumption of at least eight 8-oz glasses (~2 L) of fluids daily is recommended to facilitate the effectiveness of a high-fiber intake. Gastric obstruction and fecal impaction may occur when boluses of fibrous gels or bran are not consumed with sufficient fluid to disperse the fiber.

Recommendations for increased dietary fiber for laxation should not be implemented in patients with neuromuscular disorders, dysmotility syndromes, chronic opioid use, pelvic floor disorders or other serious GI disease (Schiller, 2008). In some conditions, such as neuromuscular disorders, a specific laxative medication regimen is a necessary part of care.

### Diarrhea

**Diarrhea** is characterized by the frequent evacuation of liquid stools, usually exceeding 300 mL, accompanied by an excessive loss of fluid and electrolytes, especially sodium and potassium. Diarrhea occurs when there is accelerated transit of intestinal contents through the small intestine, decreased enzymatic digestion of foodstuffs, decreased absorption of fluids and nutrients, increased secretion of fluids into the GIT, or exudative losses.

### Types of Diarrhea and Their Pathophysiology

Diarrhea may be related to inflammatory disease; infections with fungal, bacterial, or viral agents; medications; over consumption of sugars or other osmotic substances; or insufficient or damaged mucosal absorptive surface.

Exudative diarrheas are always associated with mucosal damage, which leads to an outpouring of mucus, fluid, blood, and plasma proteins, with a net accumulation of electrolytes and water in the gut. Prostaglandin and cytokine release may be involved. The diarrheas associated with

Crohn's disease, ulcerative colitis (UC), and radiation enteritis are often exudative.

Osmotic diarrheas occur when osmotically active solutes are present in the intestinal tract and are poorly absorbed. Examples include the diarrhea that accompanies dumping syndrome or that which follows lactose ingestion in the person with a lactase deficiency.

Secretory diarrheas are the result of active intestinal secretion of electrolytes and water by the intestinal epithelium, resulting from bacterial exotoxins, viruses, and increased intestinal hormone secretion. Unlike osmotic diarrhea, fasting does not relieve secretory diarrhea.

Malabsorptive diarrhea results when a disease process impairs digestion or absorption to the point that fat and other nutrients appear in the stool in increased amounts. Excess fat in the stool is called **steatorrhea**. Diarrhea occurs because of the osmotic action of these nutrients and the action of the bacteria on the nutrients that pass into the colon. Malabsorptive diarrhea occurs when there is not enough healthy absorptive area, inadequate production or interrupted flow of bile and pancreatic enzymes, or there is rapid transit, such as in inflammatory bowel disease (IBD) or after extensive bowel resection. Box 29-3 lists diseases and conditions associated with malabsorption and diarrhea.

Medication-induced diarrheas are frequent in hospitalized and long-term care patients. Medications such as lactulose (used in the management of hepatic encephalopathy) and sodium polystyrene sulfonate with sorbitol (used to treat hyperkalemia) create increased bowel movements as part of their mechanism of action. Some antibiotics have direct effects on GI function (see Chapter 9). For example, as a motilin agonist, erythromycin increases lower GI motility; clarithromycin and clindamycin also increase GI secretions.

In the normal GIT, bacterial "salvage" from sloughed intestinal cells and undigested foodstuffs converts osmotically active molecules (carbohydrate and amino acids) to gases and short-chain fatty acids (SCFAs). Absorption of the SCFAs facilitates absorption of electrolytes and water from the colon. Broad-spectrum antibiotics decrease the number of bacteria in the bowel and may result in increased osmotically active molecules, reduced absorption of electrolytes and water, and diarrhea.

Some antibiotics allow opportunistic proliferation of pathogenic organisms normally suppressed by competitive organisms in the GIT. The organisms or the toxins produced by some opportunistic organisms can cause colitis and increased secretion of fluid and electrolytes. The treatment of *Escherichia coli* and several other organisms has been implicated in **antibiotic-associated diarrhea (AAD)** (Schroeder, 2005). Overall, infection with *Clostridium difficile* is the most common cause of AAD, especially among patients who receive antibiotics within health care facilities. *C. difficile* is the leading cause of nosocomial (hospital-acquired) diarrhea in the United States (O'Keefe, 2010). This infection may cause colitis, secretory diarrhea, severe dilation of the colon (toxic megacolon), perforation of the bowel wall, peritonitis, or even death (Sánchez-Pérez et al., 2010).

## BOX 29-3

### Diseases and Conditions Associated with Malabsorption

#### Inadequate Digestion

- Pancreatic insufficiency
- Gastric acid hypersecretion
- Gastric resection

#### Altered Bile Salt Metabolism with Impaired Micelle Formation

- Hepatobiliary disease
- Interrupted enterohepatic circulation of bile salts
- Bacterial overgrowth
- Drugs that precipitate bile salts

#### Abnormalities of Mucosal Cell Transport

##### Biochemical or Genetic Abnormalities

- Disaccharidase deficiency
- Monosaccharide malabsorption
- Specific disorders of amino acid malabsorption
- Abetalipoproteinemia
- Vitamin B12 malabsorption
- Celiac disease

#### Inflammatory or Infiltrative Disorders

- Crohn's disease
- Amyloidosis
- Scleroderma
- Tropical sprue
- Gastrointestinal allergy
- Infectious enteritis
- Whipple's disease
- Intestinal lymphoma
- Radiation enteritis
- Drug-induced enteritis
- Endocrine and metabolic disorders
- Short-bowel syndrome (SBS)

#### Abnormalities of Intestinal Lymphatics and Vascular System

- Intestinal lymphangiectasia
- Mesenteric vascular insufficiency
- Chronic congestive heart failure

Data from Beyer PL: Short bowel syndrome. In Coulston AM, Rock CL, Monson ER, editors: Nutrition in the prevention and treatment of disease, ed 1, San Diego, 2001, Academic Press; Branski D et al: Chronic diarrhea and malabsorption, Pediatr Clin North Am 43:307, 1996; Mitra AD et al: Management of diarrhea in HIV-infected patients, Int J STD AIDS 12:630, 2001; Fine KD: Diarrhea. In Feldman M, Sleisenger MH, Scharschmidt BF, editors: Gastrointestinal and liver disease, ed 6, Philadelphia, 1998, Saunders; Podolsky DK: Inflammatory bowel disease, N Engl J Med 347:417, 2002; Sundarum A et al: Nutritional management of short bowel syndrome in adults, J Clin Gastroenterol 34:207, 2002.

*C. difficile* occurs in 50% of hospitalized patients with a stay longer than 4 weeks (DeLegge and Berry, 2009). In the mid 1990s, the incidence of *C. difficile* was reported to be between 30–40 cases per 100,000 patients, but by 2005 the incidence doubled to 84 cases per 100,000 patients (DeLegge and Berry, 2009). Additionally, resistant strains of *C. difficile* are less susceptible to treatment with antimicrobials, and cause a more severe form of the disease with increased health care costs, and higher mortality (O'Keefe, 2010).

*C. difficile* is a spore-forming organism, and the spores are resistant to common disinfectant agents. The spore-forming ability of *C. difficile* allows the organism to be spread inadvertently to other patients by health care providers (iatrogenic infection) if strict infection control procedures are not followed. The presence of this infection is detected by analysis of a stool sample for the presence of the toxin produced by the organisms. Clindamycin, penicillins, and cephalosporins are associated most often with the development of *C. difficile* infection. Its occurrence depends on the number of antibiotics used, the duration of exposure to antibiotics, and the patient's overall health. Chronic suppression of stomach acid with proton-pump inhibitor medications during broad-spectrum antibiotic therapy may also increase susceptibility to *C. difficile* infection (Howell et al., 2010; Linsky et al., 2010).

With human immunodeficiency virus (HIV) and other immune deficiency states, several factors contribute to the diarrhea, including the toxic effects of medications, proliferation of opportunistic organisms, and the GI manifestations of the disease itself (Kulkarni et al., 2009) (see Chapter 38). Increased risk of opportunistic infection is also associated with use of antineoplastic agents (such as chemotherapy) or with malnutrition.

### Medical Treatment

Because diarrhea is a symptom, not a disease, the first step in medical treatment is to identify and treat the underlying problem. The next goal is to manage fluid and electrolyte replacement. In cases of severe diarrhea, restoring fluid and electrolyte is first priority. Electrolyte losses, especially potassium and sodium, should be corrected early by using oral glucose electrolyte solutions with added potassium. Oral rehydration solutions (ORS) work because they contain concentrations of sodium and glucose that are optimal for interaction with the sodium-glucose transport (SGLT) proteins in the intestinal epithelial cells. With intractable diarrhea, especially in an infant or young child, parenteral feeding may be required. Parenteral nutrition (PN) may even be necessary if exploratory surgery is anticipated or if the patient is not expected to resume full oral intake within 5 to 7 days (see Chapter 14).

Supplementation with **probiotics** shows some promise to prevent recurrence of *C. difficile* but there is inadequate data to recommend probiotics as a primary treatment for *C. difficile* infections. (Gao et al., 2010; Lawrence et al., 2005 Pillai 2008); see *New Directions: Probiotics for the Right Balance of Bugs*.

### NEW DIRECTIONS

## Probiotics for the Right Balance of Bugs

Some gastrointestinal conditions such as *Clostridium difficile* infection, small intestine bacterial overgrowth, antibiotic-associated diarrhea, and perhaps even inflammatory bowel disease may result or have exacerbated symptoms when there are alterations to the colonies of microorganisms that exist in the small or large intestines. Exposure to broad-spectrum antibiotics causes dramatic alterations to native gastrointestinal (GI) flora, and placing the patient at risk for opportunistic GI infections. Concentrated cultures of live microorganisms such as lactobacillus, bifidobacteria, and *Saccharomyces boulardii* ingested as a supplement or in foods (yogurt or kefir) confer a health benefit on the host. It has been suggested that probiotics may restore the balance of intestinal microbes and improve symptoms and prevent or treat conditions such as antibiotic-associated diarrhea. Certain types of probiotics may be effective in reducing the duration of enterovirus-induced acute infectious diarrhea in pediatric and adult patients (Hickson et al., 2007) and in irritable bowel disease (Guyonnet et al., 2007).

One multicenter study investigated 64 patients with active or recurrent *C. difficile* infection. All patients were given a combination of oral antibiotics and 1 g/day of *S. boulardii* or a placebo for 4 weeks, then evaluated after another 4 weeks. The researchers found that patients treated with *S. boulardii* had a significantly lower risk for developing another *C. difficile* infection during the study period (Lawrence et al., 2005). Probiotics improved diarrhea by shortening duration by 1.4 days or reducing incidence by approximately 30%. There is insufficient evidence to recommend routine probiotic therapy as an adjunct to antibiotic therapy for *C. difficile* colitis (Pillai and Nelson, 2008). Improvement is not 100% in all people. Thus more controlled studies are needed (Aragon et al., 2010; Whorwell et al., 2006).

Products that combine probiotic microorganisms and a prebiotic fiber source have been described as **synbiotics** for their synergistic effects. However, there are no controlled studies that have systematically investigated the effectiveness of probiotics alone compared with synbiotics. There is a need for controlled studies to understand which strains of probiotics should be provided, as well as type and amount of prebiotic fibers.

Although there is a long history of safe use of many strains of probiotics in foods in healthy humans, there is a limited body of evidence on the use of large doses of

concentrated probiotic supplements, especially of specific strains that exhibit greater resistance to gastric acid or have increased ability to proliferate in the GIT. There is very limited safety data to support the use of concentrated probiotic supplements in patients with immunocompromised states, critical illness, or when probiotics are administered directly into the small intestine, as with jejunal feeding tubes. There have been a number of case reports of hospitalized patients receiving concentrated strains of probiotics that have become septic because of infection in the bloodstream with the very same strain of probiotic being administered (Whelan and Myers, 2010). In a review of cases of adverse events related to probiotic administration in hospitalized patients, 25% of those adverse events resulted in the death of the patient (Whelan and Myers, 2010). In a large double-blind, randomized study of a high-dose multispecies probiotic administered via jejunal feeding tube in patients with severe acute pancreatitis, there were significantly more deaths in the patients who received probiotics compared with those receiving the inactive placebo (Bessink et al., 2008).

Probiotic preparations hold promise as an adjunctive or primary treatment in several gastrointestinal conditions, but there is a need for additional studies before routine use of these preparations is adopted, especially for hospitalized or immunocompromised patients. The studies to date have been relatively small, have used varying doses and strains of probiotic microorganisms, and there remains much to be learned about true effectiveness, differences between probiotic strains, possible benefits of coadministration of prebiotics, best doses, safety, and cost-benefit of using probiotics.

## Medical Nutrition Therapy

All nutrition interventions related to diarrhea must be viewed within the context of the underlying pathologic condition responsible for the diarrhea. Replacement of necessary fluids and electrolytes is the first step, using ORSs, soups and broths, vegetable juices, and isotonic liquids. Restrictive diets, such as the BRAT diet made up of bananas, rice, applesauce, and toast, are nutrient poor and there is no evidence that they are necessary during acute diarrheal illness. However, some clinicians recommend a progression of starchy carbohydrates such as cereals, breads, and low-fat meats, followed by small amounts of vegetables and fruits, followed by fats. The goal with this progression is to limit large amounts of hyperosmotic carbohydrates that may be maldigested or malabsorbed, foods that stimulate secretion of fluids, and foods that speed the rate of GI transit.

Sugar alcohols, lactose, fructose, and large amounts of sucrose may worsen osmotic diarrheas. Because the activity of the disaccharidases and transport mechanisms decrease during inflammatory and infectious intestinal disease, sugars may need to be limited, especially in children (Robayo-Torres et al., 2006). It is important to remember that malabsorption is only one potential cause of diarrhea, and diarrhea may occur without significant malabsorption of

macronutrients (carbohydrate, fat, and protein). Absorption of most nutrients occurs in the small intestine; diarrhea related to colonic inflammation or disease preserves the absorption of most ingested nutrients.

Minimal fiber and low-residue diets are rarely indicated (Table 29-1). Patients are encouraged to resume a regular diet as tolerated that contains moderate amounts of soluble fiber. The metabolism of fiber and resistant starches by colonic bacteria leads to production of SCFAs, which in physiologic quantities serve as a substrate for colonocytes, facilitate the absorption of fluid and salts, and may help to regulate GI motility (Binder, 2010).

Fibrous material tends to slow gastric emptying, moderate overall GI transit, and pull water into the intestinal lumen. Providing fiber to patients with diarrhea does increase the volume of stool, and in some cases (such as small intestine bacterial overgrowth [SIBO]) can initially increase gas and bloating. Modest intake of prebiotic components and **soluble fibers** such as pectin or gum slows transit through the GIT.

Several probiotics have been tested for preventing AAD in children; risk reduction was higher from *Saccharomyces boulardii* than for *Lactobacillus GG* or *Lactobacillus bifidus* and *Streptococcus thermophilus* (Szajewska, 2006). Studies are needed to find the combination of probiotics, prebiotics, and antibiotics that works most effectively in each situation (Teitelbaum, 2005).

Severe and chronic diarrhea is accompanied by dehydration and electrolyte depletion. If also accompanied by prolonged infectious, immunodeficiency, or inflammatory disease, malabsorption of vitamins, minerals, and protein or fat may also occur, and nutrients may need to be replaced parenterally or enterally. In some forms of infectious diarrheas, loss of iron from GI bleeding may be severe enough to cause anemia. Nutrient deficiencies themselves cause mucosal changes such as decreased villi height and reduced enzyme secretion, further contributing to malabsorption. As the diarrhea begins to resolve, the addition of more normal amounts of fiber to the diet may help to restore normal mucosal function, increase electrolyte and water absorption, and increase the firmness of the stool.

Food in the lumen is needed to restore the compromised GIT after disease and periods of fasting. Early refeeding after rehydration reduces stool output and shortens the duration of illness. Micronutrient replacement or supplementation may also be useful for acute diarrhea, probably because it accelerates the normal regeneration of damaged mucosal epithelial cells.

## Treating Diarrhea in Infants and Children

Acute diarrhea is most dangerous in infants and small children, who are easily dehydrated by large fluid losses. In these cases replacement of fluid and electrolytes must be aggressive and immediate. Standard ORS recommended by the World Health Organization and the American Academy of Pediatrics contain a 2% concentration of glucose (20 g/L),

**TABLE 29-1****Food to Limit in a Low-Fiber (Minimal Residue) Diet**

Food	Comments
Lactose (in lactose malabsorbers)	6-12 g is normally tolerated in healthy lactase-deficient individuals, but may not be in some individuals.
Fiber (quantities >20 g)	Modest amounts (10-15 g) may help maintain normal consistency of gastrointestinal (GI) contents and normal colonic mucosa in healthy states and GI disease.
Resistant starch (especially raffinose and stachyose found in legumes)	
Sorbitol, mannitol, and xylitol (excess, >10 g/day)	
Fructose (excess, 20-25 g/meal)	
Sucrose (excess, >25-50 g/meal)	Well tolerated in moderate amounts; large amounts may cause hyperosmolar diarrhea or decreased fecal pH with fermentation to short-chain fatty acids.
Caffeine	Increases GI secretions, colonic motility.
Alcoholic beverages (especially wine and beer)	Increase GI secretions.
<i>GI</i> , Gastrointestinal.	

**TABLE 29-2****Oral Rehydration Solution: Composition and Recipes**

Element	Composition
Glucose (g/100 mL)	20
Sodium (mEq/L)	90
Potassium (mEq/L)	20
Chloride (mEq/L)	80
Bicarbonate (mEq/L)	30
Osmolarity (mOsm/L)	330
<b>Recipes*</b> (each makes 1 liter)	
2 cups Gatorade, 2 cups water, $\frac{1}{4}$ tsp salt	28 g glucose, 82 mEq Na, 1.5 eEq K
1 quart water, $\frac{1}{4}$ tsp salt, 6 teaspoons sugar	24 g glucose, 76 mEq Na, 0 mEq K

Data from Krenitsky J, McCray S: University of Virginia Health System Nutrition Support Traineeship Syllabus, Charlottesville, Va, 2010, University of Virginia Health System; World Health Organization: Guidelines for cholera control, WHO/COD/Ser/80.4, Rev 1, Geneva, 1986.

Recipes from Parrish CR: The Clinician's guide to short bowel syndrome, *Pract Gastroenterol* 29:67, 2005.

K, Potassium; Na, sodium.

\*The solution should be made fresh every 24 hr.

45 to 90 mEq/L of sodium, 20 mEq/L of potassium, and a citrate base (**Table 29-2**).

Newer reduced-osmolarity solutions (200-250 mOsm/L) have advantages over the traditional WHO-recommended ORS in treating acute diarrhea in children ([Atia and Buchman, 2009](#)). The use of reduced-osmolarity ORS in children with acute diarrhea resulted in decreased need for

intravenous therapy, significant reduction in stool output, and decreased vomiting when compared with standard WHO-recommended ORS ([Atia and Buchman, 2009](#)). Commercial solutions such as Pedialyte, Infalyte, Lytren, Equalyte, and Rehydralyte typically contain less glucose and slightly less salt and are available in pharmacies, often without prescription. Oral rehydration therapy is less invasive and less expensive than intravenous rehydration and, when used with children, allows parents to assist with their children's recovery.

A substantial proportion of children 9 to 20 months of age can maintain adequate intake when offered either a liquid or a semisolid diet continuously during bouts of acute diarrhea. Even during acute diarrhea, the intestine can absorb up to 60% of the food eaten. Some practitioners have been slow to adopt the practice of early refeeding after severe diarrhea in infants despite evidence that "resting the gut" is actually more damaging. Thus prescription of the typical hospital "full liquid" or "clear liquid" diet, which is commonly high in fructose, lactose, and other sugars, is inappropriate for recovery from diarrhea.

**Gastrointestinal Strictures and Obstruction**

Intestinal tumors or scarring from GI surgeries, IBD, peptic ulcer, or radiation enteritis may partially or completely obstruct the GIT or cause dysfunctional segments. Obstructions may be partial or complete, and may occur in the stomach (gastric outlet obstruction), small intestine or large intestine. Symptoms include bloating, abdominal distention and pain, and sometimes nausea and vomiting.

**Pathophysiology**

People with gastroparesis, Crohn's disease, scars, adhesions, dysmotility, or volvulus are all prone to obstruction. Partial

or complete obstructions are not usually caused by foods in an otherwise healthy individual; however, when sections of the GIT are partially obstructed or not moving appropriately, foods may contribute to obstruction.

Although there are no controlled studies that have investigated different diets and the frequency of obstructive symptoms, it is believed that fibrous plant foods can contribute to obstructions because the fiber in the foods may not be completely chewed or reduced in size enough to pass through abnormal or narrowed segments of the GIT.

### Medical Nutrition Therapy

Most clinicians would recommend patients prone to obstructions to chew food well and avoid excessive fiber intake. In addition, potato skins, citrus fruits, persimmons, and similar foods should be avoided by edentulous patients.

With a partial obstruction, the patient may be able to tolerate easily digestible foods and liquids, depending on the location of stricture or obstruction in the GIT. A more proximal (closer to the mouth) blockage may require a semi-solid or liquid diet. However, the more distal (closer to the anus) the blockage, the less likely altering the consistency of the diet will help.

During complete obstruction, symptoms are more severe. Patients may be intolerant of oral intake and also of their own secretions. Intensive intervention, such as surgery, may be required for complete obstruction. In some cases, enteral feeding beyond the point of obstruction may be feasible, but if enteral feeding is not possible for a prolonged period, PN may be needed. Working with the patient and physician is necessary to determine the nature, site, and duration of the obstruction, so that nutrition therapy can be individualized.

## DISEASES OF THE SMALL INTESTINE

### Celiac Disease (Gluten-Sensitive Enteropathy)

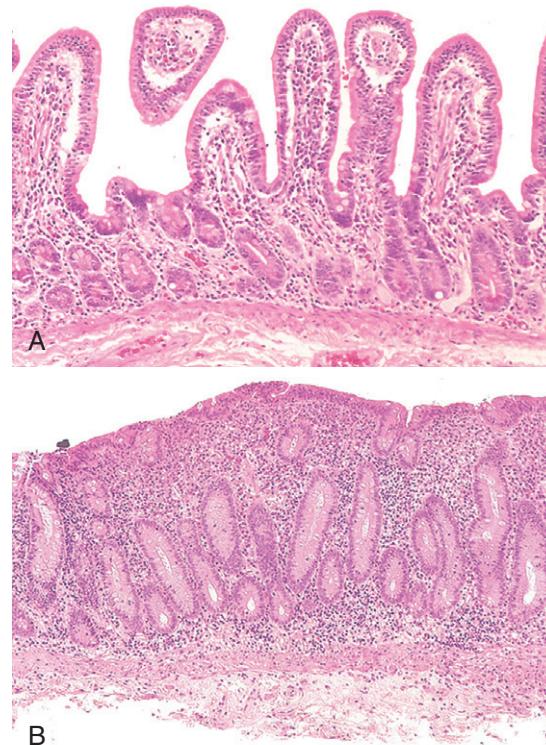

**Celiac disease (CD),** or **gluten-sensitive enteropathy**, is characterized by a combination of four factors: (1) genetic susceptibility, (2) exposure to gluten, (3) an environmental “trigger,” and (4) an autoimmune response. **Gluten** refers to specific peptide fractions of proteins (prolamines) found in wheat (glutenin and gliadin), rye (secalin), and barley (hordein). These peptides are generally more resistant to complete digestion by GI enzymes and may reach the small intestine intact. In a normal, healthy intestine, these peptides are harmless. However, in persons with CD these peptides travel from the intestinal lumen, across the intestinal epithelium, and into the lamina propria where they can trigger an inflammatory response that results in flattening of intestinal villi and elongation of the crypt cells (secretory cells), along with a more general systemic immune response (Kagnoff, 2007).

The term **gluten sensitivity** is commonly used to describe persons with nonspecific symptoms, without the immune response characteristic of CD or the consequential intestinal

damage. **Gluten intolerance** describes individuals who have symptoms, and who may or may not have CD. These two terms are used to describe symptoms such as nausea, abdominal cramps, or diarrhea after ingesting gluten. Patients who experience these symptoms should generally be advised against following a gluten-free (GF) diet without having a workup to exclude or confirm a diagnosis of CD because (1) there may be an underlying medical condition for which a GF diet is not the treatment; (2) after following a GF diet for months or years, it is difficult to diagnose CD; and (3) although generally a healthy way to eat, a GF diet can be expensive and restrictive.

### Pathophysiology

The “triggers” of CD are not well understood, but stressors (illness, inflammation, etc.) are thought to play a role. When CD remains untreated, the immune and inflammatory response eventually results in atrophy and flattening of villi. Over time, the process can cause enough damage to the intestinal mucosa to compromise normal secretory, digestive, and absorptive functions, leading to impaired micronutrient and macronutrient absorption (Chand and Mihas, 2006). Cells of the villi become deficient in the disaccharidases and peptidases needed for digestion and also in the carriers needed to transport nutrients into the bloodstream (see Figure 29-1). The disease primarily affects

**FIGURE 29-1** CD (gluten-sensitive enteropathy). **A**, Peroral jejunal biopsy specimen of diseased mucosa shows severe atrophy and blunting of villi, with a chronic inflammatory infiltrate of the lamina propria. **B**, Normal mucosal biopsy. (From Kumar V and others: Robbins and Cotran pathologic basis of disease, ed 7, Philadelphia, 2005, Saunders.)

the proximal and middle sections of the small bowel, although the more distal segments may also be involved (Bonamico et al., 2008).

The prevalence of CD has been underestimated in the past and now is considered to affect at least 1 in 133 persons in the United States. The onset and first occurrence of symptoms may appear any time from infancy to adulthood, but the peak in diagnosis occurs between the fourth and sixth decade. The disease may become apparent when an infant begins eating gluten-containing cereals. In some, it may not appear until adulthood, when it may be triggered or unmasked during GI surgery, stress, pregnancy, or viral infection. Or it may be discovered as a result of evaluation for another suspected problem. Approximately 20% of cases are diagnosed after the age of 60 years.

The presentation in young children is likely to include the more “classic” GI symptoms of diarrhea, steatorrhea, malodorous stools, abdominal bloating, apathy, fatigue, and poor weight gain. Although GI-related symptoms are often thought to be most common, an increasing number of patients present without GI symptoms. Fifty percent of celiac patients have few or no obvious symptoms, and some are overweight at presentation (Venkatasubramani et al., 2010). CD is frequently misdiagnosed as irritable bowel syndrome (IBS), lactase deficiency, gallbladder disease, or other disorders not necessarily involving the GIT, because the presentation and onset of symptoms vary so greatly.

Patients may present with one or more of a host of conditions associated with CD: anemias, generalized fatigue, weight loss or failure to thrive, osteoporosis, vitamin or mineral deficiencies, and (although rare) GI malignancy. **Dermatitis herpetiformis**, yet another manifestation of CD, presents as an itchy skin rash; its presence is diagnostic of CD. **Box 29-4** lists conditions associated with CD. Persons who are diagnosed late in life, who cannot or will not comply with the diet, or who were diagnosed as children but told they would grow out of it are at a higher risk for experiencing long-term complications from CD (Nachman et al., 2010).

## Assessment

The diagnosis of CD is made by a combination of clinical, laboratory, and histologic evaluations. Persons suspected of having CD should be evaluated for the overall pattern of symptoms and family history. Biopsy of the small intestine is the gold standard for diagnosis (Chand and Mihas, 2006). An intestinal biopsy positive for CD generally shows villous atrophy, increased intraepithelial lymphocytes, and crypt cell hyperplasia. Biopsy is not used for initial screening because of its cost and invasiveness.

Several serologic tests are used for screening. These tests identify the presence of antibodies in the blood, such as anti-tissue transglutaminase (anti-TTG), and anti-endomysial antibodies, and deamidated gliadin peptide. The sensitivity and specificity of these tests are 90% to 99% (Rostom et al., 2005). There is a higher incidence of immunoglobulin (Ig) A deficiency in patients with CD; thus physicians often measure IgA levels if serologic findings are

## BOX 29-4

### Symptoms and Conditions Associated with Celiac Disease

#### Nutritional

- Anemia (iron or folate, rarely B12)
- Osteomalacia, osteopenia, fractures (vitamin D deficiency, inadequate calcium absorption)
- Coagulopathies (vitamin K deficiency)
- Dental enamel hypoplasia
- Delayed growth, delayed puberty, underweight
- Lactase deficiency

#### Extraintestinal

- Lassitude, malaise (sometimes despite lack of anemia)
- Arthritis, arthralgia
- Dermatitis herpetiformis
- Infertility, increased risk of miscarriage
- Hepatic steatosis, hepatitis
- Neurologic symptoms (ataxia, polyneuropathy, seizures); may be partly nutrition related
- Psychiatric syndromes

#### Associated Disorders

- Autoimmune diseases: type 1 diabetes, thyroiditis, hepatitis, collagen vascular disease
- Gastrointestinal malignancy
- IgA deficiency

Data from Fasano A, Catassi C: Current approaches to diagnosis and treatment of celiac disease: an evolving spectrum, *Gastroenterology* 120:636, 2001; Hill ID et al: Celiac disease: working group report of the First World Congress of Pediatric Gastroenterology, Hepatology and Nutrition, *J Pediatr Gastroenterol Nutr* 35:785, 2002.

IgA, Immunoglobulin A.

normal but the overall clinical picture suggests CD. Using capsule endoscopy to image the entire intestinal mucosa can show inflammation related to CD, but is not currently used in the initial diagnosis (El-Matary et al., 2009). Because dietary change alters diagnostic results, initial evaluation should be done *before* the person has eliminated gluten-containing foods from his or her diet. Serologic tests may also be used to monitor the response of a newly diagnosed patient treated with a GF diet.

Lifelong, strict adherence to a GF diet is the only known treatment for CD. See **Box 29-5** for a list of safe, questionable and unsafe choices on the GF diet. The GF diet greatly diminishes the autoimmune process, and the intestinal mucosa usually reverts to normal or near normal. Within 2 to 8 weeks of starting the GF diet, most patients report that their clinical symptoms have abated. Histologic, immunologic, and functional improvements may take months to years, depending on the duration of the disease, age of the subject, and degree of dietary compliance. With strict

**BOX 29-5****The Basic Gluten-Free Diet**

<b>Foods</b>	<b>Safe Choices</b>	<b>Questionable</b>	<b>Avoid</b>
Grains and Flours	Amaranth, arrowroot, bean flours (such as garbanzo or fava bean flour), buckwheat, corn (maize) or cornstarch, flax, Job's tears, millet, potato, quinoa, ragi, rice, sorghum, soybean (soya), tapioca, teff	Carob-soy flour, buckwheat pancake mixes (often contain wheat flour), pure uncontaminated oats (note: a small percentage of people with celiac disease react to pure oats; discuss with your health care provider first)	Wheat (bulghur, couscous, durum, farina, graham, kamut, semolina, spelt, triticale, wheat germ), rye, barley, oats (except pure, uncontaminated oats), low gluten flour. Caution: “wheat free” does not necessarily mean “gluten free”
Cereals—Hot or Dry	Cream of rice, cream of buckwheat, hominy, gluten-free dry cereals, grits	Puffed rice or corn cereals (possible contamination); pure uncontaminated oats (small percentage of people with CD react to oats)	Those with wheat, rye, oats (except pure, uncontaminated), barley, barley malt, malt flavoring, wheat germ, bran
Potatoes, Rice, Starch	Any plain potatoes, sweet potatoes and yams, all types of plain rice, rice noodles, 100% buckwheat soba noodles, gluten-free pasta, polenta, hominy, corn tortillas, parsnips, yucca, turnips	Check labels for commercial potato or rice products with seasoning packets	Battered or deep-fried French fries (unless no other foods have been fried in the same oil), pasta, noodles, wheat starch, stuffing, flour tortillas, croutons
Crackers, Chips, Popcorn	Rice wafers or other gluten-free crackers, rice cakes; plain corn chips, tortilla chips, potato chips, and other root (taro, beet, etc.) chips, plain popcorn	Flavored chips	Crackers, graham crackers, rye crisps, matzo, croutons
Desserts	Sorbet, popsicles, Italian ice	Check labels on ice cream and pudding	Ice cream with bits of cookies, “crispies,” pretzels, etc; pie crust, cookies, cakes, ice cream cones, and pastries made from gluten-containing flours
Milk and Yogurt	Any plain, unflavored milk or yogurt, buttermilk, cream, half and half	Flavored milks or yogurts (check labels)	Malted milk, yogurts with added “crunchies” or toppings
Cheese	Cheese (all styles including blue cheese and gorgonzola), processed cheese (i.e., American), cottage cheese	Cheese spreads or sauces (check labels)	
Eggs	All types of plain, cooked eggs	Eggs benedict (sauce usually made with wheat flour)	
Meat, Fish, Shellfish, Poultry	Any fresh, plain untreated meat, fish, shellfish, or poultry; fish canned in brine, vegetable broth, or water	Commercially treated, preserved, or marinated meats, luncheon meats, fish, shellfish; self-basting or cured poultry	Breaded or battered meats
Beans and Legumes	Any plain frozen, fresh, dried, or canned (no flavorings or sauces added) beans: garbanzo beans, kidney beans, lentils, pinto beans, edamame, lima, black beans, etc	Check labels for added ingredients—sauces may have gluten	

**BOX 29-5****The Basic Gluten-Free Diet—cont'd**

<b>Foods</b>	<b>Safe Choices</b>	<b>Questionable</b>	<b>Avoid</b>
Soy Products and Meat Analogs or Alternatives	Plain tempeh, tofu, edamame	Check labels on miso, soy sauce, seasoned tofu and tempeh, meat analogs (imitation meat substitutes), imitation seafood	Seitan; 3-Grain Tempeh
Nuts and Seeds	Any plain (salted or unsalted) nuts, seeds or nut butters, coconut	Dry-roasted nuts (check with manufacturer—may dust with flour during processing)	Nut butters with gluten containing ingredients
Fruits and Juices	Any plain fresh, canned, frozen fruits or juices, plain dried fruit	Pie fillings (often thickened with gluten containing flour)	Dried fruit dusted with flour
Vegetables	Any plain, fresh, canned or frozen vegetables including corn, peas, lima beans, etc.		Vegetables in gluten containing sauce or gravy
Soups	Homemade soups with known allowed ingredients	Check labels on all commercial soups	
Condiments, Jams, and Syrups	Ketchup, mustard, salsa, wheat-free soy sauce, mayonnaise, vinegar (except malt vinegar), jam, jelly, honey, pure maple syrup, molasses	Check labels on soy sauce, salad dressings, commercial sauces, soup base, marinades, coating mixes	Malt vinegar
Seasonings and Flavorings	Any <i>plain</i> herb or spice; salt; pepper; brown or white sugar; or artificial sweetener (i.e., Equal, Sweet-N-Low, Splenda)	Seasoning mixes, bouillon	
Fats	Butter, margarine, all pure vegetable oils (including canola), mayonnaise, cream	Check labels on salad dressings, sandwich spreads	
Baking Ingredients	Yeast, baking soda, baking powder, cream of tartar, regular chocolate baking chips		See grains and flours; Check label on grain sweetened, carob or vegan chocolate chips
Beverages	Coffee, tea, pure cocoa powder, sodas, Silk Soymilk, Rice Dream beverage	Check labels on flavored instant coffee mixes (such as swiss mocha, cappuccino); herbal teas, soy or rice drinks (may contain barley malt or rice syrup)	Malted beverages
Alcohol	Wine, all distilled liquor including vodka, tequila, gin, rum, whiskey and pure liqueurs, gluten-free beers (Redbridge, Bard's Tale Beer, ciders)	Drink mixes	Beer, ale, lager
Candies	Check labels—many are gluten-free		Candy from bulk food bins Licorice

Adapted from Parrish CR, Krenitsky J, McCray S: University of Virginia Health System Nutrition Support Traineeship Syllabus, Charlottesville, Va, 2010, University of Virginia Health System.

CD, Celiac disease.

dietary control, levels of the specific antibodies usually become undetectable within 3 to 6 months in most persons. In some individuals, recovery may be slow or incomplete.

A small percentage of patients are “nonresponders” to diet therapy. Inadvertent gluten intake is the most common offender, but another coexisting disorder may be present (such as pancreatic insufficiency, IBS, bacterial overgrowth, fructose intolerance, other GI maladies, or unknown causes). For nonresponders, intensive interviewing to identify a source of gluten contamination or treatment of another underlying disease may resolve the symptoms. Diagnosis of **refractory celiac disease** is made when patients do not respond or respond only temporarily to a GF diet, and all external causes have been ruled out, including inadvertent gluten ingestion. Patients with refractory disease may respond to steroids, azathioprine, cyclosporine, or other medications classically used to suppress inflammatory or immunologic reactions (see *Pathophysiology and Care Management Algorithm: Celiac Disease*).

Several novel treatments for CD are being studied for their potential as alternative therapies. Researchers seek to treat CD by reducing gluten exposure (by digestion from enzymes), decreasing uptake of gluten (by tightening junctions between intestinal epithelial cells), altering the immune response to gluten, or repairing intestinal injury.

## Medical Nutrition Therapy

Elimination of gluten peptides from the diet is the only treatment of CD. The diet omits all dietary wheat, rye, and barley, which are the major sources of the prolamin fractions

In general, patients should be assessed for nutrient deficiencies before supplementation is initiated. In all newly diagnosed patients, the clinician should consider checking levels of ferritin, red blood cell folate, and 25-hydroxy vitamin D. If patients present with more severe symptoms, such as diarrhea, weight loss, malabsorption, or signs of nutrient deficiencies (night-blindness, neuropathy, prolonged prothrombin time, etc.), other vitamins such as fat-soluble vitamins (A, E, K) and minerals (zinc) should be checked.

The healing of the intestinal mucosa that occurs after initiation of a GF diet improves nutrient absorption, and many patients who eat well-balanced GF diets do not need nutritional supplementation. However, most specialty GF products are not fortified with iron and B vitamins like other grain products, so the diet may not be as complete without at least partial supplementation. Anemia should be treated with iron, folate, or vitamin B<sub>12</sub>, depending on the nature of the anemia. Patients with malabsorption may benefit from a bone density scan to assess for osteopenia or osteoporosis. Calcium and vitamin D supplementation are likely to be beneficial in these patients. Electrolyte and fluid replacement is essential for those dehydrated from severe diarrhea.

Those who continue to have malabsorption should take a general vitamin-mineral supplement to at least meet DRI

recommendations. Lactose and fructose intolerance sometimes occur secondary to CD, and sugar alcohols are not well absorbed, even in a healthy gut. A low-lactose or low-fructose diet may be useful in controlling symptoms, at least initially. Once the GIT returns to more normal function, lactase activity may also return, and the person can incorporate lactose and dairy products back into the diet.

In general, many fruits, vegetables, grains, meats, and dairy products that are plain and unseasoned are safe to eat. Oats were once thought to be questionable for persons with CD; however, extensive studies have shown that they are safe in the GF diet as long as they are pure, uncontaminated oats (Garsed and Scott, 2007). A very small population of patients with CD may not tolerate even pure oats. In general, patients do not need to be advised against including GF oats in their diet unless they have demonstrated intolerance to GF oats.

Flours made from corn, potatoes, rice, soybean, tapioca, arrowroot, amaranth, quinoa, millet, teff, and buckwheat can be substituted in recipes. Patients can expect differences in textures and flavors of common foods using the substitute flours, but new recipes can be quite palatable once the adjustment is made. In GF baked goods, gums such as xanthan, guar, and cellulose can be used to provide the elasticity needed to trap leavening gases in baked goods.

A truly GF diet requires careful scrutiny of the labels of all bakery products and packaged foods. Gluten-containing grains are not only used as a primary ingredient but may also be added during processing or preparation of foods. For example, hydrolyzed vegetable protein can be made from wheat, soy, corn, or mixtures of these grains.

The diet for the person with CD requires a major lifestyle change because of the change from traditional grains in the diet. A tremendous number of foods made with wheat (in particular breads, cereals, pastas, and baked goods) are a common part of a Western diet. However, there is increasing awareness among food companies and restaurants of the expanding demand for GF foods, and these businesses are responding. The individual and family members should all be taught about label reading, safe food additives, food preparation, sources of cross contamination (such as toasters, condiment jars, bulk bins, and buffets), and hidden sources of gluten (such as medications and communion wafers) to be compliant. Box 29-6 provides sources of hidden gluten and cross-contamination. Eating in cafeterias, restaurants, vending outlets, street markets, at friends' homes, and at social events can be challenging, especially initially.

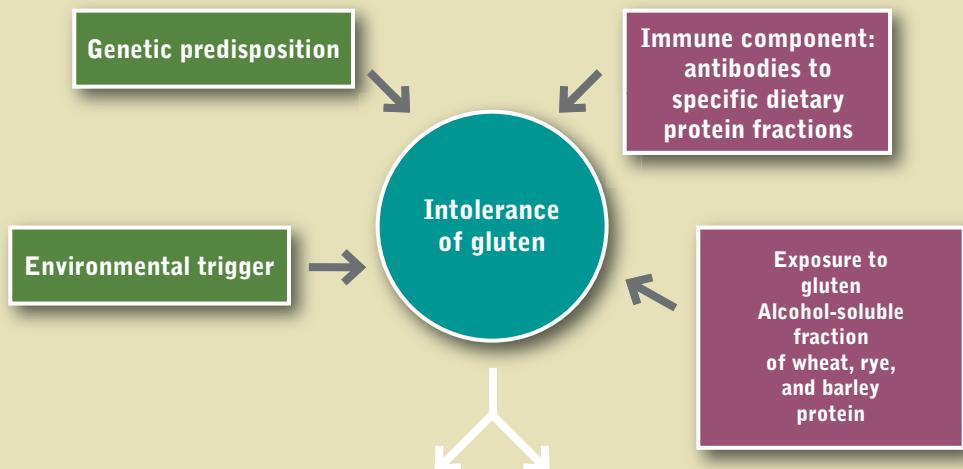

To avoid misinterpretation of information, newly diagnosed patients should be started with an in-depth instruction from a registered dietitian on the GF diet, along with reliable resources for further guidance and support. Persons with CD generally need several education or counseling sessions with a registered dietitian knowledgeable in the disease management (American Gastroenterological Association, 2006; Case, 2005). Box 29-7 lists CD resources.

## PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

### Celiac Disease (Gluten-Sensitive Enteropathy or Nontropical Sprue)

ETIOLOGY

PATHOPHYSIOLOGY

#### Damage To Small Bowel

- Atrophy and flattening of villi
- Reduced area for absorption
- Cellular deficiency of disaccharidases and peptidases
- Reduced nutrient transport carriers

#### Extraintestinal Manifestations

- Anemia
- Bone loss
- Muscle weakness
- Polyneuropathy
- Endocrine disorders (e.g., infertility)
- Follicular hyperkeratosis
- Dermatitis herpetiformis

MANAGEMENT

#### Intestinal Manifestations

- Chronic diarrhea
- Chronic constipation
- Malabsorption of vitamins and minerals

#### Medical Management

- Electrolyte and fluid replacement
- Management of other co-morbid conditions

#### Nutrition Management

- Delete gluten sources (wheat, rye, barley) from diet
- Vitamin and mineral supplementation
- Substitute with corn, potato, rice, soybean, tapioca, arrowroot, and other non-gluten flours
- Calcium and vitamin D administration
- Read food labels carefully for hidden gluten-containing ingredients
- Supplementation with ω-3 fatty acids
- Guidance to support groups and reliable internet resources

**BOX 29-6****Hidden Gluten Exposure and Cross-Contamination****Hidden Gluten Exposure**

Unfortunately, gluten is not always obvious. Review the list below for some “unsuspected” products that may contain gluten.

- Over-the-counter and prescription medications
 

The labeling requirements of the Food Allergen and Consumer Protection Act of 2004 (FALCPA) **do not apply** to medications. See [Box 27-10](#) in [Chapter 27](#). Check with your pharmacist or call the manufacturer to determine if there is any gluten in your medications.
- Note: **Dietary supplements** are covered under FALCPA regulations so wheat must be clearly listed if it is an ingredient in a vitamin, mineral or herbal supplement.
- Communion wafers
 

Gluten-free recipes are available.
- Uncommon sources
 

If laboratory values stay elevated and symptoms remain and, possible sources of gluten cannot be found in the diet, it may be worth checking into other sources such as toothpaste, mouthwash, or lipstick.

**Cross-Contamination**

Below are some of the most common sources of gluten contamination. A few crumbs that may not even be seen can

cause damage to the intestine, so it is best to avoid these situations:

- Toasters used for gluten-containing foods
 

Keep two toasters at home and designate one as gluten-free. Alternatively, there are now bags available that are designed to hold a piece of bread in the toaster.
- Bulk bins
 

Prepackaged food is a safer bet.
- Condiment jars (peanut butter, jam, mayonnaise, etc.)
 

It is best to keep a separate gluten-free jar for commonly used items and be sure to label it clearly. At the very least, make sure everyone in the house knows not to “double-dip.”
- Buffet lines
 

Other customers may use one serving utensil for multiple items. Food from one area may be spilled into another food container. It may be safer to order from the menu.
- Deep-fried foods
 

Oil is typically used over and over to fry foods. It is highly likely that French fries (or other GF foods) are fried in the same oil as battered and breaded foods like fried chicken.

Adapted from Parrish CR, Krenitsky J, McCray S: University of Virginia Health System Nutrition Support Traineeship Syllabus, Charlottesville, Va, 2010, University of Virginia Health System.

*GF*, Gluten free.

Marked gut improvement and a return to normal histologic findings occurs in the majority of patients after an average of 2 years ([Hutchinson et al., 2010](#)). Patients who are able to follow the GF diet closely have a better overall response.

**Tropical Sprue**

**Tropical sprue** is an acquired diarrheal syndrome with malabsorption that occurs in many tropical areas ([Nath, 2005](#)). In addition to diarrhea and malabsorption, anorexia, abdominal distention, and nutritional deficiency as evidenced by night blindness, glossitis, stomatitis, cheilosis, pallor, and edema can occur. Anemia may result from iron, folic acid, and vitamin  $B_{12}$  deficiencies.

**Pathophysiology**

Diarrhea appears to be an infectious type, although the precise cause and the sequence of pathogenic events remains unknown. The syndrome may include bacterial overgrowth, changes in GI motility, and cellular changes in the GIT. Identified intestinal organisms may differ from one region of the tropics to the next. As in CD, the intestinal villi may be abnormal, but the surface cell alterations are much less severe. The gastric mucosa is atrophied and inflamed, with

diminished secretion of hydrochloric acid and intrinsic factor.

**Medical Treatment**

Treatment of tropical sprue typically includes use of broad-spectrum antibiotics, folic acid, fluid, and electrolytes.

**Medical Nutrition Therapy**

Nutrition management includes restoration and maintenance of fluids, electrolytes, macronutrients, and micronutrients, and introduction of a diet that is appropriate for the extent of malabsorption (see “[Diarrhea](#)” earlier in this chapter). Along with other nutrients,  $B_{12}$  and folate supplementation may be needed if deficiency is identified. Nutritional deficiency increases susceptibility to infectious agents, further aggravating the condition.

**INTESTINAL BRUSH-BORDER ENZYME DEFICIENCIES**

Intestinal enzyme deficiency states involve deficiencies of the brush-border disaccharidases that hydrolyze disaccharides at the mucosal cell membrane. Disaccharidase deficiencies may occur as (1) rare congenital defects such as the

sucrase, isomaltase, or lactase deficiencies seen in the newborn; (2) generalized forms secondary to diseases that damage the intestinal epithelium (e.g., Crohn's disease or CD); or, most commonly, (3) a genetically acquired form (e.g., lactase deficiency) that usually appears after childhood but can appear as early as 2 years of age. For this chapter, only lactose malabsorption is described in detail (see Chapter 44 for a discussion of inborn metabolic disorders).

**Lactose Intolerance**

**Lactose intolerance** is the syndrome of diarrhea, abdominal pain, flatulence, or bloating occurring after lactose consumption. Secondary lactose intolerance can develop as a consequence of infection of the small intestine, inflammatory disorders, HIV, or malnutrition. In children it is typically secondary to viral or bacterial infections. Lactose malabsorption is commonly associated with other GI disorders, such as IBS, which is not surprising because lactose intolerance is so common.

Of the adult worldwide population, 70%, especially African, Hispanic, Asian, South American, and Native

American populations, demonstrate lactose malabsorption. However, the prevalence of lactose intolerance in the United States has not yet been accurately estimated because of limitations in the current studies (Suchy et al., 2010). Typically, lactase activity declines exponentially at weaning to about 10% of the neonatal value. Lactose malabsorption and intolerance has been reported to be low in children below age six, but increases throughout childhood, peaking at age 10–16.

There is little evidence that lactose intolerance increases with increasing adult age (Suchy et al., 2010). Even in adults who retain a high level of lactase levels (75% to 85% of white adults of Western European heritage), the quantity of lactase is approximately half that of other saccharidases such as sucrase,  $\alpha$ -dextrinase, or glucoamylase. The decline of lactase is commonly known as **hypolactasia**; the adult form involves down-regulation after weaning (Järvelä 2005) and may have a relationship with an increased risk of colon cancer in some populations (Rasinperä et al. 2005). See *Focus On: Lactose Intolerance—NOT an Uncommon Anomaly*.

## ◎ FOCUS ON

### Lactose Intolerance—NOT an Uncommon Anomaly

When lactose intolerance was first described in 1963, it appeared to be an infrequent occurrence, arising only occasionally in the white population. Because the capacity to digest lactose was measured in people from a wide variety of ethnic and racial backgrounds, it soon became apparent that disappearance of the lactase enzyme shortly after weaning, or at least during early childhood, was actually the predominant (normal) condition in most of the world's population. With a few exceptions, the intestinal tracts of adult mammals produce little, if any, lactase after weaning (the milks of pinnipeds—seals, walruses, and sea lions—do not contain lactose).

The exception of lactose tolerance has attracted the interest of geographers and others concerned with the evolution of the world's population. A genetic mutation favoring lactose tolerance appears to have arisen approximately 10,000 years ago, when dairying was first introduced. Presumably, it would have occurred in places where milk consumption was encouraged because of some degree of dietary deprivation and in groups in which milk was not fermented before consumption (fermentation breaks down much of the lactose into monosaccharides). The mutation would have selectively endured,

because it would promote greater health, survival, and reproduction of those who carried the gene.

It is proposed that the mutation occurred in more than one location and then accompanied migrations of populations throughout the world. It continues primarily among whites from northern Europe and in ethnic groups in India, Africa, and Mongolia. The highest frequency (97%) of lactose tolerance occurs in Sweden and Denmark, suggesting an increased selective advantage in those able to tolerate lactose related to the limited exposure to ultraviolet light typical of northern latitudes. Lactose favors calcium absorption, which is limited in the absence of vitamin D produced by skin exposure to sunlight (see [Chapter 3](#)).

Dairying was unknown in North America until the arrival of Europeans. Thus Native Americans and all of the non-European immigrants are among the 90% of the world's population who tolerate milk poorly, if at all. This has practical implications with respect to group feeding programs such as school breakfasts and lunches. However, many lactose-intolerant people are able to digest milk in small to moderate amounts ([Shaukat et al., 2010](#)).

### Pathophysiology

When large amounts of lactose are consumed, especially by persons who have little remaining lactase enzyme or with concurrent GI problems, loose stools or diarrhea can occur. As is the case with any malabsorbed sugar, lactose may act osmotically, and increase fecal water, as well as provide a substrate for rapid fermentation by intestinal bacteria, which may result in bloating, flatulence, and cramps. Malabsorption of lactose is due to a deficiency of lactase, the enzyme that digests the sugar in milk. Lactose that is not hydrolyzed into galactose and glucose in the upper small intestine passes into the colon, where bacteria ferment it to SCFAs, carbon dioxide, and hydrogen gas.

### Medical Treatment

Lactose malabsorption is diagnosed by (1) an abnormal hydrogen breath test, or (2) an abnormal lactose tolerance test. During a hydrogen breath test, the patient is given a standard dose of lactose after fasting, and breath hydrogen is measured. If lactose is not digested in the small intestine, it passes into the colon where it is fermented by microbes to SCFAs, CO<sub>2</sub>, and hydrogen. Hydrogen is absorbed into the bloodstream and is exhaled through the lungs. The breath hydrogen test shows increased levels 60 to 90 minutes after lactose ingestion.

During a lactose tolerance test, a dose of lactose is given and if the individual has sufficient lactase enzyme,

blood sugar will rise, reflecting the digestion of lactose to galactose and glucose. If the individual is lactose intolerant (lactase deficient) blood sugar will not rise because the lactose is not absorbed; it passes into the colon and GI symptoms may appear. The lactose tolerance test was originally based on an oral dose of lactose equivalent to the amount in 1 quart of milk (50 g). Recently, doses lower than 50 g of lactose have been used to approximate more closely the usual consumption of lactose from milk products.

Demonstrated lactose malabsorption does not always indicate a person will be symptomatic. Many factors play a role, including the amount of lactose ingested, the residual lactase activity, the ingestion of food in addition to lactose, the ability of the colonic bacteria to ferment lactose, and the sensitivity of the individual to the lactose fermentation products ([Suchy et al., 2010](#)). Consumption of small amounts should be of little consequence because the SCFAs are readily absorbed and the gases can be absorbed or passed. Larger amounts, usually greater than 12 g/day, consumed in a single food (the amount typically found in 240 mL of milk) may result in more substrate entering the colon than can be disposed of by normal processes ([Suchy et al., 2010](#)). Because serving sizes of milk drinks are increasing and more than one source of lactose might be consumed in the same meal, the amounts of lactose consumed may be more important than in years past.

## Medical Nutrition Therapy

Management of lactose intolerance requires dietary change. The symptoms are alleviated by reduced consumption of lactose-containing foods. Persons who avoid dairy products may need calcium and vitamin D supplementation or must be careful to get nondairy sources of these nutrients. A completely lactose-free diet is not necessary in lactase-deficient persons. Most lactose maldigesters can consume some lactose (up to 12 g/day) without major symptoms, especially when taken with meals or in the form of cheeses or cultured dairy products (Shaukat et al., 2010); see Chapter 3 and Table 29-3.

Many adults with intolerance to moderate amounts of milk can ultimately adapt to and tolerate 12 g or more of lactose in milk (equivalent to 240 mL of full-lactose milk) when introduced gradually, in increments, over several weeks. Incremental or continuous exposure to increasing quantities of fermentable sugar can lead to improved tolerance, not as a consequence of increased lactase enzyme production but perhaps by altered colonic flora. This has been shown with lactulose, a nonabsorbed carbohydrate that is biochemically similar to lactose (Bezkorovainy 2001).

**TABLE 29-3**

### Lactose Content of Common Foods

Product	Serving Size	Approximate Lactose Content (grams)
Milk (nonfat, 1%, 2% whole), chocolate milk, acidophilus milk, buttermilk	1 cup	10-12
Butter, margarine	1 tsp	trace
Cheese	1 ounce	0-2
• Cheddar, sharp	1 ounce	0
• American, swiss, parmesan	1 ounce	1
• Bleu cheese	1 ounce	2
Cottage cheese	½ cup	2-3
Cream (light), whipped cream	½ cup	3-4
Cream cheese	1 ounce	1
Evaporated milk	1 cup	24
Half-and-half	½ cup	5
Ice cream	½ cup	6
Ice milk	½ cup	9
Nonfat dry milk powder (unreconstituted)	1 cup	62
Sherbet, orange	½ cup	2
Sour cream	½ cup	4
Sweetened condensed milk, undiluted	1 cup	40
Yogurt, cultured, low-fat*	1 cup	5-10

\*Note: Although yogurt does contain lactose, cultured yogurt is generally well tolerated by those with lactose intolerance.

Individual differences in tolerance may relate to the state of colonic adaptation. Regular consumption of milk by lactase-deficient persons may increase the threshold at which diarrhea occurs.

Lactase enzyme and milk products treated with lactase enzyme (e.g., Lactaid) are available for lactase maldigesters who have discomfort with milk ingestion. Commercial lactase preparations may differ in their effectiveness. Fermented milk products, such as aged cheeses and yogurts, are well tolerated because the lactose content is low. Tolerance of yogurt may be the result of a microbial galactosidase in the bacterial culture that facilitates lactose digestion in the intestine. The presence of galactosidase depends on the brand and processing method. Because this microbial enzyme is sensitive to freezing, frozen yogurt may not be as well tolerated. Although the addition of probiotics may change this, evidence is lacking (Levri et al., 2005).

## Fructose Malabsorption

Consumption of fructose in the United States, especially from fruit juices, fruit drinks, and HFCS in soft drinks and confections, has increased significantly in recent years. The human small intestine has a limited ability to absorb fructose, compared with the ability to rapidly and completely absorb glucose. Breath hydrogen testing has revealed that up to 75% of healthy people will incompletely absorb a large quantity of fructose (50 g) taken alone (Barrett and Gibson, 2007). Absorption of fructose is improved when it is ingested with glucose (such as in sucrose) because glucose absorption stimulates pathways for fructose absorption.

## Pathophysiology

Although fructose malabsorption is common in healthy people, its appearance appears to depend on the amount of fructose ingested. In one study, more than 50% of people had a positive breath hydrogen test after a 25-g load, whereas 73% had a positive breath hydrogen test after a 50-g load (Beyer et al., 2005). Although some degree of fructose malabsorption may be normal, those with coexisting GI disorders may be more likely to experience GI symptoms after fructose ingestion. Patients with IBS and visceral hypersensitivity may be more sensitive to gas, distension, or pain from fructose malabsorption, whereas those with SBBO may experience symptoms from normal amounts of fructose.

## Medical Nutrition Therapy

People with fructose malabsorption and those patients with GI conditions that experience symptoms of fructose malabsorption may not have problems with foods containing balanced amounts of glucose and fructose, but may need to limit or avoid foods containing large amounts of free fructose (Beyer et al., 2005). Pear, apple, mango, and Asian pear are notable in that they have substantially more “free fructose” (more fructose than glucose) (Barrett and Gibson, 2007). Additionally, most dried fruits and fruit juices may pose a problem in larger amounts because of the amount of fructose provided per serving. Foods

sweetened with HFCS (as opposed to sucrose) are also more likely to cause symptoms. Hepatic fructose metabolism is similar to ethanol, in that they both serve as substrates for de novo lipogenesis, thus promoting hepatic insulin resistance, dyslipidemia, and hepatic steatosis (Lustig, 2010). The degree of fructose intolerance and tolerance to the symptoms of fructose malabsorption are so variable that tolerable intake of these foods must generally be individualized with each patient.

## INFLAMMATORY BOWEL DISEASES

The two major forms of **inflammatory bowel disease (IBD)** are Crohn's disease and ulcerative colitis (UC). Both Crohn's disease and UC are relatively rare disorders, but they result in frequent use of health care resources. The prevalence is approximately 130 cases per 100,000 persons for Crohn's disease and 100 per 100,000 for UC. The onset of IBD occurs most often in patients 15 to 30 years of age, but for some it occurs later in adulthood. Both sexes are equally affected. IBD occurs more commonly in developed areas of the world, in urban compared with rural environments, and in northern compared with southern climates.

**Crohn's disease** and **ulcerative colitis (UC)** share some clinical characteristics, including diarrhea, fever, weight loss, anemia, food intolerances, malnutrition, growth failure, and extraintestinal manifestations (arthritic, dermatologic, and hepatic). In both forms of IBD, the risk of malignancy increases with the duration of the disease. The reasons for the increased risk are not firmly established but are likely

related to the increased inflammatory and proliferative state and nutritional factors. Although malnutrition can occur in both forms of IBD, it is more of a lifelong concern in patients with Crohn's disease. The features that distinguish the forms of the disease in terms of genetic characteristics, clinical presentation, and treatment are discussed in Table 29-4.

### Crohn's Disease and Ulcerative Colitis

Crohn's disease may involve any part of the GIT, but approximately 50% to 60% of cases involve both the distal ileum and the colon. Only the small intestine or only the colon is involved in 15% to 25% of cases. Disease activity in UC is limited to the large intestine and rectum. In Crohn's disease, segments of inflamed bowel may be separated by healthy segments, whereas in UC the disease process is continuous (Figure 29-2). Mucosal involvement in Crohn's disease is transmural in that it affects all layers of the mucosa; in UC the disease normally is limited to the mucosa. Crohn's disease is characterized by abscesses, fistulas, fibrosis, submucosal thickening, localized strictures, narrowed segments of bowel, and partial or complete obstruction of the intestinal lumen. Bleeding is more common in UC.

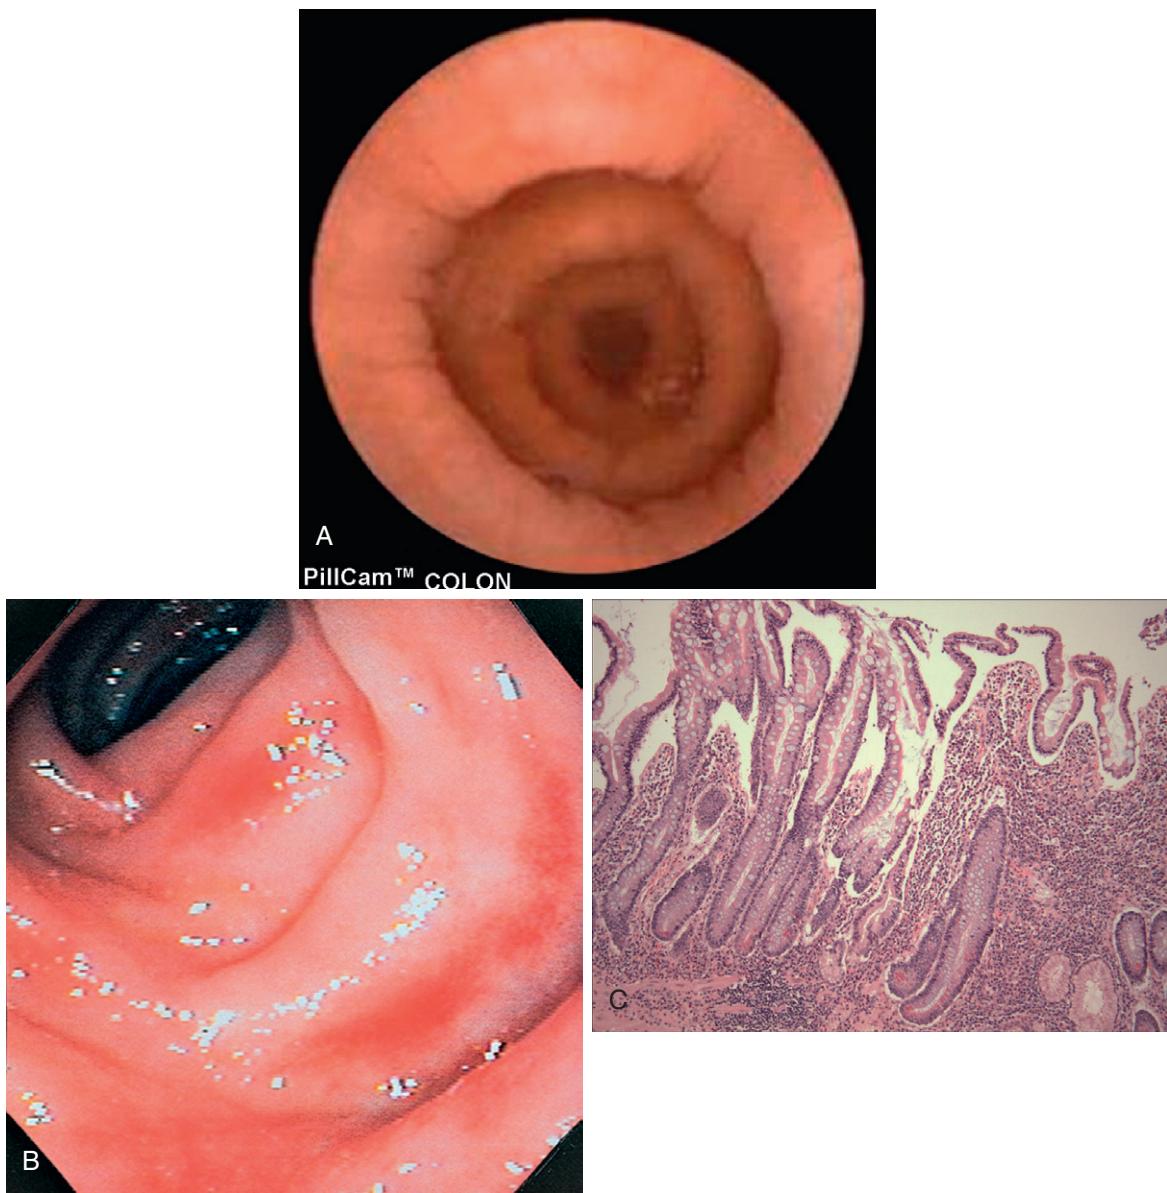

### Pathophysiology

The cause of IBD is not completely understood, but it involves the interaction of the GI immunologic system and genetic and environmental factors. The genetic susceptibility is now recognized to be diverse, with a number of possible gene mutations that affect risk and characteristics of

**TABLE 29-4**

#### Ulcerative Colitis versus Crohn's Disease

	Ulcerative Colitis	Crohn's Disease
Presentation	Bloody diarrhea	Perianal disease, abdominal pain (65%), mass in abdomen
Gross Pathology	Rectum always involved Moves continuously, proximally from rectum Thin wall Few strictures Diffuse ulceration	Rectum may not be involved Can occur anywhere along gastrointestinal tract Not continuous: "skip lesions" Thick wall Strictures common Cobblestone appearance
Histopathology	No granulomas Low inflammation Deeper ulcers (hence named ulcerative) Pseudopolyps Abscesses in crypts	Granulomas More inflammation Shallow ulcers Fibrosis
Extraintestinal Manifestations	Sclerosing cholangitis Pyoderma gangrenosum	Erythema nodosum Migratory polyarthritis Gallstones
Complications	Toxic megacolon Cancer Strictures and fistulas are very rare	Malabsorption Cancer Strictures or fistulas Perianal disease

**FIGURE 29-2** A, Normal colon, B, ulcerative colitis, C, Crohn's disease. (A, From Fireman, Z., & Kopelman, Y. (2007). *The colon—the latest terrain for capsule endoscopy. Digestive and Liver Disease*, 39(10), 895-899. B, From Black JM, Hawks JH: *Medical-surgical nursing: clinical management for positive outcomes*, ed 8, St. Louis, 2009, Saunders. C, From McGowan, CE, Lagares-Garcia, JA, & Bhattacharya, B. (2009). Retained capsule endoscope leading to the identification of small bowel adenocarcinoma in a patient with undiagnosed Crohn disease. *Annals of Diagnostic Pathology*, 13(6), 390-393.)

the disease. The diversity in the genetic alterations among individuals may help explain differences in the onset, aggressiveness, complications, location, and responsiveness to different therapies as seen in the clinical setting (Shih and Targan, 2008). The major environmental factors include resident and transient microorganisms in the GIT and dietary components.

The genes affected (e.g., C677T mutation related to methylene-tetrahydrofolate reductase) normally play a role in the reactivity of the host GI immune system to luminal antigens such as those provided by intestinal flora and the diet. In animal models inflammatory disease does not occur without the intestinal flora. Normally, when an antigenic challenge or trauma occurs, the immune response rises to

the occasion; it is then turned off and continues to be held in check after the challenge resolves. In IBD, increased exposure, decreased defense mechanisms, or decreased tolerance to some component of the GI microflora occur. Inappropriate inflammatory response and an inability to suppress it play primary roles in the disease. For example, one of the genes affected in Crohn's disease is the NOD<sub>2</sub>/CARD<sub>15</sub> gene, which codes for a small peptide that interacts with a host of GI bacteria. Failure to produce that peptide may result in abnormal immune responses (Mueller and Macpherson, 2006).

The inflammatory response (e.g., increased cytokines and acute-phase proteins, increased GI permeability, increased proteases, and increased oxygen radicals and leukotrienes)

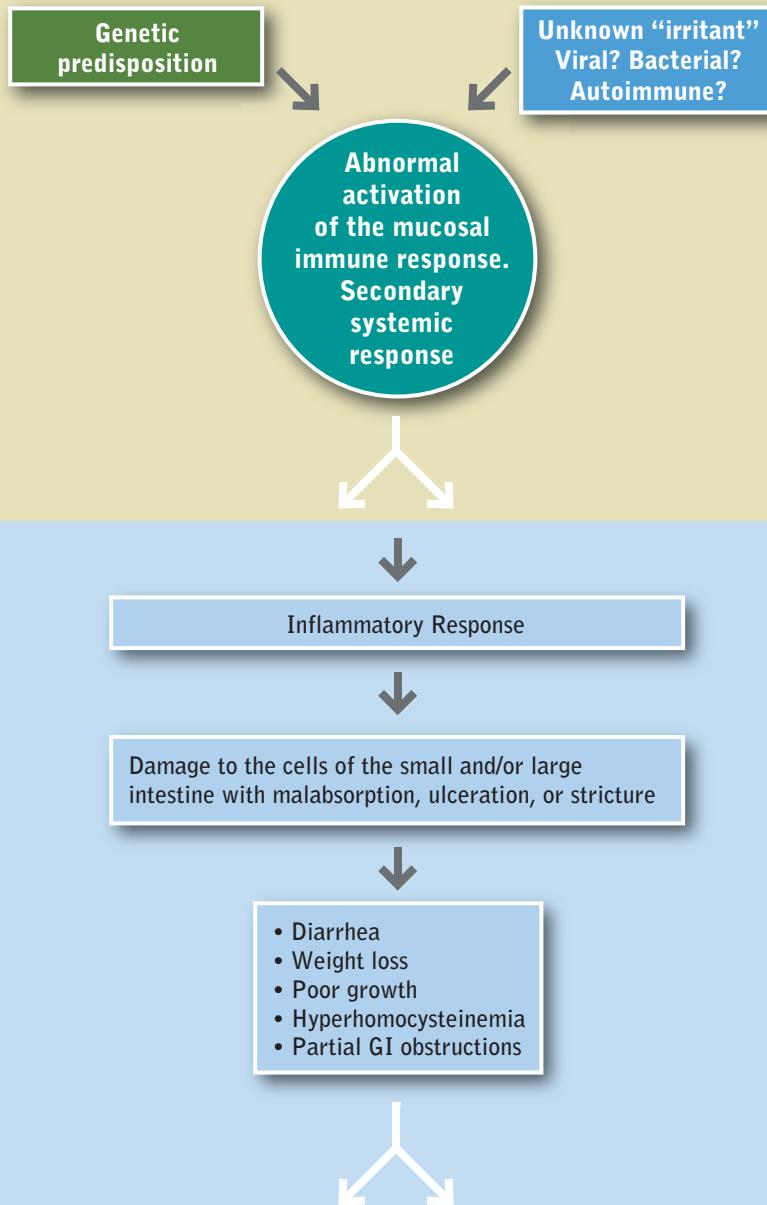

## PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

### Inflammatory Bowel Disease

**Etiology**

**Pathophysiology**

**Management**

#### Medical Management

- Corticosteroids
- Antiinflammatory agents
- Immunosuppressants
- Antibiotics
- Anticytokine medications

#### Surgical Management

- Bowel resection that can result in short bowel syndrome (SBS)

#### Nutrition Management

- Oral enteral formula (tube-feed if necessary)
- Use of foods that are well tolerated
- Parenteral nutrition in patients with severe disease or obstruction
- Multivitamin supplement containing folic acid, B<sub>12</sub>, and B<sub>6</sub>
- ω-3 fatty acid supplementation
- Consider use of prebiotics and probiotics
- Modify fiber intake as necessary
- Tests for food intolerances

results in GI tissue damage (Sanders, 2005). In IBD either the regulatory mechanisms are defective or the factors perpetuating the immune and acute-phase responses are enhanced, leading to tissue fibrosis and destruction. The clinical course of the disease may be mild and episodic or severe and unremitting (see *Pathophysiology and Care Management Algorithm: Inflammatory Bowel Disease*).

Diet is an environmental factor that may trigger relapses of IBD. Foods, microbes, individual nutrients, and incidental contaminants provide a huge number of potential antigens, especially considering the complexity and diversity of the modern diet. Malnutrition can affect the function and effectiveness of the mucosal, cellular, and immune barriers; diet can also affect the type and relative composition of the resident microflora. Several nutrients (e.g., dietary lipids) can affect the intensity of the inflammatory response.

Food allergies and other immunologic reactions to specific foods have been considered in the pathogenesis of IBD and its symptoms; however, the incidence of documented food allergies, compared with food intolerances, is relatively small. The permeability of the intestinal wall to molecules of food and cell fragments is likely increased in inflammatory states, allowing the potential for increased interaction of antigens with host immune systems (Müller et al., 2005).

Food intolerances occur more often in persons with IBD than in the population at large, but the patterns are not consistent among individuals or even between exposures from one time to the next. Reasons for specific and nonspecific food intolerances are abundant and are related to the severity, location, and complications associated with the disease process. Partial GI obstructions, malabsorption, diarrhea, altered GI transit, increased secretions, food aversions, and associations are but a few of the problems experienced by persons with IBD. However, neither food allergies nor intolerances fully explain the onset or manifestations in all patients (see Chapter 27).

### Medical Management

The goals of treatment in IBD are to induce and maintain remission and to improve nutrition status. Treatment of the primary GI manifestations appears to correct most of the extraintestinal features of the disease as well. The most effective medical agents include corticosteroids, antiinflammatory agents (aminosalicylates), immunosuppressive agents (cyclosporine, azathioprine, mercaptopurine), antibiotics (ciprofloxacin and metronidazole), and monoclonal tumor necrosis factor antagonists (anti-TNF) (infliximab, adalimumab, certolizumab, and natalizumab), agents that inactivate one of the primary inflammatory cytokines. Anti-TNF is normally used in severe cases of Crohn's disease and fistulas, but it has not been shown to be effective in UC.

Investigations of various treatment modalities for the acute and chronic stages of IBD are ongoing, and include new forms of existing drugs, as well as new agents targeted to regulate cytokines, eicosanoids, or other mediators of the inflammatory and acute-phase response (Caprilli et al., 2006; Travis et al., 2006). ω-3 fatty acid supplements (fish

oil capsules) in Crohn's disease significantly reduce disease activity (Turner et al., 2009). Use of fish oil supplements in UC appears to result in a significant medication-sparing effect, with reductions in disease activity and increased time in remission reported (Seidner et al., 2005). Use of foods and supplements containing prebiotics and probiotic cultures are being investigated because each has the potential to alter both the GI microflora and the immunologic response at the gut level (Dotan and Rachmilewitz, 2005).

### Surgical Management

In Crohn's disease, surgery may be necessary to repair strictures or remove portions of the bowel when medical management fails. Approximately 50% to 70% of persons with Crohn's disease will undergo surgery related to the disease. Surgery does not cure Crohn's disease, and recurrence often occurs within 1 to 3 years of surgery. The chance of needing subsequent surgery in the patient's life is approximately 30% to 70%, depending on the type of surgery and the age at first operation. Major resections of the intestine may result in varying degrees of malabsorption of fluid and nutrients. In extreme cases patients may have extensive or multiple resections, resulting in short-bowel syndrome (SBS) and dependence on PN to maintain adequate nutrient intake and hydration.

With UC, approximately 20% of patients have a colectomy and removal of the colon, and this resolves the disease. Inflammation does not occur in the remaining GIT. Whether a colectomy is necessary depends on the severity of the disease and indicators of increased cancer risk. After a colectomy for UC, surgeons may create an ileostomy with an external collection pouch and an internal abdominal reservoir fashioned with a segment of ileum or an ileoanal pouch, which spares the rectum, to serve as a reservoir for stool. The internal Koch pouch may also be used (see Chapter 14).

### Medical Nutrition Therapy

Persons with IBD are at increased risk of nutrition problems for a host of reasons related to the disease and its treatment. Thus the primary goal is to restore and maintain the nutrition status of the individual patient. Foods, dietary and micronutrient supplements, enteral and PN may all be used to accomplish that mission. Oral diet and the other means of nutrition support may change during remissions and exacerbations of the disease.

Persons with IBD often have fears and misconceptions regarding GI symptoms and the role of food. Patients are also often confused by dietary advice from associates, various media, and health care providers. Education is a key form of nutrition intervention. There is no single dietary regimen for reducing symptoms or decreasing the flares in IBD. Diet and specific nutrients play a supportive role in maintaining nutrition status, limiting symptom exacerbations, and supporting growth in pediatric patients.

The ability of parenteral or enteral nutrition to induce remission of IBD has been debated for several years. Evaluation is confounded by the natural course of IBD with

exacerbations and remissions, and by the genetic diversity of the patients. Studies have generally concluded that (1) nutrition support may bring about some clinical remission when used as a sole source of treatment; (2) “complete bowel rest” using PN is not necessarily required; (3) enteral nutrition has the potential to feed the intestinal epithelium and alter GI flora and is the preferred route of nutrition support; (4) enteral nutrition may temper some elements of the inflammatory process, serve as a valuable source of nutrients needed for restoration of GI defects, and be steroid sparing; (5) children benefit from the use of enteral nutrition to maintain growth and reduce the dependence on steroids that may affect growth and bone disease (Dray and Marteau, 2005; Lochs, 2006; Sanderson and Croft, 2005). Patients and caretakers must be very committed when using enteral nutrition formulas or tube feeding because it takes 4 to 8 weeks before one sees the clinical effects.

Timely nutritional support is a vital component of therapy to restore and maintain nutritional health. Malnutrition itself compromises digestive and absorptive function by increasing the permeability of the GIT to potential inflammatory agents. PN is not as nutritionally complete, has increased risk of infectious complications, and is more expensive than enteral nutrition. However, PN may be required in patients with persistent bowel obstruction, fistulas, and major GI resections that result in SBS where enteral nutrition is not possible.

Energy needs of patients with IBD are not greatly increased (unless weight gain is desired). Generally when disease activity increases basal metabolic rate, physical activity is greatly curtailed and overall energy needs are not substantially changed.

Protein requirements may be increased, depending on the severity and stage of the disease and the restoration requirements. Inflammation and treatment with corticosteroids induce a negative nitrogen balance and cause a loss of lean muscle mass. Protein losses also occur in areas of inflamed and ulcerated intestinal mucosa via defects in epithelial tight junctions. See Fig. 39-3 in Chapter 39. To maintain positive nitrogen balance, 1.3–1.5 g/kg/day of protein is recommended.

Supplemental vitamins, especially folate, B<sub>6</sub>, and B<sub>12</sub>, may be needed as well as minerals and trace elements to replace stores or for maintenance because of maldigestion, malabsorption, drug-nutrient interactions, or inadequate intake (Zezos et al., 2005). Diarrhea can aggravate losses of zinc, potassium, and selenium. Patients who receive intermittent corticosteroids may need supplemental calcium and vitamin D. Patients with IBD are at increased risk of osteopenia and osteoporosis; 25-OH vitamin D levels and bone density should be routinely monitored.

In daily life people with IBD may have intermittent “flares” of the disease characterized by partial obstructions, nausea, abdominal pain, bloating, or diarrhea. Many patients report specific, individualized food intolerances. Patients are sometimes advised to eliminate the foods they suspect are responsible for the intolerance. Often, the patient becomes increasingly frustrated as the diet becomes progressively limited and symptoms still do not resolve. Malnutrition is a

significant risk in patients with IBD, and an overly restricted diet only increases the likelihood of malnutrition and weight loss.

During acute and severe exacerbations of the disease, the diet is tailored to the individual patient. In patients with rapid intestinal transit, extensive bowel resections, or extensive small bowel disease, absorption may be compromised. Here, excessive intake of lactose, fructose, or sorbitol may contribute to abdominal cramping, gas, and diarrhea; and high fat intake may result in steatorrhea. However, the incidence of lactose intolerance is no greater in patients with IBD than in the general population. Patients with IBD who tolerate lactose should not restrict lactose-containing foods because they can be a valuable source of high quality protein, calcium, and vitamin D.

Patients with strictures or partial bowel obstruction benefit from a reduction in dietary fiber or limited food particle size. Small, frequent feedings may be tolerated better than large meals. Small amounts of isotonic, liquid oral supplements may be valuable in restoring intake without provoking symptoms. In cases in which fat malabsorption is likely, supplementation with foods made with **medium-chain triglycerides (MCTs)** may be useful in adding calories and serving as a vehicle for fat-soluble nutrients. However, these products are expensive and may be less effective than more basic treatments.

Factors associated with the development of IBD in epidemiologic studies include increased sucrose intake, lack of fruits and vegetables, a low intake of dietary fiber, use of red meat and alcohol, and altered ω-6/ω-3 fatty acid ratios. Yet dietary interventions to modify these factors during IBD flares have not resulted in significant improvements (Rajendran and Kumar, 2010).

The same foods that are responsible for GI symptoms (gas, bloating, and diarrhea) in a normal, healthy population are likely to be the triggers for the same symptoms in patients with mild stages of IBD or those in remission.

Patients receive nutritional information from a variety of sources, including support groups, Internet news groups, the audio and printed media, well-meaning friends, and food supplement salespersons. The information is sometimes inaccurate or exaggerated, or it may pertain only to one individual’s situation. The health care provider can help patients sort out the role of foods in normal, everyday GI disturbances and in IBD and teach them how to evaluate valid nutrition information from unproven or exaggerated claims. Patients’ participation in the management of their disease may help to reduce not only the symptoms of the disease but the associated anxiety level as well.

Probiotic foods and supplements have been investigated as potential therapeutic agents for IBD because of their ability to modify the microbial flora and modulate gut inflammatory response. High-dose probiotic supplements (e.g., VSL#3) improved disease activity in patients with UC who had **pouchitis**, inflammation in the ileal pouch surgically formed after colectomy (Holubar et al., 2010). However, a different probiotic supplement at a lower dose did not significantly reduce symptoms (Holubar et al., 2010). Probiotic supplements also appear to be useful

for induction and extension of remissions in pediatric and adult UC (Guandalini, 2010; Mallon et al., 2007).

Although probiotics appear useful in UC, probiotic studies to date have not demonstrated significant improvement in Crohn's disease activity in adults or pediatric patients, nor do probiotic supplements appear to prolong remission in Crohn's disease (Butterworth et al., 2008; Guandalini, 2010).

Regular intake of prebiotic foods such as oligosaccharides, fermentable fibers, and resistant starches can alter the mixture of microorganisms in the colonic flora, feeding lactobacillus and bifidobacteria to provide competition to and theoretically suppress pathogenic or opportunistic microflora. Additionally, fermentation of prebiotics leads to increased production of SCFAs, theoretically creating a more acidic and less favorable environment for opportunistic bacteria.

Use of probiotics and prebiotics may serve to prevent small intestine bacterial overgrowth in predisposed individuals and to treat diarrhea. Additional study is needed to identify the dose, the most effective prebiotic and probiotic foods, the form in which they can be used for therapeutic and maintenance purposes, and their relative value compared with other therapies (Penner et al., 2005).

### **Microscopic Colitis**

Injury of the colon caused by UC, Crohn's disease, infections, radiation injury, and ischemic insult to the colon all present with abnormalities such as edema, redness, bleeding, or ulcerations that are visible on colonoscopy examination.

**Microscopic colitis** is characterized by inflammation that is not visible by inspection of the colon during colonoscopy, and is only apparent when the colon's lining is biopsied and then examined under a microscope.

There are two types of microscopic colitis. In lymphocytic colitis, there is an accumulation of lymphocytes within the lining of the colon. In collagenous colitis, there is also a layer of collagen (like scar tissue) just below the lining. Some experts believe that lymphocytic colitis and collagenous colitis represent different stages of the same disease. Symptoms include chronic, watery diarrhea, mild abdominal cramps, and pain.

More than 30% of patients report weight loss (Simondi et al., 2010). Patients with microscopic colitis can have diarrhea for months or years before the diagnosis is made. The cause of microscopic colitis is unknown. Microscopic colitis appears more frequently in patients aged 60–70 years, and collagenous colitis occurs more frequently in females (Jobse et al., 2009; Tysk et al., 2008).

Patients with CD are 70 times more likely than the normal population to develop microscopic colitis (Green et al., 2009). Patients with CD and microscopic colitis have more severe villous atrophy and frequently require steroids or immunosuppressant therapies in addition to a GF diet to control diarrhea. Research is underway to determine possible effective treatments for microscopic colitis, including corticosteroids and immunosuppressive agents. Medical nutrition therapy is supportive in nature with efforts to maintain weight and nutrition status, avoid symptom exacerbation, and maintain hydration.

### **Irritable Bowel Syndrome**

**Irritable bowel syndrome (IBS)** is characterized by chronically recurring abdominal discomfort or pain and altered bowel habits. Other common symptoms include bloating, feelings of incomplete evacuation, presence of mucus in the stool, straining or increased urgency (depending on the type of presentation), and increased GI distress associated with psychosocial distress.

IBS is one of the most common reasons for primary care visits and consultations with gastroenterologists in the United States. IBS occurs in approximately 15% of women and 10% of men; however, it is estimated that only 25% to 50% of those with symptoms actually seek treatment. Typically, symptoms first occur between adolescence and the fourth decade of life, but many persons do not bring the problem to the attention of a physician. Persons with IBS often have increased absenteeism from school and work, decreased productivity, increased health care costs, and decreased quality of life as a result of their symptoms.

Diagnosis is based on international consensus criteria (Rome criteria) and diagnostic algorithms that help separate other medical or surgical disorders that manifest with similar symptoms (Malagelada, 2006). According to the criteria, symptoms of abdominal discomfort must be present for at least 3 days per month for the past 3 months, include at least two of three features: (1) discomfort relieved by defecation, (2) onset associated with a change in frequency of stool, and (3) onset associated with a change in form of the stool. Diagnosis further categorizes the syndrome into one of three subtypes: diarrhea predominant, constipation predominant, or mixed. Small intestinal bacterial overgrowth (SIBO) has been described in a significant number of patients with IBS, particularly diarrhea-predominant IBS (Ghoshal et al., 2010a). Positive hydrogen or lactulose breath tests have been reported in 22% to 54% of patients with IBS (Ford and Spiegel, 2009; Lombardo et al., 2010). Prevalence of CD has been reported as fourfold greater in individuals diagnosed with IBS than in individuals without IBS, likely because of misdiagnosis of IBS, and screening for CD has been determined to be cost-effective in this population (Ford and Spiegel, 2009).

### **Pathophysiology**

The normal enteric nervous system is sensitive to the presence, chemical composition, and volume of foods in the GIT, and also responds to a variety of inputs from the central nervous system (see Chapter 1). Increased awareness and sensitivity of the GIT to internal and external stimuli and altered motility appear to be primary features of IBS (Malagelada, 2006). Persons with IBS have heightened enteric sensitivity and motility in response to usual GI and environmental stimuli. They react more significantly than normal persons to intestinal distention, dietary changes, and psychosocial factors. IBS is considered a functional disorder, because it is a diagnosis by exclusion and is based on symptoms, not structural or biochemical abnormality. It is commonly described as a “brain-gut disorder” because of the association with serotonin.

The mediators of GI responses may be abnormal secretion of peptide hormones or signaling agents (e.g., neurotransmitters secreted in response to the hormones); but altered handling of intestinal gas, microbial flora, SIBO, and other contributors affect some forms of IBS. Post-infectious IBS typically appears abruptly after gastroenteritis and is essentially managed with the same approach as other forms of IBS (Ghoshal et al., 2010b). In addition to stress and dietary patterns, factors that may worsen symptoms include (1) excess use of laxatives and other over-the-counter medications; (2) antibiotics; (3) caffeine; (4) previous GI illness; and (5) lack of regularity in sleep, rest, and fluid intake. In patients with a strong family history of allergy, hypersensitivity to certain foods may aggravate IBS; a trial of food elimination and challenge may be justified (see Chapter 27).

### Medical Management

The first step in management of IBS and other functional GI disorders includes first validating the reality of the patient's complaints and establishing an effective clinician-patient relationship. Care should be tailored to help the patient deal with the symptoms and the factors that may trigger them. Education, medications, pain management, counseling, and diet each play a role in care. Depending on the predominant pattern and severity of the symptoms, medications may include those that affect GI motility, visceral hypersensitivity, or psychological symptoms. Relaxation and stress-reduction techniques may also be useful.

Osmotic laxatives are commonly used to treat constipation, although they have not been thoroughly studied. Agents that affect how the GIT responds to serotonin (5-hydroxytryptophane [5-HT], a major mediator in the sensory and motility functions of the enteric nervous system) are under investigation. Two major 5-HT receptors, 5-HT<sub>3</sub> antagonists, and 5-HT<sub>4</sub> agonists have been targeted for use in treating patients with different forms of IBS. 5-HT<sub>3</sub> antagonists have shown some success in women with diarrhea-predominant IBS, whereas 5-HT<sub>4</sub> agonists serve as prokinetic agents that stimulate peristalsis of the small and large intestine and are used in the management of constipation-predominant IBS. A number of other agents are being evaluated. Low-dose loperamide is commonly effective in patients who have diarrhea-predominant IBS.

Antispasmodic agents have been used to treat pain associated with IBS, but have not been thoroughly studied in randomized trials. Tricyclic antidepressants in low doses have been shown to reduce symptoms in some cases.

### Medical Nutrition Therapy

The goals of nutrition therapy for IBS are to ensure adequate nutrient intake, tailor the diet for the specific GI pattern of IBS, and explain the potential roles of foods in the management of symptoms. There is little scientific evidence for restricting particular foods. Large meals and certain foods may be poorly tolerated, such as excess quantities of dietary fat, caffeine, lactose, fructose, sorbitol, and alcohol. This is especially true in persons with diarrhea-predominant IBS or mixed IBS.

Most fiber studies in the IBS population to date have numerous short-comings, such as a strong placebo effect (Heizer et al., 2009). Some patients with constipation-predominant IBS may benefit from fiber in the form of bulk laxatives (e.g., psyllium) (Bijkerk et al., 2009). Supplementation of insoluble fiber, such as wheat bran, may actually worsen symptoms. Consumption of adequate fluid is recommended, especially when powdered fiber supplements are used.

Food intolerances and allergies should be evaluated objectively because patients may unnecessarily limit large groups of foods, resulting in frustration and an incomplete diet (Kalliomäki, 2005; Seibold, 2005). In clinical practice, it can be very difficult to determine if a patient's symptoms are truly from an adverse reaction to food. Systematically eliminating and reintroducing foods can be useful in determining if a patient is truly reacting to a food. A double-blind, placebo-controlled food challenge may be helpful but it is time-consuming and labor intensive (Heizer et al., 2009). See Chapter 27.

Foods with fiber, resistant starches, and oligosaccharides may serve as prebiotic foods, which favor the maintenance of healthy microflora and resistance to pathogenic infections. Results of initial studies on the use of prebiotic and probiotic supplements have been mixed. More studies comparing types of organisms, doses, and subtypes of IBS are needed. Additionally, potential benefits of prebiotics may be outweighed by poor absorption.

Some probiotic supplements may offer benefits in IBS. However, the randomized controlled trials that have been conducted have been small and have produced variable results depending on the type and dose of the probiotic as well as the individual population studied (Aragon et al., 2010). One study evaluated different doses of *Bifidobacterium infantis* in women diagnosed with IBS (Whorwell et al., 2006). The group treated with the higher dose of probiotic reported a significant improvement in abdominal pain or discomfort, bloating and distension, sensation of incomplete evacuation, passage of gas, straining, and bowel habit satisfaction.

A diet low in fermentable oligo-, di-, and monosaccharides and polyols (**FODMAPs**) has been theorized to be useful (Shepherd et al., 2008). The low FODMAP diet limits foods that contain fructose, lactose, fructo- and galactooligosaccharides (fructans and galactans), and sugar alcohols (sorbitol, mannitol, xylitol and maltitol). FODMAPs are poorly absorbed in the small intestine, highly osmotic, and rapidly fermented by bacteria. Limiting the amount of FODMAPs per meal has been shown to reduce GI symptoms in patients with IBS (Gibson and Shepherd 2010). However, a cutoff value for acceptable amounts of FODMAPs has not been well defined, and is likely patient specific. See Table 29-5 for foods containing FODMAPs as well as dietary instructions.

Peppermint oil also shows promise. One randomized controlled trial showed significant improvement in abdominal symptoms for individuals supplementing with peppermint oil (Ford et al., 2008).

**TABLE 29-5****Foods Containing FODMAPs, and Low FODMAP Diet Instructions**

<b>FODMAP</b>	<b>High FODMAP food</b>
Fructose	Fruits: apples, pears, peaches, mango, sugar snap peas, watermelon, canned fruit in natural juice, dried fruit, fruit juice Sweeteners: honey, high fructose corn syrup,
Lactose	Milk (cow, goat and sheep), ice cream, soft cheeses (e.g., ricotta, cottage cheese)
Oligosaccharides (fructans or galactans)	Vegetables: artichokes, asparagus, beets, brussel sprouts, broccoli, cabbage, fennel, garlic, leeks, okra, onions, peas, shallots Cereals: wheat and rye (in large amounts) Legumes: chickpeas, lentils, kidney beans, baked beans
Polyols	Fruits: watermelon, apples, peaches, rambutan, persimmon Fruits: apples, apricots, cherries, longon, lychee, pears, nectarine, peaches, plums, prunes, watermelon Vegetables: avocado, cauliflower, mushrooms, snow peas Sweeteners: sorbitol, mannitol, maltitol, xylitol, and others ending in “-ol”

**Low FODMAP Diet Instructions**

- Avoid foods that contain fructose in excess of glucose (unless fructose malabsorption is not demonstrated).
- Try ingesting a source of glucose with fructose-containing foods (i.e., sucrose contains equal amounts of glucose and fructose).
- Limit amount of fructose at any one meal.
- Avoid foods that contain significant amounts of fructans and galactans.
- Restrict lactose-containing foods (unless lactose malabsorption is not demonstrated).
- Avoid polyol-containing foods.

Adapted from Gibson PR, Shepherd SJ: Evidence-based dietary management of functional gastrointestinal symptoms: the FODMAP approach, J Gastroenterol Hepatol 25:252, 2010.

*FODMAP*, Fermentable oligo-, di-, and monosaccharides and polyols.

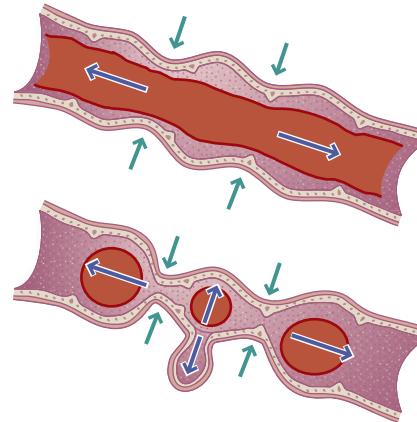

The nutrition practitioner can work with the person with IBS to identify his or her concerns and perceptions, review the characteristics of the disease and the potential role of various foods, and teach the client how to reduce food-related symptoms. Sometimes clients become trapped in a vicious cycle in which anxiety about food, GI distress, and social embarrassment leaves them with an unnecessarily restrictive diet, declining nutrition status, and worsening symptoms. Reassurance and the gradual return to a good diet with limitations of only irritating foods can greatly improve quality of life.

**Diverticular Disease**

**Diverticulosis** is the condition of having saclike herniations (diverticula) in the colonic wall. The incidence of diverticulosis increases with age. Sigmoid involvement occurs in almost all cases; right-sided colonic involvement occurs in Asians, but it is rare in whites. Most persons are asymptomatic. However, 15% to 20% of persons with diverticulosis experience colicky pain; approximately 5% experience inflammation and diverticulitis.

**Pathophysiology**

The cause of diverticulosis has not been clearly elucidated. A combination of colonic structure, motility, genetics, and a lifelong low-fiber intake results in increased intracolonic pressures (Parra-Blanco, 2006; Salzman and Lillie, 2005). The pressures result from attempts to propel small, dry,

**FIGURE 29-3** Mechanism by which low-fiber, low-bulk diets might generate diverticula. Where the colon contents are bulky (*top*), muscular contractions exert pressure longitudinally. If the fecal contents are small in diameter (*bottom*), contractions can produce occlusion and exert pressure against the colon wall, which may produce a diverticular hernia.

hard fecal material through the lumen of the bowel. Theoretically, circular muscles completely close around the fecal material when the stools are small and longitudinal muscles contract, attempting to push the contents distally. Increased pressure allows herniations of the mucosal wall to develop through weaker segments of the colon. See Fig. 29-3. This

theory is supported by multiple human and animal studies. In general, diverticular disease is relatively rare in countries where a high-fiber diet is part of the lifelong pattern, and increasing where there is “Westernization” of the diet with high intake of refined foods (Salzman and Lillie, 2005). Lack of exercise may also contribute.

### Medical and Surgical Treatment

Complications of diverticular disease range from painless, mild bleeding and altered bowel habits to diverticulitis.

**Diverticulitis** includes a spectrum of inflammation, abscess formation, acute perforation, acute bleeding, obstruction, and sepsis. Treatment typically includes antibiotics and oral intake as tolerated. A modified diet or bowel rest may be indicated based on the patient’s degree of illness, desire to eat, and likelihood of imminent surgery (Salzman and Lillie, 2005). Colon cleansers that cause hard stools, constipation, and straining are not recommended. Approximately 10% to 25% of patients with diverticulosis develop diverticulitis, and approximately one fourth to one third of those admitted to hospitals require surgery.

### Medical Nutrition Therapy

At one time it was thought that “roughage” (dietary fiber) aggravated diverticular disease; thus the classic diet therapy was low in fiber. It is now recognized that a high-fiber diet, in combination with adequate hydration, promotes soft, bulky stools that pass more swiftly and require less straining with defecation. High-fiber intakes have been found to relieve symptoms for most patients, and exercise appears to aid in preventing constipation.

Patients may require extensive encouragement to adopt the high-fiber approach. Fiber intake should be increased gradually because it may cause bloating or gas. These side effects usually disappear within 2 to 3 weeks. Recommended intakes of dietary fiber, preferably from foods, are 25 g/day for adult women and 38 g/day for men. If an individual cannot or will not consume the necessary amount of fiber, methylcellulose and psyllium fiber supplements have been used with good results. Adequate fluid intake (e.g., 2 to 3 L daily) should accompany the high-fiber intake.

During an acute flare of diverticulitis, a low-residue diet or PN may be required initially, followed by a gradual return to a high-fiber diet. Historically, health care providers have advised patients with diverticular disease to avoid seeds, nuts, or skins of plant matter to prevent complications or after bouts of diverticulitis. A recent 18-year study found no association between nut, corn, or popcorn consumption and diverticular bleeding (Strate et al., 2008). In fact, the researchers reported an inverse association between nut and popcorn consumption and the risk of diverticulitis. There is no data to support restriction.

### Intestinal Polyps and Colon Cancer

In the United States and worldwide, colorectal cancer is the third most common cancer in adults and is also the second

most common cause of cancer death. However, the number of new cases of colon cancer decreased 3% for men and 2.2% for women during the past decade. There are approximately 142,500 new cases of colorectal cancer per year, and the incidence is higher in men than women (National Cancer Institute and U.S. National Institutes of Health, 2010). The highest rates are seen in whites of northern European origin. Rates in Africa and Asia are lower, but they tend to rise with migration and westernization.

### Pathophysiology

Factors that increase the risk of colorectal cancer include family history, long-term presence of IBD, familial polyposis, adenomatous polyps, and several dietary components. Polyps are considered precursors of colon cancers (see Chapter 37 for more details). Patterns of dietary practices rather than specific nutrients may be more predictive of the risk of developing colorectal cancer. Dietary risk factors include increased meat, fat, and alcohol intake; obesity; and inadequate intake of several micronutrients, fruits, vegetables, and whole grains. Food preparation methods may also influence the carcinogenic potential of meats and fatty foods (McGarr et al., 2005; Raju and Cruz-Correa, 2006).

Use of aspirin and nonsteroidal antiinflammatory agents and exercise appear to be protective (Raju and Cruz-Correa, 2006).

Micronutrients considered protective in epidemiologic and cohort studies include vitamin D, folate, calcium, and selenium. There have been several types of supportive studies regarding the protective role of fruits and vegetables as a group, individual plant foods, high-fiber grains, ω-3 fatty acids, several antioxidants, and phytochemicals; but the data are not always consistent. The use of prebiotics and probiotics alters colonic microflora, induces glutathione transferase, increases butyrate content of the stool, reduces toxic and genotoxic compounds, and in animal models reduces the development of some precancerous lesions (McGarr et al., 2005).

### Medical Management

Patients diagnosed with colorectal polyps or cancer may require moderate to significant interventions, including medications, radiation therapy, chemotherapy, colonic surgery, or enteral or PN support.

### Medical Nutrition Therapy

Recommendations from cancer organizations that publish public health messages or consensus statements include notations that target colon cancer. These recommendations typically include sufficient exercise; weight maintenance or reduction; modest and balanced intake of lipids; adequate intake of micronutrients from fruits, vegetables, legumes, whole grains, and dairy products; and limited use of alcohol. Supplements are normally encouraged if the diet is not adequate. The diet for cancer survivors typically follows these prevention guidelines (see Chapter 37).

## NUTRITIONAL CONSEQUENCES OF INTESTINAL SURGERY

### Small Bowel Resections and Short-Bowel Syndrome

**Short-bowel syndrome (SBS)** can be defined as inadequate absorptive capacity resulting from reduced length or decreased functional bowel after resection. A loss of 70% to 75% of small bowel usually results in SBS, defined as 100–120 cm of small bowel without a colon, or 50 cm of small bowel with the colon remaining. A more practical definition of SBS is the inability to maintain nutrition and hydration needs with normal fluid and food intake, regardless of bowel length.

Patients with SBS often have complex fluid, electrolyte, and nutritional management issues (Parrish, 2005). Consequences of SBS include malabsorption of micronutrients and macronutrients, frequent diarrhea, steatorrhea, dehydration, electrolyte imbalances, weight loss, and growth failure in children. Other complications include gastric hypersecretion, oxalate renal stones, and cholesterol gallstones. Individuals who eventually need long-term PN have increased risk of catheter infection, sepsis, cholestasis, and liver disease, and reduced quality of life associated with chronic intravenous nutrition support (Diamanti et al., 2007).

### Pathophysiology

The most common reasons for major resections of the intestine in adults include Crohn's disease, radiation enteritis, mesenteric infarct, malignant disease, and volvulus (Parrish, 2005). In the pediatric population most cases of SBS result from congenital anomalies of the GIT, atresia, volvulus, or necrotizing enterocolitis.

**Duodenal Resection.** Resections of the duodenum ( $\approx 10$  in) are rare, which is fortunate as it is the preferred site for absorption of key nutrients such as iron, zinc, copper, and folate. The duodenum is a key player in the digestion and absorption of nutrients, as it is the portal of entry for pancreatic enzymes and bile salts. See Chapter 1.

**Jejunal Resections.** The jejunum (6–10 ft) is responsible for a large portion of nutrient absorption. Normally most digestion and absorption of food and nutrients occurs in the first 100 cm of small intestine. Jejunal entero-hormones play key roles in digestion and absorption. Cholecystokinin (CCK) stimulates pancreatic secretion and gallbladder contraction, and secretin stimulates secretion of bicarbonate from the pancreas. Gastric inhibitory peptide slows gastric secretion and gastric motility, whereas vasoactive inhibitory peptide inhibits gastric and bicarbonate secretion. What remains to be digested or fermented and absorbed are small amounts of sugars, resistant starch, fiber, lipids, dietary fiber, and fluids. After jejunal resections, the ileum typically adapts to perform the functions of the jejunum. The motility of the ileum is comparatively slow, and hormones, secreted in the ileum and colon help to slow

gastric emptying and secretions. Because jejunal resections result in reduced surface area and faster intestinal transit, the functional reserve for absorption of micronutrients, excess amounts of sugars (especially lactose), and lipids is reduced.

**Ileal Resections.** Significant resections of the ileum, especially the distal ileum, produce major nutritional and medical complications. The distal ileum is the only site for absorption of bile salts and the vitamin B<sub>12</sub>-intrinsic factor complex. The ileum also absorbs a major portion of the 7–10 L of fluid ingested and secreted into the GIT daily (see Chapter 1). The ileocecal valve, at the junction of the ileum and cecum, maximizes nutrient absorption by controlling the rate of passage of ileal contents into the colon and preventing reflux of colonic bacteria, which may decrease risk for SIBO.

Although malabsorption of bile salts may appear to be benign, it creates a cascade of consequences. If the ileum cannot "recycle" bile salts secreted into the GIT, hepatic production cannot maintain a sufficient bile salt pool or the secretions to emulsify lipids. The gastric and pancreatic lipases are capable of digesting some triglycerides to fatty acids and monoglycerides, but, without adequate micelle formation facilitated by bile salts, lipids are poorly absorbed. This can lead to malabsorption of fats and fat-soluble vitamins A, D, E, and K. In addition, malabsorption of fatty acids results in their combination with calcium, zinc, and magnesium to form fatty acid-mineral soaps, thus leading to their malabsorption as well. To compound matters, colonic absorption of oxalate is increased, leading to hyperoxaluria and increased frequency of renal oxalate stones. Relative dehydration and concentrated urine, which are common with ileal resections, further increase the risk of stone formation (see Chapter 36).

The colon ( $\approx 5$  ft long) is responsible for reabsorbing 1–1.5 L of electrolyte-rich (particularly sodium and chloride) fluid each day, but is capable of adapting to increase this capacity to 5–6 L daily. Preservation of colon is key to maintaining hydration status. If the patient has any colon left, malabsorption of bile salts can act as a mucosal irritant, increasing colonic motility with fluid and electrolyte losses. Consumption of high-fat diets with ileal resections and retained colon may also result in the formation of hydroxy fatty acids, which also increase fluid loss. Cholesterol gallstones occur because the ratio of bile acid, phospholipid, and cholesterol in biliary secretions is altered. Dependence on PN increases the risk of biliary "sludge," secondary to decreased stimulus for evacuation of the biliary tract (see Chapter 30).

### Medical and Surgical Management of Resections

The first step in management is assessment of the remaining bowel length from patient records or interview. Assessment should quantify dietary intake as well as stool and urine output over 24 hours. Medications and hydration status should be assessed. Medications may be prescribed to slow GI motility, decrease secretions, or treat

bacterial overgrowth. The primary “gut slowing” medications include loperamide, and, if needed, narcotic medications. Somatostatin and somatostatin analogs; glucagon-like polypeptide 2; growth hormone; and other hormones with antisecretory, antimotility, or trophic actions have been studied for use to slow both motility and secretions. Surgical procedures such as creation of reservoirs (“pouches”) to serve as a form of colon, intestinal lengthening, and intestinal transplant have been performed to help patients with major GI resections (Shatnawi et al., 2010). Intestinal transplant is very complex and is reserved for gut failure, or when patients develop significant complications from PN.

### Medical Nutrition Therapy

Most patients who have significant bowel resections require PN initially to restore and maintain nutrition status. The duration of PN and subsequent nutrition therapy will be based on the extent of the bowel resection, the health of the patient, and the condition of the remaining GIT. In general, older patients with major ileal resections, patients who have lost the ileocecal valve, and patients with residual disease in the remaining GIT do not fare as well. Enteral feeding provides a trophic stimulus to the GIT; PN is used to restore and maintain nutrient status. Some may require lifetime PN to maintain adequate fluid and nutrition status.

The more extreme and severe the problem, the slower the progression to a normal diet. Small, frequent, mini meals (6 to 10 per day) are likely to be better tolerated than larger feedings (Matarese et al., 2005; Parrish, 2005). Tube feeding may be useful to maximize intake when a patient would not typically eat, such as nighttime (see Chapter 14). Because of malnutrition and disuse of the GIT, the digestive and absorptive functions of the remaining GIT may be compromised, and malnutrition itself will delay postsurgical adaptation. The transition to more normal foods may take weeks to months, and some patients may never tolerate normal concentrations or volumes of foods.

Maximum adaptation of the GIT may take 1-2 years after surgery. Adaptation improves function, but it does not restore the intestine to normal length or capacity. Whole nutrients are the most important stimuli of the GIT. Other nutritional measures have also been studied as a means of hastening the adaptive process and decreasing malabsorption, but their evidence for use is limited. For example, **glutamine** is the preferred fuel for small intestinal enterocytes and thus may be valuable in enhancing adaptation. Nucleotides (in the form of purines, pyrimidine, ribonucleic acid) may also enhance mucosal adaptation, but unfortunately they are often lacking in parenteral and enteral nutritional products. SCFAs (e.g., butyrate, propionate, acetate) produced from microbial fermentation of carbohydrate and fibers are major fuels for the colonic epithelium.

Patients with jejunal resections and an intact ileum and colon will likely adapt quickly to normal diets. A normal balance of protein, fat, and carbohydrate sources is satisfactory. Six small feedings with avoidance of lactose, large amounts of concentrated sweets, and caffeine may help to

reduce the risk of bloating, abdominal pain, and diarrhea. Because the typical American diet may be nutritionally lacking and use of some micronutrients may be marginal, patients should be advised that the quality of their diet is of utmost importance. A multivitamin and mineral supplement may be required to meet all their nutritional needs.

Patients with ileal resections require increased time and patience in the advancement from parenteral to enteral nutrition. Because of losses, fat-soluble vitamins, calcium, magnesium, and zinc may need to be supplemented. Dietary fat may need to be limited, especially in those with remaining colon. Small amounts at each feeding are more likely to be tolerated and absorbed.

MCT products add to the caloric intake and serve as a vehicle for lipid-soluble nutrients. Because boluses of MCT oil (e.g., taken as a medication in tablespoon amounts) may add to the patient’s diarrhea, it is best to divide the doses equally in feedings throughout the day. Fluid and electrolytes, especially sodium, should be provided in small amounts and frequently.

In patients with SBS an oral diet or enteral nutrition plus the use of gut-sludging medications should be maximized to prevent dependence on PN. Frequent meals, removal of osmotic medications and foods, use of oral hydration therapies, and other interventions should be pursued. In some cases, overfeeding in an attempt to compensate for malabsorption results in further malabsorption, not only of ingested foods and liquids but also of the significant amounts of GI fluids secreted in response to food ingestion. Patients with an extremely short bowel may depend on parenteral solutions for at least part of their nutrient and fluid supply. Small, frequent snacks provide some oral gratification for these patients, but typically they can supply only a portion of their fluid and nutrient needs (see Chapter 14 for discussion of home PN).

### Small Intestine Bacterial Overgrowth

**Small intestine bacterial overgrowth (SIBO)** is a syndrome characterized by over-proliferation of bacteria within the small bowel. There are a number of physiologic processes that normally limit the amount of small intestine bacterial colonies. Gastric acid, bile, and pancreatic enzymes have bacteriostatic and bactericidal action within the small bowel. Normal propulsive action of bowel motility “sweeps” bacteria into the distal bowel. The ileocecal valve prevents migration of the large numbers of colonic bacteria into the small intestine. SIBO has also been referred to as “blind loop syndrome” because one cause of bacterial overgrowth can result from stasis of the intestinal tract as a result of obstructive disease, strictures, radiation enteritis, or surgical procedures that leaves a portion of bowel without normal flow (a blind loop or Roux limb).

### Pathophysiology

Frequently, more than one of the normal homeostatic defenses must be impaired before small intestine bacteria overproliferate to the point that symptoms develop. Chronic use of medications that suppress gastric acid allow more

bacteria to survive passage into the small bowel. Liver diseases or chronic pancreatitis can decrease the production or flow of bile and pancreatic enzymes into the bowel. Gastro-paresis, narcotic medications, or bowel dysmotility disorders decrease peristalsis and can impair the ability to propel bacterial to the distal bowel. Surgical resection of the distal ileum and ileocecal valve can result in retrograde proliferation of colonic bacteria.

One of the most common symptoms of SIBO is chronic diarrhea from fat maldigestion. Bacteria within the small bowel deconjugate bile salts resulting in impaired formation of micelles and thus impaired fat digestion and steatorrhea. Carbohydrate malabsorption occurs because of injury to the brush border secondary to the toxic effects of bacterial products and consequent enzyme loss. The expanding numbers of bacteria use the available vitamin B<sub>12</sub> and other nutrients for their own growth, and the host becomes deficient. Bacteria within the small bowel produce folic acid as a byproduct of their metabolism, and vitamin B<sub>12</sub> deficiency with normal or elevated serum folic acid is common. Bloating and distention are also frequently reported in SIBO, resulting from the action of bacteria on carbohydrates with production of hydrogen and methane within the small bowel.

### Medical Treatment

Treatment is directed toward control of the bacterial growth with antibiotics, probiotics, prebiotics, and in some cases surgical modification of the blind loop.

### Medical Nutrition Therapy

Part of the problem with bacterial overgrowth in the small intestine is that carbohydrates reaching the site where microbes are harbored serve as fuel for their proliferation, with subsequent increased production of gases and organic acids. At least theoretically a diet that limits refined carbohydrates that are readily fermented such as refined starches and sugars (e.g., lactose, fructose, alcohol sugars) and substitutes whole grains, and vegetables, can limit the proliferation and increase motility. See Table 29-5: Low FODMAP Diet.

Limited studies are available as to the effectiveness of diets and probiotic and prebiotic materials in the prevention and treatment of altered GI motility, strictures, abnormal anatomy of the GIT, and the presence of opportunistic organisms in the colon (*C. difficile* and other organisms). Because vitamin B<sub>12</sub> may be lost in fermentation and some dietary nutrients may be lacking, an assessment of the medical problem and the patient's dietary intake is in order. If bile salts are being degraded, as in the case of blind loop syndrome, MCTs may be helpful if they provide a source of lipid and energy.

## Fistulas

### Pathophysiology

A **fistula** is an abnormal passage between two organs or between an organ and the skin. An **enterocutaneous (EC)**

**fistula** is an abnormal passage beginning at the bowel and exiting at the skin. Fistulas may occur as a result of prenatal developmental error, trauma, surgery, or inflammatory or malignant disease processes. Most EC fistulas occur after surgery and usually manifest 7–10 days postoperatively. Fistulas of the intestinal tract can be serious threats to nutrition status because large amounts of fluid and electrolytes are lost and malabsorption and infection can occur.

### Medical Treatment

Fluid and electrolyte balance must be restored, infection must be brought under control, and aggressive nutrition support may be necessary to permit spontaneous closure or to maintain optimal nutritional status prior to surgical closure.

### Medical Nutrition Therapy

Nutrition management of patients with EC fistulas can be very challenging. Either PN, tube feeding, oral diet, or a combination, are used in patients with fistulas. The success rate of the chosen method depends on multiple variables, including the location of the fistula, the presence of abscesses or obstructions, the length of functional bowel, the ability to manage fistula output, and the patient's overall condition (Willcutts, 2010).

### Ileostomy or Colostomy

Patients with severe UC, Crohn's disease, colon cancer, or intestinal trauma frequently require the surgical creation of an opening from the body surface to the intestinal tract to permit defecation from the intact portion of the intestine. When the entire colon, rectum, and anus must be removed, an **ileostomy**, or an opening of the ileum at the abdominal wall, is performed. If only the rectum and anus are removed, a **colostomy** can provide entrance to the colon. In some cases a temporary opening may be made to allow surgery and healing of more distal parts of the intestinal tract.

The opening, or stoma, eventually shrinks to the size of a nickel. The output from the stoma depends on its location. The consistency of the stool from an ileostomy is liquid (effluent), whereas that from a colostomy ranges from mushy to fairly well formed. Stool from a colostomy on the left side of the colon is firmer than that from a colostomy on the right side. Odor is a major concern of the patient with an ileostomy or colostomy; however, an ileostomy effluent usually has a weakly acidic odor that is not unpleasant.

### Medical Treatment

Patients with a permanent colostomy or ileostomy require sympathetic understanding from the entire health care team. Acceptance of the condition and the problems involved in maintaining bowel regularity is usually difficult. Nursing personnel, especially enterostomal therapists (who specialize in the care of stomas), play a major role in supporting and teaching patients with ostomies. Having these patients meet other people who have undergone similar surgery may help with the adjustment. Eventually they may be encouraged by the realization that in the future they will not have the

multiple hospitalizations or chronic disabilities that accompanied their intestinal disease.

## Medical Nutrition Therapy

Malodorous stools may be caused by steatorrhea or partial digestion or bacterial fermentation of foodstuffs. SCFAs, sulfur-containing compounds, ammonia, methane, and other end products can produce odors. Because an individual patient may have different flora, types and amounts of gases and odors may differ among patients and with different dietary practices. Patients learn to observe their stools to determine which foods to eliminate; this differs from one patient to the next.

Foods that tend to cause odor from a colostomy are legumes, onions, garlic, cabbage, eggs, fish, some medications, as well as some vitamin and mineral supplements. Persistent odor may be attributable to poor stoma hygiene or to an ileostomy complication that allows bacterial overgrowth in the ileum. Deodorants are available, and modern pouch appliances are odor-proof. Gas production may cause the pouch to become tense and distended, and accidental dislodgment is likely. The nutritional recommendations for reducing flatulence, presented in this chapter, may be helpful for patients with colostomies.

The normal output from the ileum to the colon is in the range of 750 mL to 1.5 L in the intact GIT. After a colectomy and creation of an ileostomy, adaptation occurs within 1 to 2 weeks. Fecal output will lessen, and stools will become less liquid. Reduction in stool volume may not occur to the same extent in patients who have had an ileal resection in addition to a colectomy. Depending on the amount of ileum resected, the ileal output may be 1.5 to 5 times greater than that of the patient who has had only a colectomy. Patients with ileostomies have an above-average need for salt and water to compensate for excessive losses in stool. Inadequate water intake can result in small urine volumes and a predisposition for renal calculi. A normal diet provides adequate sodium, and patients should be instructed to drink at least 1 L more than their ostomy output daily.

The patient with a normal, functional ileostomy usually does not become nutritionally depleted. Surgical procedures such as ileostomy may require specific dietary changes but no greater energy intake; caloric expenditures in these patients are similar to those of normal subjects. Those who also undergo resection of the terminal ileum need vitamin B<sub>12</sub> supplementation or intravenous injections. Patients with an ileostomy may have low vitamin C and folate intakes because of low fresh vegetable and fruit intakes, and they require supplementation.

Patients with ileostomies should be guided by physiologic reasons for intolerance of foods and not by anecdotal reports. Because gastric emptying may be more rapid and foodstuffs are not fermented to the same degree after colostomy, absorption of nutrients may be somewhat better from cooked, shredded, or pureed fruits and vegetables. Because it is possible for a food bolus to get caught at the point where the ileum narrows as it enters the abdominal wall, it is

important to warn the patient to avoid very fibrous vegetables and to chew all food well. Other than this, patients with either an ileostomy or a colostomy should be encouraged to follow their normal diet, omitting only foods known to cause problems.

## Ileal Pouch after Colectomy

### Pathophysiology

As an alternative to creation of an ileostomy for persons who have had their colons removed, surgeons can create a reservoir using a portion of the distal ileum. Folds of the ileum are joined together to create a small pouch, which is then connected to the rectum and ileum. This is called an **ileal pouch**–anal anastomosis. The most common pouch is the **J-pouch**, but **S** and **W** pouches are sometimes created using additional folds of ileum. Like the colon, the pouch develops a microflora capable of at least partially fermenting fiber and carbohydrate. Because the reservoir is smaller than the colon, bowel movements are likely to occur more frequently than normal (i.e., between four and eight times daily). A Koch pouch is a type of applianceless ileostomy that uses an internal reservoir with a one-way valve, constructed from a loop of intestine, that is attached to the abdominal wall with a skin-level stoma. Patients must insert a tube or catheter into the stoma to open the valve and allow drainage of ileostomy contents. The technical difficulties of surgical construction and the potential for complications has led to decreased use of the Koch pouch in favor of the J-pouch with anal anastomosis.

### Medical Treatment

Vitamin B<sub>12</sub> injections are usually required because, as in SBBO, the microbes may compete for and bind intraluminal vitamin B<sub>12</sub>. Other problems commonly reported include obstruction; inflammation of the pouch; and increased stool output, frequency, and gas. The incidence of obstruction may be lessened with attention to particle size of fibrous foods, chewing thoroughly, and consuming small meals frequently throughout the day. Stool frequency and volume do not return to normal, however. The normal, intact colon absorbs 80% to 90% of the liter or so of fluid entering from the ileum, leaving only 100 to 200 mL. After surgery the remaining ileum does adapt to a small degree by increasing efficiency of fluid absorption, but even after adaptation, fluid output is always in the range of 300 to 600 mL.

Pouchitis is an inflammation of the mucosal tissue forming the pouch. The associated pathologic changes have been described as being somewhat similar to that of IBD (e.g., UC). The cause of pouchitis is not entirely clear, but it may be related to selected bacterial overgrowth, bile salt malabsorption, or insufficient SCFA production. Antibiotics are the primary form of therapy, but experiments with different types of dietary fiber, prebiotics and probiotics, and other nutrient components have been used successfully to reduce the incidence (Guarner, 2005; Meier and Steuerwald, 2005).

## CLINICAL SCENARIO

A 35-year-old woman, Sarah, was diagnosed with celiac disease 2 years ago and has presented to the Digestive Health Clinic with complaints of 3 weeks of diarrhea and abdominal pain. She reports losing weight, despite eating her typical diet. However, she reports recently starting a new job as a high school English teacher. She has been buying lunch at the school's cafeteria because they seem to have a good selection of hot foods that are gluten-free. Sarah reports she received education on a gluten-free diet from a registered dietitian when she was diagnosed. She seems to have a good understanding of the gluten-free diet and has connected with her local celiac support group.

### Summary of “Typical Day” Diet History

#### Breakfast

1 cup gluten-free cereal with 4 oz 1% milk; 1 cup orange juice; 1 cup coffee with 2 T 1% milk and 1 tsp sugar

#### Lunch (from the Cafeteria)

Corn tortilla with 3 oz tuna and 1 oz melted cheddar cheese  
4 oz trail mix (peanuts, cashews, raisins, and chocolate pieces)  
1 banana  
1 cup chocolate milk  
20 oz water

#### Snack

12 baby carrots  
2 T red pepper hummus  
10 oz water

#### Dinner

5 oz grilled chicken breast, marinated in gluten-free marinade  
1 cup chickpea, tomato, and spinach salad with 2 tsp olive oil or balsamic dressing  
3 oz white wine  
½ cup vanilla ice cream

### Medical Nutrition Therapy

There are few controlled studies regarding diet and ileal pouch. Food intolerances are common but relatively mild (Steenhagen et al., 2006). The same dietary measures that are used by others to reduce excessive stool output (reduced caffeine, lactose avoidance in lactase-deficient persons, limitation of fructose and sorbitol) will likely reduce stool volume and frequency in persons with pouches. Adequate fluid and electrolyte intake are especially important because of the increase in intestinal losses.

### Rectal Surgery

Nutrition care after rectal surgery such as hemorrhoidectomy should be directed toward maintaining an intake that will allow wound repair and prevent infection of the wound

Abnormal laboratory values: Tissue transglutaminase (TTG) immunoglobulin (Ig)A 60 (2 years ago), down to <4 (1 yr ago)

Diarrhea >5 days

Current Medications: loperamide (started 2 weeks ago), Fibercon (started 1 month ago)

Food intolerance to gluten

### Nutrition Diagnostic Statement

Altered gastrointestinal function related to possible inadvertent gluten ingestion as evidenced by diarrhea.

### Interventions

Recheck tTG- IgA

Review potential sources for cross-contamination, including: food preparation, buffet lines, toasters, and bulk bins.

Review potential hidden gluten sources, including food binders, coatings, and flavorings (trail mix, chocolate milk); medications (Fibercon); and communion wafers.

Recommend patient check her medications with a pharmacist or the manufacturer, to ensure they are gluten-free.

Recommend patient speak with the cafeteria manager to determine what cooked foods are safe for her to eat.

Recommend patient consider bringing her own lunch to school until she has identified what foods are safe to eat at school.

Refer to a gastroenterologist, if symptoms do not resolve after above intervention.

### Nutrition Care Questions

1. Categorize the interventions listed into those related to education, counseling, or care management.
2. Write a gluten-free menu plan that could work for one week.

by feces. The frequency of stools is minimized by the use of a minimum-residue diet (see Table 29-1). Chemically defined diets are low in residue, and their use can reduce stool volume and frequency to as little as 50 g every 6 days, making the surgical construction of a temporary colostomy unnecessary. A normal diet is resumed after healing is complete, and the patient is instructed about the benefits of eating a high-fiber diet to avoid constipation in the future.

# Medical Nutrition Therapy for Hepatobiliary and Pancreatic Disorders

### KEY TERMS

alcoholic liver disease  
aromatic amino acids (AAAs)  
ascites  
bile  
branched-chain amino acids (BCAAs)  
cholangitis  
cholecystectomy  
cholecystitis  
choledocholithiasis  
cholelithiasis  
cholestasis  
cirrhosis  
fasting hypoglycemia  
fatty liver  
fulminant liver disease  
hemochromatosis  
hepatic encephalopathy  
hepatic failure  
hepatic osteodystrophy

hepatic steatosis  
hepatitis  
hepatorenal syndrome  
jaundice  
Kayser-Fleischer ring  
Kupffer cells  
nonalcoholic fatty liver disease (NAFLD)  
nonalcoholic steatohepatitis (NASH)  
pancreaticoduodenectomy (Whipple procedure)  
pancreatitis  
paracentesis  
portal hypertension  
portal systemic encephalopathy  
primary biliary cirrhosis (PBC)  
secondary biliary cirrhosis  
steatorrhea  
varices  
Wernicke encephalopathy  
Wilson's disease

The liver is of primary importance; one cannot survive without a liver. The pancreas and liver are essential to digestion and metabolism. Although it is important, the gallbladder can be removed, and the body will adapt comfortably to its absence. Knowledge of the structure and functions of these organs is vital. When they are diseased, the necessary medical nutrition therapy (MNT) is complex.

### PHYSIOLOGY AND FUNCTIONS OF THE LIVER

#### Structure

The liver is the largest gland in the body, weighing approximately 1500 g. The liver has two main lobes: the right and left. The right lobe is further divided into the anterior and

posterior segments; the right segmental fissure, which cannot be seen externally, separates the segments. The externally visible falciform ligament divides the left lobe into the medial and lateral segments. The liver is supplied with blood from two sources: the hepatic artery, which supplies approximately one third of the blood from the aorta; and the portal vein, which supplies the other two thirds and collects blood drained from the digestive tract.

Approximately 1500 mL of blood per minute circulates through the liver and exits via the right and left hepatic veins into the inferior vena cava. Just as there is a system of blood vessels throughout the liver, there also exists a series of bile ducts. **Bile**, which is formed in the liver cells, exits the liver through a series of bile ducts that increase in size as they approach the common bile duct. It is a thick, viscous fluid secreted from the liver, stored in the gallbladder, and released into the duodenum when fatty foods enter the duodenum. It emulsifies fats in the intestine and forms compounds with fatty acids to facilitate their absorption.

## Functions

The liver has the ability to regenerate itself. Only 10% to 20% of functioning liver is required to sustain life, although removal of the liver results in death, usually within 24 hours. The liver is integral to most metabolic functions of the body and performs more than 500 tasks. The main functions of the liver include metabolism of carbohydrate, protein, and fat; storage and activation of vitamins and minerals; formation and excretion of bile; conversion of ammonia to urea; metabolism of steroids; and action as a filter and flood chamber.

The liver plays a major role in carbohydrate metabolism. Galactose and fructose, products of carbohydrate digestion, are converted into glucose in the hepatocyte or liver cell. The liver stores glucose as glycogen (glycogenesis) and then returns it to the blood when glucose levels become low (glycogenolysis). The liver also produces “new” glucose (gluconeogenesis) from precursors such as lactic acid, glycogenic amino acids, and intermediates of the tricarboxylic acid cycle (see Chapter 3).

Important protein metabolic pathways occur in the liver. Transamination and oxidative deamination are two such pathways that convert amino acids to substrates that are used in energy and glucose production as well as in the synthesis of nonessential amino acids. Blood-clotting factors such as fibrinogen; prothrombin; and serum proteins, including albumin,  $\alpha$ -globulin,  $\beta$ -globulin, transferrin, ceruloplasmin, and lipoproteins are formed by the liver.

Fatty acids from the diet and adipose tissue are converted in the liver to acetyl-coenzyme A by the process of  $\beta$ -oxidation to produce energy. Ketones are also produced. The liver synthesizes and hydrolyzes triglycerides, phospholipids, cholesterol, and lipoproteins as well.

The liver is involved in the storage, activation, and transport of many vitamins and minerals. It stores all the fat-soluble vitamins in addition to vitamin B<sub>12</sub> and the minerals zinc, iron, copper, and magnesium. Hepatically synthesized proteins transport vitamin A, iron, zinc, and copper in the

bloodstream. Carotene is converted to vitamin A, folate to 5-methyl tetrahydrofolic acid, and vitamin D to an active form (25-hydroxycholecalciferol) by the liver.

In addition to functions of nutrient metabolism and storage, the liver forms and excretes bile. Bile salts are metabolized and used for the digestion and absorption of fats and fat-soluble vitamins. Bilirubin is a metabolic end product from red blood cell destruction; it is conjugated and excreted in the bile.

Hepatocytes detoxify ammonia by converting it to urea, 75% of which is excreted by the kidneys. The remaining urea finds its way back to the gastrointestinal tract (GIT). The liver also metabolizes steroids. It inactivates and excretes aldosterone, glucocorticoids, estrogen, progesterone, and testosterone. It is responsible for the detoxification of substances, including drugs and alcohol. Finally, the liver acts as a filter and flood chamber by removing bacteria and debris from blood through the phagocytic action of **Kupffer cells** located in the sinusoids and by storing blood backed up from the vena cava as in right heart failure.

## Laboratory Assessment of Liver Function

Biochemical markers are used to evaluate and monitor patients having or suspected of having liver disease. Enzyme assays measure the release of liver enzymes, and other tests measure liver function. Screening tests for hepatobiliary disease include serum levels of bilirubin, alkaline phosphatase, aspartate amino transferase, and alanine aminotransferase. Table 30-1 elaborates common laboratory tests for liver disorders (see also Appendix 30).

## DISEASES OF THE LIVER

Diseases of the liver can be acute or chronic, inherited or acquired. Liver disease is classified in various ways: acute viral hepatitis, fulminant hepatitis, chronic hepatitis, nonalcoholic steatohepatitis (NASH), alcoholic hepatitis and cirrhosis, cholestatic liver diseases, inherited disorders, and other liver diseases.

### Acute Viral Hepatitis

Acute viral **hepatitis** is a widespread inflammation of the liver and is caused by hepatitis viruses A, B, C, D, and E (Figure 30-1, Table 30-2). Hepatitis A and E are the infectious forms, mainly spread by fecal-oral route. Hepatitis B, C, and D are the serum forms that are spread by blood and body fluids (Hoofnagle, 2007). Minor agents such as Epstein-Barr virus, cytomegalovirus, herpes simplex, yellow fever, and rubella can also cause an acute hepatitis.

The general symptoms of acute viral hepatitis are divided into four phases. The first phase, the early prodromal phase, affects approximately 25% of patients, causing fever, arthralgia, arthritis, rash, and angioedema. This is followed by the preicteric phase, in which malaise, fatigue, myalgia, anorexia, nausea, and vomiting occur. Some patients complain of epigastric or right upper quadrant pain. The third phase is the icteric phase, in which **jaundice** appears. Finally, during the

**TABLE 30-1****Common Laboratory Tests Used to Test Liver Function**

Laboratory Test	Comment
<b>Hepatic Excretion</b>	
Total serum bilirubin	When increased, may indicate bilirubin overproduction or defect in hepatic uptake or conjugation.
Indirect serum bilirubin	Unconjugated bilirubin; increased with excessive bilirubin production (hemolysis), immaturity of enzyme systems, inherited defects, drug effects.
Direct serum bilirubin	Conjugated bilirubin; increased with depressed bilirubin excretion, hepatobiliary disease, intrahepatic or benign postoperative jaundice and sepsis, and congenital conjugated hyperbilirubinemia.
Urine bilirubin	More sensitive than total serum bilirubin; confirms if liver disease is cause of jaundice.
Urine urobilinogen	Used when obstructive jaundice is expected; rarely used.
Serum bile acids	Reflects efficacy of ileal resorption and hepatic extraction of bile acids from portal circulation; levels increase with liver disease; little clinical use.
<b>Cholestasis</b>	
Serum alkaline phosphatase	Enzyme widely distributed in liver, bone, placenta, intestine, kidney, leukocytes; mainly bound to canalicular membranes in liver; increased levels suggest cholestasis but can be increased with bone disorders, pregnancy, normal growth, and some malignancies.
5'-Nucleotidase (5'-NT)	Enzyme present in canalicular and plasma membranes of hepatocytes; also in heart and pancreas; increases with liver disease.
Leucine aminopeptidase (LAP)	Cellular peptidase; usually increased in cholestasis and suggests hepatobiliary origin of elevation of alkaline phosphatase; may also increase with pregnancy.
γ-Glutamyl transpeptidase (GGT)	Enzyme associated with microsomes and plasma membranes in hepatocytes; also present in kidney, pancreas, heart, brain; increased with liver disease, but also after myocardial infarction, in neuromuscular disease, pancreatic disease, pulmonary disease, diabetes mellitus, and during alcohol ingestion.
<b>Hepatic Enzymes</b>	
Alanine aminotransferase (ALT, formerly SGPT)	Located in cytosol of hepatocyte; found in several other body tissues but highest in liver; increased with liver cell damage.
Aspartate aminotransferase (AST, formerly SGOT)	Located in cytosol and mitochondria of hepatocyte; also in cardiac and skeletal muscle, brain, pancreas, kidney, and leukocytes; increased with liver cell damage.
Serum lactic dehydrogenase	Located in liver, red blood cells, cardiac muscle, kidney; increased with liver disease but lacks sensitivity and specificity because it is found in most other body tissues.
<b>Serum Proteins</b>	
Prothrombin time (PT)	Most blood coagulation factors are synthesized in the liver; vitamin K deficiency and decreased synthesis of clotting factors increase prothrombin time and risk of bleeding.
Partial thromboplastin time (PTT)	Assesses the “intrinsic” clotting mechanism; reflects activity of all clotting factors except platelet factor E, factors VII and XIII; complementary to PT.
Serum albumin	Main export protein synthesized in the liver and most important factor in maintaining plasma oncotic pressure; decreased synthesis occurs with liver dysfunction, thyroid and glucocorticoid hormone dysfunction, abnormal plasma colloid osmotic pressure, and toxins; increased losses occur with protein-losing enteropathy, nephrotic syndrome, burns, gastrointestinal bleeding, exfoliative dermatitis.

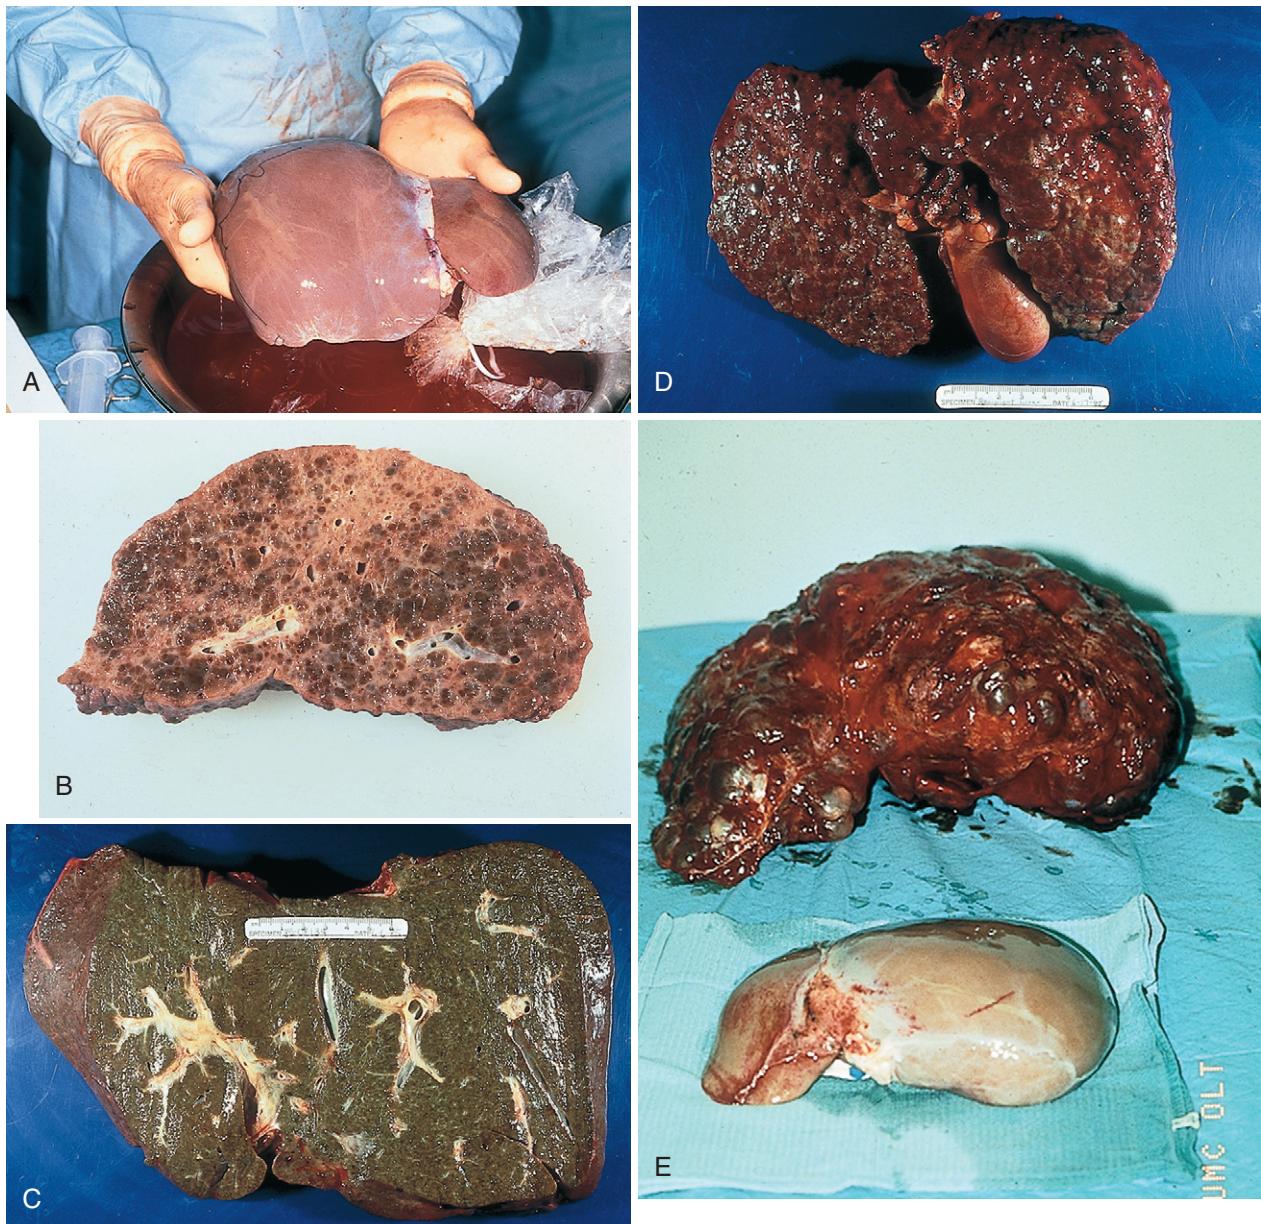

*Continued*

**TABLE 30-1****Common Laboratory Tests Used to Test Liver Function—cont'd**

Laboratory Test	Comment
Serum globulin	$\alpha_1$ and $\alpha_2$ -globulins are synthesized in the liver; levels increase with chronic liver disease; limited diagnostic use in hepatobiliary disease.
Mitochondrial antibody	90% of patients with PBC have antibodies in their serum against a lipoprotein component of the inner mitochondrial membrane; also present in 25% of patients with chronic active hepatitis and postnecrotic cirrhosis.
Antinuclear and smooth-muscle antibodies	May be positive in patients with chronic active hepatitis (usually not associated with hepatitis B or C virus) and in a minority of patients with PBC; not organ- or species-specific.
<b>Markers of Specific Liver Diseases</b>	
Serum ferritin	Major iron storage protein; increased level sensitive indicator of genetic hemochromatosis.
Ceruloplasmin	Major copper-binding protein synthesized by liver; decreased in Wilson disease.
$\alpha$ -Fetoprotein	Major circulating plasma protein; increased with hepatocellular carcinoma.
$\alpha_1$ -Antitrypsin	Main function is to inhibit serum trypsin activity; decreased levels indicate $\alpha_1$ -antitrypsin deficiency, which can cause liver and lung damage.
<b>Markers for Viral Hepatitis</b>	
IgM anti-HAV	Marker for hepatitis A; indicates current or recent infection or convalescence.
IgG anti-HAV	Marker for hepatitis A; indicates current or previous infection and immunity.
HBsAg	Marker for hepatitis B; positive in most cases of acute or chronic infection.
HBeAg	Marker for hepatitis B; transiently positive during active virus replication; reflects concentration and infectivity of virus.
IgM or IgG anti-HBc	Marker for hepatitis B; positive in all acute and chronic cases; positive in carriers; not protective.
Anti-HBe	Marker for hepatitis B; transiently positive during convalescence and in some chronic cases and carriers; not protective; reflects low infectivity.
Anti-HBs	Marker for hepatitis B; positive late in convalescence; protective.
Anti-HCV	Marker for hepatitis C; positive 5–6 weeks after onset of hepatitis C virus; not protective; reflects infectious state.
HCV-RNA	Marker for hepatitis C.
IgM or IgG anti-HDV	Marker for hepatitis D; indicates infection; not protective.
IgM anti-HEV	Marker for hepatitis E; indicates current or recent infection; not protective.
IgG anti-HEV	Marker for hepatitis E; indicates current or previous infection and immunity.
Miscellaneous	
Ammonia	Liver converts ammonia to urea; may increase with hepatic failure and portal-systemic shunts.

E, Liver with damage from polycystic liver disease (background) and normal liver (foreground). (Courtesy Baylor Transplant Institute, Baylor University Medical Center, Dallas, TX.)

**TABLE 30-2****Types of Viral Hepatitis**

Virus	Transmission	Comments
Hepatitis A	Fecal-oral route; is contracted through contaminated drinking water, food, and sewage.	Anorexia is the most frequent symptom, and it can be severe. Other common symptoms include nausea, vomiting, right upper quadrant abdominal pain, dark urine, and jaundice (icterus). Recovery is usually complete, and long-term consequences are rare. Serious complications may occur in high-risk patients; subsequently, great attention must be given to adequate nutritional intake.
Hepatitis B & C	HBV and HCV are transmitted via blood, blood products, semen, and saliva. For example, they can be spread from contaminated needles, blood transfusions, open cuts or wounds, splashes of blood into the mouth or eyes, or sexual contact.	HBV and HCV can lead to chronic and carrier states. Chronic active hepatitis can also develop, leading to cirrhosis and liver failure.
Hepatitis D	HDV is rare in the United States and depends on the HBV for survival and propagation in humans.	HDV may be a coinfection (occurring at the same time as HBV) or a superinfection (superimposing itself on the HBV carrier state). This form of hepatitis usually becomes chronic.
Hepatitis E	HEV is transmitted via the oral-fecal route.	HEV is rare in the United States (typically only occurs when imported), but it is reported more frequently in many countries of southern, eastern, and central Asia; northern, eastern, and western Africa; and Mexico. Contaminated water appears to be the source of infection, which usually afflicts people living in crowded and unsanitary conditions. HEV is generally acute rather than chronic.
Hepatitis G/GB	HGV and a virus labeled GBV-C appear to be variants of the same virus.	Although HGV infection is present in a significant proportion of blood donors and is transmitted through blood transfusions, it does not appear to cause liver disease.

*HBV*, Hepatitis B virus; *HCV*, hepatitis C virus; *HDV*, hepatitis D virus; *HEV*, hepatitis E virus; *HGV*, hepatitis G virus.

convalescent phase, jaundice and other symptoms begin to subside.

Complete recovery is expected in more than 95% of hepatitis A cases, in 90% of acute hepatitis B cases, but in only 15% to 50% of acute hepatitis C cases. Chronic hepatitis does not usually develop with hepatitis E, and symptoms and liver function tests usually normalize within 6 weeks (Hoofnagle, 2007).

### Fulminant Hepatitis

Fulminant hepatitis is a syndrome in which severe liver dysfunction is accompanied by hepatic encephalopathy, a clinical syndrome characterized by impaired mentation, neuromuscular disturbances, and altered consciousness.

**Fulminant liver disease** is defined by the absence of pre-existing liver disease and the development of hepatic encephalopathy within 2 to 8 weeks of the onset of illness. The causes of fulminant hepatitis include viral hepatitis in approximately 75% of cases, chemical toxicity (e.g., acetaminophen, drug reactions, poisonous mushrooms, industrial poisons), and other causes (e.g., Wilson's disease, fatty liver of pregnancy, Reye syndrome, hepatic

ischemia, hepatic vein obstruction, and disseminated malignancies). Extrahepatic complications of fulminant hepatitis are cerebral edema, coagulopathy and bleeding, cardiovascular abnormalities, renal failure, pulmonary complications, acid-base disturbances, electrolyte imbalances, sepsis, and pancreatitis.

### Chronic Hepatitis

To be diagnosed with chronic hepatitis, a patient must have at least a 6-month course of hepatitis or biochemical and clinical evidence of liver disease with confirmatory biopsy findings of unresolving hepatic inflammation (Hoofnagle, 2007). Chronic hepatitis can have autoimmune, viral, metabolic, or medicine or toxin causes. The most common causes of chronic hepatitis are hepatitis B, hepatitis C, and autoimmune hepatitis. Other causes are drug-induced liver disease, metabolic diseases, and NASH. Cryptogenic cirrhosis is cirrhosis of an unknown cause.

Clinical symptoms of chronic hepatitis are usually nonspecific, occur intermittently, and are mild. Common symptoms include fatigue, sleep disorders, difficulty concentrating, and mild right upper quadrant pain. Severe

advanced disease can lead to jaundice, muscle wasting, tea-colored urine, ascites, edema, hepatic encephalopathy, gastrointestinal bleeding, splenomegaly, palmar erythema, and spider angioma.

### Nonalcoholic Fatty Liver Disease

**Nonalcoholic fatty liver disease (NAFLD)** is a spectrum of liver disease ranging from steatosis to steatohepatitis. It involves the accumulation of fat droplets in the hepatocytes and can lead to fibrosis, cirrhosis, and even hepatocellular carcinoma. Steatosis is the simple accumulation of fat within the liver. Causes of NAFLD include drugs, inborn errors of metabolism, and acquired metabolic disorders (type 2 diabetes mellitus, lipodystrophy, jejunal ileal bypass, obesity, and malnutrition) (Diehl, 2007). It is commonly associated with obesity, diabetes mellitus, dyslipidemia, and insulin resistance.

**Nonalcoholic steatohepatitis (NASH)** is associated with accumulation of fibrous tissue in the liver. A two-hit hypothesis has been proposed to explain why some patients who develop NAFLD do not progress to NASH, and others do. Insulin resistance may lead to steatosis, but some type of oxidative stress is theorized to cause the disease to progress to NASH.

Patients with NASH may be asymptomatic but can experience malaise, weakness, or hepatomegaly. The treatment is often gradual weight loss, insulin-sensitizing drugs such as thiazolidinediones or possibly metformin, and treatment of dyslipidemia. Extreme, rapid weight loss can accelerate NASH developing into cirrhosis and increase the chance of gallstone development.

Chronic liver disease and cirrhosis can develop in patients with NASH. The progression to cirrhosis is variable, depending on age and the presence of obesity and type 2 diabetes, which contribute to a worsening prognosis (Diehl, 2007). Some studies suggest that vitamin E, betaine, and S-adenosylmethionine may be beneficial in reducing NASH by reducing tumor necrosis factor- $\alpha$  activity.

### Alcoholic Liver Disease

**Alcoholic liver disease** is the most common liver disease in the United States, with age-adjusted death rates of 4.2 per 100,000 people (National Institute on Alcohol Abuse and Alcoholism, 2005). Acetaldehyde is a toxic byproduct of alcohol metabolism that causes damage to mitochondrial membrane structure and function. Acetaldehyde is produced by multiple metabolic pathways, one of which involves alcohol dehydrogenase (see *Focus On: Metabolic Consequences of Alcohol Consumption*).

Several variables predispose some people to alcoholic liver disease. These include genetic polymorphisms of alcohol-metabolizing enzymes, gender (women more than men), simultaneous exposure to other drugs, infections with hepatotropic viruses, immunologic factors, and poor nutrition status. The pathogenesis of alcoholic liver disease progresses in three stages (Figure 30-2): hepatic steatosis (Figure 30-3), alcoholic hepatitis, and finally cirrhosis.

### FOCUS ON

### Metabolic Consequences of Alcohol Consumption

Ethanol is metabolized primarily in the liver by alcohol dehydrogenase. This results in acetaldehyde production with the transfer of hydrogen to nicotinamide adenine dinucleotide (NAD), reducing it to NADH. The acetaldehyde then loses hydrogen and is converted to acetate, most of which is released into the blood.

Many metabolic disturbances occur because of the excess of NADH, which overrides the ability of the cell to maintain a normal redox state. These include hyperlacticacidemia, acidosis, hyperuricemia, ketonemia, and hyperlipemia. The tricarboxylic acid (TCA) cycle is depressed because it requires NAD. The mitochondria, in turn, use hydrogen from ethanol rather than from the oxidation of fatty acids to produce energy via the TCA cycle, which leads to a decreased fatty acid oxidation and accumulation of triglycerides. In addition, NADH may actually promote fatty acid synthesis. Hypoglycemia can also occur in early alcoholic liver disease secondary to the suppression of the TCA cycle, coupled with decreased gluconeogenesis due to ethanol.

### Hepatic Steatosis

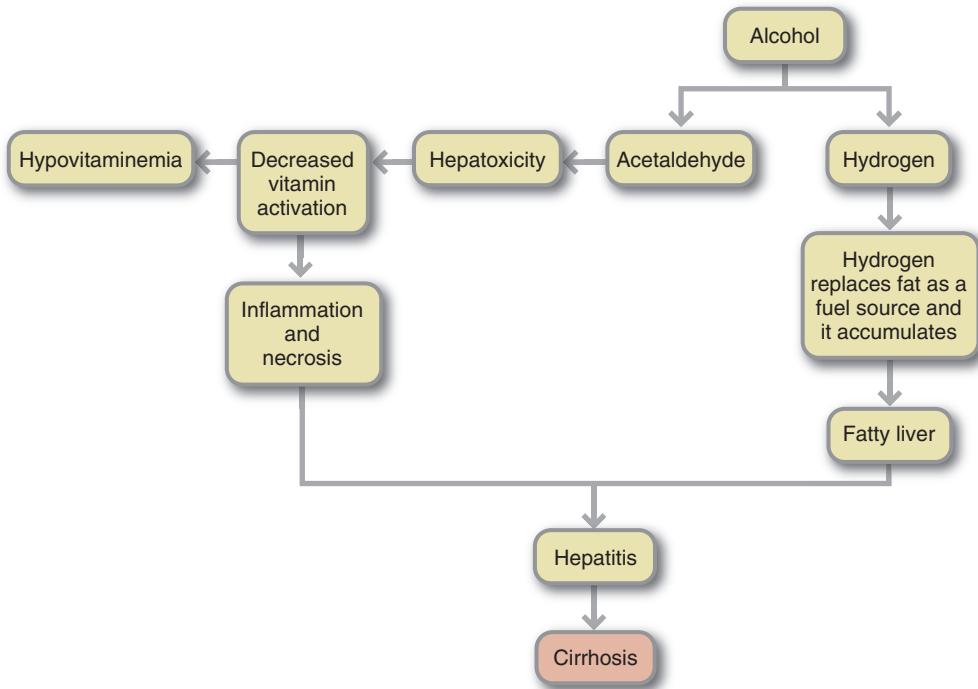

Fatty infiltration, known as **hepatic steatosis** or **fatty liver**, is caused by a culmination of these metabolic disturbances: (1) an increase in the mobilization of fatty acids from adipose tissue; (2) an increase in hepatic synthesis of fatty acids; (3) a decrease in fatty acid oxidation; (4) an increase in triglyceride production; and (5) a trapping of triglycerides in the liver. Hepatic steatosis is reversible with abstinence from alcohol. Conversely, if alcohol abuse continues, cirrhosis can develop.

### Alcoholic Hepatitis

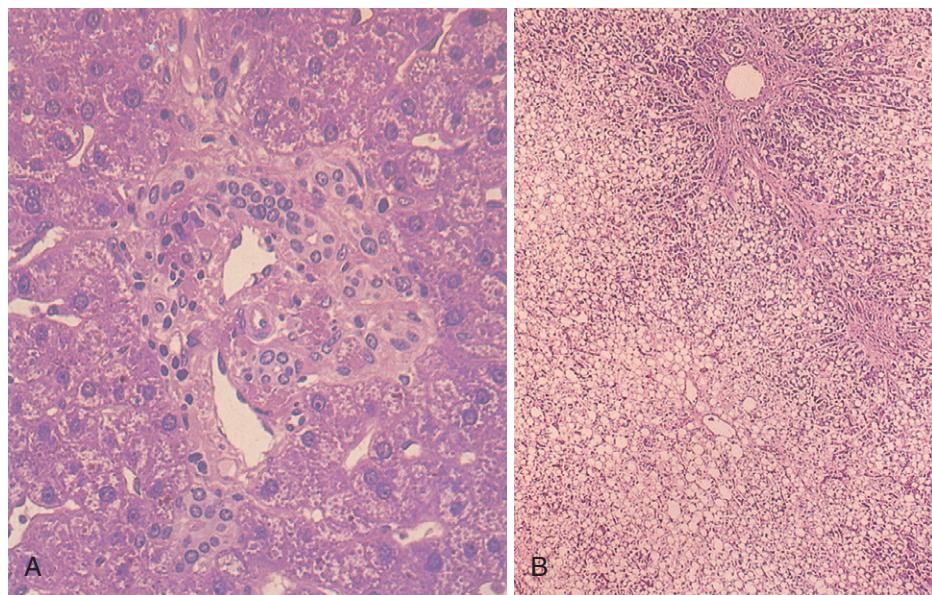

Alcoholic hepatitis is generally characterized by hepatomegaly, modest elevation of transaminase levels, increased serum bilirubin concentrations, normal or depressed serum albumin concentrations, or anemia. Patients may also have abdominal pain, anorexia, nausea, vomiting, weakness, diarrhea, weight loss, or fever. If patients discontinue alcohol intake, hepatitis may resolve; however, the condition often progresses to the third stage. Nutrition support is the main treatment in addition to counseling or support to continue avoidance of alcohol. Molecular genetics may lead to new therapies in the future (Willner and Reuben, 2005).

### Alcoholic Cirrhosis

Clinical features of alcoholic **cirrhosis**, the third stage, vary. Symptoms can mimic those of alcoholic hepatitis; or patients can develop gastrointestinal bleeding, hepatic encephalopathy, or **portal hypertension** (elevated blood pressure in the

**FIGURE 30-2** Complications of excessive alcohol consumption stem largely from excess hydrogen and from acetaldehyde. Hydrogen produces fatty liver and hyperlipidemia, high blood lactic acid, and low blood sugar. The accumulation of fat, the effect of acetaldehyde on liver cells, and other factors as yet unknown lead to alcoholic hepatitis. The next step is cirrhosis. The consequent impairment of liver function disturbs blood chemistry, notably causing a high ammonia level that can lead to coma and death. Cirrhosis also distorts liver structure, inhibiting blood flow. High pressure in vessels supplying the liver may cause ruptured varices and accumulation of fluid in the abdominal cavity. Response to alcohol differs among individuals; in particular, not all heavy drinkers develop hepatitis and cirrhosis.

**FIGURE 30-3** **A**, Microscopic appearance of a normal liver. A normal portal tract consists of the portal vein, hepatic arteriole, one to two interlobular bile ducts, and occasional peripherally located ductules. **B**, Acute fatty liver. This photomicrograph on low power exhibits fatty change involving virtually all the hepatocytes, with slight sparing of the liver cells immediately adjacent to the portal tract (top). (From Kanel G, Korula J: *Atlas of liver pathology*, Philadelphia, 1992, Saunders.)

portal venous system caused by the obstruction of blood flow through the liver). They often develop **ascites**, the accumulation of fluid, serum protein, and electrolytes within the peritoneal cavity caused by increased pressure from portal hypertension and decreased production of albumin (which maintains serum colloidal osmotic pressure). A liver biopsy usually reveals micronodular cirrhosis, but it can be macronodular or mixed. Prognosis depends on abstinence from alcohol and the degree of complications already developed. Ethanol ingestion creates specific and severe nutritional abnormalities (see *Clinical Insight: Malnutrition in the Alcoholic*).

## Cholestatic Liver Diseases

### Primary Biliary Cirrhosis

**Primary biliary cirrhosis (PBC)** is a chronic cholestatic disease caused by progressive destruction of small and intermediate-size intrahepatic bile ducts. The extrahepatic biliary tree and larger intrahepatic ducts are normal. Ninety-five percent of patients with PBC are women. This disease progresses slowly, eventually resulting in cirrhosis, portal hypertension, liver transplantation, or death (Afdhal, 2007).

PBC is an immune-mediated disease in which serum autoantibodies, elevated immunoglobulin levels, circulating immune complexes, and depressed cell-mediated immune response are present. PBC typically presents with a mild elevation of liver enzymes with physical symptoms of pruritus and fatigue. Treatment with ursodeoxycholic acid can slow progression of the disease (Afdhal, 2007). Several nutritional complications from cholestasis can occur with PBC, including osteopenia, hypercholesterolemia, and fat-soluble vitamin deficiencies.

### Sclerosing Cholangitis

Sclerosing cholangitis shows fibrosing inflammation of segments of extrahepatic bile ducts, with or without involvement of intrahepatic ducts. Progression of the disease leads to complications of portal hypertension, **hepatic failure** (liver function diminished to 25% or less), and cholangiocarcinoma. Primary sclerosing cholangitis (PSC) is the most common type. Like PBC, PSC may be an immune disorder because of its strong association with human leukocyte antigen haplotypes, autoantibodies, and multiple immunologic abnormalities. Of patients with PSC, 70% to 90% also have inflammatory bowel disease (especially ulcerative colitis), and men are more likely than women (2.3:1) to have PSC (Afdhal, 2007). Patients with PSC are also at increased risk of fat-soluble vitamin deficiencies resulting from steatorrhea associated with this disease. **Hepatic osteodystrophy** may occur from vitamin D and calcium malabsorption, resulting in secondary hyperparathyroidism, osteomalacia, or rickets. No treatment slows progression of the disease or improves survival. Ursodeoxycholic acid may improve laboratory values (serum bilirubin, alkaline phosphatase, and albumin), but has no effect on survival (Afdhal, 2007).

## CLINICAL INSIGHT

### Malnutrition in the Alcoholic

**S**everal factors contribute to the malnutrition that is common in chronic alcoholics with liver disease:

1. Alcohol can replace food in the diet of moderate and heavy drinkers, displacing the intake of adequate calories and nutrients. In light drinkers, it is usually an additional energy source, or empty calories. Although alcohol yields 7.1 kcal/g, when it is consumed in large amounts it is not used efficiently as a fuel source. When individuals consume alcohol on a regular basis but do not fulfill criteria for alcohol abuse, they are often overweight because of the increased calories (alcohol addition). This is different from the heavy drinker who replaces energy-rich nutrients with alcohol (alcohol substitution).
2. In the alcoholic, impaired digestion and absorption are related to pancreatic insufficiency, as well as morphologic and functional alterations of the intestinal mucosa. Acute and chronic alcohol intake impairs hepatic amino acid uptake and synthesis into proteins, reduces protein synthesis and secretion from the liver, and increases catabolism in the gut.
3. Use of lipids and carbohydrates is compromised. An excess of reduction equivalents (e.g., nicotinamide adenine dinucleotide phosphate) and impaired oxidation of triglycerides result in fat deposition in the hepatocytes and an increase in circulating triglycerides. Insulin resistance is also common.
4. Vitamin and mineral deficiencies occur in alcoholic liver disease as a result of reduced intake and alterations in absorption, storage, and ability to convert the nutrients to their active forms (Leevy and Moroianu, 2005). Steatorrhea resulting from bile acid deficiency is also common in alcoholic liver disease affecting fat-soluble vitamin absorption. Vitamin A deficiency can lead to night blindness (Leevy and Moroianu, 2005). Thiamin deficiency is the most common vitamin deficiency in alcoholics and is responsible for Wernicke encephalopathy (Leevy and Moroianu, 2005). Folate deficiency can occur as a result of poor intake, impaired absorption, accelerated excretion, and altered storage and metabolism. Inadequate dietary intake and interactions between pyridoxal-5'-phosphate (active coenzyme of vitamin B6) and alcohol reduce vitamin B6 status. Deficiency of all B vitamins and vitamins C, D, E, and K is also common (Leevy and Moroianu, 2005). Hypocalcemia, hypomagnesemia, and hypophosphatemia are not uncommon among alcoholics; furthermore, zinc deficiency and alterations in other micronutrients can accompany chronic alcohol intake (Leevy and Moroianu, 2005).

## Inherited Disorders

Inherited disorders of the liver include hemochromatosis, Wilson disease,  $\alpha_1$ -antitrypsin deficiency, protoporphyrria, cystic fibrosis, glycogen storage disease, amyloidosis, and sarcoidosis. The first three disorders most commonly result in liver failure.

### Hemochromatosis

**Hemochromatosis** is an inherited disease of iron overload associated with the gene HFE. Patients with hereditary hemochromatosis absorb excessive iron from the gut and may store 20 to 40 g of iron compared with 0.3 to 0.8 g in normal persons (see Chapter 33). Increased transferrin saturation ( $\geq 45\%$ ) and ferritin (more than two times normal) suggest hemochromatosis. Hepatomegaly, esophageal bleeding, ascites, impaired hepatic synthetic function, abnormal skin pigmentation, glucose intolerance, cardiac involvement, hypogonadism, arthropathy, and hepatocellular carcinoma may develop. Early diagnosis includes clinical, laboratory, and pathologic testing, including elevated serum transferrin levels. Life expectancy is normal if phlebotomy is initiated before the development of cirrhosis or diabetes mellitus.

### Wilson's Disease

**Wilson's disease** is an autosomal-recessive disorder associated with impaired biliary copper excretion. Copper accumulates in various tissues, including the liver, brain, cornea, and kidneys. **Kayser-Fleischer rings** are greenish-yellow

pigmented rings encircling the cornea just within the corneoscleral margin, formed by copper deposits. Patients can present with acute, fulminant, or chronic active hepatitis and with neuropsychiatric symptoms. Low serum ceruloplasmin levels, elevated copper concentration in a liver biopsy, and high urinary copper excretion confirm the diagnosis (Kowdley, 2007).

Copper-chelating agents and zinc supplementation (to inhibit intestinal copper absorption and binding in the liver) are used to treat Wilson disease once it is diagnosed. Copper chelation improves survival but does not prevent cirrhosis; transplantation corrects the metabolic defect (Medici, 2006). A low-copper diet is no longer required, but could be implemented if other therapies are unsuccessful (see Table 30-3). If this disease is not diagnosed until onset of fulminant failure, survival is not possible without transplantation.

### $\alpha_1$ -Antitrypsin Deficiency

$\alpha_1$ -Antitrypsin deficiency is an inherited disorder that can cause both liver and lung disease.  $\alpha_1$ -Antitrypsin is a glycoprotein found in serum and body fluids; it inhibits neutrophil proteinases. Cholestasis or cirrhosis is caused by this deficiency and there is no treatment except liver transplantation.

### Other Liver Diseases

Liver disease has several other causes. Liver tumors can be primary or metastatic, benign or malignant. Hepatocellular carcinoma usually develops in cirrhotic livers. The highest risk occurs in those with hepatitis B, hepatitis C, and

**TABLE 30-3**

#### Copper Content of Commonly Used Foods\*

Food Groups	High (>0.2 mg/Portion Commonly Used <sup>†</sup> ) (Avoid)	Moderate (0.1-0.2 mg/Portion) (No More Than 6 Servings/Day)	Low (<0.1 mg/Portion Commonly Used <sup>†</sup> ) (May Be Eaten As Desired)
Meat and meat substitutes	Lamb; pork; pheasant; quail; duck; goose; squid; salmon; all organ meats including liver, heart, kidney, brain; all shellfish, including oysters, scallops, shrimp, lobster, clams, and crab; meat gelatin; soy protein meat substitutes; tofu; all nuts and seeds	All other fish (3 oz), dark meat turkey (3 oz), peanut butter (2 tbsp)	Beef, cheese, cottage cheese, eggs, light meat turkey; cold cuts and frankfurters that do not contain pork, dark turkey or organ meats, all others not listed on high or moderate list
Fats and oil	Avocado	Olives (2 medium); cream (½ c)	Butter, cream, margarine, mayonnaise, nondairy cream substitutes, oils, sour cream, salad dressings (made from allowed ingredients), all others not listed on high or moderate list
Milk	Chocolate, cocoa, soy milk		All other daily products, milk flavored with carob

**TABLE 30-3****Copper Content of Commonly Used Foods\*—cont'd**

<b>Food Groups</b>	<b>High (&gt;0.2 mg/Portion Commonly Used<sup>†</sup>) (Avoid)</b>	<b>Moderate (0.1-0.2 mg/Portion) (No More Than 6 Servings/Day)</b>	<b>Low (&lt;0.1 mg/Portion Commonly Used<sup>†</sup>) (May Be Eaten As Desired)</b>
Starch	Dried beans, including soybeans, lima beans, baked beans, garbanzo beans, pinto beans; dried peas; lentils; millet; barley; wheat germ; bran breads and cereals; cereals with >0.2 mg of copper per serving (check label); soy flour; soy grits; sweet potatoes (fresh)	Whole-wheat bread (1 slice), potatoes in any form ( $\frac{1}{2}$ c or 1 small), pumpkin ( $\frac{3}{4}$ c), melba toast (4), whole-wheat crackers (6), parsnips ( $\frac{1}{2}$ c), winter squash ( $\frac{1}{2}$ c), green peas ( $\frac{1}{2}$ c), instant oatmeal ( $\frac{1}{2}$ c), instant Ralston ( $\frac{1}{2}$ c), cereals with 0.1-0.2 mg of copper per serving (check labels), dehydrated and canned soups (1 c)	Breads and pasta from refined flour, canned sweet potatoes, rice, regular oatmeal, cereals with <0.1 mg of copper per serving (check label), all others not listed on high or moderate list
Vegetables	Mushrooms, vegetable juice cocktail	Bean sprouts (1 c), beets ( $\frac{1}{2}$ c), spinach ( $\frac{1}{2}$ c cooked, 1 c raw), tomato juice and other tomato products ( $\frac{1}{2}$ c), broccoli ( $\frac{1}{2}$ c), asparagus ( $\frac{1}{2}$ c)	All others, including fresh tomatoes
Fruits	Nectarines; dried fruits, including raisins, dates, and prunes (dried fruits are permitted if dried at home)	Mango ( $\frac{1}{2}$ c), pears (1 medium), pineapple ( $\frac{1}{2}$ c), papaya ( $\frac{1}{4}$ average)	All others
Desserts	Desserts that contain significant amounts of any foods high in copper		All others
Sugar and sweets	Chocolate, cocoa	Licorice (1 oz), syrups (1 oz)	All others including jams, jellies, and candies made with allowed fruits; carob; flavoring extracts
Miscellaneous	Brewer's yeast	Ketchup	
Beverages <sup>‡</sup>	Instant breakfast beverages, mineral water, alcohol <sup>§</sup>	Postum and other cereal beverages	All others, including fruit-flavored beverages; lemonade

From Pemberton CM et al: Mayo Clinic diet manual: a handbook of nutrition practices, ed 7, St Louis, 1994, Mosby.

\*Copper content of the usual American diet varies, with estimates from 1 mg of copper a day to 5 mg/day. The concentration of copper in foods is affected by soil conditions, geographic location, species, diet, processing method, and contamination in processing. The exact copper content of foods is difficult to verify. It is estimated that avoiding high-copper foods and restricting moderate-copper foods result in a diet of approximately 1 mg/day. For practical purposes, diets are designed to limit foods with higher copper content rather than to achieve a specific level of copper in the diet.

<sup>†</sup>Portions commonly used are those generally accepted as typical portion sizes in various nutrient data source manuals.

<sup>‡</sup>A water sample from the patient's home water supply should be analyzed for copper content. Demineralized water should be used if the water contains more than 100 mcg/L.

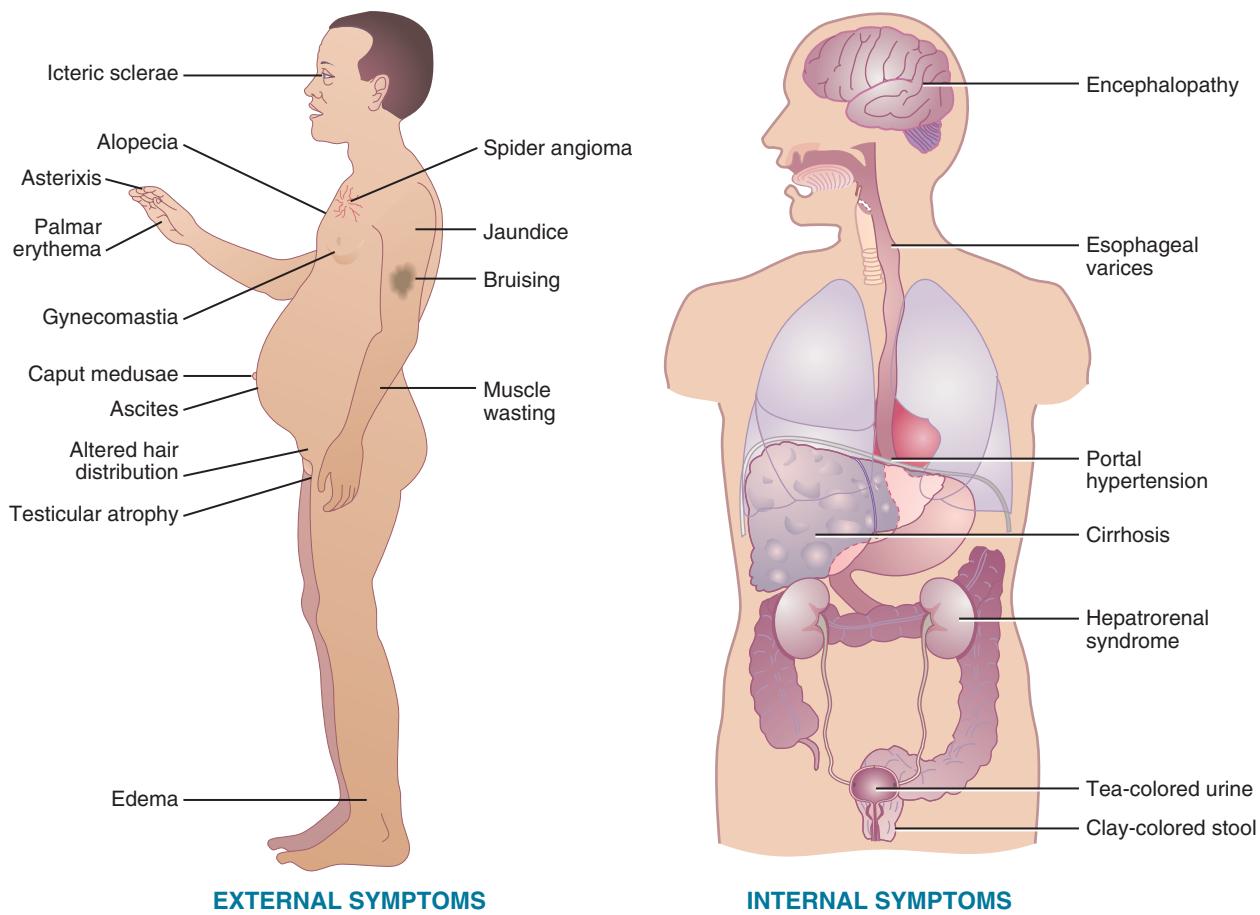

<sup>§</sup>Although not necessarily high in copper, alcohol is discouraged because of its action as a hepatotoxin.

hereditary hemochromatosis. The liver can also be affected by systemic diseases such as rheumatoid arthritis, systemic lupus erythematosus, polymyalgia, temporal arteritis, polyarteritis nodosa, systemic sclerosis, and Sjögren's syndrome. When hepatic blood flow is altered, as in acute ischemic and chronic congestive hepatopathy, Budd-Chiari syndrome, and hepatic venoocclusive disease, dysfunction occurs. Individuals with hepatic or portal vein thromboses should be evaluated for a myeloproliferative disorder. Parasitic,

bacterial, fungal, and granulomatous liver diseases also occur. Finally, cryptogenic cirrhosis is any cirrhosis for which the cause is unknown.

## **TREATMENT OF CIRRHOSIS AND ITS COMPLICATIONS**

Cirrhosis has many clinical manifestations, as illustrated in Figure 30-4. Several major complications of cirrhosis

**FIGURE 30-4** Clinical manifestations of cirrhosis.

and end-stage liver disease (ESLD), including malnutrition, ascites, hyponatremia, hepatic encephalopathy, glucose alterations, fat malabsorption, hepatorenal syndrome, and osteopenia, have nutritional implications. When appropriate nutrition therapy is provided to patients with liver disease, malnutrition can be reversed, and clinical outcomes improved. Studies to date have shown positive outcomes with oral and enteral nutrition (EN) in malnourished patients with cirrhosis, including improvement in nutrition status and clinical complications of cirrhosis such as ascites, encephalopathy, and infection (Campillo et al., 2005).

## Nutrition Assessment

A specific nutrition assessment must be performed to determine the extent and cause of malnutrition. Many traditional markers of nutrition status are affected by liver disease and its consequences, making traditional assessment difficult. Table 30-4 summarizes the factors that affect interpretation of nutrition assessment parameters in patients with liver dysfunction.

Objective parameters that are helpful when monitored serially include anthropometric measurements and dietary intake evaluation (see Chapter 9). The best way to perform a nutrition assessment may be to combine these parameters

with the subjective global assessment (SGA) approach, which has demonstrated an acceptable level of reliability and validity. This method uses a few readily available parameters obtained by an experienced clinician. The SGA gives a broad perspective, but it is not sensitive to changes in nutrition status. Other available parameters should also be reviewed. The SGA approach is summarized in Box 30-1.

## Malnutrition

Moderate to severe malnutrition is a common finding in patients with advanced liver disease (Figure 30-5). This is extremely significant, considering that malnutrition plays a major role in the pathogenesis of liver injury and has a profound negative effect on prognosis. The prevalence of malnutrition depends on nutrition assessment parameters used, type and degree of liver disease, and socioeconomic status.

Numerous coexisting factors are involved in the development of malnutrition in liver disease (see *Pathophysiology and Care Management Algorithm: Malnutrition in Liver Disease*). Inadequate oral intake, a major contributor, is caused by anorexia, dysgeusia, early satiety, nausea, or vomiting associated with liver disease and the drugs used to treat it. Another cause of inadequate intake is dietary restriction.

**TABLE 30-4****Factors That Affect Interpretation of Nutrition Assessment in Patients With End-Stage Liver Disease**

Parameter	Factors Affecting Interpretation
Body weight	Affected by edema, ascites, and diuretic use.
Anthropometric measurements	Questionable sensitivity, specificity, and reliability. Multiple sources of error. Unknown if skinfold measurements reflect total body fat. References do not account for variation in hydration status and skin compressibility.
Creatinine-height index	Affected by malnutrition, aging, decreased body mass, and protein intake. Affected by renal function. Creatinine is a metabolic end product of creatine synthesized in the liver; therefore severe liver disease alters creatinine synthesis rates.
Nitrogen balance studies	Nitrogen is retained in the body in the form of ammonia.
3-Methyl histidine excretion	Hepatorenal syndrome can affect the excretion of nitrogen.
Visceral protein levels	Affected by dietary intake, trauma, infection, and renal function.
Immune function tests	Synthesis of visceral proteins is decreased.
Bioelectrical impedance	Affected by hydration status, malabsorption, and renal insufficiency. Affected by hepatic failure, electrolyte imbalances, infection, and renal insufficiency. Invalid with ascites and edema.

Modified from Hasse J: Nutritional aspects of adult liver transplantation. In Busuttil RW, Klintmalm GB, editors: Transplantation of the liver, ed 2, Philadelphia, 2005, Saunders.

**BOX 30-1****Subjective Global Assessment Parameters for Nutrition Evaluation of Liver Disease Patients****History**

Weight change (consider fluctuations resulting from ascites and edema)  
Appetite

## PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

### Malnutrition in Liver Disease

#### Clinical Findings

- Abnormal liver function tests
- Jaundice
- Ascites and edema
- Hepatic encephalopathy
- Portal hypertension and varices
- Vitamin/mineral deficits
- Glucose intolerance or fasting hypoglycemia

#### Nutrition Assessment

- Serial monitoring of body weight and anthropometry
- Dietary intake
- Subjective global assessment
- Laboratory tests for nutritional deficiencies such as vitamins, magnesium, iron, and others

#### Medical Management

- Diuretic therapy
- Medication for encephalopathy (e.g., lactulose, rifaximin)
- Management of portal hypertensive bleeding (e.g., pharmacologic therapy, shunts, banding)
- Monitoring of blood glucose

#### Nutrition Management

- Increased energy intake via small, frequent meals
- Sodium restriction for fluid retention
- Fluid restriction for hyponatremia
- Carbohydrate-controlled diets for hyperglycemia
- Vitamin and mineral supplements
- Oral liquid supplements or enteral (tube) feeding

**Etiology**

**Pathophysiology**

**Management**

Maldigestion and malabsorption also play a role. **Steatorrhea**, presence of fat in the stool, is common in cirrhosis, especially if there is disease involving bile duct injury and obstruction. Medications may also cause specific malabsorptive losses. In addition, altered metabolism secondary to liver dysfunction causes malnutrition in various ways. Micronutrient function is affected by altered storage in the liver, decreased transport by liver-synthesized proteins, and renal losses associated with alcoholic and advanced liver

disease. Abnormal macronutrient metabolism and increased energy expenditure can also contribute to malnutrition. Finally, protein losses can occur from large-volume **paracentesis** when fluid from the abdomen (ascites) is removed through a needle.

#### Nutrition Intake Problems

Because anorexia, nausea, dysgeusia, and other gastrointestinal symptoms are common, adequate nutrition intake is

difficult to achieve. With ascites, early satiety is also a frequent complaint. Smaller, more frequent meals are better tolerated than three traditional meals. In addition, frequent feedings may also improve nitrogen balance and prevent hypoglycemia. Oral liquid supplements should be encouraged, and, when necessary, enteral tube feedings used. Adjunctive nutrition support should be given to malnourished patients with liver disease if their intake is less than dietary reference intake (DRI) levels of 0.8 g of protein and 30 calories/kg of body weight daily and if they are at risk for fatal complications from the disease. Esophageal varices are usually not a contraindication for tube feeding (Crippin, 2006).

## Nutrient Requirements

### Energy

Energy requirements vary among patients with cirrhosis. Several studies have measured resting energy expenditure (REE) in patients with liver disease to determine energy requirements. Some found that patients with ESLD had normal metabolism and that others had hypometabolism or hypermetabolism. Ascites or shunt placement may increase energy expenditure slightly.

In general, energy requirements for patients with ESLD and without ascites are approximately 120% to 140% of the REE. Requirements increase to 150% to 175% of REE if ascites, infection, and malabsorption are present or if nutritional repletion is necessary. This equates to approximately 25 to 35 calories per kilogram body weight. Estimated dry body weight should be used in calculations to prevent overfeeding. Oral nutritional supplements or tube feeding can increase or ensure optimal intake in malnourished patients, thus reducing complications and prolonging survival (Plauth et al., 2006).

### Carbohydrates

Determining carbohydrate needs is challenging in liver failure because of the primary role of the liver in carbohydrate metabolism. Liver failure reduces glucose production and peripheral glucose use. The rate of gluconeogenesis is decreased, with preference for lipids and amino acids for energy. Alterations in the hormones insulin, glucagon, cortisol, and epinephrine are responsible in part for the preference for alternative fuels. In addition, insulin resistance can be present with liver dysfunction.

### Lipid

In cirrhosis, plasma free fatty acids, glycerol, and ketone bodies are increased in the fasting state. The body prefers lipids as an energy substrate. Lipolysis is increased with active mobilization of lipid deposits, but the net capacity to store exogenous lipid is not impaired. A range of 25% to 40% of calories as fat is generally recommended.

### Protein

Protein is by far the most controversial nutrient in liver failure, and its management is also the most complex.

Cirrhosis has long been thought of as a catabolic disease with increased protein breakdown, inadequate resynthesis, depleted status, and muscle wasting. However, protein kinetic studies demonstrate increased nitrogen losses only in patients with fulminant hepatic failure or decompensated disease but not in stable cirrhosis.

Patients with cirrhosis also have increased protein use. Studies suggest that 0.8 g of protein/kg/day is the mean protein requirement to achieve nitrogen balance in stable cirrhosis. Therefore in uncomplicated hepatitis or cirrhosis without encephalopathy, protein requirements range from 0.8 to 1 g/kg of dry weight per day to achieve nitrogen balance.

To promote nitrogen accumulation or positive balance, at least 1.2 to 1.3 g/kg daily is needed. In situations of stress such as alcoholic hepatitis or decompensated disease (sepsis, infection, gastrointestinal bleeding, or severe ascites), at least 1.5 g of protein per kilogram per day should be provided.

### Vitamins and Minerals

Vitamin and mineral supplementation is needed in all patients with ESLD because of the intimate role of the liver in nutrient transport, storage, and metabolism, in addition to the side effects of drugs (Table 30-5). Vitamin deficiencies can contribute to complications. For example, folate and vitamin B<sub>12</sub> deficiencies can lead to macrocytic anemia. Deficiency of pyridoxine, thiamin, or vitamin B<sub>12</sub> can result in neuropathy. Confusion, ataxia, and ocular disturbances can result from a thiamin deficiency.

Deficiencies of fat-soluble vitamins have been found in all types of liver failure, especially in cholestatic diseases in which malabsorption and steatorrhea occur. Impaired dark adaptation can occur from vitamin A deficiency. Hepatic osteodystrophy or osteopenia can develop from vitamin D deficiency. Therefore supplementation is necessary, and may require using water-soluble forms. Intravenous or intramuscular vitamin K is often given for 3 days to rule out vitamin K deficiency as the cause of a prolonged prothrombin time. Water-soluble vitamin deficiencies associated with liver disease include thiamin (which can lead to **Wernicke encephalopathy**), pyridoxine (B<sub>6</sub>), cyanocobalamin (B<sub>12</sub>), folate, and niacin (B<sub>3</sub>). Large doses (100 mg) of thiamin are given daily for a limited time if deficiency is suspected.

Mineral nutriture is also altered in liver disease. Iron stores may be depleted in patients experiencing gastrointestinal bleeding; however, iron supplementation should be avoided by persons with hemochromatosis or hemosiderosis (see Chapter 33). Elevated serum copper levels are found in cholestatic liver diseases (i.e., PBC and PSC). Because copper and manganese are excreted primarily via bile, supplements should not contain these minerals. Manganese deposition has been noted to accumulate in brains of patients with cirrhosis leading to impaired motor function (Garcia-Tsao, 2007).

In Wilson's disease, excess copper in various organs causes severe damage. Oral chelating agents such as zinc acetate or *d*-penicillamine are the primary treatment. Dietary copper

**TABLE 30-5****Vitamin and Mineral Deficits in Severe Hepatic Failure**

Vitamin or Mineral	Predisposing Factors	Signs of Deficiency
Vitamin A	Steatorrhea, neomycin, cholestyramine, alcoholism	Night-blindness, increased infection risk
Vitamin B1 (thiamine)	Alcoholism, high CHO diet	Neuropathy, ascites, edema, CNS dysfunction
Vitamin B3 (niacin)	Alcoholism	Dermatitis, dementia, diarrhea, inflammation of mucous membranes
Vitamin B <sub>6</sub> (pyridoxine)	Alcoholism	Mucous membrane lesions, seborrheic dermatitis, glossitis, angular stomatitis, blepharitis, peripheral neuropathy, microcytic anemia, depression
Vitamin B <sub>12</sub> (Cyanocobalamin)	Alcoholism, cholestyramine	Megaloblastic anemia, glossitis, CNS dysfunction
Folate	Alcoholism	Megaloblastic anemia, glossitis, irritability
Vitamin D	Steatorrhea, glucocorticoids, cholestyramine	Osteomalacia, rickets (in children), possible link to cancer or autoimmune disorders
Vitamin E	Steatorrhea, cholestyramine	Peripheral neuropathy, ataxia, skeletal myopathy, retinopathy, immune system impairment
Vitamin K	Steatorrhea, antibiotics, cholestyramine	Excessive bleeding; bruising
Iron	Chronic bleeding	Stomatitis, microcytic anemia, malaise
Magnesium	Alcoholism, diuretics	Neuromuscular irritability, hypokalemia, hypocalcemia
Phosphorus	Anabolism, alcoholism	Anorexia, weakness, cardiac failure, glucose intolerance
Zinc	Diarrhea, diuretics, alcoholism	Immunodeficiency, impaired taste acuity, wound healing, protein synthesis

CNS, central nervous system.

restriction (see Table 30-3) is not routinely prescribed unless other therapies are unsuccessful. A vegetarian diet may be useful as adjunctive therapy; copper is less available.

Zinc and magnesium levels are low in liver disease related to alcoholism, in part because of diuretic therapy. Calcium, as well as magnesium and zinc, may be malabsorbed with steatorrhea. Therefore the patient should take supplements of these minerals at least at the level of the DRI.

### Herbal Supplements

There are multiple case reports of different herbal supplements resulting in liver failure. Terpenoid-containing dietary supplements have been implicated in causing severe and sometimes fatal hepatotoxicity, including *teucrium polium* (germander), *Sho-saiko-to*, *Centella asiatica*, and black cohosh (Chitturi and Farrell, 2008). Liver injury has also been caused by N-nitrosofenfluramine, ephedra alkaloids, Boh-Gol-Zhee, Kava, and pyrrolizidine alkaloids (Chitturi and Farrell, 2008).

Two herbal supplements have become popular in the treatment of liver disease. Milk thistle is popular among those suffering from viral hepatitis or alcoholic liver disease. The active component in milk thistle is silymarin. It is proposed to reduce free radical production and lipid peroxidation associated with hepatotoxicity. *S-adenosyl-L-methionine* (SAMe) is another popular complementary medicine product purported to act as a methyl donor for methylation reactions and participate in glutathione (an antioxidant) synthesis. A

Cochrane review did not show any evidence to support or refute a beneficial effect of either milk thistle or SAMe in patients with alcoholic liver disease (Rambaldi et al., 2006, 2007).

### Portal Hypertension

#### Pathophysiology and Medical Treatment

Portal hypertension increases collateral blood flow and can result in swollen veins (**varices**) in the GIT. These varices often bleed, causing a medical emergency. Treatment includes administration of  $\alpha$ -adrenergic blockers to decrease heart rate, endoscopic banding or variceal ligation, and radiologic or surgical placement of shunts. During an acute bleeding episode, somatostatin analog may be administered to decrease bleeding, or a nasogastric tube equipped with an inflatable balloon is placed to tamponade bleeding vessels.

### Medical Nutrition Therapy

During acute bleeding episodes, nutrition cannot be administered enterally. Parenteral nutrition (PN) is indicated if a patient will be taking nothing orally for at least 5 days. Repeated endoscopic therapies may cause esophageal strictures or impair a patient's swallowing. Finally, surgically or radiologically placed shunts may increase the incidence of encephalopathy and reduce nutrient metabolism because blood is shunted past the liver cells.

## Ascites

### Pathophysiology and Medical Treatment

Fluid retention is common, and ascites (accumulation of fluid in the abdominal cavity) is a serious consequence of liver disease. Portal hypertension, hypoalbuminemia, lymphatic obstruction, and renal retention of sodium and fluid contribute to fluid retention. Increased release of catecholamines, renin, angiotensin, aldosterone, and antidiuretic hormone secondary to peripheral arterial vasodilation causes renal retention of sodium and water.

Large-volume paracentesis may be used to relieve ascites. Diuretic therapy is often used and includes spironolactone and furosemide. These drugs are often used in combination for best effect. Major side effects of loop diuretics such as furosemide include hyponatremia, hypokalemia, hypomagnesemia, hypocalcemia, and hypochloremic acidosis. Conversely, spironolactone is potassium sparing. Therefore serum potassium levels must be monitored carefully and supplemented or restricted if necessary because deficiency or excess can contribute to metabolic abnormalities. Weight; abdominal girth; urinary sodium concentration; and serum levels of urea nitrogen, creatinine, albumin, uric acid, and electrolytes should be monitored during diuretic therapy.

### Medical Nutrition Therapy

Dietary treatment for ascites includes sodium restriction in addition to diuretic therapy. Sodium is commonly restricted to 2 g/day (see Chapter 34 and Appendix 37 for discussion of low-sodium diets). More severe limitations may be imposed; however, caution is warranted because of limited palatability and the risk of overrestricting sodium. Adequate protein intake is also important when a patient undergoes frequent paracentesis.

## Hyponatremia

### Pathophysiology

Hyponatremia often occurs because of decreased ability to excrete water resulting from the persistent release of antidiuretic hormone, sodium losses via paracentesis, excessive diuretic use, or overly aggressive sodium restriction.

### Medical Nutrition Therapy

Fluid intake is usually restricted to 1 to 1.5 L/day, depending on the severity of the edema and ascites. A moderate sodium intake should be continued because excessive sodium intake will worsen fluid retention and the dilution of serum sodium levels.

## Hepatic Encephalopathy

### Pathophysiology and Medical Treatment

**Hepatic encephalopathy** is a syndrome characterized by impaired mentation, neuromuscular disturbances, and altered consciousness. Gastrointestinal bleeding, fluid and electrolyte abnormalities, uremia, infection, use of sedatives,

### BOX 30-2

#### Four Stages of Hepatic Encephalopathy

Stage	Symptoms
I	Mild confusion, agitation, irritability, sleep disturbance, decreased attention
II	Lethargy, disorientation, inappropriate behavior, drowsiness
III	Somnolent but arousable, incomprehensible speech, confused, aggressive behavior when awake
IV	Coma

hyperglycemia or hypoglycemia, alcohol withdrawal, constipation, azotemia, dehydration, portosystemic shunts, and acidosis can precipitate hepatic encephalopathy. Subclinical or minimal hepatic encephalopathy also affects patients with chronic hepatic failure. Hepatic or **portal systemic encephalopathy** results in neuromuscular and behavioral alterations. Box 30-2 describes the four stages of hepatic encephalopathy.

There are three main theories regarding the mechanism by which hepatic encephalopathy occurs. Ammonia accumulation is considered an important causal factor in the development of encephalopathy. When the liver fails, it is unable to detoxify ammonia to urea, and ammonia is a direct cerebral toxin. Ammonia levels are elevated in the brain and bloodstream, leading to impaired neural function through cytotoxicity, cell swelling, and depletion of glutamate (Fitz, 2006). The main source of ammonia is its endogenous production by the GIT from the metabolism of protein and from the degradation of bacteria and blood from gastrointestinal bleeding. Exogenous protein is also a source of ammonia. Some clinicians suggest that dietary protein causes an increase in ammonia levels and subsequently hepatic encephalopathy, but this has not been proven in studies.

Drugs such as lactulose and rifaximin are given. Lactulose is a nonabsorbable disaccharide. It acidifies the colonic contents, retaining ammonia as the ammonium ion. It also acts as an osmotic laxative to remove the ammonia. Rifaximin is a nonabsorbable antibiotic that helps decrease colonic ammonia production.

Another suggested mechanism involves the  $\gamma$ -aminobutyric acid (GABA) receptor complex in contributing to neuronal inhibition in hepatic encephalopathy. Flumazenil or other benzodiazepine receptor antagonists may help reduce hepatic encephalopathy.

A final hypothesis is the “altered neurotransmitter theory.” A plasma amino acid imbalance exists in ESLD in which the **branched-chain amino acids (BCAAs)** valine, leucine, and isoleucine are decreased. The BCAAs furnish as much as 30% of energy requirements for skeletal muscle, heart, and brain when gluconeogenesis and ketogenesis are depressed causing serum BCAA levels to fall. **Aromatic**

**amino acids (AAAs)** tryptophan, phenylalanine, and tyrosine, plus methionine, glutamine, asparagine, and histidine are increased. Plasma AAAs and methionine are released into circulation by muscle proteolysis, but the synthesis into protein and liver clearance of AAAs is depressed. This changes the plasma molar ratio of BCAAs to AAAs and may contribute to the development of hepatic encephalopathy. High levels of AAAs may limit the cerebral uptake of BCAAs because they compete for carrier-mediated transport at the blood-brain barrier.

### Medical Nutrition Therapy

The practice of protein restriction in patients with low-grade hepatic encephalopathy is based on the premise that protein intolerance causes hepatic encephalopathy, but it has never been proven in a study. True dietary protein intolerance is rare except in fulminant hepatic failure, or in a rare patient with chronic endogenous hepatic encephalopathy. Unnecessary protein restriction may worsen body protein losses and must be avoided.

Patients with encephalopathy often do not receive adequate protein. More than 95% of patients with cirrhosis can tolerate mixed-protein diets up to 1.5 g/kg of body weight. Studies evaluating the benefit of supplements enriched with BCAAs and restricted in AAAs have varied in study design, sample size, composition of formulas, level of encephalopathy, type of liver disease, duration of therapy, and control groups. When high methodologic quality studies are evaluated, there are no significant improvements or survival benefits associated with giving extra BCAAs to patients.

Other theories postulate that vegetable proteins and casein may improve mental status compared with meat protein. Casein-based diets are lower in AAAs and higher in BCAAs than meat-based diets. Vegetable protein is low in methionine and ammoniagenic amino acids, but BCAA-rich. The high-fiber content of a vegetable-protein diet may also play a role in the excretion of nitrogenous compounds.

Finally, it has been proposed that probiotics and synbiotics (sources of gut-friendly bacteria and fermentable fibers) can be used to treat hepatic encephalopathy. Probiotics (see Chapter 29) may improve hepatic encephalopathy by reducing ammonia portal blood (Pereg et al., 2010) or by preventing production or uptake of lipopolysaccharides in the gut (Gratz et al., 2010). Thus they decrease inflammation and oxidative stress in the hepatocyte (thus increasing hepatic clearance of toxins including ammonia), and minimizing uptake of other toxins.

### Glucose Alterations

#### Pathophysiology

Glucose intolerance occurs in almost two thirds of patients with cirrhosis, and 10% to 37% of patients develop overt diabetes. Glucose intolerance in patients with liver disease occurs because of insulin resistance in peripheral tissues. Hyperinsulinism also occurs in patients with cirrhosis,

possibly because insulin production is increased, hepatic clearance is decreased, portal systemic shunting occurs, there is a defect in the insulin-binding action at the receptor site, or there is a postreceptor defect.

**Fasting hypoglycemia**, or low blood glucose, can occur because of the decreased availability of glucose from glycogen in addition to the failing gluconeogenic capacity of the liver when the patient has ESLD. Hypoglycemia occurs more often in acute or fulminant liver failure than in chronic liver disease. Hypoglycemia may also occur after alcohol consumption in patients whose glycogen stores are depleted by starvation because of the block of hepatic gluconeogenesis by ethanol.

### Medical Nutrition Therapy

Patients with diabetes should receive standard medical and nutrition therapy to achieve normoglycemia (see Chapter 31). Patients with hypoglycemia should eat frequently to prevent this condition (see *Clinical Insight: Fasting Hypoglycemia*).

### Fat Malabsorption

#### Pathophysiology

Fat absorption may be impaired in liver disease. Possible causes include decreased bile salt secretion (as in PBC, sclerosing cholangitis, and biliary strictures), administration of neomycin or cholestyramine, and pancreatic enzyme

### CLINICAL INSIGHT

#### Fasting Hypoglycemia

Two-thirds of the glucose requirement in an adult is used by the central nervous system. During fasting, plasma glucose concentrations are maintained for use by the nervous system and the brain because liver glycogen is broken down, or new glucose is made from nonglucose precursors such as alanine. Fasting hypoglycemia occurs when there is reduced synthesis of new glucose or reduced liver glycogen breakdown.

Causes of fasting hypoglycemia include cirrhosis, consumption of alcohol, extensive intrahepatic cancer, deficiency of cortisol and growth hormone, or non-β cell tumors of the pancreas. The method for detecting it involves measuring plasma insulin when plasma glucose is low. The diagnostic hallmark of an insulinoma is altered insulin secretion in the presence of hypoglycemia. Fasting hypoglycemia may also be caused by spontaneously produced antibodies. All patients with liver or pancreatic disease should be monitored for fasting hypoglycemia. Nutrition therapy involves balanced meals with small, frequent snacks to avoid periods of fasting. Monitoring of blood glucose and insulin levels is required.

insufficiency. Stools may be greasy, floating, or light- or clay-colored, signifying malabsorption, which can be verified by a 72-hour fecal fat study (see Chapter 29 and Appendix 30).

### Medical Nutrition Therapy

If significant steatorrhea is present, replacement of some of the long-chain triglycerides or dietary fat with medium-chain triglycerides (MCTs) may be useful. Because MCTs do not require bile salts and micelle formation for absorption, they are readily taken up via the portal route (see Chapter 29). Some nutrition supplements contain MCTs, which can be used in addition to liquid MCT oil (see Chapter 14).

Significant stool fat losses may warrant a trial of a low-fat (40 g/day) diet. If diarrhea does not resolve, fat restriction should be discontinued because it decreases the palatability of the diet and severely hampers adequate calorie intake.

### Renal Insufficiency and Hepatorenal Syndrome

#### Pathophysiology, Medical and Nutrition Therapies

**Hepatorenal syndrome** is renal failure associated with severe liver disease without intrinsic kidney abnormalities. Hepatorenal syndrome is diagnosed when the urine sodium level is less than 10 mEq/L and oliguria persists in the absence of intravascular volume depletion. If conservative therapies, including discontinuation of nephrotoxic drugs, optimization of intravascular volume status, treatment of underlying infection, and monitoring of fluid intake and output fail, dialysis may be required. In any case, renal insufficiency and failure may necessitate alteration in fluid, sodium, potassium, and phosphorus intake (see Chapter 36).

### Osteopenia

#### Pathophysiology

Osteopenia often exists in patients with PBC, sclerosing cholangitis, and alcoholic liver disease. Depressed osteoblastic function and osteoporosis also can occur in patients with hemochromatosis, and osteoporosis is prevalent in patients who have had long-term treatment with corticosteroids. Corticosteroids increase bone resorption; suppress osteoblastic function; and affect sex hormone secretion, intestinal absorption of dietary calcium, renal excretion of calcium and phosphorus, and the vitamin D system.

### Medical Nutrition Therapy

Prevention or treatment options for osteopenia include weight maintenance, ingestion of a well-balanced diet, adequate protein to maintain muscle mass, 1500 mg of calcium per day, adequate vitamin D from the diet or supplements, avoidance of alcohol, and monitoring for steatorrhea, with diet adjustments as needed to minimize nutrient losses.

## LIVER RESECTION AND TRANSPLANTATION

Liver resection and ablation are fairly common now that problem areas can be located by means of tomography and arteriography. As with any major surgery, protein and energy needs increase after liver resection. Needs are also increased for liver cell regeneration. EN is vital because of the role of portal hepatotropic factors necessary for liver cell proliferation. Optimal nutrition is most important for patients with poor nutrition status before hepatectomy (e.g., patients with hepatocellular carcinoma or cholangiocarcinoma).

Liver transplantation has become an established treatment for ESLD. Malnutrition is common in liver transplant candidates. Dietary intake can often be enhanced if patients eat small, frequent, nutrient-dense meals; oral nutritional supplements may also be well tolerated. Enteral tube feeding is indicated when oral intake is inadequate or contraindicated. Varices are not an absolute contraindication for placement of a feeding tube. Because PN can adversely affect liver function, EN is preferred. PN is reserved for patients without adequate gut function. (See Chapter 14.)

In the acute posttransplant phase, nutrient needs are increased to promote healing, deter infection, provide energy for recovery, and replenish depleted body stores. Nitrogen requirements are elevated in the acute posttransplant phase and can be met with early postoperative tube feeding. Probiotics and fiber added to tube feeding may reduce postoperative infection rate better than tube feeding or fiber alone (Rayes et al, 2005).

Multiple medications used after transplant have nutritional side effects such as anorexia, gastrointestinal upset, hypercatabolism, diarrhea, hyperglycemia, hyperlipidemia, sodium retention, hypertension, hyperkalemia, and hypercalcuria. Therefore dietary modification is based on the specific side effects of drug therapy (Table 30-6). During the posttransplant phase, nutrient requirements are adjusted to prevent or treat problems of obesity, hyperlipidemia, hypertension, diabetes mellitus, and osteopenia. Table 30-7 summarizes nutrient needs following liver transplantation.

## PHYSIOLOGY AND FUNCTIONS OF THE GALLBLADDER

The gallbladder lies on the undersurface of the right lobe of the liver (Figure 30-6). The main function of the gallbladder is to concentrate, store, and excrete bile, which is produced by the liver. During the concentration process, water and electrolytes are resorbed by the gallbladder mucosa. The chief constituents of bile are cholesterol, bilirubin, and bile salts. Bilirubin, the main bile pigment, is derived from the release of hemoglobin from red blood cell destruction. It is transported to the liver, where it is conjugated and excreted via bile. Bile salts are made by liver cells from cholesterol and are essential for the digestion and absorption of fats, fat-soluble vitamins, and some minerals (see Chapter 1).

**TABLE 30-6****Drugs Commonly Used After Liver Transplantation**

Immunosuppressant Drug	Possible Nutritional Side Effects	Proposed Nutrition Therapy
Azathioprine	Macrocytic anemia Mouth sores Nausea, vomiting, diarrhea, anorexia, sore throat, stomach pain, decreased taste acuity	Give folate supplements. Adjust food and meals as needed; monitor intake.
Antithymocyte globulin (ATG), antilymphocyte globulin (ALG)	Nausea, vomiting	Adjust food and meals as needed; monitor intake.
Basiliximab	None reported	Decrease sodium intake.
Cyclosporine	Sodium retention Hyperkalemia Hyperlipidemia	Decrease potassium intake. Limit fat and simple carbohydrate intake.
	Hyperglycemia Decreased serum magnesium level	Decrease simple carbohydrate intake. Increase magnesium intake; give supplements.
	Hypertension Nausea, vomiting	Limit sodium intake. Adjust food and meals as needed; monitor intake.
Daclizumab	None reported	Decrease sodium intake.
Glucocorticoids	Sodium retention Hyperglycemia Hyperlipidemia	Decrease simple carbohydrate intake. Limit fat and simple carbohydrate intake.
	False hunger Protein wasting with high doses Decreased absorption of calcium and phosphorus	Avoid overeating. Increase protein intake.
Muromonab-CD3	Nausea, vomiting, anorexia	Increase calcium and phosphorus intake; give supplements as needed. Adjust food and meals as needed; monitor intake.
Mycophenolate mofetil, mycophenolic acid	Nausea, vomiting, diarrhea	Adjust food and meals as needed; monitor intake.
Sirolimus	Possible GI symptoms	Adjust food and meals as needed; monitor intake.
	Hyperlipidemia	Limit fat and simple carbohydrate intake.
Tacrolimus	Hyperglycemia Hyperkalemia Nausea, vomiting	Decrease simple carbohydrate intake. Decrease potassium intake. Adjust food and meals as needed; monitor intake.

GI, Gastrointestinal.

The primary transporter responsible for bile salt secretion is the bile salt export pump (BSEP). Overall, bile salts play a key role in a wide range of physiologic and pathophysiologic processes (Lam et al., 2010). Excreted into the small intestine via bile, bile salts are later resorbed into the portal system (enterohepatic circulation). This is the primary excretory pathway for the minerals copper and manganese.

Bile contains immunoglobulins that support the integrity of the intestinal mucosa. Fibroblast growth factor receptor (FGFR) 4 controls bile acid metabolism and protects the

liver from fibrosis; FGFR1 and FGFR2 assist in regeneration of the liver (Böhm et al., 2010). Molecular crosstalk between bile acid–activated nuclear receptors and proinflammatory nuclear mediators provides new understanding of inflammation-induced cholestasis (Kosters and Karpen, 2010).

Bile is removed by the liver via bile canaliculi that drain into intrahepatic bile ducts. The ducts lead to the left and right hepatic ducts, which leave the liver and join to become the common hepatic duct. The bile is directed to the gallbladder via the cystic duct for concentration and storage.

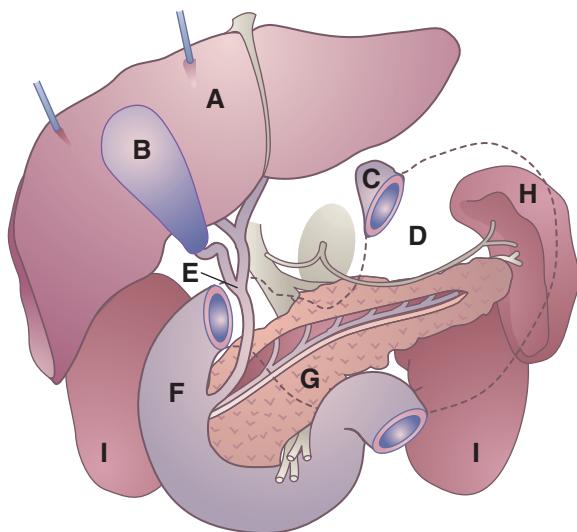

**TABLE 30-7****Nutrition Care Guidelines for Liver Transplant Patient**

	<b>Pretransplantation</b>	<b>Immediate Posttransplantation (First 2 Posttransplant Months)</b>	<b>Long-Term Posttransplantation</b>
Calories & protein*	High calorie (basal + 20% or more) Moderate protein (1-1.5 g/kg) As needed	Moderate calorie (basal + 15%-30%) High protein (1.2-1.75 g/kg) Approximately 30% of calories	Weight maintenance (basal + 10%-20%) Moderate protein (1 g/kg) Moderate fat (30% of calories)
Fat			Reduced simple carbohydrate, especially if diabetes or obesity present
Carbohydrate	Reduced simple carbohydrate if diabetes or obesity present	Reduced simple carbohydrate if diabetes present	
Sodium	2 g/day	2-4 g/day (as indicated)	
Fluid	Restrict to 1000-1500 mL/day (if hyponatremic)	As needed	2-4 g/day (as indicated)
Calcium	800-1200 mg/day	800-1200 mg/day	1200-1500 mg/day
Vitamins	Multivitamin/mineral supplementation to DRI levels; additional water- and fat-soluble vitamins as indicated	Multivitamin/mineral supplementation to DRI levels; additional water- and fat-soluble vitamins as indicated	Multivitamin/mineral supplementation to DRI levels

Modified from Porayko MK et al: Impact of malnutrition and its therapy on liver transplantation, Semin Liv Dis 11(4):305, 1991.

DRI, Dietary reference intake.

\*Use estimated dry or ideal weight.

**FIGURE 30-6** Schematic drawing showing relationship of organs of the upper abdomen. A, Liver (retracted upward); B, gallbladder; C, esophageal opening of stomach; D, stomach (shown in dotted outline); E, common bile duct; F, duodenum; G, pancreas and pancreatic duct; H, spleen; I, kidneys. (Courtesy Cleveland Clinic, Cleveland, Ohio, 2002.)

The cystic duct joins the common hepatic duct to form the common bile duct. The bile duct then joins the pancreatic duct, which carries digestive enzymes.

During the course of digestion, food reaches the duodenum, causing the release of intestinal hormones such as cholecystokinin (CCK) and secretin. This stimulates the gallbladder and pancreas and causes the sphincter of Oddi to relax, allowing pancreatic juice and bile to flow into the duodenum at the ampulla of Vater to assist in fat digestion. For this reason diseases of the gallbladder, liver, and pancreas are often interrelated.

## DISEASES OF THE GALLBLADDER

Disorders of the biliary tract affect millions of people each year, causing significant suffering and even death by precipitating pancreatitis and sepsis. A diverse spectrum of disease affects the biliary system, often presenting with similar clinical signs and symptoms. Treatment may involve diet, medication, or surgery.

### Cholestasis

#### Pathophysiology and Medical Management

**Cholestasis** is a condition in which little or no bile is secreted or the flow of bile into the digestive tract is obstructed. This can occur in patients without oral or enteral feeding for a prolonged period, such as those requiring PN, and can

predispose to acalculous cholecystitis. BSEP deficiency results in several different genetic forms of cholestasis and acquired forms of cholestasis such as drug-induced cholestasis and intrahepatic cholestasis of pregnancy (Lam et al., 2010). Prevention of cholestasis requires stimulation of biliary motility and secretions by at least minimum enteral feedings. If this is not possible, drug therapy is used.

## Cholelithiasis

### Pathophysiology

The formation of gallstones (calculi) is **cholelithiasis**. Virtually all gallstones form within the gallbladder. Gallstone disease affects millions of Americans each year and causes significant morbidity. In most cases gallstones are asymptomatic. Gallstones that pass from the gallbladder into the common bile duct may remain there indefinitely without causing symptoms, or they may pass into the duodenum with or without symptoms.

**Choledocholithiasis** develops when stones slip into the bile ducts, producing obstruction, pain, and cramps. If passage of bile into the duodenum is interrupted, cholecystitis can develop. In the absence of bile in the intestine, lipid absorption is impaired, and without bile pigments, stools become light in color (acholic). If uncorrected, bile backup can result in jaundice and liver damage (**secondary biliary cirrhosis**). Obstruction of the distal common bile duct can lead to pancreatitis if the pancreatic duct is blocked.

Most gallstones are unpigmented cholesterol stones composed primarily of cholesterol, bilirubin, and calcium salts. Bacteria also play a role in gallstone formation. Low-grade chronic infections produce changes in the gallbladder mucosa, which affect its absorptive capabilities. Excess water or bile acid may be absorbed as a result. Cholesterol may then precipitate out and cause gallstones (Volzke et al., 2005).

High dietary fat intake over a prolonged period may predispose a person to gallstone formation because of the constant stimulus to produce more cholesterol for bile synthesis required in fat digestion. Rapid weight loss (as with jeunoileal and gastric bypass and fasting or severe calorie restriction) is associated with a high incidence of biliary sludge and gallstone formation.

Indeed, cholelithiasis and fatty liver disease share risk factors including central obesity, insulin resistance, and diabetes (Weikert et al., 2010).

Risk factors for cholesterol stone formation include female gender, pregnancy, older age, family history, obesity and truncal body fat distribution, diabetes mellitus, inflammatory bowel disease, and drugs (lipid-lowering medications, oral contraceptives, and estrogens). Certain ethnic groups are at greater risk of stone formation, including Pima Indians, Scandinavians, and Mexican-Americans.

Pigmented stones typically consist of bilirubin polymers or calcium salts. They are associated with chronic hemolysis. Risk factors associated with these stones are age, sickle cell anemia and thalassemia, biliary tract infection, cirrhosis, alcoholism, and long-term PN (Abayli et al., 2005).

## Medical & Surgical Management

**Cholecystectomy** is surgical removal of the gallbladder, especially if the stones are numerous, large, or calcified. The cholecystectomy may be done as a traditional open laparotomy or as a less invasive laparoscopic procedure. Recently, it has been noted that cholecystectomy is a predictor of the development of cirrhosis and is associated with elevated serum liver enzymes (Ioannou, 2010).

Chemical dissolution with the administration of bile salts, chenodeoxycholic acid, and ursodeoxycholic acid (litholytic therapy) or dissolution by extracorporeal shockwave lithotripsy may also be used less often than surgical techniques. Patients with gallstones that have migrated into the bile ducts may be candidates for endoscopic retrograde cholangiopancreatography techniques (Adler et al., 2005).

## Medical Nutrition Therapy

No specific dietary treatment is available to prevent cholelithiasis in susceptible persons. Gallstones are more prevalent in low-fiber, high-fat, Westernized diets. Consumption of large amounts of animal protein and animal fat, especially saturated fat, and a lack of dietary fiber, promote gallstone development.

There may also be some benefit in replacing simple sugars and refined starches with high-fiber carbohydrates. Individuals consuming refined carbohydrates have a 60% greater risk for developing gallstones, compared with those who consumed the most fiber, in particular insoluble fiber (Tsai, 2005). Thus plant-based diets may reduce the risk of cholelithiasis. Vegetarian diets are high in fiber and low in fat, consisting primarily of unsaturated fat. Vitamin C, which is generally high in vegetarian diets, affects the rate-limiting step in the catabolism of cholesterol to bile acids and is inversely related to the risk of gallstones in women.

Weight cycling (repeatedly losing and regaining weight), fasting, and very-low-calorie diets increase the likelihood of cholelithiasis. Along with weight reduction, there is some evidence that physical activity will reduce the risk of cholecystitis. In cholecystitis, MNT includes a high-fiber, low-fat, plant-based diet to prevent gallbladder contractions. Data are conflicting as to whether intravenous lipids stimulate gallbladder contraction.

After surgical removal of the gallbladder, oral feedings can be advanced to a regular diet as tolerated. In the absence of the gallbladder, bile is secreted directly by the liver into the intestine. The biliary tract dilates, forming a “simulated pouch” over time, to allow bile to be held in a manner similar to the original gallbladder.

## Cholecystitis

### Pathophysiology

Inflammation of the gallbladder is known as **cholecystitis**, and it may be chronic or acute. It is usually caused by gallstones obstructing the bile ducts (calculous cholecystitis), leading to the backup of bile. Bilirubin, the main bile pigment, gives bile its greenish color. When biliary tract obstruction prevents bile from reaching the intestine, it

backs up and returns to the circulation. Bilirubin has an affinity for elastic tissues; therefore when it overflows into the general circulation, it causes the yellow skin pigmentation and eye discoloration typical of jaundice.

Acute cholecystitis without stones (acalculous cholecystitis) may occur in critically ill patients or when the gallbladder and its bile are stagnant. Impaired gallbladder emptying in chronic acalculous cholecystitis appears to be due to diminished spontaneous contractile activity and decreased contractile responsiveness to CCK. The walls of the gallbladder become inflamed and distended, and infection can occur. During such episodes, the patient experiences upper-quadrant abdominal pain accompanied by nausea, vomiting, and flatulence.

Chronic cholecystitis is long-standing inflammation of the gallbladder. It is caused by repeated, mild attacks of acute cholecystitis. This leads to thickening of the walls of the gallbladder. The gallbladder begins to shrink and eventually loses the ability to perform its function: concentrating and storing bile. Eating foods that are high in fat may aggravate the symptoms of cholecystitis, because bile is needed to digest such foods. Chronic cholecystitis occurs more often in women than in men, and the incidence increases after the age of 40. Risk factors include the presence of gallstones and a history of acute cholecystitis.

### Surgical Management

Acute cholecystitis requires surgical intervention unless medically contraindicated. Without surgery, the condition may either subside or progress to gangrene.

### Medical Nutrition Therapy

**Acute Cholecystitis.** In an acute attack, oral feedings are discontinued. PN may be indicated if the patient is malnourished and it is anticipated that he or she will not be taking anything orally for a prolonged period. When feedings are resumed, a low-fat diet is recommended to decrease gallbladder stimulation. A hydrolyzed low-fat formula or an oral low-fat diet consisting of 30 to 45 g of fat per day can be given. *Table 30-8* shows a fat-restricted diet.

Following cholecystectomy, patients may experience symptoms of gastritis secondary to duodenogastric reflux of bile acids. The reflux may also be responsible for symptoms in this postcholecystectomy syndrome. At present, there are no well-established pharmacologic approaches in the management of postcholecystectomy gastritis. The symptoms are not caused, but exacerbated, by the cholecystectomy. It has been proposed that the addition of soluble fiber to the diet will act as a sequestering agent and bind the bile in the stomach between meals to avoid gastritis.

**Chronic Cholecystitis.** Patients with chronic conditions may require a long-term, low-fat diet that contains 25% to 30% of total kilocalories as fat. Stricter limitation is undesirable because fat in the intestine is important for some stimulation and drainage of the biliary tract. The degree of food intolerance varies widely among persons with gallbladder disorders; many complain of foods that cause flatulence and bloating. For this reason it is best to

determine with the patient which foods should be eliminated. See *Chapter 29* for a discussion of potential gas-forming foods. Administration of water-soluble forms of fat-soluble vitamins may be of benefit in patients with chronic gallbladder conditions or in those in whom fat malabsorption is suspected.

### Cholangitis

#### Pathophysiology and Medical Management

Inflammation of the bile ducts is known as **cholangitis**. Patients with acute cholangitis need resuscitation with fluids and broad-spectrum antibiotics. If the patient does not improve with conservative treatment, placement of a percutaneous biliary stent or cholecystectomy may be needed.

Sclerosing cholangitis can result in sepsis and liver failure. Most patients have multiple intrahepatic strictures, which makes surgical intervention difficult, if not impossible. Patients are generally on broad-spectrum antibiotics. Percutaneous ductal dilation may provide short-term bile duct patency in some patients. When sepsis is recurrent, patients may require chronic antibiotic therapy. See the section on **sclerosing cholangitis** in the liver disease section.

## PHYSIOLOGY AND FUNCTIONS OF THE EXOCRINE PANCREAS

The pancreas is an elongated, flattened gland that lies in the upper abdomen behind the stomach. The head of the pancreas is in the right upper quadrant below the liver within the curvature of the duodenum, and the tapering tail slants upward to the hilum of the spleen. This glandular organ has both an endocrine and exocrine function. Pancreatic cells manufacture glucagon, insulin, and somatostatin for absorption into the bloodstream (endocrine function) for regulation of glucose homeostasis (see *Chapter 31*). Other cells secrete enzymes and other substances directly into the intestinal lumen, where they aid in digesting proteins, fats, and carbohydrates (exocrine function).

In most people the pancreatic duct, which carries the exocrine pancreatic secretions, merges with the common bile duct into a unified opening through which bile and pancreatic juices drain into the duodenum at the ampulla of Vater. Many factors regulate exocrine secretion from the pancreas. Neural and hormonal responses play a role, with the presence and composition of ingested foods being a large contributor. The two primary hormonal stimuli for pancreatic secretion are secretin and CCK (see *Chapter 1*).

Factors that influence pancreatic secretions during a meal can be divided into three phases: (1) the cephalic phase, mediated through the vagus nerve and initiated by the sight, smell, taste, and anticipation of food that leads to the secretion of bicarbonate and pancreatic enzymes; (2) gastric distention with food initiates the gastric phase of pancreatic secretion, which stimulates enzyme secretion;

**TABLE 30-8****Fat-Restricted Diet\***

<b>Food Allowed</b>	<b>Food Excluded</b>
<b>Beverages</b> Skim milk or buttermilk made with skim milk; coffee, tea, Postum, fruit juice, soft drinks, cocoa made with cocoa powder and skim milk	Whole milk, buttermilk made with whole milk, chocolate milk, cream in excess of amounts allowed under fats
<b>Bread and Cereal Products</b> Plain, nonfat cereals; spaghetti, noodles, rice, macaroni; plain whole grain or enriched breads, air-popped popcorn, bagels, English muffins	Biscuits, breads, egg or cheese bread, sweet rolls made with fat, pancakes, doughnuts, waffles, fritters, popcorn prepared with fat, muffins, natural cereals and breads to which extra fat is added
<b>Cheese</b> Cottage cheese, $\frac{1}{4}$ c to be used as substitute for 1 oz of cheese, or low-fat cheeses containing less than 5% butterfat	Whole-milk cheeses
<b>Desserts</b> Sherbet made with skim milk; nonfat frozen yogurt; nonfat frozen nondairy desserts; fruit ice; sorbet; gelatin; rice, bread, cornstarch, tapioca, or pudding made with skim milk; fruit whips with gelatin, sugar, and egg white; fruit; angel food cake; graham crackers; vanilla wafers; meringues	Cake, pie, pastry, ice cream, or any dessert containing shortening, chocolate, or fats of any kind, unless especially prepared using part of fat allowance
<b>Eggs</b> Three per week prepared only with fat from fat allowance; egg whites as desired; low-fat egg substitutes	More than one/day unless substituted for part of the meat allowed
<b>Fats</b> Choose up to the limit allowed among the following (1 serving in the amount listed equals 1 fat choice): 1 tsp butter or margarine 1 Tbsp reduced-fat margarine 1 tsp shortening or oil 1 tsp mayonnaise 2 tsp Italian or French dressing 1 Tbsp reduced-fat salad dressing 1 strip crisp bacon $\frac{1}{8}$ avocado (4-inch diameter) 2 Tbsp light cream 1 Tbsp heavy cream 6 small nuts 5 small olives	Any in excess of amount prescribed on diet; all others
<b>Fruits</b> As desired	Avocado in excess of amount allowed on fat list
<b>Lean Meat, Fish, Poultry, and Meat Substitutes</b> Choose up to the limit allowed among the following: poultry without skin, fish, veal (all cuts), liver, lean beef, pork, and lamb, all with visible fat removed—1 oz cooked weight equals 1 equivalent; $\frac{1}{4}$ c water packed tuna or salmon equals 1 equivalent; tofu or tempeh—3 oz equals 1 equivalent	Fried or fatty meats, sausage, scrapple, frankfurters, poultry skins, stewing hens, spareribs, salt pork, beef unless lean, duck, goose, ham hocks, pig's feet, luncheon meats (unless reduced fat), gravies unless fat-free, tuna and salmon packed in oil, peanut butter

**TABLE 30-8****Fat-Restricted Diet\*—cont'd**

<b>Food Allowed</b>	<b>Food Excluded</b>	
<b>Milk</b>		
Skim, buttermilk, or yogurt made from skim milk	Whole, 2%, 1%, chocolate, buttermilk made with whole milk	
<b>Seasonings</b>		
As desired	None	
<b>Soups</b>		
Bouillon, clear broth, fat-free vegetable soup, cream soup made with skimmed milk, packaged dehydrated soups	All others	
<b>Sweets</b>		
Jelly, jam, marmalade, honey, syrup, molasses, sugar, hard sugar candies, fondant, gumdrops, jelly beans, marshmallows, cocoa powder, fat-free chocolate sauce, red and black licorice	Any candy made with chocolate, nuts, butter, cream, or fat of any kind	
<b>Vegetables</b>		
All plainly prepared vegetables	Potato chips; buttered, au gratin, creamed, or fried potatoes and other vegetables unless made with allowed fat; casseroles or frozen vegetables in butter sauce	
<b>Daily Food Allowances for 40-g-Fat Diet</b>		
<b>Food</b>	<b>Amount</b>	<b>Approximate Fat Content (g)</b>
Skim milk	2 c or more	0
Lean meat, fish, poultry	6 oz or 6 equivalents	18
Whole egg or egg yolks	3 per week	2
Vegetables	3 servings or more, at least 1 or more dark green or deep yellow	0
Fruits	3 or more servings, at least 1 citrus	0
Breads, cereals	As desired, fat-free	0
Fat exchanges*	4-5 exchanges daily	20-25
Desserts and sweets	As desired from permitted list	0
	Total Fat	38-43

\*Fat content can be reduced further by reducing the fat exchanges. 1 Fat exchange = 5 g of fat.

and (3) the intestinal phase, mediated by the release of CCK, with the most potent effect.

## DISEASES OF THE EXOCRINE PANCREAS

### Pancreatitis

#### Pathophysiology and Medical Management

**Pancreatitis** is an inflammation of the pancreas and is characterized by edema, cellular exudate, and fat necrosis. The disease can range from mild and self-limiting to severe, with autodigestion, necrosis, and hemorrhage of pancreatic tissue. Ranson and colleagues (1974) identified 11 signs that could be measured during the first 48 hours of admission

and that have prognostic significance (Box 30-3). By using these observations, one can determine the likely outcome of hospitalization. Surgical intervention may be necessary. Pancreatitis is classified as either acute or chronic, the latter with pancreatic destruction so extensive that exocrine and endocrine function are severely diminished, and malabsorption and diabetes may result.

The symptoms of pancreatitis can range from continuous or intermittent pain of varying intensity to severe upper abdominal pain, which may radiate to the back. Symptoms may worsen with the ingestion of food. Clinical presentation may also include nausea, vomiting, abdominal distention, and steatorrhea. Severe cases are complicated by hypotension, oliguria, and dyspnea. There is extensive destruction of pancreatic tissue with subsequent fibrosis, enzyme production is diminished, and serum amylase and lipase may

**BOX 30-3****Ranson's Criteria to Classify the Severity of Pancreatitis****At Admission or Diagnosis**

Age >55 yr  
 White blood cell count >16,000 m<sup>3</sup>  
 Blood glucose level >200 mg/100 mL  
 Lactic dehydrogenase >350 units/L  
 Aspartate transaminase >250 units/L

**During the Initial 48 Hours**

Hematocrit decrease of >10%  
 Blood urea nitrogen increase of >5 mg/dL  
 Arterial PO<sub>2</sub> <60 mm Hg  
 Base deficit >4 mEq/L  
 Fluid sequestration >6000 mL  
 Serum calcium level <8 mg/mL

Modified from Ranson JH et al: Prognostic signs and the role of operative management in acute pancreatitis, Surg Gynecol Obstet 139:69, 1974.

**TABLE 30-9****Some Tests of Pancreatic Function**

Test	Significance
Secretin stimulation test	Measures pancreatic secretion, particularly bicarbonate, in response to secretin stimulation
Glucose tolerance test	Assesses endocrine function of the pancreas by measuring insulin response to a glucose load
72-hr stool fat test	Assesses exocrine function of the pancreas by measuring fat absorption that reflects pancreatic lipase secretion

appear normal. However, absence of enzymes to aid in the digestion of food leads to steatorrhea and malabsorption. **Table 30-9** describes several tests used to determine the extent of pancreatic destruction.

**Medical Nutrition Therapy**

Alcohol use, smoking, body weight, diet, genetic factors, and medications all affect the risk of developing pancreatitis. Thus diet modification has an important role after diagnosis. Dietary recommendations differ, depending on whether the condition is acute or chronic. Obesity appears to be a risk factor for the development of pancreatitis and an increased severity.

Depressed serum calcium levels are common. Hypoalbuminemia occurs, with subsequent third spacing of fluid. The calcium, which is bound to albumin, is thus affected and may appear artificially low. Another occurrence is “soap”

formation in the gut by calcium and fatty acids, created by the fat necrosis that results in less calcium absorption. Checking an ionized calcium level is a method of determining available calcium.

**Acute Pancreatitis.** Pain associated with acute pancreatitis (AP) is partially related to the secretory mechanisms of pancreatic enzymes and bile. Therefore nutrition therapy is adjusted to provide minimum stimulation of these systems (see *Pathophysiology and Care Management Algorithm: Pancreatitis*). In the past the pancreas was put “at rest.” During acute attacks all oral feeding is withheld, and hydration maintained intravenously. In less severe attacks, a clear liquid diet with negligible fat may be given in a few days. The patient should be monitored for any symptoms of pain, nausea, or vomiting. The diet should be progressed as tolerated to easily digested foods with a low fat content and then advanced as tolerated. Foods may be better tolerated if they are divided into six small meals (see Table 30-8).

Severe AP results in a hypermetabolic, catabolic state with immediate metabolic alterations in the pancreas and also in remote organs. Metabolic demands are similar to those of sepsis. Amino acids are released from muscle and used for gluconeogenesis. These patients often exhibit signs of malnutrition such as decreased serum levels of albumin, transferrin, and lymphocytes. Attention should be given to a nutrition regimen with adequate protein in an effort to achieve positive nitrogen balance.

Oral nutrition must be further delayed when the acute illness persists longer than a few days as evidenced by persistent or recurrent elevation of serum amylase, continued abdominal pain, and ileus; or when cessation of nasogastric suction is followed by return of symptoms, the presence of a complication such as pancreatic abscess or pseudocyst, or a suspected obstruction to the main pancreatic ducts.

The optimal route of nutrition in AP has been the subject of much controversy over the years. Failure to use the GIT in patients with AP may exacerbate the stress response and disease severity, leading to more complications and prolonged hospitalization; thus EN is preferred for nutrition therapy (McClave et al., 2006; Louie et al., 2005). There is a substantial cost savings with EN and fewer septic complications. Most patients with AP have a return of bowel function within 2 to 3 days following an attack and can advance quickly from intravenous fluids to diet.

Both PN and EN are equally effective in terms of days to normalization of serum amylase, days to resumption of oral feeding, serum albumin levels, nosocomial infections, and clinical outcome in patients with mild to moderate pancreatitis (Petrov, 2009). The favorable effect of either EN or PN on patient outcome may be enhanced by supplementation with modulators of inflammation and systemic immunity (McClave et al., 2006).

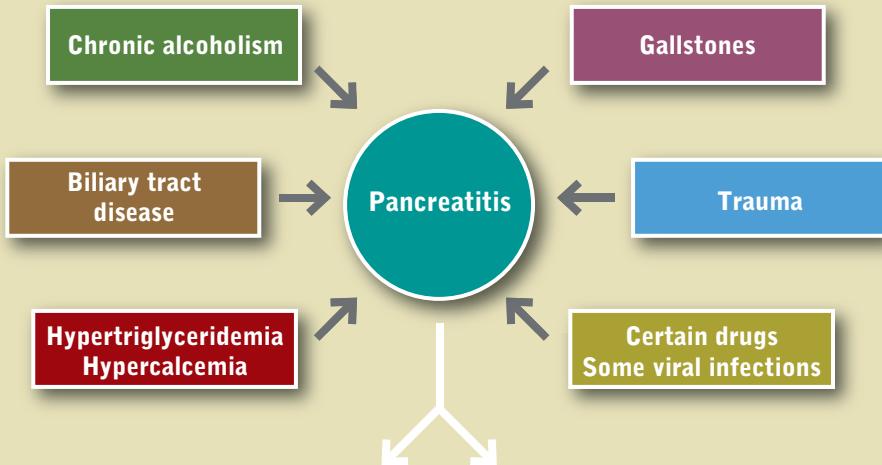

Aggressive nutrition support may include attempts to use the GIT. The location of the feeding and the composition of the formula determine the degree of pancreatic stimulation. Infusion into the jejunum eliminates the

## PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

### Pancreatitis

**Etiology**

**PATHOPHYSIOLOGY**

#### Diagnosis

- I: Apply Ranson's criteria
- II: Tests of pancreatic function
  - Secretin stimulation test
  - Glucose tolerance test
  - 72-hour stool fat test

#### Clinical Findings

- Symptoms:**
- Abdominal pain and distention
  - Nausea
  - Vomiting
  - Steatorrhea
- In severe form:**
- Hypotension
  - Oliguria
  - Dyspnea

**MANAGEMENT**

#### Medical Management

- Acute:**
- Withhold oral feeding
  - Give IV fluids
  - Administer H<sub>2</sub>-receptor antagonists, somatostatin
- Chronic:**
- Manage intestinal pH with:
    - Antacids
    - H<sub>2</sub>-receptor antagonists
    - Proton pump inhibitors
  - Administer insulin for glucose intolerance

#### Nutrition Management

- Acute:**
- Withhold oral and enteral feeding
  - Support with IV fluids
  - If oral nutrition cannot be initiated in 5 to 7 days, start tube feeding
  - Once oral nutrition is started, provide
    - Easily digestible foods
    - Low-fat diet
    - 6 small meals
    - Adequate protein intake
    - Increased calories
- Chronic:**
- Provide oral diet as in acute phase
  - TF can be used when oral diet is inadequate or as a treatment to reduce pain
  - Supplement pancreatic enzymes
  - Supplement fat-soluble vitamins and vitamin B<sub>12</sub>

cephalic and gastric phases of exocrine pancreatic stimulation (McClave et al., 2006; Stanga et al., 2005). Although various formulations have been used in pancreatitis, no studies have determined the relative merits of standard, partially digested, elemental, or “immune-enhanced” formulations. Polymeric formulas infused at various sections of the gut stimulate the pancreas more than elemental and hydrolyzed formulas. Close observation for patient tolerance is important. When the patient is allowed to eat, supplemental pancreatic enzymes may be needed to treat steatorrhea. See Chapter 14) for jejunal feeding details.

In severe, prolonged cases, PN may be necessary. Patients with mild to moderate stress can tolerate dextrose-based solutions, whereas patients with more severe stress require a mixed fuel system of dextrose and lipid to avoid complications of glucose intolerance. Lipid emulsion should not be included in a PN regimen if hypertriglyceridemia is the cause of the pancreatitis. A serum triglyceride level should be obtained before PN with lipids is initiated. Lipids may be given to patients with triglyceride values less than 400 mg/dL. Because of the possibility of pancreatic endocrine abnormalities and a relative insulin resistance, close glucose monitoring is also warranted. H<sub>2</sub>-receptor antagonists may be prescribed to decrease hydrochloric acid production, which will reduce stimulation of the pancreas. Somatostatin is considered the best inhibitor of pancreatic secretion and may be added to the PN solution.

**Chronic Pancreatitis.** In contrast to AP, chronic pancreatitis (CP) evolves insidiously over many years. CP is characterized by recurrent attacks of epigastric pain of long duration that may radiate into the back. The pain can be precipitated by meals. Associated nausea, vomiting, or diarrhea makes it difficult to maintain adequate nutrition status. Patients with CP are at increased risk of developing protein-calorie malnutrition because of pancreatic insufficiency and inadequate oral intake. Patients with CP admitted to a tertiary care center usually have malnutrition, increased energy requirements, weight loss, deficits of lean muscle and adipose tissue, visceral protein depletion, and impaired immune function.

The objective of therapy for patients is to prevent further damage to the pancreas, decrease the number of attacks of acute inflammation, alleviate pain, decrease steatorrhea, and correct malnutrition. Dietary intake should be as liberal as possible, but modifications may be necessary to minimize symptoms.

The first goal of MNT is to provide optimal nutrition support, and the second is to decrease pain by minimizing stimulation of the exocrine pancreas. Because CCK stimulates secretion from the exocrine pancreas, one approach is to decrease CCK levels. If postprandial pain is a limiting factor, alternative enteral therapies that minimally stimulate the pancreas are warranted. Nutrition counseling, antioxidants, and pancreatic enzymes may play a role in effective management of CP as well.

Idiopathic CP is often associated with a cystic fibrosis gene mutation, and therapies directed toward cystic fibrosis may benefit these patients. When pancreatic function is

diminished by approximately 90%, enzyme production and secretion are insufficient; maldigestion and malabsorption of protein and fat thus become a problem. Large meals with high-fat foods and alcohol should be avoided.

The patient may present with weight loss despite adequate energy intake and will complain of bulky, greasy stools. Pancreatic enzyme replacement is mandatory at this time. Pancreatic enzyme replacements are given orally with meals; the dosage should be at least 30,000 units of lipase with each meal. To promote weight gain, the level of fat in the diet should be the maximum a patient can tolerate without increased steatorrhea or pain. Additional therapies that may be tried to maintain nutrition status and minimize symptoms in patients with maximum enzyme supplementation include a lower-fat diet (40 to 60 g/day) or substitution of some dietary fat with MCT oil to improve fat absorption and weight gain. Meals should be small and frequent.

The diet should be low fat, primarily from vegetable-based oils such as olive oil. Reduce significantly or eliminate trans-fatty acids, found in commercially baked goods. Substitution of dietary fat with MCT oil may relieve steatorrhea and lead to weight gain. Malabsorption of the fat-soluble vitamins may occur in patients with significant steatorrhea. Also, deficiency of pancreatic protease, necessary to cleave vitamin B<sub>12</sub> from its carrier protein, could potentially lead to vitamin B<sub>12</sub> deficiency. With appropriate supplemental enzyme therapy, vitamin absorption should be improved; however, the patient should still be monitored periodically for vitamin deficiencies. Water-soluble forms of the fat-soluble vitamins or parenteral administration of vitamin B<sub>12</sub> may be necessary (see Chapter 33). There is some evidence that increasing intake of antioxidants (found in fruits and vegetables) may help protect against pancreatitis or alleviate symptoms of the condition.

Because pancreatic bicarbonate secretion is frequently defective, medical management may also include maintenance of an optimal intestinal pH to facilitate enzyme activation. Antacids, H<sub>2</sub>-receptor antagonists, or proton pump inhibitors that reduce gastric acid secretion may be used to achieve this effect.

In chronic cases with extensive pancreatic destruction, the insulin-secreting capacity of the pancreas decreases, and glucose intolerance develops. Treatment with insulin and nutrition therapy is then required (see Chapter 31). Management is delicate and should focus on control of symptoms rather than normoglycemia.

Effort should be made to cater to the patient's tolerances and preferences for nutritional management; however, alcohol is prohibited because of the possibility of exacerbating the pancreatic disease. There is evidence that the progressive destruction of the pancreas will be slowed in the alcoholic patient who abstains from alcohol.

## Pancreatic Surgery

A surgical procedure often used for pancreatic carcinoma is a **pancreaticoduodenectomy (Whipple procedure)**. A

A 40-year-old man is admitted to the hospital with chief complaints of right upper quadrant pain, anorexia, nausea, dysgeusia, and frequent loose stools. On physical examination, he has mild peripheral edema with a slightly jaundiced appearance. No asterixis is noted. The patient's mental status is clear, but he appears lethargic. He reports no history of portal hypertension, ascites, or gastrointestinal bleeding. Muscle wasting is noted along with stomatitis. A liver biopsy shows steatosis and fibrosis. The patient has a significant alcohol abuse history spanning 15 years, suggesting alcoholic hepatitis. Abnormal laboratory values include elevated liver enzymes and total bilirubin; serum albumin, 2.5 g/dL; transferrin, 150 mg/dL; megaloblastic anemia profile; ammonia, 75 mmol/L. Nutritional data include height, 177.8 cm; weight, 67 kg; ideal body weight, 75 kg ± 10%; usual body weight, 82 kg (5 years ago), 73 kg (6 months ago).

cholecystectomy, vagotomy, or a partial gastrectomy may also be done during the surgery. The pancreatic duct is reanastomosed to the jejunum. Partial or complete pancreatic insufficiency can result, depending on the extent of the pancreatic resection. Most patients who have undergone pancreatic resection are at risk for vitamin and mineral deficiencies and will benefit from vitamin and mineral supplementation. Nutrition care is similar to that for CP.

type 1 diabetes mellitus (T1DM)  
type 2 diabetes mellitus (T2DM)  
United Kingdom Prospective Diabetes Study (UKPDS)  
Whipple triad

Diabetes mellitus is a group of diseases characterized by high blood glucose concentrations resulting from defects in insulin secretion, insulin action, or both. Insulin is a hormone produced by the  $\beta$ -cells of the pancreas that is necessary for the use or storage of body fuels (carbohydrate, protein, and fat). Persons with diabetes do not produce adequate insulin; with **insulin deficiency, hyperglycemia** (elevated blood glucose) occurs.

Diabetes mellitus contributes to a considerable increase in morbidity and mortality rates, which can be reduced by early diagnosis and treatment. Direct medical expenditures such as inpatient care, outpatient services, and nursing home care total are astronomical and indirect costs such as disability, work loss, and premature mortality are equally high. Average medical expenditures among people with diabetes is double that of people who do not have diabetes. Thus providing medical nutrition therapy (MNT) for prevention and treatment of diabetes has tremendous potential to reduce these costs. Fortunately, people with diabetes can take steps to control the disease and lower the risk of complications and premature death.

## INCIDENCE AND PREVALENCE

In 2007 total prevalence of diabetes in the United States for all ages was 23.6 million people, or 7.8% of the population. Of these, 17.9 million are diagnosed and 5.7 million undiagnosed. In 2007 1.6 million new cases of diabetes were diagnosed in people age 20 years or older (Centers for Disease Control and Prevention [CDC], 2007).

Much of the increase is because type 2 diabetes mellitus (T2DM) is no longer a disease that affects mainly older adults. Between 1990 and 1998, the prevalence of diabetes increased by 76% among people in their 30s. Among youth, the prevalence of T2DM also increased dramatically in recent decades.

The prevalence of T2DM is highest in ethnic groups in the United States. Diabetes has been diagnosed, in people aged 20 years or older, in 14.2% of American Indians and Alaska Natives, 11.8% of non-Hispanic blacks, 10.4% of Hispanics, and 7.5% of Asian Americans. Among Hispanics, rates were 12.6% for Puerto Ricans, 11.9% for Mexican Americans, and 8.2% for Cubans (CDC, 2007). In addition, another 57 million people (25% of adults 20 years or older and 35% of adults 60 years or older) have **prediabetes**, which includes impaired glucose tolerance (IGT) (2-hour postchallenge glucose of 140–199 mg/dL) and impaired fasting glucose (IFG) (fasting plasma glucose [FPG] 100–25 mg/dL) (CDC, 2007). Persons with prediabetes are at high risk for conversion to T2DM and cardiovascular disease (CVD) if lifestyle prevention strategies are not implemented.

## CATEGORIES OF GLUCOSE INTOLERANCE

Assigning a type of diabetes to an individual often depends on the circumstances present at the time of diagnosis, and

many individuals do not easily fit into a single category. Thus it is less important to label the particular type of diabetes than it is to understand the pathogenesis of the hyperglycemia and to treat it effectively (American Diabetes Association [ADbA], 2011a). What is clear is the need to intervene early with lifestyle interventions, beginning with prediabetes and continuing through the disease process. Categories of glucose intolerance are listed in Table 31-1.

### Prediabetes

Individuals with a stage of impaired glucose homeostasis that includes IFG and IGT are often referred to as having prediabetes, indicating their relatively high risk for the development of diabetes and CVD. People at risk have IFG, IGT, both, or a hemoglobin A1C (A1C) of 5.7% to 6.4% and should be counseled about strategies, such as weight loss and physical activity, to lower their risks.

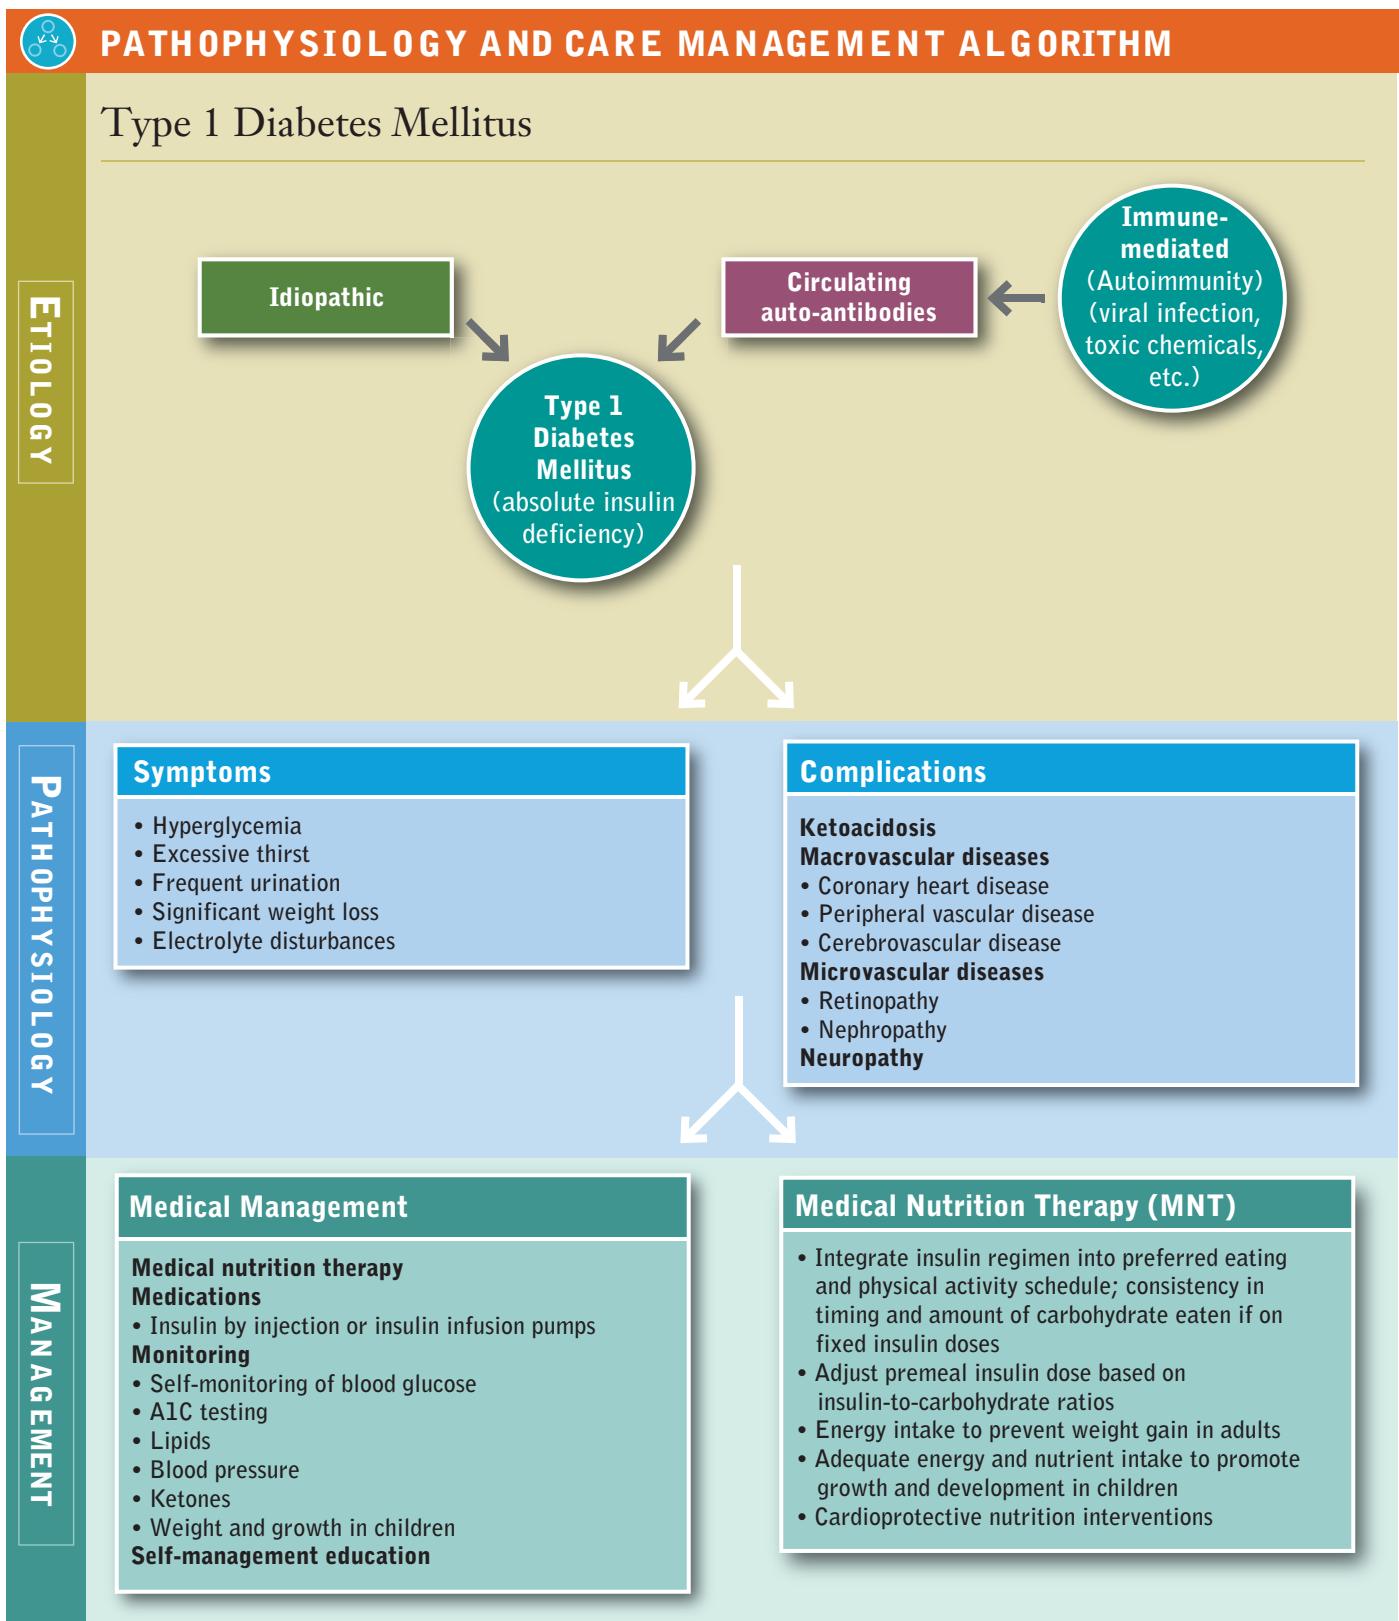

### Type 1 Diabetes

At diagnosis, people with **type 1 diabetes mellitus (T1DM)** are often lean and experience excessive thirst, frequent urination, and significant weight loss. The primary defect is pancreatic  $\beta$ -cell destruction, usually leading to absolute insulin deficiency and resulting in hyperglycemia, **polyuria** (excessive urination), **polydipsia** (excessive thirst), weight loss, dehydration, electrolyte disturbance, and ketoacidosis. The rate of  $\beta$ -cell destruction is quite variable, proceeding rapidly in infants and children and slowly in others (mainly adults). The capacity of a healthy pancreas to secrete insulin is far in excess of what is needed normally. Therefore the clinical onset of diabetes may be preceded by an extensive asymptomatic period of months to years, during which  $\beta$ -cells are undergoing gradual destruction (see *Pathophysiology and Care Management Algorithm: Type 1 Diabetes Mellitus*).

T1DM accounts for 5% to 10% of all diagnosed cases of diabetes. Persons with T1DM depend on exogenous insulin to prevent ketoacidosis and death. Although it may occur at any age, even in the eighth and ninth decades of life, most cases are diagnosed in people younger than 30 years of age, with a peak incidence at around ages 10 to 12 years in girls and ages 12 to 14 years in boys (ADbA, 2011a). T1DM has been increasing 3% to 4% per year in children and youth, and even more in young children younger than age 5.

T1DM has two forms: immune-mediated and idiopathic. **Immune-mediated diabetes mellitus** results from an autoimmune destruction of the  $\beta$ -cells of the pancreas, the only cells in the body that make the hormone insulin. **Idiopathic T1DM** refers to forms of the disease that have no known cause, found mostly in persons of African or Asian origin (ADbA, 2011a).

Risk factors for T1DM may be genetic, autoimmune, or environmental. The genetic predisposition to T1DM is the result of the combination of human leukocyte antigen (HLA)-DQ coded genes for disease susceptibility offset by genes that are related to disease resistance (ADbA, 2011a). However, the genetic factors that confer susceptibility or

protection remain unclear. A 50% discordance rate of T1DM exists between identical twins, suggesting that specific genes are necessary but not sufficient for its development. A trigger, likely environmental, is necessary for the expression of the genetic propensity. At this time there are no known means to prevent T1DM.

### Pathophysiology

Regardless of the trigger, early T1DM is first identified by the appearance of active autoimmunity directed against pancreatic  $\beta$ -cells and their products. At diagnosis, 85% to 90% of patients with T1DM have one or more circulating autoantibodies to islet cells, endogenous insulin, or other

**TABLE 31-1****Types of Diabetes and Prediabetes**

Classification	Distinguishing Characteristics
Type 1 diabetes	Characterized by $\beta$ -cell destruction, usually leading to absolute insulin deficiency; immune-mediated diabetes (resulting from cellular-mediated autoimmune destruction) and idiopathic diabetes (no known causes) are two forms. Affected persons are usually children and young adults, although it can occur at any age, and depend on exogenous insulin to prevent ketoacidosis and death. Immune-mediated type 1 diabetes accounts for 5% to 10% of all diagnosed cases of diabetes.
Type 2 diabetes	Results from a progressive insulin secretory defect (insulin deficiency) on the background of insulin resistance. Affected persons are often older than 30 years at diagnosis, although it is now occurring frequently in young adults and children. Initially, individuals do not depend on exogenous insulin for survival but often require it as the disease progresses for adequate glycemic control. Type 2 diabetes accounts for ~90% to 95% of those with diabetes.
Prediabetes	Fasting or glucose tolerance test results above normal, but not diagnostic of diabetes. These persons should be monitored closely because they have an increased risk of developing diabetes.
GDM	Diabetes diagnosed in some women during pregnancy. Approximately 7% of all pregnancies (ranging from 1% to 14%, depending on the population) are complicated by GDM.
Other specific types	Diabetes that results from specific genetic syndromes, surgery, drugs, malnutrition, infections, or other illnesses.

Data from American Diabetes Association: Diagnosis and classification of diabetes mellitus (Position Statement), Diabetes Care 34:S63, 2011.  
GDM, Gestational diabetes mellitus.

antigens that are constituents of islet cells. Antibodies identified as contributing to the destruction of  $\beta$ -cells are (1) islet cell autoantibodies; (2) insulin autoantibodies, which may occur in persons who have never received insulin therapy; (3) antibodies against islet tyrosine phosphatase (known as IA-2 and IA-2 $\beta$ ); and (4) autoantibodies to glutamic acid decarboxylase (GAD), a protein on the surface of  $\beta$ -cells. GAD autoantibodies appear to provoke an attack by the T cells (killer T lymphocytes), which may destroy the  $\beta$ -cells in diabetes.

The clinical onset of diabetes may be abrupt, but the pathophysiologic insult is a slow, progressive process. Hyperglycemia and symptoms develop only after greater than 90% of the secretory capacity of the  $\beta$ -cell mass has been destroyed.

Frequently, after diagnosis and the correction of hyperglycemia, metabolic acidosis, and ketoacidosis, endogenous insulin secretion recovers. During this **honeymoon phase** exogenous insulin requirements decrease dramatically for up to 1 year or longer, and good metabolic control may be easily achieved. However, the need for increasing exogenous insulin replacement is inevitable and should always be anticipated. Intensive insulin therapy along with attention to MNT and self-monitoring of glucose from early diagnosis has been shown to prolong insulin secretion. Within 5 to 10 years after clinical onset,  $\beta$ -cell loss is complete, and circulating islet cell antibodies can no longer be detected.

**Amylin**, a glucoregulatory hormone is also produced in the pancreatic  $\beta$ -cell and co-secreted with insulin. Amylin complements the effects of insulin by regulating postprandial glucose levels and suppressing glucagon secretion.

T1DM is an amylin-deficient state. Individuals with T1DM are also prone to other autoimmune disorders such as Grave's disease, Hashimoto's thyroiditis, Addison's disease, vitiligo, celiac disease, autoimmune hepatitis, myasthenia gravis, and pernicious anemia.

**Latent autoimmune diabetes in adults (LADA)** may account for as many as 10% of cases of insulin-requiring diabetes in older individuals and represents a slowly progressive form of autoimmune diabetes that is frequently confused with T2DM. Adults with LADA have HLA genetic susceptibility as well as autoantibodies. They may retain sufficient  $\beta$ -cell function so as to not require insulin for approximately six years, but eventually require intensive insulin interventions (Rosario, 2005).

**Type 2 Diabetes**

**Type 2 diabetes mellitus (T2DM)** accounts for 90% to 95% of all diagnosed cases of diabetes and is a progressive disease that, in many cases, is present long before it is diagnosed. Hyperglycemia develops gradually and is often not severe enough in the early stages for the person to notice any of the classic symptoms of diabetes. Although undiagnosed, these individuals are at increased risk of developing macrovascular and microvascular complications.

Risk factors for T2DM include genetic and environmental factors, including a family history of diabetes; older age; obesity, particularly intraabdominal obesity; physical inactivity; a prior history of gestational diabetes; prediabetes; and race or ethnicity. Adiposity and a longer duration of obesity are powerful risks factors for T2DM, and even small weight losses are associated with a change in glucose

levels toward normal in persons with prediabetes. Nevertheless, T2DM is found in persons who are not obese, and many obese persons never develop T2DM. Therefore obesity combined with a genetic predisposition may be necessary for T2DM to occur (see *Pathophysiology and Care Management Algorithm: Type 2 Diabetes Mellitus*).

### Pathophysiology

T2DM is characterized by a combination of insulin resistance and  $\beta$ -cell failure. Endogenous insulin levels may be normal, depressed, or elevated; but they are inadequate to overcome concomitant **insulin resistance** (decreased tissue sensitivity or responsiveness to insulin). As a result, hyperglycemia ensues.

Insulin resistance is first demonstrated in target tissues, mainly muscle, liver, and adipose cells. Initially there is a compensatory increase in insulin secretion (hyperinsulinemia), which maintains glucose concentrations in the normal or prediabetic range. In many persons the pancreas is unable to continue to produce adequate insulin, hyperglycemia occurs, and the diagnosis of diabetes is made. Therefore insulin levels are always deficient relative to elevated glucose levels before hyperglycemia develops.

Hyperglycemia is first exhibited as an elevation of **post-prandial (after a meal) blood glucose** caused by insulin resistance at the cellular level and is followed by an elevation in fasting glucose concentrations. As insulin secretion decreases, hepatic glucose production increases, causing the increase in **preprandial (fasting) blood glucose** levels. The insulin response is also inadequate in suppressing alpha-cell glucagon secretion, resulting in glucagon hypersecretion and increased hepatic glucose production. Compounding the problem is **glucotoxicity**, the deleterious effect of hyperglycemia on both insulin sensitivity and insulin secretion; hence the importance of achieving near-euglycemia in persons with T2DM.

Insulin resistance is also demonstrated at the adipocyte level, leading to lipolysis and an elevation in circulating free fatty acids. In particular, excess intraabdominal obesity, characterized by an excess accumulation of visceral fat around and inside abdominal organs, results in an increased flux of free fatty acids to the liver, leading to an increase in insulin resistance. Increased fatty acids also cause a further decrease in insulin sensitivity at the cellular level, impair pancreatic insulin secretion, and augment hepatic glucose production (**lipotoxicity**). These defects contribute to the development and progression of T2DM and are also primary targets for pharmacologic therapy.

Persons with T2DM may or may not experience the classic symptoms of uncontrolled diabetes, and they are not prone to develop ketoacidosis. The progressive loss of  $\beta$ -cell secretory function means that persons with T2DM will require more medications over time to maintain the same level of glycemic control; eventually exogenous insulin will be required. Insulin is also required sooner for control during periods of stress-induced hyperglycemia, such as during illness or surgery.

### Gestational Diabetes Mellitus

**Gestational diabetes mellitus (GDM)** occurs in approximately 7% of all pregnancies (ranging from 1% to 14% depending on the population studied), resulting in more than 200,000 cases annually (ADbA, 2011a). After delivery, approximately 90% of all women with GDM become normoglycemic but are at increased risk of developing GDM earlier in subsequent pregnancies. Immediately after pregnancy, 5% to 10% of women with GDM are diagnosed with T2DM. Women who have had GDM have a 40% to 60% chance of developing diabetes in the next 5 to 10 years (CDC, 2007). Lifestyle modifications aimed at reducing or preventing weight gain and increasing physical activity after pregnancy may reduce the risk of subsequent diabetes.

Previously GDM was defined as any degree of glucose intolerance with onset or first recognition during pregnancy. However, the number of pregnant women with undiagnosed diabetes has increased and therefore it has now been recommended that high-risk women found to have diabetes at their initial prenatal visit receive a diagnosis of overt, not gestational, diabetes (ADbA, 2011b). The majority of cases of GDM will be diagnosed during the second or third trimester of pregnancy because of the increase in insulin-antagonist hormone levels and normal insulin resistance that occurs at this time.

An oral glucose challenge was previously used as an indication of the need for diagnostic testing for GDM. However, new guidelines have been proposed. Women at high risk should be tested during the first trimester. Women with an A1C of greater than 6.5%, a fasting glucose of more than 126 mg/dL (7 mmol/L), or a 1-hour glucose or more than 200 mg/dL (11.1 mmol/L) likely had diabetes before becoming pregnant and should be treated for GDM. Screening should be done during the 24th to 28th week of pregnancy using a 75-g oral glucose tolerance test (OGTT). A fasting glucose of more than 92 mg/dL (5.1 mmol/L), a 1-hour glucose of more than 180 mg/dL (10 mmol/L), or a 2-hour glucose of 153 mg/dL (8.4 mmol/L) or more is diagnostic of GDM.

During pregnancy, treatment to normalize maternal blood glucose levels reduces the risk of adverse maternal, fetal, and neonatal outcomes. Extra glucose from the mother crosses the fetal placenta and the fetus's pancreas responds by releasing extra insulin to cope with the excess glucose. The excess glucose is converted to fat, which results in **macrosomia**. The fetus may become too large for a normal birth, resulting in the need for cesarean delivery. Neonatal hypoglycemia at birth is another common problem. The above-normal levels of maternal glucose have caused the fetus to produce extra insulin. However, after birth the extra glucose is no longer available to the fetus; until his or her pancreas can adjust, the neonate may require extra glucose through intravenous feedings for a day or two to keep blood glucose levels normal.

GDM does not cause congenital anomalies. Such malformations occur in women with diabetes prior to pregnancy who have uncontrolled blood glucose levels during the first

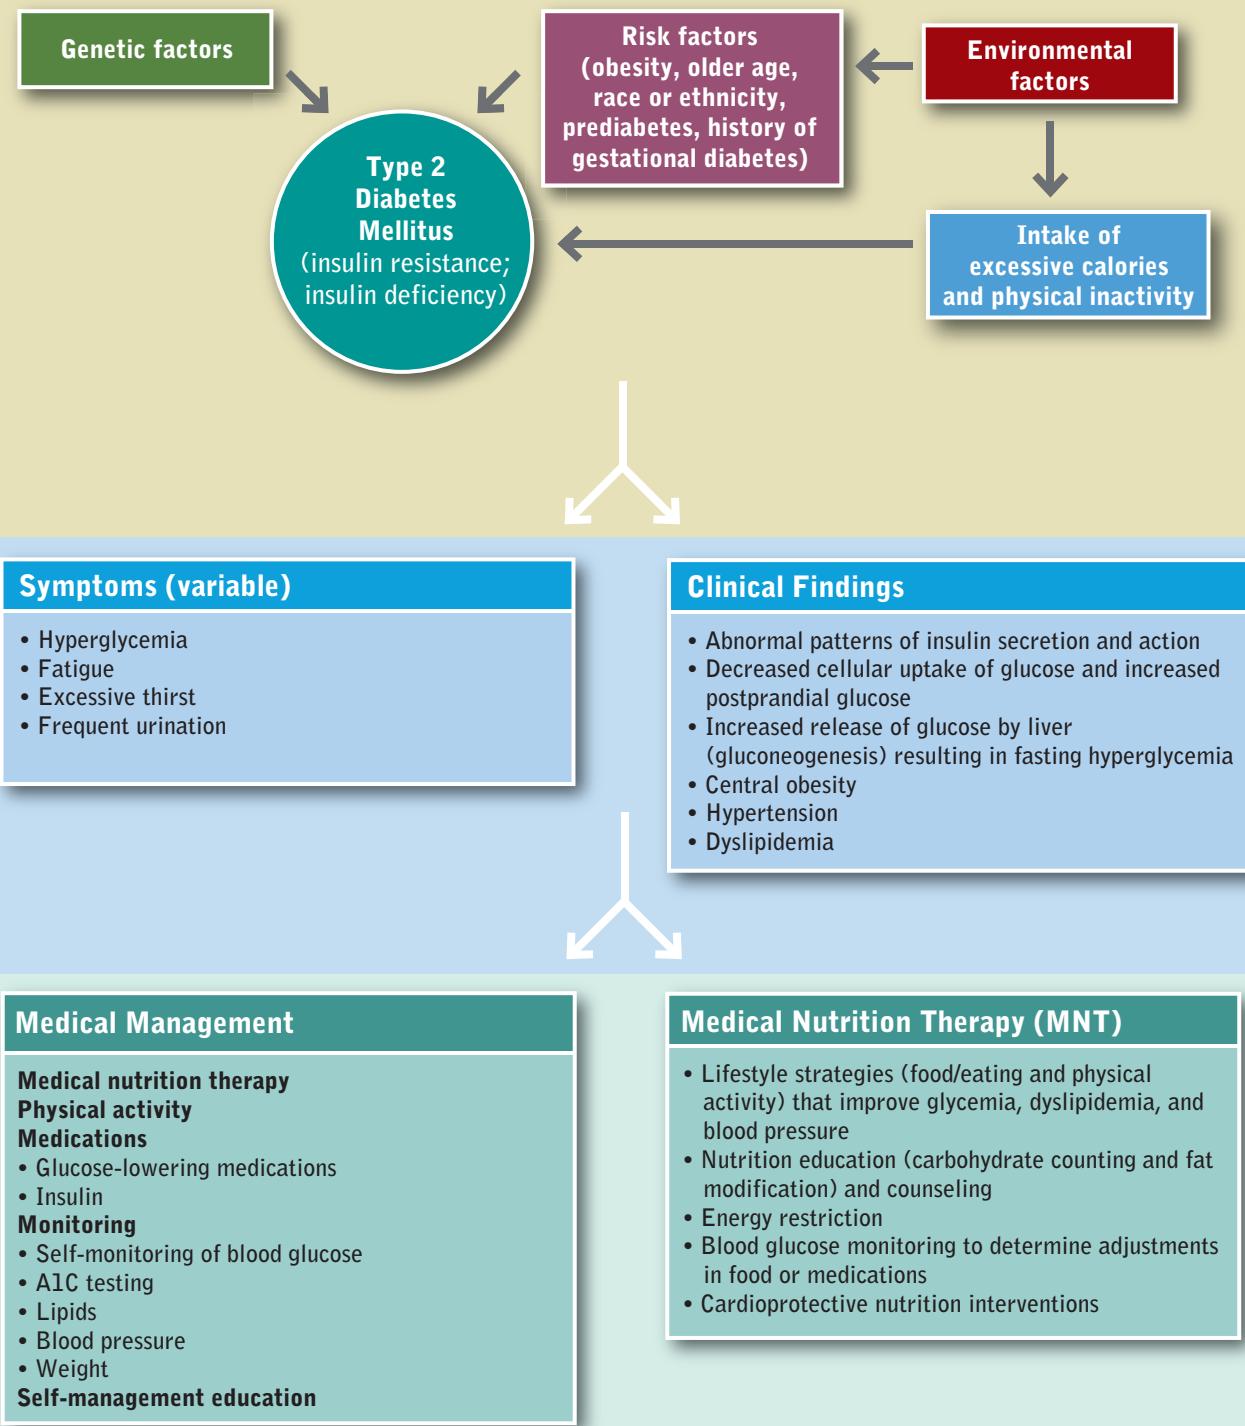

## PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

### Type 2 Diabetes Mellitus

**Etiology**

**Pathophysiology**

**Management**

six to eight weeks of pregnancy when fetal organs are being formed. Because GDM doesn't appear until later in pregnancy, the fetal organs were formed before hyperglycemia became a problem.

When optimal blood glucose levels are not being maintained with MNT or the rate of fetal growth is excessive, pharmacologic therapy is needed (American Dietetic Association [ADA], 2009a). Research supports the use of insulin, insulin analogs, metformin, and glyburide during pregnancy. Women with GDM should be screened for diabetes 6 to 12 weeks postpartum and should be followed with subsequent screening for the development of diabetes or prediabetes (ADbA, 2011b).

### Other Types of Diabetes

This category includes diabetes associated with specific genetic syndromes (such as maturity-onset diabetes of youth), diseases of the exocrine pancreas (such as cystic fibrosis), drug- or chemical-induced (such as in the treatment of acquired immune deficiency syndrome or after organ transplantation), surgery, infections, and other illnesses. Such types of diabetes may account for 1% to 5% of all diagnosed cases of diabetes (ADbA, 2011a).

## SCREENING AND DIAGNOSTIC CRITERIA

Testing or screening for diabetes should be considered in all adults who are overweight (body mass index [BMI] of 25 kg/m<sup>2</sup> or more) and who have one or more additional risk factors for T2DM in the following list. In those without these risk factors, testing should begin at age 45 years. If tests are normal, testing should be done at 3-year intervals; A1C, FPG, or 2-hour OGTT can be used to test for either prediabetes or diabetes (ADbA, 2011b). Additional risk factors for diabetes are:

- Physical inactivity
- First-degree relative with diabetes
- Members of a high-risk population (African American, Latino, Native American, Asian-American, and Pacific Islander)
- Women who have delivered a baby weighing more than 9 lb or have been diagnosed with GDM
- Hypertensive (blood pressure 140/90 mm Hg or more or taking medication for hypertension)
- High-density lipoprotein (HDL) cholesterol level of less than 35 mg/dL (0.9 mmol/L) or a triglyceride level of more than 250 mg/dL (2.82 mmol/L)
- Women with polycystic ovary syndrome (PCOS)
- A1C of 5.7% or more, IGT, or IFG on previous testing
- Severe obesity
- **Acanthosis nigricans** (gray-brown skin pigmentation)
- History of CVD

Consistent with screening recommendations for adults, children and youth at increased risk for T2DM should be

tested. The age of initiation of screening is age 10 years or at onset of puberty, and the frequency is every 3 years (ADbA, 2011b). Youth who are overweight (BMI greater than the 85th percentile for age and sex, weight for height greater than the 85th percentile, or weight of more than 120% of ideal for height) and have any two of the following risk factors should be screened: family history of T2DM, members of high-risk ethnic populations, signs of insulin resistance (acanthosis nigricans, hypertension, dyslipidemia, PCOS, small for gestational age birthweight, or maternal history of diabetes or GDM during the child's gestation.)

Diagnostic criteria for diabetes and prediabetes are summarized in Table 31-2. Four diagnostic methods may be used to diagnose diabetes and each, in the absence of unequivocal hyperglycemia, must be confirmed on a subsequent day by repeat testing. It is preferable that the same test be repeated for confirmation (ADbA, 2011b).

The use of A1C for diagnosing diabetes was not previously recommended. However, the A1C assay is now highly standardized and is a reliable measure of chronic glucose levels. The A1C test reflects longer-term glucose concentrations and is assessed from the results of **glycosylated hemoglobin** (simplified as **A1C**) tests. When hemoglobin and other proteins are exposed to glucose, the glucose becomes attached to the protein in a slow, nonenzymatic, and concentration-dependent fashion. Measurements of A1C therefore reflect a weighted average of plasma glucose concentration over the preceding weeks. In nondiabetic persons A1C values are 4% to 6%; these values correspond to mean blood glucose levels of approximately 70 to 126 mg/dL (3.9 to 7 mmol/L). A1C values vary less than FPG and testing is more convenient as patients are not required to be fasting or to undergo an OGTT. For conditions with abnormal red cell turnover, such as pregnancy or anemias from hemolysis and iron deficiency, the diagnosis of diabetes must use glucose criteria exclusively (ADbA, 2011b).

## MANAGEMENT OF PREDIABETES

In no other disease does lifestyle—healthy and appropriate food choices and physical activity—play a more important role in both prevention and treatment than in diabetes. Studies comparing lifestyle modifications to medication have provided support for the benefit of weight loss (reduced energy intake) and physical activity as the first choice to prevent or delay diabetes. Clinical trials comparing lifestyle interventions to a control group have reported risk reduction for T2DM from lifestyle interventions ranging from 29% to 67% (ADbA, 2011b). Two frequently cited studies are the Finnish Diabetes Prevention Study and the Diabetes Prevention Program in which lifestyle interventions focused on a weight loss of 5% to 10%, physical activity of at least 150 min/week of moderate activity, and ongoing counseling and support. Both reported a 58% reduction in the incidence of T2DM in the intervention group compared with the control group and persistent reduction in the rate of conversion to T2DM within 3 to

**TABLE 31-2****Diagnosis of Diabetes Mellitus and Impaired Glucose Homeostasis (Prediabetes)**

Diagnosis	Criteria
Diabetes	A1C ≥ 6.5%* OR FPG ≥ 126 mg/dL (≥7 mmol/L)* OR 2-hour PG ≥ 200 mg/dL (≥11.1 mmol/L) during an OGTT* OR In patients with classic symptoms of hyperglycemia or hyperglycemic crisis, a random PG ≥ 200 mg/dL (≥11.1 mmol/L)
Prediabetes	FPG 100-125 mg/dL (5.6-7 mmol/L) [Impaired fasting glucose] OR 2-hour PG 140-199 mg/dL (7.8-11 mmol/L) [Impaired glucose tolerance] OR A1C 5.7%-6.4%
Normal	FPG < 100 mg/dL (<5.6 mmol/L) 2-hour PG < 140 mg/dL (<7.8 mmol/L)

Data from American Diabetes Association: Diagnosis and classification of diabetes mellitus (Position Statement), Diabetes Care 34:S63, 2011.

\*In the absence of unequivocal hyperglycemia, criteria should be confirmed by repeat testing.

14 years postintervention follow-up (Diabetes Prevention Program, 2009; Li, 2008; Lindström, 2006).

## Medical Management

Use of the pharmacologic agents metformin,  $\alpha$ -glucosidase inhibitors, orlistat, and thiazolidinediones (TZDs) has been shown to decrease incidence of diabetes by various degrees (ADbA, 2011b). At this time, metformin is the only drug that should be considered for use in diabetes prevention. It is the most effective in those with a BMI of at least 35 kg/m<sup>2</sup> and who are younger than age 30. For other drugs, issues of cost, side effects, and lack of persistence of effect are of concern.

Medical management must include lifestyle changes. Physical activity is important to prevent weight gain and maintain weight loss. For cardiovascular fitness and to reduce risk of T2DM, recommendations include moderate-intensity aerobic physical activity for a minimum of 30 minutes 5 days per week (150 min/week) (i.e., walking 3 to 4 miles/hour) or vigorous-intensity aerobic physical activity for a minimum of 20 minutes 3 days per week (90 min/week). Muscle-strengthening activities involving all major muscle groups 2 or more days per week are also recommended (U.S. Department of Health and Human Services, 2008). Physical activity independent of weight loss improves insulin sensitivity.

## Bariatric Surgery and Prediabetes

For morbidly obese individuals, bariatric surgery can reduce the incidence of diabetes. Because improvement in glucose occurs rapidly and before significant weight loss, decreased

risk may be related to diversion of nutrients away from the gastrointestinal tract (Guidone et al., 2006) or by changes from bariatric surgery on the signaling mechanism of the gut to pancreatic islet cells, muscles, fat, liver, and other organs (Wilson and Pories, 2010).

## Medical Nutrition Therapy for Prediabetes

Goals of MNT for prediabetes emphasize the importance of food choices that facilitate moderate weight loss (Box 31-1). Because of the effects of obesity on insulin resistance, weight loss is an important goal (see Chapter 22). In addition, studies have reported a relationship between higher levels of total dietary fat and greater insulin resistance.

Whole grains and dietary fiber are associated with reduced risk of diabetes. Increased intake of whole grain-containing foods improves insulin sensitivity independent of body weight, and increased intake of dietary fiber has been associated with improved insulin sensitivity and improved ability to secrete insulin adequately to overcome insulin resistance (Mayer-Davis et al., 2006). Moderate consumption of alcohol (1 to 3 drinks per day [15 to 45 g alcohol]) is linked with decreased risk of T2DM, coronary heart disease (CHD), and stroke. But the data do not support recommending alcohol consumption to persons at risk for diabetes who do not already drink alcoholic beverages (ADbA, 2008).

## MANAGEMENT OF DIABETES

Two classic clinical trials have demonstrated beyond a doubt the clear link between glycemic control and the

**BOX 31-1****Goals of Medical Nutrition Therapy for Diabetes Mellitus****Goals of Medical Nutrition Therapy That Apply to Persons at Risk for Diabetes or with Prediabetes:**

1. To decrease risk of diabetes and cardiovascular disease by promoting healthy food choices and physical activity leading to moderate weight loss that is maintained

**Goals of Medical Nutrition Therapy for Persons with Diabetes**

1. To the extent possible, achieve and maintain:
  - Blood glucose levels in the normal range or as close to normal as is safely possible
  - A lipid and lipoprotein profile that reduces the risk for vascular disease
  - Blood pressure levels that reduce the risk for vascular disease
2. To prevent, or at least slow the rate of, development of the chronic complications of diabetes by modifying nutrient intake and lifestyle as appropriate
3. To address individual nutrition needs, taking into account personal and cultural preferences and willingness to change
4. To limit food choices only based on evidence and to maintain the pleasure of eating

**Goals of Nutrition Therapy That Apply to Specific Situations:**

1. For youth with type 1 diabetes, youth with type 2 diabetes, pregnant and lactating women, and older adults with diabetes, to meet the nutritional needs of these unique times in the life cycle
2. For individuals treated with insulin or insulin secretagogues, to provide self-management training for safe conduct of exercise, prevention and treatment of hypoglycemia, and treatment of acute illness

Adapted from American Diabetes Association: Nutrition recommendations and interventions for diabetes (position statement), *Diabetes Care* 31:S61, 2008.

development of complications in persons with T1DM and T2DM, as well as the importance of nutrition therapy in achieving control. The **Diabetes Control and Complications Trial (DCCT)** studied approximately 1400 persons with T1DM treated with either intensive (multiple injections of insulin or use of insulin infusion pumps guided by blood glucose monitoring results) or conventional (one or two insulin injections per day) regimens. Patients who achieve control similar to the intensively treated patients can expect a 50% to 75% reduction in the risk of progression to retinopathy, nephropathy, neuropathy, and fewer long-term cardiovascular complications (**Diabetes Control and Complications Trial**, 2005). Another study, the **United**

**Kingdom Prospective Diabetes Study (UKPDS)** demonstrated conclusively that glucose and blood pressure control decreased the risk of long-term complications in T2DM. A reduction in energy intake was at least as important, if not more important, than the actual weight lost.

**Medical Management**

There is a progressive nature in T2DM. The “diet” doesn’t fail; the pancreas fails to secrete enough insulin to maintain adequate glucose control. As the disease progresses, MNT alone is not enough to keep A1C level at 7% or less. Therapy needs to be intensified over time. Medication, and often insulin, need to be combined with nutrition therapy.

The management of all types of diabetes includes MNT, physical activity, monitoring, medications, and self-management education. An important goal of treatment is to provide the patient with the necessary tools to achieve the best possible control of glycemia, lipidemia, and blood pressure to prevent, delay, or arrest the microvascular and macrovascular complications while minimizing hypoglycemia and excess weight gain (ADbA, 2011b). Optimal control of diabetes also requires the restoration of normal carbohydrate, protein, and fat metabolism.

Insulin is both anticatabolic and anabolic and facilitates cellular transport (Table 31-3). In general, the **counterregulatory (stress) hormones** (glucagon, growth hormone, cortisol, epinephrine, and norepinephrine) have the opposite effect of insulin.

The American Diabetes Association’s (ADbA) glycemic treatment goals for persons with diabetes are listed in Table 31-4. Achieving goals requires open communication and appropriate self-management education. Patients can assess day-to-day glycemic control by **self-monitoring of blood glucose (SMBG)** and measurement of urine or blood ketones. Longer-term glycemic control is assessed by A1C testing. Lipid levels and blood pressure must also be monitored (Table 31-5). Lipids should be measured annually, and blood pressure should be monitored at every diabetes management visit (ADbA, 2011b).

**Medical Nutrition Therapy for Diabetes**

MNT is integral to total diabetes care and management. Effective integration of MNT into the overall management of diabetes requires a coordinated team effort, including a registered dietitian (RD) who is knowledgeable and skilled in implementing current nutrition therapy recommendations for diabetes. MNT requires an individualized approach and effective nutrition self-management education and counseling. Monitoring glucose, A1C and lipid levels, blood pressure, weight, and quality-of-life issues is essential in evaluating the success of nutrition-related recommendations. If desired outcomes from MNT are not met, changes in overall diabetes care and management should be recommended (ADbA, 2008).

The American Dietetic Association (ADA) published evidence-based nutrition practice guidelines (EBNPG) for T1DM and T2DM in adults in their Evidence Analysis Library (ADA, 2008) and in print (Franz et al., 2010a). The

**TABLE 31-3****Action of Insulin on Carbohydrate, Protein, and Fat Metabolism**

<b>Effect</b>	<b>Carbohydrates</b>	<b>Protein</b>	<b>Fat</b>
Anticatabolic (prevents breakdown)	Decreases breakdown and release of glucose from glycogen in the liver	Inhibits protein degradation, diminishes gluconeogenesis	Inhibits lipolysis, prevents excessive production of ketones and ketoacidosis
Anabolic (promotes storage)	Facilitates conversion of glucose to glycogen for storage in liver and muscle	Stimulates protein synthesis	Facilitates conversion of pyruvate to free fatty acids, stimulating lipogenesis
Transport	Activates the transport system of glucose into muscle and adipose cells	Lowers blood amino acids in parallel with blood glucose levels	Activates lipoprotein lipase, facilitating transport of triglycerides into adipose tissue

**TABLE 31-4****Recommendations for Glycemic Control for Adults with Diabetes**

<b>Glycemic Control</b>	<b>Criteria</b>
A1C	<7.0%*
Preprandial capillary plasma glucose	70–130 mg/dL (3.9–7.2 mmol/L)
Peak postprandial capillary plasma glucose <sup>†</sup>	<180 mg/dL (<10 mmol/L)

CVD, Cardiovascular disease; HDL, high-density lipoprotein; LDL, low-density lipoprotein.

\*In individuals with overt CVD, a lower LDL cholesterol goal of <70 mg/dL (1.8 mmol/L), using a high dose of a statin, is an option.

ADbA nutrition recommendations are summarized in their annual standards of care (ADb, 2010b) and in a position statement (ADbA, 2008). Although numerous studies have attempted to identify the optimal percentages of macronutrients for the meal plan of persons with diabetes, it is unlikely that one such combination of macronutrients exists. The best mix appears to vary, depending on individual circumstances (ADbA, 2008). If guidance is needed, the RD should encourage consumption of macronutrients based on the dietary reference intakes (DRIs) for healthy eating (ADA, 2008), which recommend that adults should consume 45% to 65% of total energy from carbohydrate, 20% to 35% from fat, and 10% to 35% from protein.

**Goals and Desired Outcomes**

The goals for MNT for diabetes emphasize the role of lifestyle in improving glucose control, lipid and lipoprotein profiles, and blood pressure. To date, Medicare reimburses qualified dietitian providers for providing evidence-based MNT for diabetes management to eligible participants.

Improving health through food choices and physical activity is the basis of all nutrition recommendations for the treatment of diabetes (see Box 31-1). Interventions include reduced energy and fat intake, carbohydrate counting, simplified meal plans, healthy food choices, individualized meal-planning strategies, exchange lists, low-fat vegan diet, insulin-to-carbohydrate ratios, physical activity, and behavioral strategies.

Besides being skilled and knowledgeable in assessing and implementing MNT, RDs must also be aware of expected outcomes from MNT, when to assess outcomes, and what feedback, including recommendations, should be given to referral sources. Furthermore, the effect of MNT on A1C will be known by 6 weeks to 3 months, at which time the RD must assess whether the goals of therapy have been met by changes in lifestyle or whether changes or additional medications are needed (ADA, 2008).

Research supports MNT as an effective therapy in reaching diabetes treatment goals. Clinical trials and outcomes studies have reported decreases in A1C levels at 3 to 6

months ranging from 0.25% to 2.9% (average 1% to 2%) with higher reductions seen in T2DM of shorter duration (Franz et al., 2008). These outcomes are similar to those from oral **glucose-lowering medications**. MNT is reported to reduce low-density lipoprotein (LDL) cholesterol by 9% to 12% compared with baseline values or to a Western-type diet (Van Horn et al., 2008). After initiation of MNT, improvements are apparent in 3 to 6 months. MNT provided by RDs for hypertension report an average reduction in blood pressure of approximately 5 mm Hg for both systolic and diastolic blood pressure (ADA, 2009b).

### Carbohydrate Intake

*Sugars, starch, and fiber* are the preferred carbohydrate terms. Blood glucose levels after eating are primarily determined by the rate of appearance of glucose from carbohydrate digestion and absorption into the bloodstream and the ability of insulin to clear glucose from the circulation. Low-carbohydrate diets might seem to be a logical approach to lowering postprandial glucose. However, foods that contain carbohydrates (whole grains, fruits, vegetables, and low-fat milk) are excellent sources of vitamins, minerals, dietary fiber, and energy. Therefore these foods are important components of a healthy diet for all Americans, including those with diabetes (ADbA, 2008).

The long-held belief that sucrose must be restricted based on the assumption that sugars are more rapidly digested and absorbed than starches is not justified. The total amount of carbohydrate eaten at a meal, regardless if the source is starch or sucrose, is the primary determinant of postprandial glucose levels. The glycemic effect of carbohydrate foods cannot be predicted based on their structure (i.e., starch versus sugar) owing to the efficiency of the human digestive tract in reducing starch polymers to glucose. Starches are rapidly metabolized into 100% glucose during digestion, in contrast to sucrose, which is metabolized into only approximately 50% glucose and approximately 50% fructose. Fructose has a very low glycemic response, which has been attributed to its slow rate of absorption and its storage in the liver as glycogen (see Chapters 3 and 9, and Appendix 43).

Although numerous factors influence glycemic response to foods, monitoring total grams of carbohydrates, whether by use of carbohydrate counting, exchanges, or experienced-based estimation remains a key strategy in achieving glycemic control (ADA, 2008; ADbA, 2011b). Numerous studies have reported that when individuals are allowed to choose from a variety of starches and sugars, the glycemic response is nearly identical if the total amount of carbohydrate is similar.

Day-to-day consistency in the amount of carbohydrate eaten at meals and snacks is reported to improve glycemic control, especially in persons on either MNT alone, glucose-lowering medications, or fixed insulin regimens. In persons with T1DM or T2DM who adjust their mealtime insulin doses or who are on insulin pump therapy, insulin doses should be adjusted to match carbohydrate intake, known as the *insulin-to-carbohydrate ratios* (ADA, 2008). Several

methods are used to estimate the nutrient content of foods.

In **carbohydrate counting** food portions contributing 15 g of carbohydrates (regardless of the source) are considered as one carbohydrate serving. Testing premeal and postmeal glucose levels is important for making adjustments in either food intake or medication to achieve glucose goals.

**Exchange lists** group foods into lists—carbohydrates, which includes starches, fruits, milk, sweets, desserts, and other carbohydrates, and nonstarchy vegetables; meat and meat substitutes; fats; and free foods. Each food list is a group of measured foods of approximately the same nutritional value. Combination foods such as casseroles, pizza, and soups, which fit into more than one food group, and fast foods are also listed. In addition, symbols are used to identify foods that are high in fiber, contain extra fat, or are high in sodium.

### Glycemic Index and Glycemic Load

The **glycemic index (GI)** of food was developed to compare the physiologic effects of carbohydrates on glucose. The GI index measures the relative area under the postprandial glucose curve of 50 g of digestible carbohydrates compared with 50 g of a standard food, either glucose or white bread. When bread is the reference food, the GI index for the food is multiplied by 0.7 to obtain the value that is comparable to glucose being used as the reference food (glycemic index of glucose = 100, white bread = 70). The index does not measure how rapidly blood glucose levels increase. The peak glucose response for individual foods (Brand-Miller et al., 2009) and meals, either high or low glycemic index, occurs at approximately the same time.

The estimated **glycemic load (GL)** of foods, meals, and dietary patterns is calculated by multiplying the GI by the amount of carbohydrates in each food and then totaling the values for all foods in a meal or dietary pattern. In studies comparing low- and high-GI diets, total carbohydrate is first kept consistent. However, for some individuals use of the GI and GL may provide an additional modest benefit (ADbA, 2010b).

A major problem with the GI is the variability of response to a specific carbohydrate food. For example, Australian potatoes are reported to have a high GI, whereas potatoes in the United States and Canada have moderate GIs (Fernandes et al., 2005). The mean glycemic response and standard deviation of 50 g of carbohydrate from white bread tested in 23 subjects was  $78 \pm 73$  with an individual coefficient of variation (CV) of 94%. Although the average GI of bread from three tests was 71%, the range of GI values was broad, ranging from 44 to 132 and the CV 34% (Vega-López et al., 2007).

Studies, primarily of short duration, report mixed effects on A1C levels (ADA, 2008). These studies are complicated by differing definitions of “high GI” or “low GI” diets or quartiles; GIs in the low GI diets range from 38% to 77% and in the high GI diets from 63% to 98%. More recently, two trials, each one year in duration, reported no significant differences in A1C levels from low GI versus high GI diets

(Wolever et al., 2008) or ADbA diets (Ma et al., 2008). Furthermore, most people likely already consume a moderate GI diet. It is unknown whether further lowering of the dietary GI can be achieved in the long term.

## Fiber

Evidence is lacking to recommend a higher fiber intake for people with diabetes than for the population as a whole. Thus recommendations for fiber intake for people with diabetes are similar to the recommendations for the general public. Although diets containing 44 to 50 g of fiber daily improve glycemia, more usual fiber intakes (less than 24 g daily) have not shown beneficial effects. It is unknown if individuals living at home can daily consume the amount of fiber needed to improve glycemia. However, consuming foods containing 25 to 30 g of fiber per day, with special emphasis on soluble fiber sources (7-13 g) is recommended as part of cardioprotective nutrition therapy (ADA, 2008).

Grams of fiber (and sugar alcohols) are included on food labels and are calculated as having approximately half the energy (2 kcal/g) of most other carbohydrates (4 kcal/g). Adjustments in carbohydrate intake values is practical only if the amount per serving is more than 5 g. In that case, counting half of the carbohydrate grams from fiber (and sugar alcohols) would be useful in calculating exchanges and food choices for food labels or recipes and for individuals who are using insulin-to-carbohydrate ratios for managing their diabetes (Wheeler, 2008).

## Sweeteners

Even though sucrose restriction cannot be justified on the basis of its glycemic effect, it is still good advice to suggest that persons with diabetes be careful in their consumption of foods containing large amounts of sucrose. Sucrose intakes of 10% to 35% of total energy intake do not have a negative effect on glycemic or lipid responses when substituted for isocaloric amounts of starch (ADA, 2008). If sucrose is included in the food and meal plan, it should be substituted for other carbohydrate sources or, if added, be adequately covered with insulin or other glucose-lowering medications. Care should be taken to avoid excess energy intake (ADbA, 2008).

There appears to be no significant advantage of alternative nutritive sweeteners such as fructose versus sucrose. Fructose provides 4 kcal/g, as do other carbohydrates, and even though it does have a lower glycemic response than sucrose and other starches, large amounts (15% to 20% of daily energy intake) of fructose have an adverse effect on plasma lipids. However, there is no reason to recommend that persons with diabetes avoid fructose, which occurs naturally in fruits and vegetables as well as in foods sweetened with fructose (ADbA, 2008).

Reduced-calorie sweeteners approved by the Food and Drug Administration (FDA) include sugar alcohols (erythritol, sorbitol, mannitol, xylitol, isomalt, lactitol, and hydrogenated starch hydrolysates) and tagatose. They produce a lower glycemic response and contain, on average, 2 calories/g. As for fiber, persons using insulin-

to-carbohydrate ratios can subtract one half of sugar alcohol grams from total carbohydrate when the grams are more than 5 (Wheeler et al., 2008). There is no evidence that the amounts of sugar alcohols likely to be consumed will reduce glycemia or energy intake (ADbA, 2008.) Although their use appears to be safe, some people report gastric discomfort after eating foods sweetened with these products, and consuming large quantities may cause diarrhea, especially in children.

Saccharin, aspartame, neotame, acesulfame potassium, and sucralose are nonnutritive sweeteners currently approved by the FDA. All such products must undergo rigorous testing by the manufacturer and scrutiny from the FDA before they are approved and marketed to the public. For all food additives, including nonnutritive sweeteners, the FDA determines an **acceptable daily intake (ADI)**, defined as the amount of a food additive that can be safely consumed on a daily basis during a person's lifetime without risk. The ADI generally includes a 100-fold safety factor and greatly exceeds average consumption levels. For example, aspartame actual daily intake in persons with diabetes is 2 to 4 mg/kg of body weight daily, well below the ADI of 50 mg/kg daily.

In December 2008 the FDA stated that the stevia-derived sweetener, Rebaudioside A, is generally recognized as safe and it is currently being marketed. All FDA-approved non-nutritive sweeteners, when consumed within the established daily intake levels, can be used by persons with diabetes, including pregnant women (ADbA, 2008). As new so-called "natural" and other sweeteners appear in the market, people with diabetes should be aware that many do contain energy and carbohydrate, as do foods sweetened with them, that need to be accounted for.

## Protein Intake

The amount of protein usually consumed by persons with diabetes (15% to 20% of energy intake) has minimal acute effects on glycemic response, lipids, and hormones, and no long-term effect on insulin requirements, and therefore does not need to be changed. Exceptions are in persons who consume excessive protein choices high in saturated fatty acids, have a protein intake less than the recommended daily allowance, or in the presence of diabetic nephropathy (ADA, 2008). Although nonessential amino acids undergo gluconeogenesis, in well-controlled diabetes the glucose produced does not appear in the general circulation. Although protein has no long-term effect on insulin needs, it is just as potent a stimulant of acute insulin release as carbohydrate. Furthermore, protein does not slow the absorption of carbohydrates and adding protein to the treatment of hypoglycemia does not prevent subsequent hypoglycemia.

Short-term studies with small numbers of subjects with diabetes suggest that diets with protein contents greater than 20% of total energy may improve glucose and insulin concentrations, reduce appetite, and improve satiety. However, such diets appear to be difficult to follow and the long-term effects of increased protein intake on regulation

of energy intake, satiety, and weight loss have not been adequately studied.

### Dietary Fat

Studies in persons with diabetes demonstrating the effects of specific percentages of dietary saturated and *trans*-fatty acids and specific amounts of cholesterol on CVD risk are limited. However, persons with diabetes are considered to have a risk of CVD similar to those with a past history of CVD. Therefore after focusing on achieving glycemic control, cardioprotective nutrition interventions should be implemented in the initial series of encounters (ADA, 2008). See Chapter 34 for recommendations for the prevention and treatment of CVD.

In metabolic studies in which energy intake is maintained so that subjects do not lose weight, diets high in either carbohydrates or monounsaturated fat lower LDL cholesterol equivalently. The concern has been the potential of a high-carbohydrate diet (more than 55% of energy intake) to increase triglycerides and postprandial glucose compared with a high-monounsaturated fat diet. However, in other studies when energy intake is reduced, the adverse effects of high-carbohydrate diets are not observed. Therefore energy intake appears to be a factor in determining the effects of a high-carbohydrate versus a high-monounsaturated fat diet.

There is evidence from the general population that foods containing  $\omega$ -3 polyunsaturated fatty acids are beneficial and two to three servings of fish per week are recommended. Although most studies in persons with diabetes who have used  $\omega$ -3 supplements show beneficial lowering of triglycerides, an accompanying rise in LDL cholesterol also has been noted. If supplements are used, the effects on LDL cholesterol should be monitored.

### Alcohol

The same precautions that apply to alcohol consumption for the general population apply to persons with diabetes. Abstention from alcohol should be advised for people with a history of alcohol abuse or dependence; for women during pregnancy; and for people with medical problems such as liver disease, pancreatitis, or advanced neuropathy. If individuals choose to drink alcohol, daily intake should be limited to one drink or less for adult women and two drinks or less for adult men (1 drink = 12 oz beer, 5 oz of wine, or 1½ oz of distilled spirits). Each drink contains approximately 15 g of alcohol. The type of alcoholic beverage consumed does not make a difference (ADbA, 2008).

Moderate amounts of alcohol ingested with food have minimum, if any, acute effect on glucose and insulin levels. Alcoholic beverages should be considered an addition to the regular food and meal plan for all persons with diabetes. No food should be omitted, given the possibility of alcohol-induced hypoglycemia and because alcohol does not require insulin to be metabolized. Excessive amounts of alcohol (three or more drinks per day) on a consistent basis contribute to hyperglycemia, which improves as soon as alcohol use is discontinued.

In persons with diabetes, light to moderate amounts of alcohol (1 to 2 drinks per day; 15 to 30 g of alcohol) are associated with a decreased risk of CHD, perhaps because of the concomitant increase in HDL cholesterol and improved insulin sensitivity associated with alcohol consumption. Ingestion of light to moderate amounts of alcohol does not raise blood pressure, whereas excessive, chronic ingestion of alcohol does raise blood pressure and may be a risk factor for stroke.

### Micronutrients

No clear evidence has been established for benefits from vitamin or mineral supplements in persons with diabetes (compared with the general population) who do not have underlying deficiencies (ADbA, 2008). In select groups such as the elderly, pregnant or lactating women, strict vegetarians, or those on calorie-restricted diets, a multivitamin supplement may be needed.

Because diabetes may be a state of increased oxidative stress, there has been interest in prescribing antioxidant vitamins in people with diabetes. Clinical trial data not only indicate the lack of benefit from antioxidants on glycemic control and progression of complications but also provide evidence of the potential harm of vitamin E, carotene, and other antioxidant supplements. Routine supplementation with antioxidants such as vitamins E and C and carotene is not advised because of lack of evidence of effectiveness and concern related to long-term safety (ADbA, 2008).

### Dietary Supplements

Alpha-lipoic acid (ALA), which functions as an antioxidant, may have potential benefits for persons with diabetes and peripheral neuropathy. Short-term trials of intravenous and oral ALA reported improvements in symptoms of neuropathy. A long-term, multicenter trial is currently assessing the role of ALA given orally to determine whether ALA slows the progression of neuropathy versus only improving the neuropathy symptoms.

Several small studies have suggested a role for chromium supplementation in the management of glucose intolerance, gestational diabetes, body weight, and corticosteroid-induced diabetes. A systematic review of 41 studies regarding the effect of chromium supplementation on glucose metabolism and lipid levels reported no significant effect of chromium on lipid or glucose metabolism in people without diabetes and inconsistent effects in subjects with diabetes. However, the evidence is limited by the overall poor quality and heterogeneity of available studies (Balk et al., 2007). In addition, there is no benefit of chromium picolinate supplementation in reducing body weight. Benefit from chromium supplementation has not been clearly demonstrated and therefore is not recommended (ADbA, 2008).

### Physical Activity and Exercise

Physical activity involves bodily movement produced by the contraction of skeletal muscles that requires energy expenditure in excess of resting energy expenditure. Exercise is a subset of physical activity: planned, structured,

and repetitive bodily movement performed to improve or maintain one or more components of physical fitness. Aerobic exercise consists of rhythmic, repeated, and continuous movements of the same large muscle groups for at least 10 minutes at a time. Examples include walking, bicycling, jogging, swimming, and many sports. Resistance exercise consists of activities that use muscular strength to move a weight or work against a resistive load. Examples include weight lifting and exercises using resistance-providing machines.

Physical activity should be an integral part of the treatment plan for persons with diabetes. Exercise helps all persons with diabetes improve insulin sensitivity, reduce cardiovascular risk factors, control weight, and improve well being. Given appropriate guidelines, the majority of people with diabetes can exercise safely. The activity plan varies depending on interest, age, general health, and level of physical fitness.

Despite the increase in glucose uptake by muscles during exercise, glucose levels change little in individuals without diabetes. Muscular work causes insulin levels to decline while counterregulatory hormones (primarily glucagon) rise. As a result, the increased glucose use by the exercising muscles is matched with increased glucose production by the liver. This balance between insulin and counterregulatory hormones is the major determinant of hepatic glucose production, underscoring the need for insulin adjustments in addition to adequate carbohydrate intake during exercise for people with diabetes.

In persons with T1DM, the glycemic response to exercise varies, depending on overall diabetes control, plasma glucose and insulin levels at the start of exercise; timing, intensity, and duration of the exercise; previous food intake; and previous conditioning. An important variable is the level of plasma insulin during and after exercise. Hypoglycemia can occur because of insulin-enhanced muscle glucose uptake by the exercising muscle.

In persons with T2DM, blood glucose control can improve with physical activity, largely because of decreased insulin resistance and increased insulin sensitivity, which results in increased peripheral use of glucose not only during but also after the activity. This exercise-induced enhanced insulin sensitivity occur independent of any effect on body weight. Structured exercise interventions of at least 8 weeks' duration are reported to lower A1C. Exercise also decreases the effects of counterregulatory hormones; this in turn reduces the hepatic glucose output, contributing to improved glucose control.

### Potential Problems with Exercise

Hypoglycemia is a potential problem associated with exercise in persons taking insulin or **insulin secretagogues**. Hypoglycemia can occur during, immediately after, or many hours after exercise. Hypoglycemia has been reported to be more common after exercise, especially exercise of long duration, strenuous activity or play, or sporadic exercise, than during exercise. This is because of increased insulin sensitivity after exercise and the need to replete liver and

muscle glycogen, which can take up to 24 to 30 hours (see Chapter 23). However, hypoglycemia can also occur during or immediately after exercise. Blood glucose levels before exercise reflect only the value at that time, and it is unknown if this is a stable blood glucose level or a blood glucose level that is dropping. If blood glucose levels are dropping before exercise, adding exercise can contribute to hypoglycemia during exercise. Furthermore, hypoglycemia on the day before exercise may increase the risk of hypoglycemia on the day of exercise as well.

Hyperglycemia can also result from exercise of high intensity, likely as a result of the effects of counterregulatory hormones. When a person exercises at what for him or her is a high level of exercise intensity, there is a greater-than-normal increase in counterregulatory hormones. As a result, hepatic glucose release exceeds the rise in glucose use. The elevated glucose levels may also extend into the postexercise state. Hyperglycemia and worsening ketosis can also result in persons with T1DM who are deprived of insulin for 12 to 48 hours and are ketotic. Vigorous activity should probably be avoided in the presence of ketosis (ADbA, 2011b). However, high-intensity exercise is more likely to be the cause of hyperglycemia than insulin deficiency.

### Exercise Guidelines

The variability of glucose responses to exercise contributes to the difficulty in giving precise guidelines for exercising safely. Frequent blood glucose monitoring before, during, and after exercise helps individuals identify their response to physical activities. To meet their individual needs, patients must modify general guidelines to reduce insulin doses before (or after) or ingest carbohydrates after (or before) exercise.

**Carbohydrate for Insulin or Insulin Secretagogue Users.** During moderate-intensity exercise, glucose uptake is increased by 8 to 13 g/hour; this is the basis for the recommendation to add 15 g carbohydrate for every 30 to 60 minutes of activity (depending on the intensity) over and above normal routines. Moderate exercise for less than 30 minutes usually does not require any additional carbohydrate or insulin adjustment. Added carbohydrates should be ingested if preexercise glucose levels are less than 100 mg/dL (5.6 mmol/L). Supplementary carbohydrate is generally not needed in individuals who are not treated with insulin or insulin secretagogues (ADbA, 2011b).

In all persons, blood glucose levels decline gradually during exercise, and ingesting a carbohydrate feeding during prolonged exercise can improve performance by maintaining the availability and oxidation of blood glucose. For the exerciser with diabetes whose blood glucose levels may drop sooner and lower than the exerciser without diabetes, ingesting carbohydrate after 40 to 60 minutes of exercise is important and may also assist in preventing hypoglycemia. Drinks containing 6% or less of carbohydrates empty from the stomach as quickly as water and have the advantage of providing both needed fluids and

carbohydrates (see Chapter 23). Consuming carbohydrates immediately after exercise optimizes repletion of muscle and liver glycogen stores. For the exerciser with diabetes, this takes on added importance because of increased risk for late-onset hypoglycemia.

**Insulin Guidelines.** It is often necessary to adjust the insulin dosage to prevent hypoglycemia. This occurs most often with moderate to strenuous activity lasting more than 45 to 60 minutes. For most persons a modest decrease (of approximately 1 to 2 units) in the rapid- or short-acting insulin during the period of exercise is a good starting point. For prolonged vigorous exercise, a larger decrease in the total daily insulin dosage may be necessary. After exercise, insulin dosing may also need to be decreased.

**Precautions for Persons with Type 2 Diabetes.** Persons with T2DM may have a lower  $\text{Vo}_{2\text{max}}$  and therefore need a more gradual training program. Rest periods may be needed, but this does not impair the training effect from physical activity. Autonomic neuropathy or medications, such as for blood pressure, may not allow for increased heart rate, and individuals must learn to use perceived exertion as a means of determining exercise intensity. Blood pressure may also increase more in persons with diabetes than in those who do not have diabetes, and exercise should not be undertaken if systolic blood pressure is greater than 180 to 200 mm Hg (ADbA, 2010b).

**Heat Intolerance.** When persons with diabetes live and exercise in hot climates, they may experience “heat unawareness” because of their impaired ability to sweat and sense thirst. It is important to suggest adequate hydration techniques to counteract this effect.

## Exercise Recommendations

People with diabetes should be advised to perform at least 150 min/week of moderate-intensity aerobic physical activity (50% to 70% of maximum heart rate) or at least 90 min/week of vigorous aerobic exercise (more than 70% of maximum heart rate.) The physical activity should be distributed over at least 3 days/week and with no more than 2 consecutive days without physical activity. In the absence of contraindications, people with T2DM should be encouraged to perform resistance exercise three times a week, targeting all major muscle groups, progressing to three sets of 8 to 10 repetitions at a weight that cannot be lifted more than eight to ten times. There is an additive benefit of combined aerobic and resistance training in adults with T2DM (ADbA, 2011b).

It is recommended that providers assess patients for conditions that might contraindicate certain types of exercise or predispose to injury. High-risk patients should be encouraged to start with short periods of low-intensity exercise and increase the intensity and duration slowly (ADbA, 2011b).

## Medications

A consensus statement on the approach to management of hyperglycemia in T2DM has been published by the ADbA and the European Association for the Study of Diabetes

(Nathan et al., 2009). Interventions at the time of diagnosis include lifestyle (MNT and physical activity) and metformin. If A1C is 7% or more, the next well-validated therapies are to add either a sulfonylurea or basal insulin. The alternative path is to add the less well-validated therapies of pioglitazone or an incretin glucagon-like peptide 1 (GLP-1) agonist. The overall objective is to achieve and maintain glycemic control and to change interventions, including the use of insulin, when therapeutic goals are not being met (ADbA, 2011b).

All persons with T1DM and many persons with T2DM who no longer produce adequate endogenous insulin need replacement of insulin. In persons with T2DM, insulin may be needed to restore glycemia to near normal. Circumstances that require the use of insulin in T2DM include the failure to achieve adequate control with administration of oral medications; periods of acute injury, infection, extreme heat exposure, surgery, or pregnancy.

## Glucose-Lowering Medications for Type 2 Diabetes

Understanding that T2DM is a progressive disease is important for the understanding of treatment choices. Assisting individuals with diabetes to understand the disease process also helps them to understand and accept changes in medications that occur over time. Diabetes is first diagnosed when there is insufficient insulin available to maintain euglycemia and as insulin deficiency progresses medications and eventually insulin will be required to achieve glycemic goals. This is not a “diet failure” or a “medication failure” but rather a failure of the insulin secreting capacity of the  $\beta$ -cells.

Glucose-lowering medications target different aspects of the pathogenesis of T2DM—insulin resistance at the cellular level, incretin system defects, endogenous insulin deficiency, elevated levels of glucagon, and excessive hepatic glucose release. Because the mechanisms of action differ, the medications can be used alone or in combination. Table 31-6 lists the generic and brand names of glucose-lowering medications for persons with T2DM, their principal sites of action, and expected decreases in A1C when used as monotherapy.

**Biguanides.** Metformin suppresses hepatic glucose production, is not associated with hypoglycemia, may cause small weight losses when therapy begins, and is relatively inexpensive. The most common side effects are gastrointestinal, which often disappear with time. To minimize these effects, the medication should be taken with food consumption and the smallest dose (500 mg) given twice a day for a week and gradually increased to maximum doses. A rare side effect is severe lactic acidosis, which can be fatal. Acidosis usually occurs in patients who use alcohol excessively, have renal dysfunction, or have liver impairments (Nathan et al., 2009).

**Sulfonylureas.** The sulfonylureas promote insulin secretion by the beta cells of the pancreas. First- and second-generation sulfonylurea drugs differ from one another in their potency, pharmacokinetics, and metabolism. Disadvantages of their use include weight gain and the potential

**TABLE 31-6****Glucose-Lowering Medications for Type 2 Diabetes**

<b>Class and Generic Names</b>	<b>Recommended Dose</b>	<b>Principal Action</b>	<b>Mean Decrease in A1C</b>
<b>Class: Biguanide</b>			
Metformin (Glucophage) Metformin Extended Release (Glucophage XR)	500-850 mg tid or 1000 mg bid 500-2000 mg once daily	Decrease hepatic glucose production	1.5% to 2%
<b>Class: Sulfonylureas (Second-generation)</b>			
Glipizide (Glucotrol) Glipizide (Glucotrol XL) Glyburide (Glynase Prestabs) Glimepiride (Amaryl)	2.5-20 mg single or divided dose; single dose for XL 12 mg daily 4-8 mg daily	Stimulate insulin secretion from the $\beta$ -cells	1% to 2%
<b>Class: Thiazolidinediones</b>			
Pioglitazone (Actos)	15-45 mg daily	Improve peripheral insulin sensitivity	1% to 2%
<b>Class: GLP-1 Agonists</b>			
Exenatide (Byetta) Liraglutide (Victoza)	Initially dosed at 5 mcg twice a day—at breakfast and lunch; increased to 10 mcg twice a day Once daily at any time, independent of meals; initially 0.6 mg/day for 1 week, then increased to 1.2 mg/day; maximum dose 1.8 mg/day	Enhances glucose-dependent insulin secretion and suppresses postprandial glucagon secretion	0.5% to 0.9%
<b>Class: Alpha Glucosidase Inhibitors</b>			
Acarbose (Precose) Miglitol (Glyset)	25-100 mg three times daily with meals 25-100 mg three times daily with meals	Delay carbohydrate absorption	0.5% to 1%
<b>Class: Glinides</b>			
Repaglinide (Prandin) Nateglinide (Starlix)	0.5-4 mg before meals 120 mg before meals	Stimulate insulin secretion from $\beta$ -cells	1% to 2%
<b>Class: Amylin Agonists</b>			
Pramlintide (Symlin)	Initially dosed at 60 mcg before meals; dose increased directly to 120 mcg if no clinically significant nausea occurs after 3-7 days	Decreases glucagon production, which decreases mealtime hepatic glucose release and prevents postprandial hyperglycemia	0.4% to 0.7%
<b>Class: DPP-4 Inhibitors</b>			
Sitagliptin (Januvia) Saxagliptin (Onglyza)	100 mg once daily 5 mg once daily	Enhance the effects of GLP-1 and GIP by preventing degradation	0.5% to 0.8%
<b>Insulin</b>	No dose limit	Supplements endogenous insulin	Unlimited

*GLP*, glucagon-like peptide; *tid*, three times daily.

to cause hypoglycemia. They have the advantage of being inexpensive.

**Thiazolidinediones.** TZDs or glitazones decrease insulin resistance in peripheral tissues and thus enhance the ability of muscle and fat cells to take up glucose. TZDs also have a favorable effect on lipids and do not independently cause hypoglycemia. Adverse effects include weight gain and edema.

**Glucagon-like Peptide-1 Agonist.** Exenatide (Byetta) and liraglutide (Victoza) are incretin mimetic or incretin-like agents that have many of the same glucose-lowering effects as the body's naturally occurring incretin, GLP-1. **Incretins** are hormones made by the gastrointestinal tract and released during nutrient absorption, which increase glucose-dependent insulin secretion, slow gastric emptying, decrease glucagon production, and decrease appetite. GLP-1 agonists are associated with reduction in A1C and modest weight loss. Typically exenatide is injected twice a day, at breakfast and at the evening meal and liraglutide is injected once a day, at any time, independent of meals. They often cause gastrointestinal disturbances, which tend to abate over time (Nathan et al., 2009.) A once-weekly injection of a GLP-1 agonist is currently being tested.

**Alpha Glucosidase Inhibitors.** Acarbose (Precose) and miglitol (Glyset) are alpha-glucosidase inhibitors that work in the small intestine to inhibit enzymes that digest carbohydrates, thereby delaying carbohydrate absorption and lowering postprandial glycemia. They do not cause hypoglycemia or weight gain when used alone, but they can frequently cause flatulence, diarrhea, cramping, or abdominal pain. Symptoms may be alleviated by initiating therapy at a low dose and gradually increasing the dose to therapeutic levels.

**Glinides.** The meglitinides differ from the sulfonylureas in that they have short metabolic half-lives, which result in brief episodic stimulation of insulin secretion. They are given before meals, decreasing postprandial glucose excursions and less risk of hypoglycemia. Nateglinide only works in the presence of glucose and is a somewhat less potent secretagogue. Risk of weight gain is similar to sulfonylureas (Nathan et al., 2009).

**Dipeptidyl Peptidase 4 Inhibitors.** GLP-1 and glucose-dependent insulinotropic peptide, the main intestinal stimulants of insulin are rapidly degraded by dipeptidyl peptidase 4 (DPP-4) inhibitors. DPP-4 inhibitors prolong their half-lives. They are relatively well tolerated, are weight-neutral, and do not cause hypoglycemia when used as monotherapy (Nathan et al., 2009).

**Amylin Agonists (Pramlintide).** Pramlintide is a synthetic analog of the  $\beta$ -cell hormone amylin. It is injected before meals slowing gastric emptying and inhibiting glucagon production resulting in a decrease in postprandial glucose excursions. It is approved for use as adjunctive therapy with regular insulin or rapid-acting insulin (Nathan et al., 2009).

**Insulin.** For persons with T2DM the transition to insulin often begins with a long-acting or premixed insulin given at bedtime or before the evening meal to control

fasting glucose levels. However, eventually many patients with T2DM require a more physiologic insulin regimen at bedtime or an evening meal to achieve control (see following section). If large doses of insulin are required, oral medications such as insulin sensitizers are often combined with the insulin regimen.

## Insulin

Insulin has three characteristics: onset, peak, and duration (Table 31-7). U-100 is the concentration of insulin available in the United States. This means it has 100 units of insulin per milliliter of fluid (100 units/mL). U-100 syringes deliver U-100 insulin; however, insulin pens are now being used more frequently as an alternative to the traditional syringe-needle units.

**Rapid-acting Insulins.** Rapid-acting insulins include insulin lispro (Humalog), insulin aspart (Novolog), and insulin glulisine (Apidra) and are used as bolus (meal-time) insulins. They are insulin analogs that differ from human insulin in amino acid sequence but bind to insulin receptors and thus function in a manner similar to human insulin. All have an onset of action within 15 minutes, a peak in activity at 60 to 90 minutes, and a duration of 3 to 5 hours. They result in fewer hypoglycemic episodes compared with regular insulin.

**Regular Insulin.** Regular insulin is a short-acting insulin with an onset of action 15 to 60 minutes after injection and a duration of action ranging from 5 to 8 hours. For best results the slow onset of regular insulin requires it to be taken 30 to 60 minutes before meals.

**Intermediate-acting Insulin.** Neutral protamine Hagedorn (NPH) is the only available intermediate-acting insulin; Lente insulin has been discontinued. Its appearance is cloudy, and its onset of action is about 2 hours after injection, with a peak effect from 6 to 10 hours.

**Long-acting Insulins.** Insulin glargine (Lantus) and insulin detemir (Levemir) are long-acting insulins; Ultralente has been discontinued. Insulin glargine is an insulin analog that, because of its slow dissolution at the injection site, results in a relatively constant and peakless delivery over 24 hours. Because of its acidic pH, it cannot be mixed with any other insulin in the same syringe before injection and is usually given at bedtime. However, glargine can be given before any meal, but, whichever time is chosen, it must be given consistently at that time. Insulin detemir is absorbed from the subcutaneous tissue relatively quickly but then binds to albumin in the bloodstream, resulting in a prolonged action time of approximately 17 hours. Therefore it may need to be given twice a day. Basal insulin analogs decrease the chances of hypoglycemia, especially nocturnal hypoglycemia (Rosenstock et al., 2005).

**Premixed Insulins.** Premixed insulins include 70% NPH/30% regular, 75% lispro protamine (NPL [addition of neutral protamine to lispro to create an intermediate-acting insulin])/25% lispro, 50% lispro protamine and 50% lispro, and 70% protamine (addition of neutral protamine to aspart to create an immediate-acting insulin)/30% aspart. Persons using premixed insulins must eat at specific

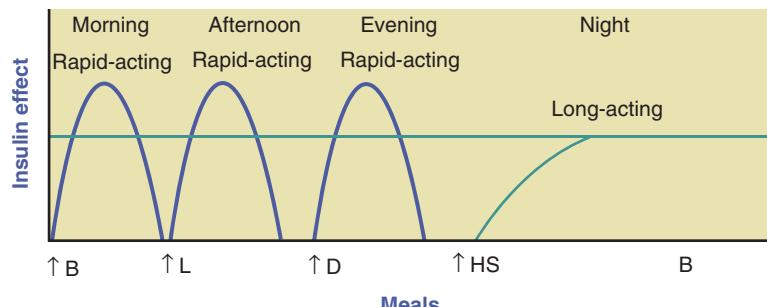

**TABLE 31-7****Action Times of Human Insulin Preparations**

Type of Insulin	Onset of Action	Peak Action	Usual Effective Duration	Monitor Effect In
<b>Rapid-Acting</b>	<15 min	1-2 hr	3-5 hr	1-2 hr
Insulin lispro (Humalog)				
Insulin aspart (NovoLog)				
Insulin glulisine (Apidra)				
<b>Short-Acting</b>				
Regular	0.5-1 hr	2-3 hr	3-6 hr	≈4 hr
<b>Intermediate-Acting</b>				
NPH	2-4 hr	4-10 hr	10-16 hr	8-12 hr
<b>Long-Acting</b>				
Insulin glargine (Lantus)	2-4 hr	Peakless	20-24 hr	10-12 hr
Insulin detemir (Levemir)	2-4 hr	Peakless	18-24 hr	10-12 hr
<b>Mixtures</b>				
70/30 (70% NPH, 30% regular)	0.5 to 1 hr	Dual	10-16 hr	
Humalog Mix 75/25 (75% NPL, 25% lispro)	<15 min	Dual	10-16 hr	
Humalog Mix 50/50 (50% protamine lispro, 50% lispro)	<15 min	Dual	10-16 hr	
Novolog Mix 70/30 (70% NPA, 30% aspart)	<15 min	Dual	10-16 hr

times and be consistent in carbohydrate intake to prevent hypoglycemia.

**Insulin Regimens.** All persons with T1DM and those with T2DM who no longer produce adequate endogenous insulin need replacement of insulin that mimics normal insulin action. After individuals without diabetes eat, their plasma glucose and insulin concentrations increase rapidly,

peak in 30 to 60 minutes, and return to basal concentrations within 2 to 3 hours. To mimic this, rapid-acting (or short-acting) insulin is given before meals, and this is referred to as *bolus* or *mealtime insulin* (Figure 31-1).

Mealtime insulin doses are adjusted based on the amount of carbohydrate in the meal. An insulin-to-carbohydrate ratio can be established for an individual that will guide

decisions on the amount of mealtime insulin to inject. Basal or background insulin dose is that amount of insulin required in the postabsorptive state to restrain endogenous glucose output primarily from the liver. Basal insulin also limits lipolysis and excess flux of free fatty acids to the liver. Long-acting insulins are used for basal insulin. The type and timing of insulin regimens should be individualized, based on eating and exercise habits and blood glucose concentrations.

These physiologic insulin regimens allow increased flexibility in the type and timing of meals. For normal-weight persons with T1DM, the required insulin dosage is approximately 0.5 to 1 unit/kg of body weight per day. Approximately 50% of the total daily insulin dose is used to provide for basal or background insulin needs. The remainder (rapid-acting insulin) is divided among the meals either proportionately to the carbohydrate content or by giving approximately 1 to 1.5 units of insulin per 10 to 15 g of carbohydrates consumed. The larger amount is usually needed to cover breakfast carbohydrates as a result of the presence in the morning of higher levels of counterregulatory hormones. Persons with T2DM may require insulin doses in the range of 0.5 to 1.2 units/kg of body weight daily. Large doses, even more than 1.5 units/kg of body weight daily, may be required at least initially to overcome prevailing insulin resistance.

Insulin pump therapy provides basal rapid-acting or short-acting insulin pumped continuously by a mechanical device in micro amounts through a subcutaneous catheter that is monitored 24 hours a day. Both lispro and aspart work well in insulin pumps, resulting in improved glycemia and less hypoglycemia than with regular insulin. Boluses of the insulin are given before meals. Pump therapy requires a committed and motivated person who is willing to do a minimum of four blood glucose tests per day, keep blood glucose and food records, and learn the technical features of pump use.

## Self-Management Education

Diabetes management is a team effort. Persons with diabetes must be at the center of the team because they have the responsibility for day-to-day management. RDs, nurses, physicians, and other health care providers contribute their expertise to developing therapeutic regimens that help the person with diabetes achieve the best metabolic control possible. The goal is to provide patients with the knowledge, skills, and motivation to incorporate self-management into their daily lifestyles. Dietitians can demonstrate their specialized diabetes knowledge by obtaining certification beyond the RD credential. Two diabetes care certifications available to RDs are the certified diabetes educator, a specialty certification, and board certified-advanced diabetes management, an advanced practice certification.

## Monitoring

The health care team, including the individual with diabetes, should work together to implement blood glucose

monitoring and establish individual **target blood glucose goals** (see Table 31-4).

## Self-monitoring of Blood Glucose

SMBG is used on a day-to-day basis to manage diabetes effectively and safely; however, measurement of A1C levels provides the best available index of overall diabetes control. Patients can perform SMBG up to eight times per day—before breakfast, lunch, and dinner; at bedtime; 1 to 2 hours after meals; and during the night or whenever needed to determine causes of hypoglycemia or hyperglycemia. For patients using multiple insulin injections or insulin pump therapy, SMBG is recommended three or more times daily, generally prior to each meal. For persons using less frequent insulin injections, noninsulin therapies, or MNT alone, SMBG may be useful as a guide to the success of the therapy (ADbA, 2011b). For these persons, SMBG is often performed one to four times a day, often before breakfast and before and 2 hours after the largest meal but only 3 or 4 days per week.

The ADA EBNPG for diabetes reviewed the evidence on glucose monitoring and recommended that for persons with T1DM or T2DM on insulin therapy, at least three to four glucose tests per day are needed to determine the accuracy of the insulin doses and to guide adjustments in insulin doses, food intake, and physical activity. Once established, some insulin regimens require less frequent SMBG. For persons on MNT alone or MNT in combination with glucose-lowering medications, frequency and timing depend on diabetes management goals and therapies.

Self management education and training is necessary to use SMBG devices and data correctly (ADA, 2008). Individuals need to be taught how to adjust their management program based on the results of SMBG. The first step in using such records is to learn how to identify patterns in blood glucose levels taken at the same time each day that are outside the target range—generally high readings for three or more days in a row or low readings two days in a row. The next step is to determine if a lifestyle factor (meal times, carbohydrate intake, quantity and time of physical activity) or medication dose adjustment is needed.

If changes in medication doses such as insulin are needed, adjustments are made in the insulin (or medications) acting at the time of the problem glucose readings. After pattern management is mastered, algorithms for insulin dose changes to compensate for an elevated or low glucose value can be used. A commonly used formula determines the insulin sensitivity, or **correction factor (CF)**, which defines how many milligrams per deciliter a unit of rapid-acting (or short-acting) insulin will lower blood glucose levels over a 2- to 4-hour period (Kaufman, 2008). The CF is determined by using the “1700 rule,” in which 1700 is divided by the total daily dose (TDD) of insulin the individual typically takes. For example, if the TDD is 50 units of insulin, the  $CF = 1700/50 = 35$ . In this case, 1 unit of insulin should lower the individual’s blood glucose level by 35 mg/dL (2 mmol/L).

In using blood glucose monitoring records, it should be remembered that factors other than food affect blood glucose concentrations. An increase in blood glucose can be the result of insufficient insulin or insulin secretagogue; too much food; or increases in glucagon and other counterregulatory hormones as a result of stress, illness, or infection. Factors that contribute to hypoglycemia include too much insulin or insulin secretagogue, not enough food, unusual amounts of exercise, and skipped or delayed meals. Urine glucose testing, used in the past, has so many limitations that it should not be used.

It is now possible to do **continuous glucose monitoring (CGM)**, which measures glucose in interstitial fluid and provides readings every 5 to 10 minutes. Other features include alarms for glucose highs and lows and the ability to download data and track trends over time. The ADbA recommends that CGM in conjunction with intensive insulin regimens can be a useful tool to lower A1C in selected adults (age 25 years and older) with T1DM. Evidence is less strong for A1C lowering in children, teens, and younger adults (ADbA, 2011b). After reviewing the evidence, the ADA EBNPG for diabetes concluded that persons experiencing unexplained elevations in A1C or unexplained hypoglycemia may benefit from use of CGM or more frequent SMBG (ADA, 2008).

### A1C Monitoring

A1C tests should be done at least twice a year in persons who are meeting treatment goals and have stable glycemic control. They should be done quarterly in persons whose therapy has changed or who are not meeting glycemic goals. In persons without diabetes A1C values are 4% to 6%. These values correspond to mean plasma glucose levels of approximately 70-126 mg/dL (3.9-7 mmol/L). Correlation between A1C levels and average glucose levels have recently been verified (ADbA, 2011b). An A1C of 6% reflects an average glucose level of 126 mg/dL. In general, each 1% change in A1C reflects a change of approximately 28-29 mg/dL.

### Ketone, Lipid, and Blood Pressure Monitoring

Urine or blood testing can be used to detect ketones. Testing for ketonuria or ketonemia should be performed regularly during periods of illness and when blood glucose levels consistently exceed 240 mg/dL (13.3 mmol/L). The presence of persistent, moderate, or large amounts of ketones, along with elevated blood glucose levels, requires insulin adjustments. Persons with T2DM rarely have ketosis; however, ketone testing should be done when the person is seriously ill.

For most adults, lipids should be measured at least annually; however, in adults with low-risk lipid values, assessments may be repeated every 2 years. Blood pressure should be measured at every routine diabetes visit (ADbA, 2011b).

## IMPLEMENTING THE NUTRITION CARE PROCESS

The nutrition care process articulates the consistent and specific steps used to deliver MNT (ADA, 2011). For some individuals with diabetes MNT will be implemented in individual sessions and for others in group sessions. Providing nutrition interventions in groups is becoming increasingly more important; however, group interventions must also allow for individualization of MNT and evaluation of outcomes. The following sections review implementation of individual MNT.

The ADA EBNPG recommend that MNT be provided by a RD in an initial series of three to four encounters each lasting 45 to 90 minutes. This series, beginning at diagnosis of diabetes or at first referral to an RD for MNT for diabetes, should be completed within 3 to 6 months and the RD should determine if additional encounters are needed after the initial series based on the nutrition assessment of learning needs and progress toward desired outcomes. At least one follow-up encounter is recommended annually to reinforce lifestyle changes and to evaluate and monitor outcomes that affect the need for changes in MNT or medication. The RD should again determine if additional MNT encounters are needed. Although glycemic control is the primary focus for diabetes management, cardioprotective nutrition interventions for the prevention and treatment of CVD should also be implemented in the initial series of encounters (ADA, 2008).

### Nutrition Assessment

The **nutrition assessment** involves obtaining information before and during the encounter needed to identify nutrition-related problems. Assessment data can be obtained from the referral source or the patient's medical records and from the patient. Patient data can be collected from forms the patient completes before the first encounter or directly from the patient. By collecting as much data as possible before the first session, completion of the assessment and implementation of interventions can begin more efficiently. Nutrition assessment is an ongoing process that involves not only initial data collection, but also reassessment and analysis of patient data and needs. Box 31-2 provides a summary of assessment categories.

The ADA EBNPG for diabetes highlights three specific assessment recommendations. First, the RD should assess food intake (focusing on carbohydrate), medication, metabolic control (glycemia, lipids, and blood pressure), anthropometric measurements, and physical activity as the basis for the implementation of the nutrition prescription, goals, and interventions. Second, the RD should assess glycemic control and focus MNT to achieve and maintain blood glucose levels in the target range. However, the need for cardioprotective nutrition interventions should also be assessed. Third, the RD should assess the relative importance of weight management for persons with diabetes who are overweight or obese. They note that although modest

**BOX 31-2****Nutrition Assessment****Nutrition Assessment Categories**

- Biochemical data, medical tests, and procedures, which include laboratory data such as for A1C, glucose, lipids, kidney function, and blood pressure measurements  
 Anthropometric measurements, which include height, weight, body mass index, waist circumference, growth rate, and rate of weight change

**Client History, Which Includes**

- General patient information, such as age, gender, race and ethnicity, language, literacy, and education  
 Medical and health history and medical treatment, including goals of medical therapy and prescribed medications related to medical condition for which medical nutrition therapy is being implemented  
 Readiness to change nutrition-related behaviors  
 Weight management goals  
 Physical activity history and goals  
 Social history, such as social and medical support, cultural and religious beliefs, and socioeconomic status  
 Other medical or surgical treatments, therapy, and alternative medicine  
 Food and nutrition history  
 Food intake, nutrition and health knowledge and beliefs  
 Food availability  
 Supplement use

weight loss has been shown to improve insulin resistance in overweight and obese insulin-resistant individuals, research on sustained weight loss interventions lasting 1 year or longer reports inconsistent effects on A1C (ADA, 2008).

**Nutrition Diagnosis**

The nutrition diagnosis identifies and describes a specific nutrition problem that can be resolved or improved through treatment or intervention by an RD (see Chapter 11). Patients may have more than one nutrition diagnoses, in which case the RD must prioritize them in the nutrition intervention step. The nutrition diagnostic language includes three domains: (1) intake problems related to the quantity of intake versus requirements; (2) clinical findings and problems related to medical (or physical) condition; and (3) behavioral-environmental findings and problems related to knowledge, attitudes and beliefs, physical environment, and access to food. A nutrition diagnosis is formatted according to problem, etiology, and signs and symptoms (PES). Examples of diabetes-related nutrition diagnoses are listed in Box 31-3.

**BOX 31-3****Examples of PES Statements Related to Diabetes Mellitus****Nutrition Diagnosis: Inconsistent Carbohydrate Intake**

Inconsistent carbohydrate intake (P) related to incorrect application of carbohydrate counting (E) as evidenced by food records revealing two additional carbohydrate servings for many meals and wide fluctuations in blood glucose levels, most days of the week (S)

**Nutrition Diagnosis: Inconsistent Carbohydrate Intake**

Inconsistent carbohydrate intake (P) related to inconsistent timing of meals (E) as evidenced by wide fluctuations in blood glucose levels (S)

**Nutrition Diagnosis: Excessive Carbohydrate Intake**

Excessive carbohydrate intake (P) compared with insulin dosing related to inaccurate carbohydrate counting (E) as evidenced by the number of carbohydrate servings per meal noted in food record and postmeal glucose levels consistently >200 mg/dL (S)

**Nutrition Diagnosis: Inappropriate Intake of Food Fats**

Excessive saturated fat intake (P) related to lack of knowledge of saturated fat content of foods (E) as evidenced by self-report of high saturated fat intake (S)

**Nutrition Diagnosis: Altered Laboratory Values**

Altered blood glucose values (P) related to insufficient insulin (E) as evidenced by hyperglycemia despite very good eating habits (S)

**Nutrition Diagnosis: Overweight or Obesity**

Overweight (P) related to excessive energy intake with limited physical activity (E) as evidenced by a body mass index of 30 and food history indicating consumption of 2800 kcal per day vs 2200 calories (estimated needs) and sedentary lifestyle (S)

**Nutrition Diagnosis: Food- and Nutrition-Related Knowledge Deficit**

Food- and nutrition-related knowledge deficit (P) related to lack of exposure to information (E) as evidenced by new diagnosis of diabetes (or prediabetes, lipid disorder, hypertension) (S)

**Nutrition Diagnosis: Not Ready for Lifestyle Change**

Not ready for lifestyle change (P) related to denial of need to change in precontemplation (E) as evidenced by reluctance to begin participation in physical activity program (S)

## Nutrition Intervention

Nutrition interventions include two distinct steps: planning the nutrition goals and implementing the actual interventions. Planning involves prioritizing the nutrition diagnoses, conferring with the persons with diabetes and others, reviewing current nutrition practice guidelines for diabetes, setting goals, determining the nutrition prescription, and choosing specific intervention strategies.

Implementation is the action phase. In the food and nutrient delivery phase, an individualized food and meal plan is developed, and specific nutrient recommendations as needed are included. Nutrition education involves the transfer of knowledge to the specific deficits identified in the nutrition diagnosis statements. Nutrition counseling involves behavior and attitude change through the use of strategies that promote behavior changes and motivation and intention to change. However, nutrition care must also be coordinated with other health care providers who can assist in the implementation of the nutrition prescription and nutrition therapy. If home care is needed, follow-up should take place.

### Nutrition Therapy Interventions for Specific Populations

**Type 1 Diabetes and Patients Requiring Insulin Therapy.** The first priority is to integrate an insulin regimen into the usual eating habits and physical activity schedule. With the many insulin options now available (rapid- and long-acting insulins), an insulin regimen can be planned that will conform to an individual's preferred meal routines and food choices (ADA, 2008). It is no longer necessary to create unnatural or artificial divisions of meals and snacks.

Physiologic insulin regimens that mimic natural insulin secretion involve multiple injections (three or more insulin injections per day) or use of an insulin infusion pump. These types of insulin regimens allow increased flexibility in choosing when and what to eat. Mealtime insulin doses are adjusted to match carbohydrate intake (insulin-to-carbohydrate ratios.) This can be accomplished by comprehensive nutrition education and counseling on interpretation of blood glucose patterns, nutrition-related medication management, and collaboration with the health care team (ADA, 2008). For persons who receive fixed insulin regimens such as with the use of premixed insulins or those who do not adjust their mealtime insulin doses, day-to-day consistency in the timing and amount of carbohydrates eaten is recommended.

Attention must also be paid to total energy intake as well as carbohydrate intake. Weight gain may adversely affect glycemia, lipids, blood pressure, and general health; thus prevention of weight gain in adults is desirable.

**Type 2 Diabetes with MNT Alone or with Glucose-Lowering Medications.** The first priority is to adopt lifestyle interventions that improve the metabolic abnormalities of glycemia, dyslipidemia, and hypertension. Lifestyle interventions independent of weight loss that can

improve glycemia include reduced energy intake and increased energy expenditure through physical activity. Because many persons also have dyslipidemia and hypertension, limitation of saturated and *trans*-fatty acids, cholesterol, and sodium is recommended. These interventions should be implemented as soon as the diagnosis of diabetes is made.

MNT interventions for established T2DM differ from interventions for prevention. Because of the progressive nature of T2DM, MNT interventions progress from prevention of obesity, to the prevention or delay of T2DM, to strategies for improved metabolic control. Modest weight loss is beneficial in persons with insulin resistance, but, as the disease progresses to insulin deficiency, medications usually need to be combined with MNT. Emphasis should be on blood glucose control, improved food choices, increased physical activity, and moderate energy restriction rather than weight loss alone because it is unclear whether weight loss alone will improve glycemic control (ADA, 2008).

The first step in food and meal planning is teaching which foods are carbohydrates (fruits, grains, starchy vegetables, milk, sweets), average portion sizes, and how many servings to select at meals (and snacks, if desired). Limiting fats, especially saturated and *trans*-fats, encouraging physical activity, and using blood glucose monitoring to adjust food and eating patterns and medications are also important components of successful MNT for T2DM. Frequent follow-up with an RD can provide the problem-solving techniques, encouragement, and support that lifestyle changes require.

Physical activity improves insulin sensitivity, acutely lowers blood glucose in persons with diabetes, and may also improve cardiovascular status. By itself it has only a modest effect on weight; however, it is essential for long-term weight maintenance. Cardiorespiratory fitness in persons with diabetes appears to be more important than thinness in relation to all-cause and cardiovascular mortality. Therefore it is important to counsel patients to increase physical activity and fitness levels.

Weight-loss drugs may be beneficial in the treatment of overweight persons with T2DM and can help achieve a 5% to 10% weight loss when combined with lifestyle modifications. It is generally recommended that they be used only in people with a BMI greater than 27.

Bariatric surgery can be an effective weight-loss treatment for severely obese patients with T2DM and can result in marked improvements in glycemia. Bariatric surgery should be considered for adults with BMI of more than 35 kg/m<sup>2</sup> and T2DM, especially if the diabetes and associated comorbidities are difficult to control with lifestyle and pharmacologic therapy (ADA, 2011b; see Chapter 22).

**Type 1 Diabetes in Youth.** Involvement of a multidisciplinary team, including a physician, RD, nurse, and behavioral specialist, all trained in pediatric diabetes, is the best means of achieving optimal diabetes management in youth. However, the most important team members are the child or adolescent and his or her family.

A major nutrition goal for children and adolescents with T1DM is maintenance of normal growth and development. Possible causes of poor weight gain and linear growth include poor glycemic control, inadequate insulin, and over-restriction of calories. The last may be a consequence of the common erroneous belief that restricting food, rather than adjusting insulin, is the way to control blood glucose. Other reasons unrelated to diabetes management include thyroid abnormalities and malabsorption syndromes. Excessive weight gain can be caused by excessive caloric intake, overtreatment of hypoglycemia, or overinsulinization. Other causes include low physical activity levels and hypothyroidism, accompanied by poor linear growth (Silverstein et al., 2005).

The nutrition prescription is based on the nutrition assessment. Newly diagnosed children often present with weight loss and hunger; as a result, the initial meal plan must be based on adequate calories to restore and maintain appropriate body weight. In about 4 to 6 weeks the initial caloric level may need to be modified to meet more usual caloric requirements. Nutrient requirements for children and adolescents with diabetes appear to be similar to those of children and adolescents without diabetes. The DRIs can be used to determine energy requirements (Institute of Medicine, 2002). However, it may be preferable to use a food and nutrition history of typical daily intake, providing that growth and development are normal, to determine an individual child's or adolescent's energy needs.

Consultation with an RD to develop and discuss the medical nutrition plan is encouraged (Silverstein et al., 2005). Because energy requirements change with age, physical activity, and growth rate, an evaluation of height, weight, BMI, and the nutrition plan must be updated at least every year. Good metabolic control is essential for normal growth and development (for growth charts see *Appendices 9 through 16*). However, withholding food or having the child eat consistently without an appetite for food in an effort to control blood glucose should be discouraged. Calories should be adequate for growth and restricted if the child becomes overweight.

Individualized food and meal plans, insulin regimens using basal (background) and bolus (mealtime) insulins, and insulin algorithms or insulin pumps can provide flexibility for children with T1DM and their families. This approach accommodates irregular meal times and schedules and varying appetites and activity levels (ADbA, 2008). Blood glucose records are essential to assist in making appropriate changes in insulin regimens. Daily eating patterns in young children generally include three meals and two or three snacks, depending on the length of time between meals and the child's physical activity level. Children often prefer smaller meals and snacks. Snacks can prevent hypoglycemia between meals and provide adequate calories. Older children and teens may prefer only three meals. Blood glucose monitoring data are then used to integrate an insulin regimen into the meal, snack, and exercise schedules.

After the appropriate nutrition prescription has been determined, the meal planning approach can be selected. A

number of meal planning approaches can be used. Carbohydrate counting for food planning provides youth and their families with guidelines that facilitate glycemic control while still allowing the choice of many common foods that children and adolescents enjoy. However, whatever approach to food planning is used, the youth and family must find it understandable and applicable to their lifestyle.

**Type 2 Diabetes in Youth.** Childhood obesity has been accompanied by an increase in the prevalence of T2DM among children and adolescents. IGT has been shown to be highly prevalent in obese youth, irrespective of ethnic group, and is associated with insulin resistance. Once T2DM develops,  $\beta$ -cell failure is also a factor. Thus T2DM in youth appears to follow a progressive pattern similar to T2DM in adults.

Successful lifestyle treatment of T2DM in children and adolescents involves cessation of excessive weight gain, promotion of normal growth and development, and the achievement of blood glucose and A1C goals. Nutrition guidelines should also address comorbidities such as hypertension and dyslipidemia. Offer behavior modification strategies to decrease intake of high-caloric, high-fat, and high-carbohydrate foods (extra-large desserts) and drinks (regular soda and other high-sugar beverages) while encouraging healthy eating habits and regular physical activity for the entire family (ADbA, 2008). In addition, metformin is used when lifestyle strategies alone have not achieved target glucose goals. Youth with T2DM may also require insulin therapy to achieve adequate glycemic control.

**Preexisting Diabetes and Pregnancy.** Normalization of blood glucose levels during pregnancy is very important for women who have preexisting diabetes or who develop GDM. Table 31-8 lists glucose goals for pregnancy. The MNT goals are to assist in achieving and maintaining optimal blood glucose control and to provide adequate maternal and fetal nutrition throughout pregnancy, energy intake for appropriate maternal weight gain, and necessary

**TABLE 31-8**

**Plasma Glucose Goals during Pregnancy**

<b>Preexisting Diabetes (Type 1 or Type 2)</b>	<b>Gestational Diabetes</b>
Premeal, bedtime, and overnight glucose 60-99 mg/dL (3.3-5.4 mmol/L)	Preprandial $\leq$ 95 mg/dL (5.3 mmol/L)
Peak postprandial glucose 100-129 mg/dL (5.4-7.1 mmol/L)	1 h postmeal $\leq$ 140 mg/dL (7.8 mmol/L)
A1C $<$ 6.0%	2 h postmeal $\leq$ 120 mg/dL (6.7 mmol/L)

*A1C*, Hemoglobin A1C.

vitamins and minerals (ADA, 2008). Nutrition recommendations during pregnancy and lactation appear to be similar for women with and without diabetes; therefore the DRIs can be used to determine energy and nutrient requirements during pregnancy and for lactation (Institute of Medicine, 2002).

Preconception counseling and the ability to achieve near-normal blood glucose levels before pregnancy have been shown to be effective in reducing the incidence of anomalies in infants born to women with preexisting diabetes to nearly that of the general population. As a result of hormonal changes during the first trimester, blood glucose levels are often erratic. Although caloric needs do not differ from those preceding pregnancy, the meal plan may need to be adjusted to accommodate the metabolic changes. Women should be educated about the increased risk of hypoglycemia during pregnancy and cautioned against overtreatment.

The need for insulin increases during the second and third trimesters of pregnancy. At 38 to 40 weeks' postconception, insulin needs and levels peak at two to three times prepregnancy levels. Pregnancy-associated hormones that are antagonistic to the action of insulin lead to elevated blood glucose levels. For women with preexisting diabetes, this increased insulin need must be met with increased exogenous insulin.

Meal plan adjustments are necessary to provide the additional calories required to support fetal growth, and weight should be monitored. During pregnancy the distribution of energy and carbohydrate intake should be based on the woman's food and eating habits and blood glucose responses. Insulin regimens can be matched to food intake, but maintaining consistency of times and amounts of food eaten are essential to avoid hypoglycemia caused by the continuous fetal draw of glucose from the mother. Smaller meals and more frequent snacks are often needed. A late-evening snack is often necessary to decrease the likelihood of overnight hypoglycemia and fasting ketosis. Records of food intake and blood glucose values are essential for determining whether glycemic goals are being met and for preventing and correcting ketosis.

Regular follow-up visits during pregnancy are needed to monitor caloric and nutrient intake, blood glucose control, and whether there is starvation ketosis. Urine or blood ketones during pregnancy may signal starvation ketosis that can be caused by inadequate energy or carbohydrate intake, omission of meals or snacks, or prolonged intervals between meals (e.g., more than 10 hours between the bedtime snack and breakfast). Ketonemia during pregnancy has been associated with reduced IQ scores in children, and women should be instructed to test for ketones periodically before breakfast.

**Gestational Diabetes Mellitus.** MNT for GDM primarily involves a carbohydrate-controlled meal plan that promotes optimal nutrition for maternal and fetal health with adequate energy for appropriate gestational weight gain, achievement and maintenance of normoglycemia, and absence of ketosis. Specific nutrition and food

recommendations are determined and modified based on individual assessment and blood glucose records. Monitoring blood glucose, fasting ketones, appetite, and weight gain can aid in developing an appropriate, individualized meal plan and in adjusting the meal plan throughout pregnancy.

Nutrition practice guidelines for gestational diabetes have been developed and field-tested (ADA, 2009a). All women with GDM should receive MNT at diagnosis of GDM. Monitoring records guide nutrition therapy and are used to determine if additional therapy is needed. Insulin, metformin, or glyburide therapy is added if glucose goals exceed target range (see Table 31-8) on two or more occasions in a 1- to 2-week period without some obvious explanation. Lack of weight gain and ketone testing can be useful in determining whether women are undereating to keep glucose levels within target range in an effort to avoid insulin therapy.

Carbohydrates should be distributed throughout the day into three small to moderate size meals and two to four snacks. All women require a minimum of 175 g of carbohydrates daily (Institute of Medicine, 2002). An evening snack is usually needed to prevent accelerated ketosis overnight. Carbohydrates are not as well tolerated at breakfast as they are at other meals because of increased levels of cortisol and growth hormones. To compensate, the initial food plan may have approximately 30 g of carbohydrate at breakfast. To satisfy hunger, protein foods can be added because they do not affect blood glucose levels.

Although caloric restriction must be viewed with caution, a modest energy restriction to slow weight gain is recommended for overweight or obese women with GDM. A slight calorie restriction results in a slowing of maternal weight gain in obese women with GDM without causing maternal or fetal compromise or ketonuria (ADA, 2009a). Energy intake of less than approximately 1700 to 1800 kcal/day is not advised. Weight gain during pregnancy for women with GDM should be similar to that of women without diabetes.

Exercise assists in overcoming peripheral resistance to insulin and in controlling fasting and postprandial hyperglycemia and may be used as an adjunct to nutrition therapy to improve maternal glycemia. The ideal form of exercise is unknown, but a brisk walk after meals is often recommended.

Women with GDM (and women with preexisting diabetes) should be encouraged to breastfeed because breastfeeding is associated with a reduced incidence of future T2DM (Stuebe, 2005). For women with GDM who are overweight or obese or with above-recommended weight gain during pregnancy, weight loss is advised after delivery. Weight loss reduces the risks of recurrent GDM or future development of T2DM (ADA, 2009a).

**Older Adults.** The prevalence of diabetes and prediabetes increases dramatically as people age. Many factors predispose older adults to diabetes: age-related decreases in insulin production and increases in insulin resistance, adiposity, decreased physical activity, multiple prescription medications, genetics, and coexisting illnesses. A major

factor appears to be insulin resistance. Controversy persists as to whether the insulin resistance is itself a primary change or whether it is attributable to reduced physical activity, decreased lean body mass (sarcopenia), and increased adipose tissue, which are common in older adults. Furthermore, medications used to treat coexisting diseases may complicate diabetes therapy in older persons.

Despite the increase in glucose intolerance with age, aging per se should not be a reason for suboptimal control of blood glucose. Even if it is incorrectly assumed that preventing long-term diabetic complications is not relevant to the care of older adults, persistent hyperglycemia has deleterious effects on the body's defense mechanisms against infection. It also increases the pain threshold by exacerbating neuropathic pain, and it has a detrimental effect on the outcome of cerebrovascular accidents.

Nutrition recommendations for older adults with diabetes must be extrapolated from what is known from the general population and should address nutrition-related cardiovascular risk factors common in older adults and encourage consumption of a variety of foods. Because of the loss of lean body mass and exercise patterns, the energy requirements of older adults are 20% to 30% lower than those of younger adults (ADbA, 2008). Physical activity can significantly reduce the decline in aerobic capacity that occurs with age, improve risk factors for atherosclerosis, slow the decline in age-related lean body mass, decrease central adiposity, and improve insulin sensitivity; thus it should be encouraged.

Malnutrition, not obesity, is the more prevalent nutrition-related problem in older adults. It often remains subclinical or unrecognized because the result of malnutrition—excessive loss of lean body mass—resembles the signs and symptoms of the aging process. Both malnutrition and diabetes adversely affect wound healing and defense against infection, and malnutrition is associated with depression and cognitive deficits. The most reliable indicator of poor nutrition status in older adults is a change in body weight; involuntary weight gain or loss of more than 10 pounds or 10% of body weight in less than 6 months indicates a need to evaluate the reason for the change in weight.

It is essential that older adults, especially those in long-term care settings, receive a diet that meets their nutritional needs, enables them to attain or maintain a reasonable body weight, helps control blood glucose, and is palatable. Dietary restriction is not warranted for older residents in long-term health facilities. Residents should be served the regular, unrestricted menu with consistency in the amount and timing of carbohydrates (ADbA, 2008). A multivitamin and mineral supplement to meet the DRIs may be necessary.

Hyperglycemia and dehydration can lead to a serious complication of diabetes in older adults: **hypoglycemic hyperosmolar state (HHS)**. Patients with HHS have a very high blood glucose level (ranging from 400 to 2800 mg/dL, [22.2–155.6 mmol/L] with an average of 1000 mg/dL [55.6 mmol/L]) without ketones. Patients are markedly dehydrated, and mental alterations range from mild confusion to hallucinations or coma. Patients who have HHS have

sufficient insulin to prevent lipolysis and ketosis. Treatment consists of hydration and small doses of insulin to control hyperglycemia.

### The Nutrition Prescription

To develop, educate, and counsel patients regarding the nutrition prescription, it is essential to learn about the patient's lifestyle and eating habits. Food and eating histories can be done several ways, with the objective being to determine a schedule and pattern of eating that will be the least disruptive to the lifestyle of the individual with diabetes and, at the same time, will facilitate improved metabolic control. With this objective in mind, asking the individual either to record or report what, how much, and when he or she typically eats during a 24-hour period may be the most useful. Another approach is to ask the patient to keep and bring a 3-day or 1-week food intake record. The request to complete a food record can be made when an appointment with the RD is scheduled. It is also important to learn about the patient's daily routine and schedule. The following information is needed: (1) time of waking; (2) usual meal and eating times; (3) work schedule or school hours; (4) type, amount, and timing of exercise; and (5) usual sleep habits.

Using the assessment data and food and nutrition history information, a preliminary food and meal plan can then be designed, and, if the patient desires, sample menus provided. Developing a food and meal plan does not begin with a set calorie or macronutrient prescription; instead, it is determined by modifying the patient's usual food intake as necessary. The worksheet in Figure 31-2 can be used to record the usual foods eaten and to modify the usual diet as necessary. The macronutrient and caloric values for the food lists are listed on the form and in Table 31-9; see Appendix 34 for portion sizes of the foods on the food lists. These tools are useful in evaluating nutrition assessments.

Using the form in Figure 31-2, the RD begins by totaling the number of servings from each food list and multiplying this number by the grams of carbohydrate, protein, and fat contributed by each. Next the grams of carbohydrate, protein, and fat are totaled from each column; the grams of carbohydrates and protein are then multiplied by 4 (4 kcal/g of carbohydrates and protein), and the grams of fat are multiplied by 9 (9 kcal/g of fat). Total calories and percentage of calories from each macronutrient can then be determined. Numbers derived from these calculations are then rounded off. Figure 31-3 provides an example of a preliminary food and meal plan. In this example the nutrition prescription is the following: 1900 to 2000 calories, 230 g of carbohydrates (50%), 90 g of protein (20%), 65 g of fat (30%). The number of carbohydrate choices for each meal and snack is the total of the starch, fruit, and milk servings. Vegetables, unless starchy or eaten in very large amounts (three or more servings per meal), are generally considered "free foods." The carbohydrate choices are circled under each meal and snack column.

The next step is to evaluate the preliminary meal plan. First and foremost, does the patient think it is feasible to

	Meal/Snack/Time						Total servings/day	CHO (g)	Protein (g)	Fat (g)	Calories
Food Group	Breakfast	Snack	Lunch	Snack	Dinner	Snack					
Starches							15	3	1	80	
Fruit							15			60	
Milk							12	8	1	100	
Vegetables							5	2		25	
Meats/Substitutes								7	5(3)	75(55)	
Fats									5	45	
CHO Choices						Total grams					
						Calories/gram	X4=	X4=	X9=	Total calories	
						Percent calories					

Calculations are based on medium-fat meats and skim/very low-fat milk. If diet consists predominantly of low-fat meats, use the factor 3 g instead of 5 g fat; if predominantly high-fat meats, use 8 g fat. If low-fat (2%) milk is used, use 5 g fat; if whole milk is used, use 8 g fat.

**FIGURE 31-2** Worksheet for assessment and design of a meal or food plan. CHO, Carbohydrate.

**TABLE 31-9**

**Macronutrient and Caloric Values for Food Lists\***

The following chart shows the macronutrients and calories from each list.

Food List	Carbohydrate (grams)	Protein (grams)	Fat (grams)	Calories
<b>Carbohydrates</b>				
Starch: breads, cereals and grains, starchy vegetables, crackers, snacks, and beans, peas, and lentils	15	0-3	0-1	80

Calculations are based on medium-fat meats and skim/very low-fat milk. If diet consists predominantly of low-fat meats, use the factor 3 g, instead of 5 g fat; if predominantly high-fat meats, use 8 g fat. If low-fat (2%) milk is used, use 5 g fat; if whole milk is used, use 8 g fat.

**FIGURE 31-3** An example of a completed worksheet from the assessment, the nutrition prescription, and a sample 1900- to 2000-calorie meal plan. CHO, Carbohydrate.

implement the meal plan into his or her lifestyle? Second, is it appropriate for diabetes management? Third, does it encourage healthful eating?

To discuss feasibility, the food and meal plan is reviewed with the patient in terms of general food intake. Timing of meals and snacks and approximate portion sizes and types of foods are discussed. Calorie levels are only approximate and adjustments in calories can be made during follow-up visits. A meal-planning approach can be selected later that will assist the patient in making his or her own food choices. At this point it needs to be determined whether this meal plan is reasonable.

To determine the appropriateness of the meal plan for diabetes management, distribution of the meals or snacks must be assessed along with the types of medications prescribed and treatment goals. For patients with T2DM receiving MNT alone or MNT with glucose-lowering medications, often the meal plan begins with three or four carbohydrate servings per meal for adult women and four or five for adult men and, if desired, one or two for a snack. Results of blood glucose monitoring before the meal and 2 hours after the meal, plus feedback from the patient, are used to assess if these recommendations are feasible and realistic and to determine if target glucose goals are being achieved.

For patients who require insulin, the timing of eating is important because insulin must be synchronized with food consumption (see “**Medications**” earlier in the chapter). If the eating pattern is determined first, an insulin regimen can be selected that will fit with it. To prevent overnight hypoglycemia, some patients may require a bedtime snack. The best way to ensure that the meal plan encourages healthful eating is to encourage patients to eat a variety of foods from all the food groups. The Dietary Guidelines for Americans, with its suggested number of servings from each food group, can be used to compare the patient’s meal plan with the nutrition recommendations for all Americans (see Chapter 12).

### Nutrition Education and Counseling

Implementation of MNT begins with the RD selecting from a variety of interventions (reduced energy and fat intake, carbohydrate counting, simplified meal plans, healthy food choices, individualized meal planning strategies, exchange lists, insulin-to-carbohydrate ratios, and physical activity and behavioral strategies) (ADA, 2008). All of these interventions have been shown to lead to improved metabolic outcomes. Furthermore, nutrition education and counseling must be sensitive to the personal needs, willingness to change, and ability to make changes of the individual with

diabetes. No single meal-planning approach has been shown to be more effective than any other, and the meal-planning approach selected should allow individuals with diabetes to select appropriate foods for meals and snacks.

A popular approach to meal planning is carbohydrate counting. It can be used as a basic meal-planning approach or for more intensive management. Carbohydrate-counting educational tools are based on the concept that after eating it is the carbohydrate in foods that is the major predictor of postprandial blood glucose levels. One carbohydrate serving contributes 15 g of carbohydrates. Basic carbohydrate counting emphasizes the following topics: basic facts about carbohydrates, primary food sources of carbohydrate, average portion sizes and the importance of consistency and accurate portions, amount of carbohydrates that should be eaten, and label reading. Advanced carbohydrate counting emphasizes the importance of record keeping, calculating insulin-to-carbohydrate ratios, and pattern management.

An important goal of nutrition counseling is to facilitate changes in existing food and nutrition-related behaviors and the adoption of new ones. The combined use of behavior change theories may potentially have a greater effect than any individual theory or technique used alone (Franz et al., 2010b). The following “five As” can guide the education and counseling sessions: ask, assess, advise, agree, and arrange. The “ask” step emphasizes the importance of questions as the RD aims to develop a relationship with the client. Motivational interviewing techniques are used initially and throughout all of the encounters.. In the “assess” step, the RD evaluates the client’s readiness to change. Different intervention strategies may be needed for individuals at different stages of the change process (see Chapter 15). The “advise” step uses a client-centered framework that adapts nutrition interventions to meet the client’s needs, wants, priorities, preferences, and expectations. In the “agree” step the RD facilitates the client’s process of setting his or her own short-term goals related to nutrition, physical activity, or glucose monitoring (if appropriate) and helps outline the client’s potential methods for accomplishing lifestyle changes. In the “arrange” step, plans for follow-up are identified to evaluate responses to nutrition interventions. The patient is also given information on how to call or e-mail with questions and concerns. In making plans for the next encounter, the patient is asked to keep a 3-day or weekly food record with blood glucose-monitoring data.

## Nutrition Monitoring and Evaluation

Food intake, medication, metabolic control (glycemia, lipids, and blood pressure), anthropometric measurements, and physical activity should be monitored and evaluated (ADA, 2008). Medical and clinical outcomes should be monitored after the second or third visit to determine whether the patient is making progress toward established goals. If no progress is evident, the individual and RD need to reassess and perhaps revise nutrition interventions. Blood glucose monitoring results can be used to determine whether adjustments in foods and meals will be sufficient to achieve blood glucose goals or if medication additions or

adjustments need to be combined with MNT. Nutrition care must be coordinated with an interdisciplinary team.

Documentation in the patient’s medical record serves as a communication tool for members of the health care team. The medical record also serves as a legal document of what was done and not done and supports reimbursement of nutrition services billed to insurance carriers. There are many different formats available for medical record documentation. The appropriate format depends on where the RD practices and whether electronic health records are used. Regardless of the specific format, the RD can document using the ADIME content (Writing Group of the Nutrition Care Process, 2008).

## Follow-Up Encounters

Successful nutrition therapy involves a process of assessment, problem solving, adjustment, and readjustment. Food records can be compared with the meal plan, which will help to determine whether the initial meal plan needs changing, and can be integrated with the blood glucose-monitoring records to determine changes that can lead to improved glycemic control.

Nutrition follow-up visits should provide encouragement and ensure realistic expectations for the patient. A change in eating habits is not easy for most people, and they become discouraged without appropriate recognition of their efforts. Patients should be encouraged to speak freely about problems they are having with food and eating patterns. Furthermore, there may be major life changes that require changes in the meal plan. Job and schedule changes, travel, illness, and other factors all have affect the meal plan.

## ACUTE COMPLICATIONS

Hypoglycemia and diabetic ketoacidosis (DKA) are the two most common acute complications related to diabetes.

### Hypoglycemia

A low blood glucose, or **hypoglycemia** (or **insulin reaction**), is a common side effect of insulin therapy, although patients taking insulin secretagogues can also be affected. **Autonomic symptoms** arise from the action of the autonomic nervous system and are often the first signs of mild hypoglycemia. Adrenergic symptoms include shakiness, sweating, palpitations, anxiety, and hunger. **Neuroglycopenic symptoms**, related to an insufficient supply of glucose to the brain, can also occur at similar glucose levels as autonomic symptoms but with different manifestations. The earliest signs of neuroglycopenia include a slowing down in performance and difficulty concentrating and reading. As blood glucose levels drop further, the following symptoms occur: frank mental confusion and disorientation, slurred or rambling speech, irrational or unusual behaviors, extreme fatigue and lethargy, seizures, and unconsciousness. Symptoms differ for different people but tend to be consistent from episode to episode for any one person. Several common causes of hypoglycemia are listed in Box 31-4.

**BOX 31-4****Common Causes of Hypoglycemia**

- Inadvertent or deliberate errors in medication (generally insulin) dosages
- Excessive insulin or oral secretagogue dosages
- Improper timing of insulin in relation to food intake
- Intensive insulin therapy
- Inadequate food intake
- Omitted or inadequate meals or snacks
- Delayed meals or snacks
- Unplanned or increased physical activities or exercise
- Prolonged duration or increased intensity of exercise
- Alcohol intake without food

Adapted from Kaufman F: Medical management of type 1 diabetes, ed 5, Alexandria, Va, 2008, American Diabetes Association.

The form of carbohydrates (i.e., liquid or solid) used to treat does not make a difference. If patients are unable to swallow, administration of subcutaneous or intramuscular glucagon may be needed. Parents, roommates, and spouses should be taught how to mix, draw up, and administer glucagon so that they are properly prepared for emergency situations. Kits that include a syringe prefilled with diluting fluid are available.

SMBG is essential for prevention and treatment of hypoglycemia. Changes in insulin injections, eating, exercise schedules, and travel routines warrant increased frequency of monitoring. Some patients experience hypoglycemia unawareness, which means that they do not experience the usual symptoms of hypoglycemia. Patients need to be reminded of the need to treat hypoglycemia, even in the absence of symptoms. Short-term relaxation of glycemic targets generally assists in the correction of hypoglycemia unawareness (ADbA, 2011b).

**BOX 31-5****Treatment of Hypoglycemia**

- Immediate treatment with carbohydrates is essential.
- If the blood glucose level falls below 70 mg/dL (3.9 mmol/L), treat with 15 g of carbohydrates, which is equivalent to:
  - 15 g carbohydrate from glucose tablets (3) or glucose gel
  - 4 to 6 ounces of fruit juice or regular soft drinks
  - 6 saltine crackers
  - 1 tablespoon of syrup or honey
- Retest in approximately 10 to 15 minutes. If the blood glucose level remains <70 mg/dL (<3.9 mmol/L), treat with an additional 15 g of carbohydrates.
- Repeat testing and treatment until the blood glucose level returns to within normal range.
- If it is more than 1 hour to the next meal, test again 60 minutes after treatment as additional carbohydrate may be needed.

Adapted from Kaufman F: Medical management of type 1 diabetes, ed 5, Alexandria, Va, 2008, American Diabetes Association.

In general, a blood glucose of 70 mg/dL (3.9 mmol/L) or lower should be treated immediately. Treatment of hypoglycemia requires ingestion of glucose or carbohydrate-containing food. Although any carbohydrate will raise glucose levels, glucose is the preferred treatment. Commercially available glucose tablets have the advantage of being premeasured to help prevent overtreatment. Ingestion of 15 to 20 g of glucose is an effective but temporary treatment. Initial response to treatment should be seen in approximately 10 to 20 minutes; however, blood glucose should be evaluated again in approximately 60 minutes because additional carbohydrate may be necessary (Box 31-5).

**Hyperglycemia and Diabetic Ketoacidosis**

Hyperglycemia can lead to **diabetic ketoacidosis (DKA)**, a life-threatening but reversible complication characterized by severe disturbances in carbohydrate, protein, and fat metabolism. DKA is always the result of inadequate insulin for glucose use. As a result, the body depends on fat for energy, and ketones are formed. Acidosis results from increased production and decreased use of acetoacetic acid and 3-β-hydroxybutyric acid from fatty acids. These ketones spill into the urine; hence the reliance on testing for ketones.

DKA is characterized by elevated blood glucose levels (greater than 250 mg/dL but generally less than 600 mg/dL) and the presence of ketones in the blood and urine. Symptoms include polyuria, polydipsia, hyperventilation, dehydration, the fruity odor of ketones, and fatigue. SMBG, testing for ketones, and medical intervention can all help prevent DKA. If left untreated, DKA can lead to coma and death. Treatment includes supplemental insulin, fluid and electrolyte replacement, and medical monitoring. Acute illnesses such as flu, colds, vomiting, and diarrhea, if not managed appropriately, can lead to the development of DKA. Patients need to know the steps to take during acute illness to prevent DKA (Box 31-6). During acute illness, oral ingestion of approximately 150 to 200 g of carbohydrates per day (45 to 50 g every 3 to 4 hours) should be sufficient, along with medication adjustments, to keep glucose in the goal range and to prevent starvation ketosis (ADbA, 2008).

Fasting hyperglycemia is a common finding in persons with diabetes. The amount of insulin required to normalize blood glucose levels during the night is less in the predawn period (from 1:00 to 3:00 AM) than at dawn (4:00 to 8:00 AM). The increased need for insulin at dawn causes a rise in fasting blood glucose levels referred to as the **dawn phenomenon**. It results if insulin levels decline between predawn and dawn or if overnight hepatic glucose output becomes excessive as is common in T2DM. To identify the dawn phenomenon, blood glucose levels are monitored at bedtime and at 2:00 to 3:00 AM. With the dawn phenomenon, predawn blood glucose levels will be in the low range of normal but

**BOX 31-6****Sick-Day Guidelines for Persons with Diabetes**

1. During acute illnesses, usual doses of insulin and other glucose-lowering medications are required. The need for insulin continues, or may even increase, during periods of illness. Fever, dehydration, infection, or the stress of illness can trigger the release of counterregulatory or “stress” hormones, causing blood glucose levels to become elevated.
2. Blood glucose levels and urine or blood testing for ketones should be monitored at least four times daily (before each meal and at bedtime). Blood glucose readings exceeding 250 mg/dL and the presence of ketones are danger signals indicating that additional insulin is needed.
3. Ample amounts of liquid need to be consumed every hour. If vomiting, diarrhea, or fever is present, small sips—1 or 2 tablespoons every 15 to 30 min—can usually be consumed. If vomiting continues and the individual is unable to take fluids for longer than 4 hours, the health care team should be notified.
4. If regular foods are not tolerated, liquid or soft carbohydrate-containing foods (such as regular soft drinks, soup, juices, and ice cream) should be eaten. Eating approximately 10 to 15 g of carbohydrate every 1–2 hours (or 50 g of carbohydrate every 3 to 4 hours) is usually sufficient.
5. The health care team should be called if illness continues for more than 1 day.

Adapted from Kaufman F: Medical management of type 1 diabetes, ed 5, Alexandria, Va, 2008, American Diabetes Association.

not in the hypoglycemic range. For patients with T2DM, metformin is often used because it decreases hepatic glucose output. For persons with T1DM, administering insulin that does not peak at 1:00 to 3:00 AM such as a long-acting insulin should be considered.

Hypoglycemia followed by “rebound” hyperglycemia is called the **Somogyi effect**. This phenomenon originates during hypoglycemia with the secretion of counterregulatory hormones (glucagon, epinephrine, growth hormone, and cortisol) and is usually caused by excessive exogenous insulin doses. Hepatic glucose production is stimulated, thus raising blood glucose levels. If rebound hyperglycemia goes unrecognized and insulin doses are increased, a cycle of overinsulinization may result. Decreasing evening insulin doses or, as for the dawn phenomenon, taking a long-acting insulin should be considered.

**LONG-TERM COMPLICATIONS**

Long-term complications of diabetes include macrovascular diseases, microvascular diseases, and neuropathy.

**Macrovascular diseases** involve diseases of large blood vessels; **microvascular diseases** associated with diabetes involve the small blood vessels and include nephropathy and retinopathy. In contrast, diabetic neuropathy is a condition characterized by damage to the nerves. MNT is important in managing several long-term complications of diabetes. Nutrition therapy is also a major component in reducing risk factors for chronic complications, especially those related to macrovascular disease.

**Macrovascular Diseases**

Insulin resistance, which may precede the development of T2DM and macrovascular disease by many years, induces numerous metabolic changes known as the **metabolic syndrome** (see Chapters 9 and 32). It is characterized by intraabdominal obesity or the android distribution of adipose tissue (waist circumference greater than 102 cm [40 in] in men and greater than 88 cm [35 in] in women) and is associated with dyslipidemia, hypertension, glucose intolerance, and increased prevalence of macrovascular complications. Other risk factors include genetics, smoking, sedentary lifestyle, high-fat diet, renal failure, and microalbuminuria.

Macrovascular diseases, including CHD, peripheral vascular disease, and cerebrovascular disease are more common, tend to occur at an earlier age, and are more extensive and severe in people with diabetes. Persons with diabetes have the same CVD risk equivalent as persons with preexisting CVD and no diabetes (Buse et al., 2007). Furthermore, in women with diabetes the increased risk of mortality from heart disease is greater than in men, in contrast to the non-diabetic population, in which heart disease mortality is greater in men than in women.

**Dyslipidemia**

Patients with diabetes have an increased prevalence of lipid abnormalities that contribute to higher rates of CVD. In T2DM the prevalence of an elevated cholesterol level is approximately 28% to 34%. Approximately 5% to 14% of patients with T2DM have high triglyceride levels; also, lower HDL cholesterol levels are common. Persons with T2DM typically have smaller, denser LDL particles, which increase atherogenicity even if the total LDL cholesterol level is not significantly elevated. Lifestyle intervention, including MNT, increased physical activity, weight loss, and smoking cessation should always be implemented. MNT should focus on the reduction of saturated and *trans*-fatty acids and cholesterol (see Chapter 33).

**Hypertension**

Hypertension is a common comorbidity of diabetes, with approximately 73% of adults with diabetes having blood pressure of 130/80 mm Hg or higher or using prescription medications for hypertension (CDC, 2007). Treatment of hypertension in persons with diabetes should be vigorous to reduce the risk of macrovascular and microvascular disease. Blood pressure should be measured at every routine visit with a goal for blood pressure control of less than 130/80 mm Hg. Patients with systolic blood pressure of 130

to 139 mm Hg or a diastolic blood pressure of 80 to 89 mm Hg should be given MNT for hypertension (see Chapter 33).

## **Microvascular Diseases**

### **Nephropathy**

In the United States and Europe diabetic nephropathy has become the most common single cause of end-stage renal disease (ESRD), accounting for approximately 40% of new cases. Approximately 20% to 40% of patients with diabetes develop evidence of nephropathy, but in T2DM a considerably smaller number progress to ESRD. However, because of the much greater prevalence of T2DM, such patients constitute more than half of the patients with diabetes currently starting on dialysis.

The earliest clinical evidence of nephropathy is the appearance of low but abnormal urine albumin levels (30 to 299 mg/24 hr), referred to as *microalbuminuria* or *incipient nephropathy*. Microalbuminuria is also a marker of increased CVD risk. Without specific interventions, progression to overt nephropathy or clinical albuminuria (300 mg/24 hr or more) occurs over a period of years. An annual screening for microalbuminuria should be performed in patients who have had T1DM for more than 5 years, and in all patients with T2DM at diagnosis and during pregnancy (ADbA, 2010b). The preferred screening method is by measurement of albumin-to-creatinine ratio in a random spot collection. Two of three tests within a 3 to 6 month period should be abnormal before a patient is designated as having microalbuminuria. Serum creatinine should be measured at least annually in all adults with diabetes regardless of the degree of urine albumin excretion. The serum creatinine is used to estimate glomerular filtration rate (GFR) and stage the level of chronic kidney disease, if present. Studies have found decreased GFR in the absence of increased urine albumin excretion in a substantial percentage of adults with diabetes.

Although diabetic nephropathy cannot be cured, the clinical course of the disease can be modified. To reduce the risk or slow the progression of nephropathy, glucose and blood pressure control should be optimized. In the treatment of both microalbuminuria and macroalbuminuria, either angiotensin-converting enzyme inhibitors or angiotensin receptor blockers should be used, except during pregnancy. If one class is not tolerated, the other should be substituted, and their combination will decrease albuminuria more than use of either agent alone (ADbA, 2011b).

Research on low-protein diets delaying the progression of renal disease has been controversial. In eight trials with duration greater than 6 months, the low-protein diets (prescribed 0.6 g/kg/day; actual intake 0.9 g/kg/day) compared with usual protein diets (1.3 g/kg/day) were not significantly associated with a change in GFR or creatinine clearance rate, but did result in a decline in urinary protein excretion (Pan et al., 2008).

The ADA EBPG recommends a protein intake of less than 1 g/kg/day for persons with diabetic nephropathy.

Studies implementing lower-protein diets in the management of diabetic nephropathy are inconclusive. For persons with late-stage diabetic nephropathy, hypoalbuminemia (an indicator of malnutrition) and energy intake must be monitored and changes in protein and energy intake made to correct deficits. A protein intake of approximately 0.7 g/kg/day has been associated with hypoalbuminemia, whereas a protein intake of approximately 0.9 g/kg/day has not (ADA, 2008). With microalbuminuria there may be additional benefits in lowering phosphorus to 500 to 1000 mg/day along with the low-protein diet. Although several studies have explored the potential of plant versus animal protein, the data are inconclusive (see Chapter 36).

### **Retinopathy**

Diabetic retinopathy is estimated to be the most frequent cause of new cases of blindness among adults 20 to 74 years of age. Glaucoma, cataracts, and other disorders of the eye also occur earlier and more frequently with diabetes (ADbA, 2011b). Laser photocoagulation surgery can reduce the risk of further vision loss but usually does not restore lost vision—thus a screening program to detect diabetic retinopathy is important. Adults and adolescents with T1DM should have an initial dilated and comprehensive eye examination by an ophthalmologist or optometrist within 5 years after the onset of diabetes and patients with T2DM should be examined shortly after the diagnosis of diabetes. Subsequent examinations for both groups should be done annually. Less frequent examinations may be considered (every 2 to 3 years) if the eye examination is normal (ADbA, 2011b).

There are three stages of diabetic retinopathy. The early stage of *nonproliferative diabetic retinopathy* (NPDR) is characterized by microaneurysms, a pouchlike dilation of a terminal capillary, lesions that include cotton-wool spots (also referred to as *soft exudates*), and the formation of new blood vessels as a result of the great metabolic need of the retina for oxygen and other nutrients supplied by the bloodstream. As the disease progresses to the middle stages of moderate, severe, and very severe NPDR, gradual loss of the retinal microvasculature occurs, resulting in retinal ischemia. Extensive intraretinal hemorrhages and microaneurysms are common reflections of increasing retinal nonperfusion.

The most advanced stage, termed *proliferative diabetic retinopathy*, is the final and most vision-threatening stage of diabetic retinopathy. It is characterized by the onset of ischemia-induced new vessel proliferation at the optic disk or elsewhere in the retina. The new vessels are fragile and prone to bleeding, resulting in vitreous hemorrhage. With time the neovascularization tends to undergo fibrosis and contraction, resulting in retinal traction, retinal tears, vitreous hemorrhage, and retinal detachment. Diabetic macular edema, which involves thickening of the central (macular) portion of the retina, and glaucoma, in which fibrous scar tissue increases intraocular pressure, are other clinical findings in retinopathy.

## Neuropathy

Chronic high levels of blood glucose are also associated with nerve damage and 60% to 70% of people with diabetes have mild to severe forms of nervous system damage (CDC, 2007). Intensive treatment of hyperglycemia reduces the risk and slows progression of diabetic neuropathy, but does not reverse neuronal loss. Peripheral neuropathy usually affects the nerves that control sensation in the feet and hands. Autonomic neuropathy affects nerve function controlling various organ systems. Cardiovascular effects include postural hypotension and decreased responsiveness to cardiac nerve impulses, leading to painless or silent ischemic heart disease. Sexual function may be affected, with impotence the most common manifestation.

Damage to nerves innervating the gastrointestinal tract can cause a variety of problems. Neuropathy can be manifested in the esophagus as nausea and esophagitis, in the stomach as unpredictable emptying, in the small bowel as loss of nutrients, and in the large bowel as diarrhea or constipation.

**Gastroparesis** is characterized by delayed gastric emptying in the absence of mechanical obstruction of the stomach (Camilleri, 2007). Symptoms are reported by 5% to 12% of persons with diabetes. It results in delayed or irregular contractions of the stomach, leading to various gastrointestinal symptoms such as feelings of fullness, bloating, nausea, vomiting, diarrhea, or constipation. Gastroparesis should be suspected in individuals with erratic glucose control.

The first step in management of patients with neuropathy should be to aim for stable and optimal glycemic control. MNT involves minimizing abdominal stress. Small, frequent meals may be better tolerated than three full meals a day; and these meals should be low in fiber and fat. If solid foods are not well tolerated, liquid meals may need to be recommended. For patients using insulin, as much as possible, the timing of insulin administration should be adjusted to match the usually delayed nutrient absorption. Insulin injections may even be required after eating. Frequent blood glucose monitoring is important to determine appropriate insulin therapy.

Prokinetic agents most commonly used to treat gastroparesis include metoclopramide and erythromycin. Antiemetic agents may be helpful for the relief of symptoms. In very severe cases, generally with unintentional weight loss, a feeding tube is placed in the small intestine to avoid the stomach. Gastric electric stimulation with electrodes surgically implanted in the stomach may be used when medications fail to control nausea and vomiting.

## HYPOGLYCEMIA OF NONDIABETIC ORIGIN

**Hypoglycemia of nondiabetic origin** has been defined as a clinical syndrome with diverse causes in which low levels of plasma glucose eventually lead to neuroglycopenia.

*Hypoglycemia* means low (hypo) blood glucose (glycemia). Normally the body is remarkably adept at maintaining fairly steady blood glucose levels—usually between 60 and 100 mg/dL (3.3 to 5.6 mmol/L), despite the intermittent ingestion of food. Maintaining normal levels of glucose is important because body cells, especially the brain and central nervous system, must have a steady and consistent supply of glucose to function properly. Under physiologic conditions the brain depends almost exclusively on glucose for its energy needs. Even with hunger, either because it has been many hours since food was eaten or because the last meal was small, blood glucose levels remain fairly consistent.

## Pathophysiology

In a small number of people, blood glucose levels drop too low. Symptoms are often felt when blood glucose is below 65 mg/dL (3.6 mmol/L). If the brain and nervous system are deprived of the glucose they need to function, symptoms such as sweating, shaking, weakness, hunger, headaches, and irritability can develop. Symptoms of hypoglycemia have been recognized at plasma glucose levels of approximately 60 mg/dL, and impaired brain function has occurred at levels of approximately 50 mg/dL.

Hypoglycemia can be difficult to diagnose because these typical symptoms can be caused by many different health problems. For example, adrenaline (epinephrine) released as a result of anxiety and stress can trigger the symptoms similar to those of hypoglycemia. The only way to determine whether hypoglycemia is causing these symptoms is to measure blood glucose levels while an individual is experiencing the symptoms. Hypoglycemia can best be defined by the presence of three features known as the **Whipple triad**: (1) a low plasma or blood glucose level, (2) symptoms of hypoglycemia at the same time, and (3) amelioration of the symptoms by correction of the hypoglycemia.

A fairly steady blood glucose level is maintained by the interaction of several mechanisms. After eating, food is broken down into glucose and enters the bloodstream. As blood glucose levels rise, the pancreas responds by releasing the hormone insulin, which allows glucose to leave the bloodstream and enter various body cells, where it fuels the body's activities. Glucose is also taken up by the liver and stored as glycogen for later use.

When glucose concentrations from the last meal decline, the body goes from a “fed” to a “fasting” state. Insulin levels decrease, which keeps the blood glucose levels from falling too low. Stored glucose is released from the liver back into the bloodstream with the help of **glucagon** from the pancreas. Normally the body's ability to balance glucose, insulin, and glucagon (and other counterregulatory hormones) keeps glucose levels within the normal range. Glucagon provides the primary defense against hypoglycemia; without it, full recovery does not occur. Epinephrine is not necessary for counterregulation when glucagon is present. However, in the absence of glucagon, epinephrine has an important role.

## Types of Hypoglycemia

Two types of hypoglycemia can occur in people who do not have diabetes. If blood glucose levels fall below normal limits within 2 to 5 hours after eating, this is **postprandial (reactive) hypoglycemia**. It can be caused by an exaggerated or late insulin response caused by either insulin resistance or elevated GLP-1; alimentary hyperinsulinism; renal glycosuria; defects in glucagon response; high insulin sensitivity; rare syndromes such as hereditary fructose intolerance, galactosemia, leucine sensitivity; or a rare  $\beta$ -cell pancreatic tumor (insulinoma), causing blood glucose levels to drop too low. Alimentary hyperinsulinism is common after gastric surgery, associated with rapid delivery of food to the small intestine, rapid absorption of glucose, and exaggerated insulin response. These patients respond best to multiple, frequent feedings.

The ingestion of alcohol after a prolonged fast or the ingestion of large amounts of alcohol and carbohydrates on an empty stomach (“gin-and-tonic” syndrome) may also cause hypoglycemia within 3 to 4 hours in some healthy persons.

Idiopathic reactive hypoglycemia is characterized by normal insulin secretion but increased insulin sensitivity and, to some extent, reduced response of glucagon to acute hypoglycemia symptoms. The increase in insulin sensitivity associated with a deficiency of glucagon secretion leads to hypoglycemia late postprandially. Idiopathic reactive hypoglycemia has been inappropriately overdiagnosed by both physicians and patients, to the point that some physicians doubt its existence. Although rare, it does exist but can be documented only in persons with hypoglycemia that occurs spontaneously and who meet the criteria of Whipple triad.

**Fasting hypoglycemia**, or postabsorptive hypoglycemia, is often related to an underlying disease. This food-deprived hypoglycemia may occur in response to having gone without food for 8 hours or longer and can be caused by conditions that upset the body's ability to balance blood glucose. These include eating disorders and other serious underlying medical conditions, including hormone deficiency states (e.g., hypopituitarism, adrenal insufficiency, catecholamine or glucagon deficiency), acquired liver disease, renal disease, certain drugs (e.g., alcohol, propranolol, salicylate), insulinoma (of which most are benign, but 6% to 10% can be malignant), and other nonpancreatic tumors. Taking high doses of aspirin may also lead to fasting hypoglycemia. Factitious hypoglycemia, or self-administration of insulin or sulfonylurea in persons who do not have diabetes, is a cause as well. Symptoms related to fasting hypoglycemia tend to be particularly severe and can include a loss of mental acuity, seizures, and unconsciousness. If the underlying problem can be resolved, hypoglycemia is no longer a problem.

## Diagnostic Criteria

One of the criteria used to confirm the presence of hypoglycemia is a blood glucose level of less than 50 mg/dL

(2.8 mmol/L.) Previously the OGTT test was the standard test for this condition; however, this test is no longer used. Recording fingerstick blood glucose measurements during spontaneous, symptomatic episodes at home is used to establish the diagnosis. An alternative method is to perform a glucose test in a medical office setting, in which case the patient is given a typical meal that has been documented in the past to lead to symptomatic episodes; the Whipple triad can be confirmed if symptoms occur. If blood glucose levels are low during the symptomatic period and if the symptoms disappear on eating, hypoglycemia is probably a responsible diagnosis. It is essential to make a correct diagnosis in patients with fasting hypoglycemia because the implications are serious.

## Management of Hypoglycemia

The management of hypoglycemic disorders involves two distinct components: (1) relief of neuroglycopenic symptoms by restoring blood glucose concentrations to the normal range, and (2) correction of the underlying cause. The immediate treatment is to eat foods or beverages containing carbohydrates. As the glucose from the breakdown of carbohydrates is absorbed into the bloodstream, it increases the level of glucose in the blood and relieves the symptoms. If an underlying problem is causing hypoglycemia, appropriate treatment of this disease or disorder is essential.

Almost no research has been done to determine what type of food-related treatment is best for the prevention of hypoglycemia. Traditional advice has been to avoid foods containing sugars and to eat protein- and fat-containing foods. Recent research on the GI and sugars has raised questions about the appropriateness of restricting only sugars because these foods have been reported to have a lower GI than many of the starches that were encouraged in the past. Restriction of sugars may contribute to a decreased intake in total carbohydrates, which may be more important than the source of the carbohydrates.

The goal of treatment is to adopt eating habits that will keep blood glucose levels as stable as possible (International Diabetes Center, 2007). To stay symptom free, it is important for individuals to eat five to six small meals or snacks per day. Doing this provides manageable amounts of glucose to the body. Recommended guidelines are listed in **Box 31-7**.

Patients with hypoglycemia may also benefit from learning carbohydrate counting and, to prevent hypoglycemia, eating three to four carbohydrate servings (15 g of carbohydrate per serving) at meals and one to two for snacks (see **Appendix 34**). Foods containing protein that are also low in saturated fat can be eaten at meals or with snacks. These foods are expected to have minimum effect on blood glucose levels and can add extra food for satiety and calories. However, because both protein and carbohydrate stimulate insulin release, a moderate intake may be advisable.

**BOX 31-7**

### Guidelines for Preventing Hypoglycemic Symptoms in People Who Do Not Have Diabetes

1. Eat small meals, with snacks interspersed between meals and at bedtime. This means eating five to six small meals rather than two to three large meals to steady the release of glucose into the bloodstream.
2. Spread the intake of carbohydrate foods throughout the day. Most individuals can eat two to four servings of carbohydrate foods at each meal and one to two servings at each snack. If carbohydrates are removed from the diet completely, the body loses its ability to handle carbohydrates properly, so this is not recommended. Carbohydrate foods include starches, fruits and fruit juices, milk and yogurt, and foods containing sugar.
3. Avoid or limit foods high in sugar and carbohydrate, especially on an empty stomach. Examples of these foods are regular soft drinks, syrups, candy, fruit juices, regular fruited yogurts, pies, and cakes.
4. Avoid beverages and foods containing caffeine. Caffeine can cause the same symptoms as hypoglycemia and make the individual feel worse.
5. Limit or avoid alcoholic beverages. Drinking alcohol on an empty stomach and without food can lower blood glucose levels by interfering with the liver's ability to release stored glucose (gluconeogenesis). If an individual chooses to drink alcohol, it should be done in moderation (one or two drinks no more than twice a week), and food should always be eaten along with the alcoholic beverage.

### Nutrition Assessment

#### Client History

Debra Smith, a 45-year-old women with known diagnosis of T2DM for 3 years, has been referred for nutrition counseling. She has not had a medical check-up for 2 years, although she reports continuing to take metformin. She is on no lipid or blood pressure medications. She returns at this time with a primary complaint of chronic fatigue. She states she hasn't returned for any follow-up visits because the only advice she gets is to lose weight, which she has tried to do numerous times without success. Food and nutrition history includes a usual intake of about 2,300 calories and frequent skipping of meals, especially breakfast. She eats few fruits and vegetables and because she has been told to avoid carbohydrate foods, she eats 5–6 oz of meat per meal, contributing to a high saturated fat intake. She drinks a glass of wine only on special occasions. She is willing to try to make some changes in her eating habits. She also reports being physically inactive but is willing to start a walking program.

#### Biochemical Data

Hemoglobin A1C: 8.3%

Low-density lipoprotein cholesterol: 119 mg/dL

Triglycerides: 275 mg/dL

High-density lipoprotein cholesterol: 34 mg/dL

Blood pressure: 148/88 mm Hg

#### Anthropometric Data

Height 64 in; weight 175 lb; body mass index 30

#### Medications

Metformin (Glucophage) 1000 mg twice daily

#### Nutrition Diagnostic Statements

Food- and nutrition-related knowledge deficit related to no education or counseling for appropriate medical nutrition therapy as evidenced by food history of inappropriate food choices despite belief that she is making appropriate choices.

Inconsistent carbohydrate intake related to lack of knowledge of appropriate food choices as evidenced by food history with either limited or excessive carbohydrate food choices at meals.

#### Nutrition Interventions

Nutrition prescription: Carbohydrate counting beginning with 3 to 4 carbohydrate servings per meal

Nutrition education: Update patient's knowledge of appropriate nutrition therapy for diabetes beginning with glycemic outcomes; at follow-up visits address cardioprotective nutrition interventions; encourage physical activity starting with short walks

Nutrition counseling: Collaborate with patient to identify behavior change goals

#### Nutrition Monitoring and Evaluation

Food and blood glucose monitoring records

Weight change

Physical activity

Schedule follow-up session in 4 weeks

## CHAPTER 32

Sheila Dean, DSc, RD, LD, CCN, CDE

# Medical Nutrition Therapy for Thyroid and Related Disorders

### KEY TERMS

5'-deiodinase  
adrenal fatigue  
autoimmune thyroid disorders (AITDs)  
calcitonin  
cortisol  
cretinism  
euthyroid sick syndrome  
goitriin  
Graves' disease  
Hashimoto's thyroiditis  
hyperthyroidism  
hypothalamus  
hypothalamic-pituitary-thyroid (HPT) axis

hypothyroidism  
pituitary gland  
polycystic ovary syndrome (PCOS)  
reverse T3 (rT3)  
Schmidt's syndrome  
thyroid-binding globulin (TBG)  
thyroglobulin antibodies (TGB Ab)  
thyroid peroxidase (TPO)  
thyroid peroxidase antibodies (TPO Ab)  
thyroid-stimulating hormone (TSH)  
thyrotropin-releasing hormone (TRH)  
thyroxine (T4)  
triiodothyronine (T3)  
tyrosine

Diabetes mellitus appears to be the most common endocrine-related chronic disease (American Diabetes Association [ADbA], 2007). However, according to the American Association of Clinical Endocrinologists (2005), 27 million Americans have thyroid-related disorders and more than half remain undiagnosed. Furthermore, individuals with diabetes tend to have a higher prevalence of thyroid disorders.

Thyroid-related diseases are often poorly diagnosed, and there is much about their treatment that requires greater clarification and study. For example, radiation exposure of the thyroid at a young age is a risk factor for the development of thyroid cancer, lasting for a lifetime after exposure (Sinnott et al., 2010). Efforts to reduce exposure from medical x-ray examinations can protect the thyroid gland.

Genetic factors promote the endocrine autoimmune diseases. Recent genome-wide association studies (GWAS) have enabled identification of relevant immune response

pathways; the same allele that predisposes to a certain autoimmune disease can be protective in another (Wiebolt et al., 2010). Thus endocrine GWAS are needed, especially for Graves' disease, Hashimoto's thyroiditis, and Addison's disease. Each of these disorders has stages beginning with genetic susceptibility, environmental triggers, and active autoimmunity, followed by metabolic derangements with overt symptoms of disease (Michels and Eisenbarth, 2010). Research is needed to clarify how nutrients interact with genetics, especially in the **autoimmune thyroid disorders (AITDs)**.

### THYROID PHYSIOLOGY

The thyroid gland is a small, butterfly-shaped gland found just below the Adam's apple. Although it weighs less than an ounce, it produces hormones that influence essentially

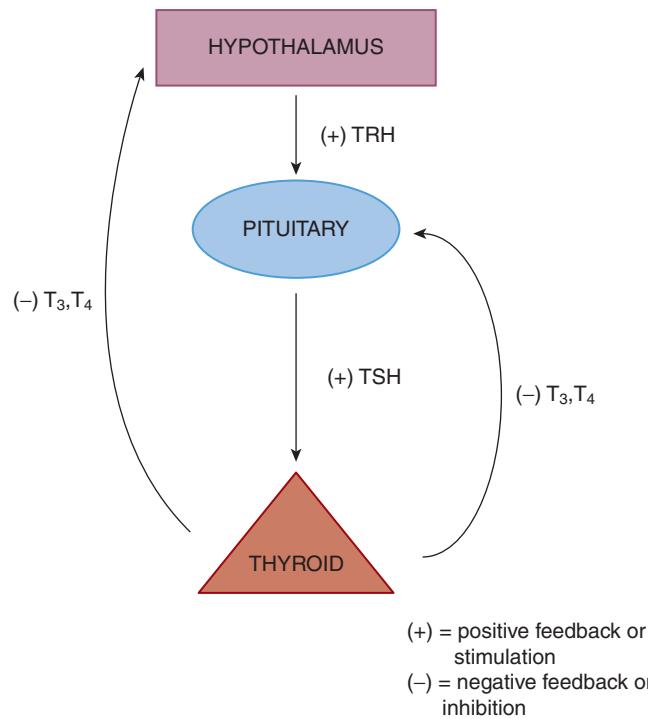

every organ, tissue, and cell in the body, thus having an enormous effect on health. The thyroid gland responds to stimulation by **thyroid-stimulating hormone (TSH)**, a hormone secreted by the pituitary gland. When stimulated, the thyroid gland produces two main hormones: **thyroxine (T<sub>4</sub>)**, a thyroid hormone named for its four molecules of iodine, and **triiodothyronine (T<sub>3</sub>)**, a thyroid hormone named for its three molecules of iodine. T<sub>3</sub> is the most predominant and active form of thyroid hormone that the body can use. The thyroid gland regulates many processes in the body, including fat and carbohydrate metabolism, body temperature, and heart rate. The thyroid also produces **calcitonin**, a hormone that helps regulate the amount of blood calcium. Last, **reverse T<sub>3</sub> (rT<sub>3</sub>)** an isomer of T<sub>3</sub>, is derived from T<sub>4</sub> through the action of deiodinase. The body cannot use rT<sub>3</sub>.

The synthesis of these hormones requires **tyrosine**, a key amino acid involved in the production of thyroid hormone, and the trace mineral iodine. Within the cells of the thyroid gland, iodide is oxidized to iodine by hydrogen peroxide, a reaction termed the *organification* of iodide. Two additional molecules of iodine bind to the tyrosyl ring in a reaction that involves **thyroid peroxidase (TPO)**, an enzyme in the thyroid responsible for thyroid hormone production. Completed thyroid hormones are released into the circulation; however, metabolic effects of thyroid hormones result when the hormones ultimately occupy specific thyroid receptors. It is estimated a cell needs five to seven times more T<sub>4</sub> to bind to the nuclear receptors to have a physiologic effect compared with T<sub>3</sub>.

The biosynthetic processes resulting in generation of thyroid hormones within the thyroid gland are controlled by feedback mechanisms within the **hypothalamic-pituitary-thyroid axis (HPT axis)**. The HPT axis is part of the endocrine system responsible for the regulation of metabolism. As its name suggests, it depends on the **hypothalamus** (a tiny, cone-shaped structure located in the lower center of the brain that communicates between the nervous and endocrine systems), the **pituitary gland** (the master gland of the endocrine system located at the base of the brain), and the thyroid gland (Figure 32-1).

The hypothalamus produces and secretes **thyrotropin-releasing hormone (TRH)**, which travels to the pituitary gland, stimulating it to release TSH, which signals the thyroid gland to upregulate its synthetic machinery. Although T<sub>4</sub>, T<sub>3</sub>, and rT<sub>3</sub> are generated within the thyroid gland, T<sub>4</sub> is quantitatively the major secretory product. All T<sub>4</sub> found in circulation is generated in the thyroid unless exogenously administered. Production of T<sub>3</sub> and rT<sub>3</sub> within the thyroid is relegated to very small quantities and is not considered significant compared with their peripheral production (Figure 32-2).

When T<sub>4</sub> is released from the thyroid, it is primarily in a bound form with **thyroid-binding globulin (TBG)**, a protein that transports thyroid hormones through the bloodstream, with lesser amounts bound to T<sub>4</sub>-binding prealbumin. It is estimated that only 0.03% to 0.05% of T<sub>4</sub> within the circulatory system is in a free or unbound

**FIGURE 32-1** The hypothalamus-pituitary-thyroid axis.

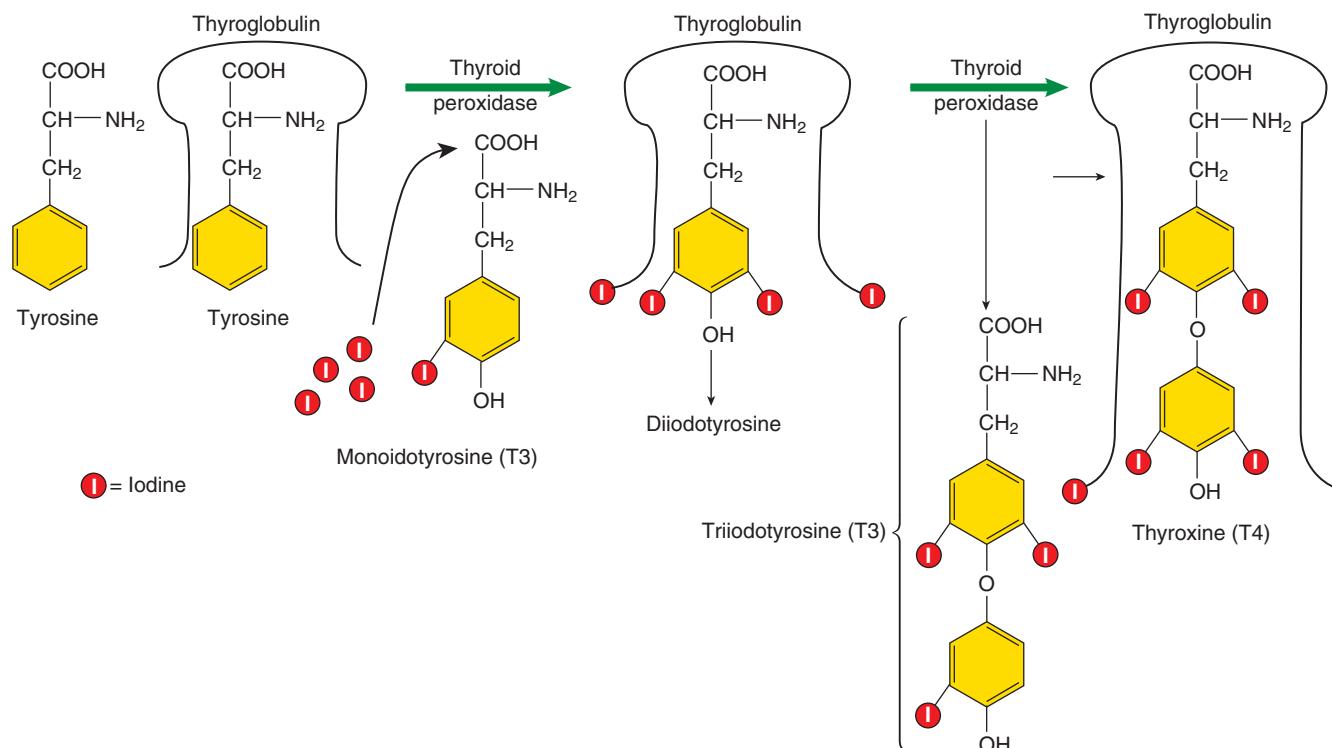

form; this unbound T<sub>4</sub> is called *free T<sub>4</sub>*. In peripheral tissues, approximately 70% of T<sub>4</sub> produced is either deiodinated and converted to T<sub>3</sub> or rT<sub>3</sub>, or eliminated. As mentioned, T<sub>3</sub> is considered to be the most metabolically active thyroid hormone. Although some T<sub>3</sub> is produced in the thyroid, approximately 80% to 85% is generated outside the thyroid, primarily by conversion of T<sub>4</sub> in the liver and kidneys. The pituitary and nervous system are capable of converting T<sub>4</sub> to T<sub>3</sub>, so are not reliant on T<sub>3</sub> produced in the liver or kidney. Within the liver and kidney, the enzyme responsible for production of T<sub>3</sub> is a selenium-dependent enzyme called **5'-deiodinase**, an enzyme that removes one molecule of iodine from T<sub>4</sub> to form either T<sub>3</sub> or rT<sub>3</sub> (Figure 32-3).

## ASSESSMENT IN THYROID DISORDERS

Assessment begins with an evaluation of thyroid status based on laboratory data such as a full thyroid panel. It may also include a diet history to evaluate micronutrients pertaining to thyroid health along with an evaluation of calorie and carbohydrate intake. Additionally, an assessment of dietary intake of goitrogenic foods may be warranted.

### Laboratory Norms: Functional versus Pathological Ranges

A typical (statistical) reference range for TSH in many laboratories is approximately 0.2–5.5 mIU/L. Individuals with TSH values greater than 2 mIU/L have an increased risk of developing overt hypothyroidism during the next 20 years. Subclinical autoimmune thyroid disease is so

**FIGURE 32-2** Constructing thyroid hormones. (1) Accumulation of the raw materials tyrosine and iodide (I-), (2) fabrication or synthesis of the hormone, and (3) secretion of free hormone into the blood.

Hypothalamus sends Thyroid Releasing Hormone (TRH) to the pituitary gland.

Pituitary gland releases Thyroid Stimulating Hormone (TSH) to the thyroid gland.

TSH stimulates Thyroid Peroxidase (TPO) activity to use iodine and tyrosine to create T4 and T3 hormones.

93% is T4                      7% is T3

60% of T4 is converted to T3 in the liver (inactive)

Remaining T4 is converted to T3 in peripheral tissues                      20% goes to reverse T3

**FIGURE 32-3** Thyroid metabolism.

common in the population that laboratory reference ranges derived from testing apparently healthy subjects could easily be misconstrued for those with disease. Importantly, several studies have detected an increase in TPO antibody positivity with TSH concentrations outside the narrow range of 0.2-1.9 mIU/L (Downs et al., 2008). This fact provides evidence that TSH in the upper reference range is often associated with abnormal pathologic findings (Hak et al., 2000; Saravanan et al., 2002). Additional evidence that thyroid function within the laboratory reference ranges can be associated with adverse outcomes is shown in Table 32-1. Conversely, decreased TSH levels combined with normal to high T4 or T3 levels may be suggestive of hyperthyroidism.

Changes in 5'-deiodination occur in a number of situations, such as stress, poor nutrition, illness, selenium deficiency, and drug therapy. Toxic metals such as cadmium, mercury and lead have been associated with impaired hepatic 5'-deiodination in animal models. Free radicals are also involved in inhibition of 5'-deiodinase activity. In the course of chronic liver disease such as hepatic cirrhosis, alterations in hepatic deiodination resulting in increased rT3 and a simultaneous decrease in T3 levels have also been observed (Box 32-1).

**TABLE 32-1**

**Variation In Thyroid Function within Reference Range and Adverse Outcomes**

TSH > 2 mIU/L*	Increased 20-year risk of hypothyroidism
TSH > 2 mIU/L*	Increased frequency of thyroid autoantibodies
TSH > 4 mIU/L*	Increased risk of heart disease
TSH 2-4 mIU/L*	Cholesterol values respond to thyroxine replacement
Free T4 < 10.4 pmol/L <sup>†</sup>	Impaired psychomotor development of infant if occurs in first trimester of pregnancy

T3, Triiodothyronine; T4, thyroxine; TSH, thyroid-stimulating hormone.

\*Typical reference ranges: TSH 0.2-5.5 mIU/L

<sup>†</sup>Typical reference ranges: free T4 9.8-25 pmol/L

**BOX 32-1**  
**5'-Deiodinase Inhibitors**

- Selenium deficiency
- Inadequate protein, excess carbohydrates
- High insulin
- Chronic illness
- Stress (cortisol)
- Cd, Hg, Pb and other heavy metal toxins
- Compromised liver or kidney function

## HYPOTHYROIDISM

Of the detected cases of underactive thyroid (**hypothyroidism**), more than half are due to an autoimmune disorder called **Hashimoto's thyroiditis**, in which the immune system attacks and destroys thyroid gland tissue. A common clinical presentation of patients with functional changes of the endocrine system is altered thyroid function. Indeed *subclinical* hypothyroidism represents the first signs of thyroid hormone dysfunction for many individuals. Typical symptoms include low energy, cold hands and feet, fatigue, hypercholesterolemia, muscle pain, depression, and cognitive deficits (Box 32-2). Evaluating thyroid hormone metabolism is needed before thyroid hormone replacement therapy.

Women are five to eight times more likely than men to suffer from hypothyroidism. In addition, individuals who have celiac disease may be at risk (see *Clinical Insight: Was It Gluten That Caused Her Hypothyroidism?*)

### Pathophysiology

Hashimoto's thyroiditis is an autoimmune disorder in which the immune system attacks and destroys the thyroid gland. It is the most common form of hypothyroidism. The enlarged, chronically inflamed thyroid gland becomes non-functional, with reactive parts of the gland deteriorating after several years. Thyroid autoantibodies indicate the body's immune system is attacking itself and whether an autoimmune thyroid condition is present, be it hypothyroidism or hyperthyroidism.

Specific antibody tests identify Hashimoto's thyroiditis. **Thyroid peroxidase antibodies (TPO Ab)** are immune cells

### BOX 32-2

**Common Symptoms of Hypothyroidism and Hyperthyroidism**

**Hypothyroidism**

- Fatigue
- Forgetfulness
- Depression
- Heavy menses
- Dry, coarse hair
- Mood swings
- Weight gain
- Hoarse voice
- Dry, coarse skin
- Constipation

**Hyperthyroidism**

- Heat intolerance, sweating
- Weight loss
- Alterations in appetite
- Frequent bowel movements
- Changes in vision
- Fatigue and muscle weakness
- Menstrual disturbance
- Impaired fertility
- Mental disturbances
- Sleep disturbances
- Tremors
- Thyroid enlargement

From Shomon M: Thyroid disease symptoms—hypothyroidism and hyperthyroidism, 2008. Accessed July 15, 2010 from [http://thyroid.about.com/cs/basics\\_starthere/a/symptoms.htm](http://thyroid.about.com/cs/basics_starthere/a/symptoms.htm).

 CLINICAL INSIGHT

## Was It Gluten That Caused Her Hypothyroidism?

A case report described a 23-year-old woman with a diagnosis of hypothyroidism caused by Hashimoto's thyroiditis and autoimmune Addison's disease who was found in evaluation to have elevated antiendomysium antibody levels. During a 3-month period on a gluten-free diet, the patient demonstrated remarkable clinical improvement in both her GI related symptoms and, more importantly, in her thyroid function. She required progressively less thyroid and adrenal replacement therapy. After 6 months her endomysium antibody level became negative, her antithyroidal antibody titer decreased significantly, and thyroid medication was discontinued. This case report points out the important effect of a hypoallergenic diet on thyroid function in relation to the potential reduction of antithyroidal antibodies.

A number of studies show the importance of gluten in the induction of endocrine autoantibodies and organ system

dysfunction in adolescent celiac patients (Cassio et al., 2010; Meloni et al., 2009). Furthermore, the genetic risk for celiac disease is largely related to human leukocyte antigen genotypes, which in turn is largely accountable for its link to autoimmune thyroid disease (Barker and Liu, 2008). It has been reported that gluten-dependent diabetes and thyroidal-related antibodies were found in patients with celiac disease, but were abolished after a gluten-free diet was followed (Duntas, 2009). Similarly, there is a high prevalence of thyroid disorders in untreated adult patients with celiac disease; gluten withdrawal through dietary avoidance may single-handedly reverse this abnormality. This is another important dietary variable that can modify thyroid hormone activity. Because rice has low antigenicity and is gluten-free, a rice-based diet may be desirable in these patients.

that indicate the immune system is attacking TPO in the thyroid gland. The TPO Ab test is the most important, because TPO is the enzyme responsible for the production of thyroid hormones, and the most frequent target of attack in Hashimoto's. **Thyroglobulin antibodies (TGB Ab)** are immune cells that indicate the immune system is attacking thyroglobulin in the thyroid gland. Sometimes this test is necessary as well because it is the second most common target for Hashimoto's disease.

**Schmidt's syndrome** refers to hypothyroidism with other endocrine disorders, including Addison's disease (adrenal insufficiency), hypoparathyroidism, and diabetes mellitus, all of which may be autoimmune in nature. **Euthyroid sick syndrome** is hypothyroidism, associated with a severe systemic illness that causes decreased peripheral conversion of T4 to T3, an increased conversion of T3 to the inactive rT3, and decreased binding of thyroid hormones. Conditions commonly associated with this syndrome include protein-calorie malnutrition, surgical trauma, myocardial infarction, chronic renal failure, diabetic ketoacidosis, anorexia nervosa, cirrhosis, thermal injury, and sepsis. Once the underlying cause is treated, the condition is usually resolved (see *Pathophysiology and Care Management Algorithm: Thyroid Dysfunction*).

### Triggers

**Adrenal Stress and Oxidative Stress.** Low thyroid function is almost always secondary to some other condition, often **adrenal fatigue** (Abdullatif and Ashraf, 2006). Adrenal fatigue (adrenal stress) denotes a syndrome caused by the decreased ability of the adrenal glands to respond

adequately to stress (Wilson, 2008). The adrenal glands are the two glands that sit over the kidneys and are primarily responsible for governing the body's adaptations to stress of any kind. Chronic adrenal stress causes the following:

- Affects communication between the brain and hormone-secreting glands. The hypothalamus and pituitary gland direct hormone production, including that of the thyroid. When the hypothalamus and pituitary weaken because of chronic adrenal stress, they are not able to communicate well with the thyroid gland.
- Increases thyroid-binding protein activity, so that thyroid hormones cannot get into cells to do their job.
- Hampers the conversion of T4 to active forms of T3 that the body can use.
- Interferes with the detoxification pathways through which unnecessary thyroid hormones exit the body, leading to thyroid hormone resistance.
- Causes cells to lose sensitivity to thyroid hormones.
- Weakens the immune barriers of the digestive tract, lungs, and brain; promotes poor immune regulation.

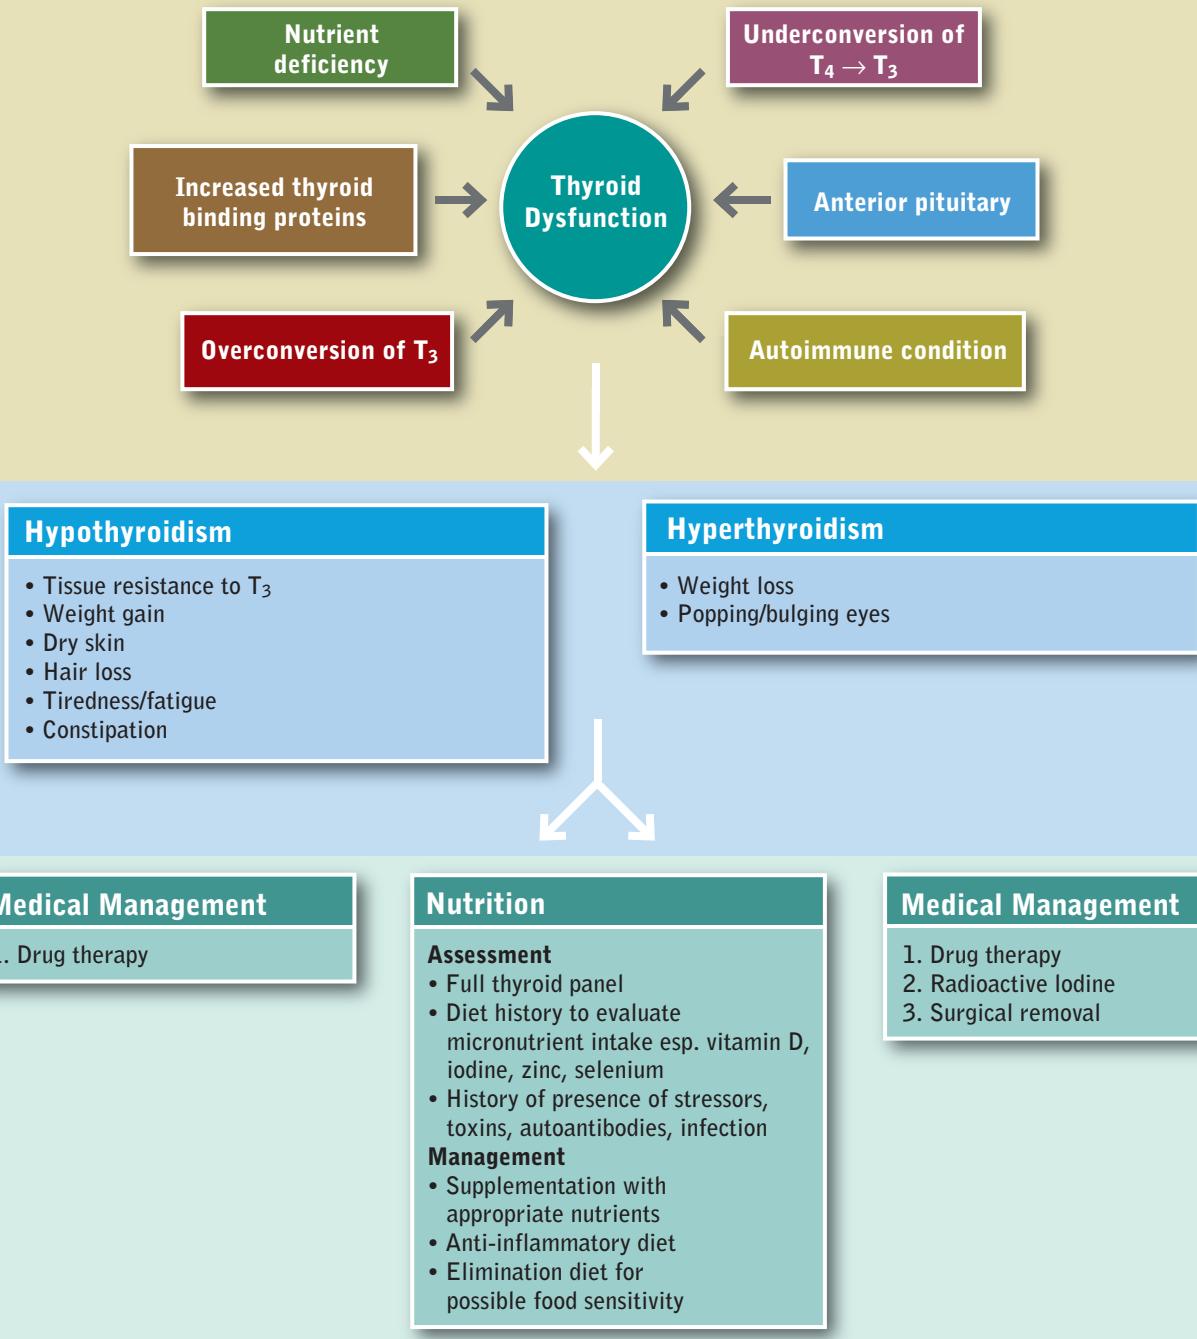

These factors increase the risk for triggering Hashimoto's or exacerbating it. These are some of the ways adrenal stress directly affect thyroid function.

Chronic adrenal stress affects other systems of the body, which in turn, decrease thyroid function. For example, the adrenal hormone **cortisol** plays a big role in thyroid health. Cortisol raises blood sugar when it drops too low. When

## PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

### Thyroid Dysfunction

this happens repeatedly, it exhausts the adrenal and thyroid glands, as well as the hypothalamus and the pituitary gland. Over time, this exhaustion leads to functional hypothyroidism. Additionally, constant cortisol production weakens the gastrointestinal (GI) tract, making it more susceptible to inflammation, dysbiosis, and infection. Thus a vicious cycle weakens the thyroid.

**Ageing.** Maintaining thyroid hormone function throughout the aging process appears to be an important hallmark of healthy aging. The incidence of hypothyroidism (underactive thyroid) increases with age. By age 60, 9% to 17% of men and women have an underactive thyroid. The absence of circulating thyroid autoantibodies in healthy centenarians is noted. Because unhealthy aging is associated with a progressively increasing prevalence of organ-specific and non-organ-specific autoantibodies, the absence of these antibodies may represent a significantly reduced risk for cardiovascular disease and other chronic age-related disorders.

**Pregnancy.** Thyroid dysfunction has been related to obstetrical complications such as premature delivery, gestational hypertension, preeclampsia, and placental abruption. Nearly 1 out of 50 women in the United States is diagnosed with hypothyroidism during pregnancy. Out of every 100 miscarriages, 6 are associated with thyroid hormone deficiency during pregnancy; up to 18% of women are diagnosed with postpartum thyroiditis; and approximately 25% of women develop permanent hypothyroidism (De Vivo et al., 2010; Yassa et al., 2010).

The World Health Organization (WHO) recently increased the recommended iodine intake during pregnancy from 200 to 250 mcg/d and suggested that a median urinary

iodine (UI) concentration of 150–249 mcg/L indicates adequate iodine intake in pregnant women. In areas of severe iodine deficiency, maternal and fetal hypothyroxinemia can cause cretinism and adversely affect cognitive development in children. To prevent fetal damage, iodine should be given before or early in pregnancy. In countries or regions where less than 90% of households are using iodized salt and the median UI concentration in school-age children is less than 100 mcg/L, the WHO recommends iodine supplementation in pregnancy and infancy (Zimmermann, 2009).

## Medical Management

When the thyroid is underactive (hypothyroidism) because of autoimmune disease (Hashimoto's disease), radioactive iodine treatment, congenital defects, or surgical removal (thyroidectomy), the conventional pharmacologic approach for treatment is prescription thyroid hormone replacement medication. Table 32-2 provides an overview of key forms of thyroid hormone replacement. With the further elucidation of the effects of genetics, new agents are likely to become available as adjunct therapy (Anderson, 2008).

## Medical Nutrition Therapy

It is well established that several nutrients are involved in thyroid health, particularly iodine and selenium. Because of the critical role of iodine in the synthesis of thyroid hormone, this trace mineral has received the most attention historically with respect to thyroid disorders. Other deficiencies of micronutrients such as iron, selenium, vitamin A, and

**TABLE 32-2**

### Pharmacologic Treatments for Hypothyroidism

Medication Brand Name	Medication Generic Name	Use and Comments
Synthroid, Levoxyt	levothyroxine—(synthetic T4)	Most commonly prescribed synthetic form of thyroid hormone replacement drug (thyroxine).
Cytomel	liothyronine—(synthetic T3)	Synthetic form of T3, which can also be compounded. Sometimes prescribed in addition to T4.
Armour Thyroid	desiccated natural thyroid	Prepared from dried or powdered porcine (pig) or mixed beef and pork thyroid gland for therapeutic use. Available by prescription and frequently used as an alternative to synthetic thyroid drugs. All brands contain a mixture of approximately 80% T4 and 20% T3. Difficult to standardize
Thyrolar	liotrix—(synthetic T4-T3 combination)	Synthetic combination of T4 and T3 Sometimes used in lieu of Armour Thyroid because of problem with standardization.

From Shomon M: *All about thyroid drugs*, 2007. Accessed May 16, 2011 from <http://thyroid.about.com/cs/thyroiddrugs/a/overview.htm>.  
T3, Triiodothyronine; T4, thyroxine.

possibly zinc may interact with iodine nutriture and thyroid function (Hess, 2010).

**Fasting or Restrictive Diets.** Calorie and carbohydrate restriction may substantially reduce thyroid hormone activity. There is a wide range of variation between individuals; genetics, obesity, gender, and the macronutrient content of the hypocaloric diet influence the response. Nutritional status and energy expenditure both influence thyroid function centrally at the level of TSH secretion, deiodination, and possibly elsewhere. Because an increase of rT3 is found at the expense of T3 during caloric restriction, it is possible that the hepatic pathways play a substantial role in metabolic control during energy balance. However, when caloric restriction is longer than three weeks, T4 and rT3 levels return to normal values.

Fasting also exerts a powerful influence on the metabolism of thyroid hormones. Mild elevations in endogenous cortisol levels might be partly responsible. Ketones generated from calorie deprivation do not appear to suppress T3 generation and hepatic 5'-deiodinase activity. However, it is not clear whether ketones have a similar effect in a calorie-sufficient diet. On a low-calorie diet, elimination of rT3 by 5'-deiodination is decreased. Calories and energy balance might also influence thyroid hormone metabolism during increased caloric consumption, during which the clearance of rT3 by 5'-deiodination is actually increased. On a low-calorie diet, elimination of rT3 by 5'-deiodination is decreased; however, the clearance of rT3 by 5'-deiodination is actually increased with a high calorie diet.

**Goitrogens.** Cyanogenic plant foods (cauliflower, broccoli, cabbage, Brussel sprouts, mustard seed, turnip, radish, bamboo shoot, and cassava) exert antithyroid activity through inhibition of TPO. The hydrolysis of some glucosinolates found in cruciferous vegetables (e.g., progoitrin) may yield **goitrin**, a compound known to interfere with thyroid hormone synthesis. The hydrolysis of indole glucosinolates results in the release of thiocyanate ions, which can compete with iodine for uptake by the thyroid gland. Increased exposure to thiocyanate ions from cruciferous vegetable consumption, however, does not increase the risk of hypothyroidism unless accompanied by iodine deficiency.

Soybean, an important source of protein in many developing countries, also has goitrogenic properties when iodine intake is limited. The isoflavones, genistein and daidzein, inhibit the activity of TPO and can lower thyroid hormone synthesis. Furthermore, soybean interrupts the enterohepatic cycle of thyroid hormone metabolism. However, high intakes of soy isoflavones do not appear to increase the risk of hypothyroidism when iodine consumption is adequate.

Since the addition of iodine to soy-based formulas in the 1960s, there have been no further reports of hypothyroidism developing in soy formula-fed infants. Soybeans are by far the most concentrated source of isoflavones in the human diet. Small amounts are found in a number of legumes, grains, and vegetables. Average dietary isoflavone intakes in Asian countries, in particular in Japan and China, range from 11–47 mg/day because of intake of the traditional foods made from soybeans, including tofu, tempeh, miso,

and matte, whereas intakes are considerably lower in Western countries (2 mg/day). Soy products (meat substitutes, soy milk, soy cheese, and soy yogurt), however, are gaining popularity in Western countries. Although research has not determined the exact effect of soy on the metabolic fate of thyroid hormones, excessive soy consumption is best approached cautiously in those with suspected impairment of thyroid metabolic pathways.

**Iodine.** As a trace element, iodine is present in the human body in amounts of 10–15 mg and 70% to 80% of it is located in the thyroid gland (Melse-Boonstra and Jaiswal, 2010) (see Chapter 3). Ninety percent of it is organically bound to thyroglobulin (Tg). Iodide is actively absorbed in the thyroid gland to help produce the biochemically active thyroid hormones, T4 and T3 (see Figure 32-2). It is estimated the thyroid gland must capture a minimum of 60 mcg of iodide (the ionic form of iodine) daily to ensure an adequate supply for the production of thyroid hormone (Gropper et al., 2009). Inadequate intake of iodine impairs thyroid function and results in a spectrum of disorders. Randomized controlled intervention trials in iodine deficient populations have shown that providing iron along with iodine results in greater improvements in thyroid function and volume than providing iodine alone (Hess, 2010). It is also vital to thyroid function, as it is a major cofactor and stimulator for the enzyme TPO.

In autoimmune Hashimoto's, supplementing with iodine may exacerbate the condition. Because iodine stimulates production of TPO, this in turn increases the levels of TPO antibodies (TPO Abs) dramatically, indicating an autoimmune flare-up. Some people develop symptoms of an overactive thyroid, whereas others have no symptoms despite tests showing an elevated level of TPO Abs. Therefore one must be cautious regarding the use of iodine. Furthermore, although iodine deficiency is the most common cause of hypothyroidism for most of the world's population (Melse-Boonstra and Jaiswal, 2010), in the United States and other westernized countries, Hashimoto's accounts for the majority of cases (Ebert, 2010; Sloka et al., 2005).

Although the risk of iodine deficiency for populations living in iodine-deficient areas without adequate iodine fortification programs is well recognized, concerns have been raised that certain subpopulations may not consume adequate iodine in countries considered iodine-sufficient. Vegetarian and nonvegetarian diets that exclude iodized salt, fish, and seaweed have been found to contain very little iodine. Furthermore, UI excretion studies suggest that iodine intakes are declining in Switzerland, New Zealand, and the United States, possibly because of increased adherence to dietary recommendations to restrict salt intake for reducing the incidence of hypertension.

Severe iodine deficiency during pregnancy has been shown to increase the risk of stillbirths, spontaneous abortions, and congenital abnormalities. The most severe is **cretinism**, which is a state of mental retardation mostly in combination with dwarfism, deaf-mutism, and spasticity (Chen and Hetzel, 2010). These conditions are largely

irreversible. The consequences of severe iodine deficiency during pregnancy on pregnancy outcome and early infant development have been described extensively (Zimmermann, 2009); other details can be found in Chapter 16.

**Iron.** Historically, it has been thought that low thyroid function may cause anemia. Recent studies suggest that low thyroid function may be secondary to low iron status or anemia. The reason for this is because TPO is a glycosylated heme enzyme that is iron-dependent. The insertion of heme iron into TPO is necessary for the enzyme to translocate to the apical cell surface of thyrocytes (or thyroid epithelial cells), thus assisting TPO to catalyze the two initial steps of thyroid hormone synthesis (Zimmermann, 2006). A full assessment of iron status could likely help to identify the cause of many cases of thyroid malfunction (Titchenal et al., 2009).

**Selenium.** Selenium, as selenocysteine, is a cofactor for 5'-deiodinase. If selenium is deficient, the deiodinase activity is impaired, resulting in a decreased ability to deiodinate T4 to T3. In animals, deficiencies of selenium are associated with impaired 5'-deiodinase activity in the liver and kidney, as well as reduced T3 levels. Evidence suggests a strong linear association between lower T3/T4 ratios and reduced selenium status, even among individuals considered to be euthyroid based on standard laboratory parameters. This association is particularly strong in older adults, possibly as the result of impaired peripheral conversion. An inverse relationship between T3 and breast cancer is associated with decreased selenium status, even when plasma T4 and TSH concentrations may be similar. This combination of factors strongly suggests that low T3 may be due to faulty conversion of T4 to T3 expected in selenium deficiency.

Selenium participates in the antioxidant network. It assists in detoxification as part of glutathione peroxidase, an enzyme whose main biologic role is to protect the organism from oxidative damage. Several studies reported on the benefit of selenium treatment both in Hashimoto's thyroiditis and Graves' disease.

Evidence also suggests that high intakes of selenium might exert a detrimental influence on thyroid hormone metabolism. Although individuals exposed to high dietary levels of selenium typically have normal levels of T4, T3, and TSH, a significant inverse correlation has been found between T3 and selenium. Some researchers have hypothesized the activity of 5'-deiodinase might become depressed after a high dietary intake of selenium, suggesting a safe level of dietary selenium at or below 500 mcg daily (Kohrle and Gartner, 2009).

## POLYCYSTIC OVARY SYNDROME

**Polycystic ovary syndrome (PCOS)** is a common endocrine disorder of unknown cause that affects an estimated 3% to 12% of women of reproductive age in Western societies (Moran et al., 2010). The condition is characterized by reproductive issues such as amenorrhea or other menstrual irregularities, anovulation, enlarged ovaries with multiple cysts, and infertility. More generalized symptoms include acne, hirsutism (excessive or abnormal distribution of hair growth), male-pattern baldness, obesity, and sleep apnea (Table 32-3).

### Pathophysiology

Biochemical and endocrine abnormalities in women with PCOS include elevated levels of androgens (dehydroepiandrosterone, testosterone, and androstenedione), hyperinsulinemia (which results from insulin resistance), impaired glucose tolerance, and hyperlipidemia. Hyperandrogenism is responsible for many of the symptoms of PCOS, such as reproductive and menstrual abnormalities, hirsutism, and acne. Elevated androgen levels, in turn, appear to be due in part to hyperinsulinemia, which triggers the increase in androgen production. Thus interventions that improve insulin resistance and hyperinsulinemia may reverse some of the manifestations of PCOS.

**TABLE 32-3**

#### Nutrition Treatment For Polycystic Ovary Syndrome

Obesity	• Institute weight management program of diet and exercise.
Insulin resistance	• Restrict refined carbohydrates (low glycemic index diet) and total calories. • Increase high fiber foods. • Recommend small, frequent meals. • Monitor carefully to ascertain benefit from high- versus low-carbohydrate diet. • Consider supplementation with chromium picolinate.
Low serum 25 hydroxy vitamin D	• Administer vitamin D <sub>3</sub> (cholecalciferol).
Clomiphene-citrate resistant infertility	• Use short-term NAC as adjunct.
Laboratory or clinical evidence of hypothyroidism	• Institute thyroid hormone replacement.
<i>NAC</i> , N-acetylcysteine.	• Use foods or supplements with selenium and iodine.

The insulin resistance seen in women with PCOS is unique in that it occurs independent of body weight to some extent and is not always corrected by weight loss. It appears to result from a postreceptor defect in an insulin-mediated signaling pathway (Diamanti-Kandarakis and Papavassiliou, 2006). Conventional treatment of PCOS includes diet and exercise to promote weight loss. In women who are obese, weight loss may improve insulin resistance, decrease androgen levels and hirsutism, and restore ovulation in some cases. Low-glycemic index diets have historically been recommended without evidence of their clinical effectiveness. However, the capacity of dietary carbohydrates to increase postprandial blood sugar response may be an important consideration for optimizing metabolic and clinical outcomes in PCOS. Furthermore, independent of weight loss, a low-glycemic index diet appears to result in greater improvements in health, including improved insulin sensitivity, improved menstrual regularity, better emotion scores (on a questionnaire designed to detect changes in quality of life), and decreased markers of inflammation as compared with a conventional low-fat diet when matched closely for macronutrient and fiber content (Marsh et al., 2010).

## Medical Management

Hypothyroidism occurs in some cases of PCOS. Laboratory tests for thyroid function are frequently normal in patients with clinical evidence of hypothyroidism, and treatment with thyroid hormone results in clinical improvement in many patients. Therefore an empirical trial of thyroid hormone should be considered for patients with PCOS who have clinical evidence of hypothyroidism.

Thyroid antibody status should be taken into account when considering empirical treatment with thyroid hormone in women with PCOS. Metformin is frequently prescribed to improve insulin resistance, and treatment with this drug may lead to resumption of ovulation. Other therapies include the drugs clomiphene citrate (to induce ovulation) and spironolactone (an antiandrogen), as well as oral contraceptives (to treat menstrual irregularities and hirsutism).

## Medical Nutrition Therapy

Nutritional interventions that may be beneficial for women with PCOS include dietary modifications designed to enhance insulin sensitivity. This includes restricting refined carbohydrates and total calories; consuming high-fiber foods; and eating small, frequent meals. Some patients with insulin resistance fare better on a diet high in complex carbohydrates (approximately 60% of total calories), whereas others respond better to a low-carbohydrate diet ( $\leq 40\%$  of total calories). Additionally, supplementation with vitamin D<sub>3</sub> (800–1200 IU/day), and chromium picolinate (200–1000 mcg/day) has been reported to improve glucose tolerance, insulin secretion, and insulin sensitivity (Lydic et al., 2006). Short-term treatment with N-acetylcysteine (600 mg twice a day) may be useful as an adjunct to clomiphene citrate in women with clomiphene citrate-resistant infertility (Rizk et al., 2005). In addition, treatment with thyroid

hormone may be beneficial for women who have laboratory or clinical evidence of hypothyroidism (Table 32–3).

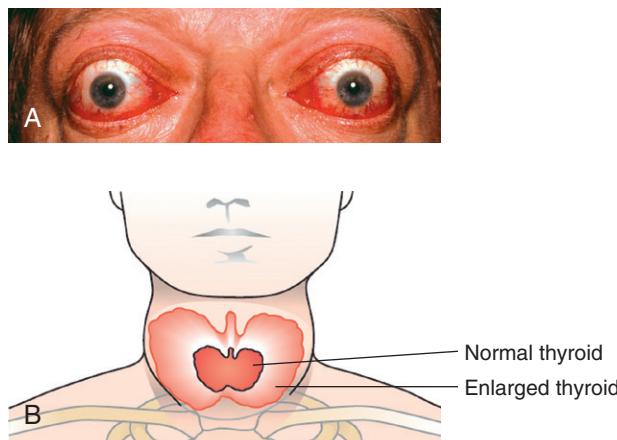

## HYPERTHYROIDISM

**Graves' disease** is an autoimmune disease in which the thyroid is diffusely enlarged (goiter) and overactive, producing an excessive amount of thyroid hormones. It is the most common cause of **hyperthyroidism** (overactive thyroid) in the United States. Physical symptoms frequently include red, dry, swollen, puffy, and bulging eyes (exophthalmos), heat intolerance, difficulty sleeping, and anxiety (see Box 32–2). However the most common sign of Graves' disease is goiter or thyroid enlargement (Figure 32–4). The excessive thyroid hormones may cause a serious metabolic imbalance, thyrotoxicosis. The prevalence of maternal thyrotoxicosis is approximately 1 case per 500 persons, with maternal Graves' disease being the most common cause (American Thyroid Association, 2008).

## Pathophysiology

Commonly, patients have a family history involving a wide spectrum of autoimmune thyroid diseases, such as Graves' disease, Hashimoto's thyroiditis, or postpartum thyroiditis. In Graves's disease, the TRH receptor itself is the primary autoantigen and is responsible for the manifestation of hyperthyroidism. The thyroid gland is under continuous stimulation by circulating autoantibodies against the TRH receptor, and pituitary TSH secretion is suppressed because of the increased production of thyroid hormones. These thyroid-stimulating antibodies cause release of thyroid hormone and Tg and they also stimulate iodine uptake, protein synthesis, and thyroid gland growth.

The Tg and TPO Abs appear to have little role in Graves' disease. However, as mentioned earlier, they are markers of Hashimoto's autoimmune disease against the thyroid. A TSH antibody—typically referred to as *thyroid-stimulating immunoglobulin*—test is used to identify hyperthyroidism, or Graves' disease.

**FIGURE 32-4** A, Exophthalmos. (From SPL/Photo Researchers, Inc.) B, Thyroid enlargement. (From Buck C: 2011 ICD-9-CM, for Hospitals, Volumes 1, 2 and 3, Professional Edition, St. Louis, 2011, Saunders.)

## Triggers

Graves' disease is an autoimmune disorder, influenced by a combination of environmental and genetic factors. Genetic factors contribute to approximately 20% to 30% of overall susceptibility. Other factors include infection, excessive iodide intake, stress, female gender, steroids, and toxins. Smoking has been implicated in the worsening of Graves' ophthalmopathy. Graves' disease has also been associated with infectious agents such as *Yersinia enterocolitica* and *Borrelia burgdorferi*.

**Genetics.** Several autoimmune thyroid disease susceptibility genes have been identified and appear to be specific to either Graves' disease or Hashimoto's thyroiditis, whereas others confer susceptibility to both conditions. The genetic predisposition to thyroid autoimmunity may interact with environmental factors or events to precipitate the onset of Graves' disease. *HLA-DRB1* and *HLA-DQB1* appear to be associated with Graves' disease susceptibility.

**Stress.** Stress can be a factor for thyroid autoimmunity. Acute stress-induced immunosuppression may be followed by immune system hyperactivity, which could precipitate autoimmune thyroid disease. This may occur during the postpartum period, in which Graves' disease may occur 3–9 months after delivery. Estrogen may influence the immune system, particularly the β-cells. Trauma to the thyroid has also been reported to be associated with Graves' disease. This may include surgery of the thyroid gland, percutaneous injection of ethanol, and infarction of a thyroid adenoma.

## Medical Management

For patients with sustained forms of hyperthyroidism, such as Graves's disease or toxic nodular goiter, antithyroid medications can be used. The goal with this form of drug therapy is to prevent the thyroid from producing hormones (Table 32-4).

The effects of immunotherapy are also being evaluated (Michels and Eisenbarth, 2010). See *Pathophysiology and Care Management Algorithm: Thyroid Dysfunction*.

## MANAGING IMBALANCES OF THE HYPOTHALAMUS-PITUITARY-THYROID AXIS

The thyroid has a relationship to hypothalamic, pituitary, immune, adrenal, and cardiovascular functions that affect clinical, cellular, and molecular outcomes. A checklist of considerations is found in Box 32-3, and is discussed here.

1. *Provide adequate precursors for the formation of T4.* Iodide is a limiting nutrient in many individuals for the production of T4. Adequate levels of organic iodide, which can come from sea vegetables, iodized salt, and seafood, are important in T4 production. Adequate dietary protein intake is important in establishing proper protein calorie nutrition. Supplementation with tyrosine does not appear to have a beneficial effect on elevating thyroid hormones.
2. *Reduce antithyroidal antibodies.* A variety of food antigens could induce antibodies that crossreact with the thyroid gland. A food elimination diet using gluten-free grains and possible elimination of casein, the predominant milk protein, might be considered for hypothyroidism of unexplained origin. It has also been suggested that environmental toxins may play a role in inducing autoimmune thyroiditis and thyroid dysfunction. Implementing nutritional support and providing adequate levels of vitamin D to support the immune system may be beneficial.

**TABLE 32-4**

### Treatments for Hyperthyroidism

Medication Brand Name	Medication Generic Name	Use and Comments
Tapazole	methimazole (MMI)	<ul style="list-style-type: none"> <li>Both drugs interfere with the thyroid gland's production of hormones.</li> <li>Both have side effects which include rash, itching, joint pain, and fever.</li> </ul>
Northyx	propylthiouracil (PTU)	<ul style="list-style-type: none"> <li>Liver inflammation or reduction in white blood cells may occur.</li> <li>Underlying hyperthyroidism can return when patient is no longer taking the medication.</li> </ul>
Radioactive iodine		<ul style="list-style-type: none"> <li>Most widely recommended permanent treatment of hyperthyroidism.</li> <li>Thyroid cells absorb radioactive iodine, which damages or kills them.</li> <li>If too many of the thyroid cells are damaged, remaining thyroid does not produce enough hormone, resulting in hypothyroidism and supplemental thyroid hormone may be necessary.</li> </ul>
<b>Surgical Treatment</b>		
<ul style="list-style-type: none"> <li>Thyroid is either partially or completely removed.</li> <li>Not as common as pharmacologic modes of treatment.</li> </ul>		

**BOX 32-3****Factors Promoting Thyroid Health In Adults****Consider**

Protein: 0.8 g/kg/day

Iodine (once autoimmune disease has been ruled out):

150 mcg/day

Selenium (as L-selenomethionine): 75-200 mcg/day

Zinc (as zinc citrate): 10 mg/day

Vitamin D (as D3 or cholecalciferol): 400 IU/day

Vitamin E (as d-alpha tocopherol succinate): 100 IU/day

Vitamin C (as ascorbic acid): 100-500 mg/day

Guggulsterones (from guggul extract): 100 mg/day

Ashwaganda: 100 mg/day

**Reduce or Eliminate**

Gluten (found in wheat, rye, oats, and barley)

Processed soy

Excessive uncooked goitrogenic foods

administration (1 mg/100 g body weight) increases iodine uptake by the thyroid, increases TPO activity, and decreases lipid peroxidation, suggesting that increased peripheral generation of T3 might be mediated by this plant's antioxidant effects.

*Withania somnifera* (ashwagandha) root extract (1.4 g/kg) may increase T3 and T4 concentrations without changing 5'-deiodinase activity.

6. *Avoid disruption of thyroid hormone metabolism from flavonoids.* Flavonoids, both natural and synthetic, have the potential to disrupt thyroid hormone metabolism. Synthetic flavonoid derivatives can decrease serum T4 concentrations and inhibit both the conversion of T4 to T3 and the metabolic clearance of rT3 by the selenium-dependent 5'-deiodinase. Naturally occurring flavonoids appear to have a similar inhibitory effect. Of the naturally occurring flavonoids, luteolin (most often found in leaves, but also seen in celery, thyme, dandelion, green pepper, thyme, perilla, camomile tea, carrots, olive oil, peppermint, rosemary, and oregano) is the most active inhibitor of 5'-deiodinase activity. Because isolated or concentrated flavonoids are increasingly used as therapeutic interventions, more research on the potential influence of these substances on thyroid hormone metabolism is desirable.
7. *Use caution with supplements.* Lipoic acid reduces the conversion of T4 to T3. Because it is usually not a therapeutic advantage to decrease peripheral activation of T3 subsequent to T4 therapy, use of lipoic acid supplements in hypothyroid patients receiving exogenous hormone therapy should be approached with caution.
8. *Maintain vitamin sufficiency.* One nutrient that is critically important for establishing immune balance and preventing the production of autoantibodies is vitamin D. Vitamin D is considered a prohormone with antiproliferative, differentiating, and immunosuppressive activities. Vitamin D is an effective immune modulator (Baeke et al., 2010) and may suppress the development of autoimmune diseases, such as arthritis and multiple sclerosis. Conversely, a vitamin D deficiency is associated with numerous autoimmune conditions, including Hashimoto's. More than 90% of people with autoimmune thyroid disease have a genetic defect affecting their ability to metabolize vitamin D (Lin et al., 2006; Stefanic et al., 2008). Vitamin D also appears to work with other nutritional factors to help regulate immune sensitivity and may protect against development of autoantibodies. After exposure to heavy metals, decreases in a variety of hepatic antioxidant lipid peroxidation (the oxidative degradation of lipids) systems have been observed. Ascorbic acid has been shown to be effective in preventing cadmium-induced decreases in T3 and hepatic 5'-deiodination.

3. *Improve the conversion of T4 to T3.* Nutritional agents that help support proper deiodination by the type 1 5'-deiodinase enzyme include selenomethionine (as L-selenomethionine) and zinc (as zinc glycinate or zinc citrate). Human studies have repeatedly demonstrated consequent reduced concentrations of thyroid hormones when a zinc deficiency is present (Blazewicz et al., 2010). In children with Down syndrome, zinc sulfate may reduce thyroidal antibodies, improve thyroid function, and reduce the incidence of subclinical hypothyroidism.

4. *Enhance T3 influence on mitochondrial bioenergetics.* A number of important nutritional relationships improve thyroid hormones' effect on the mitochondria. Selenium supplementation in animals can improve the production of T3 and lower autoantibodies to thyroid hormones, while improving energy production. Supplementation with selenomethionine results in improved deiodination of T4, which may improve adenosine triphosphate formation by supporting improved mitochondrial activity. Food sources of selenium include the Brazil nut, snapper, cod, halibut, yellow fin tuna, salmon, sardines, shrimp, mushrooms, and barley.

5. *Monitor use of botanical products.* Based on animal studies, it appears that certain botanical preparations influence thyroid activity. The most significant products include *Commiphora mukul* (guggulsterones, from guggul extract) and *Withania somnifera* (ashwagandha). *Commiphora mukul* demonstrates strong thyroid stimulatory action. Its

## OTHER ENDOCRINE SYSTEM DISORDERS

### Cushing's Syndrome

In Cushing's syndrome, too much cortisol remains in the bloodstream over a long period. The exogenous form occurs when individuals take steroids or other similar medications and ceases when the medication is stopped. Endogenous Cushing's syndrome is rare and occurs as the result of a tumor on the adrenal or pituitary gland. Weight gain, easy bruising, depression, muscle loss, and weakness are common symptoms. A weight management protocol may be needed.

### Addison's Disease

Primary adrenal insufficiency, also known as Addison's disease, is rare. In this condition, insufficient steroid hormones are produced in spite of adequate levels of the hormone ACTH. Regulation of blood glucose levels and stress management are affected. Loss of appetite, fatigue, low blood pressure, nausea and vomiting, and darkening of skin on the face and neck may occur. Patients with Addison's disease should not restrict their salt intake unless they have concurrent hypertension. Those patients who live in warm climates and therefore have increased losses through perspiration, may need to increase salt intake.

## CLINICAL SCENARIO

Frank is a 72-year-old man from Jamaica who moved to the United States 2 years ago. He has been diagnosed with hypothyroidism this past year. He comes to your clinic with his medicine and traditional folk remedies, including Synthroid, garlic, and chamomile. His diet history indicates daily use of chicken, rice, celery, dandelion, green pepper, mango, and papaya. He states that he has been very tired lately, has little energy, and has constipation. His hormone levels on his last medical report were thyroxine (T4): 1.7, triiodothyronine (T3): 75, and thyroid-stimulating hormone (TSH) : 15, indicative that his hypothyroidism is still not well controlled.

### Nutrition Diagnostic Statement

Food-drug interaction related to mixing Synthroid with foods and herbs that aggravate thyroid function as evidenced by fatigue, constipation, high TSH, and low serum T3 and T4.

### Nutrition Care Questions

- What other information do you need for a more thorough assessment?
- What advice would you offer Frank about his diet?
- What foods and herbs conflict with Synthroid?
- Because traditional folk remedies are commonly used, how do you plan to discuss these issues with Frank?

# Medical Nutrition Therapy for Anemia

### KEY TERMS

anemia  
aplastic anemia  
ferritin  
ferroprotein  
hematocrit  
heme iron  
hemochromatosis  
hemoglobin  
hemolytic anemia  
hepcidin  
holotranscobalamin II (holo TCII)  
hypochromic  
intrinsic factor (IF)  
iron-deficiency anemia  
koilonychia  
macrocytic anemia  
meat-fish-poultry (MFP) factor

megaloblastic anemia  
microcytic anemia  
nonheme iron  
pagophagia  
pernicious anemia  
plasma  
protoporphyrin  
reticulocytosis  
restless legs syndrome (RLS)  
serum  
sickle cell anemia (SCA)  
sideroblastic (pyridoxine-responsive) anemia  
soluble serum transferrin receptors (STFRs)  
thalassemia  
total iron-binding capacity (TIBC)  
transferrin  
transferrin receptor  
transferrin saturation

It is important for nutrition professionals to understand the myriad terms related to blood disorders. **Hemoglobin** is a conjugated protein containing four heme groups and globin; it is the oxygen-carrying pigment of the erythrocytes. The **hematocrit** is the volume percentage of erythrocytes in the blood. **Plasma** is the liquid portion of whole blood containing coagulation factors; **serum** is the liquid portion of whole blood without coagulation factors.

**Anemia** is a deficiency in the size or number of red blood cells (RBCs) or the amount of hemoglobin they

contain. This deficiency limits the exchange of oxygen and carbon dioxide between the blood and the tissue cells. Anemia classification is based on cell size—*macrocytic* (larger than normal), *normocytic* (normal), and *microcytic* (small)—and on hemoglobin content—*hypochromic* (pale color from deficiency of hemoglobin) and *normochromic* (normal color; (Table 33-1). **Macrocytic anemia** presents with larger-than-normal RBCs, plus increased mean corpuscular volume (MCV) and mean corpuscular hemoglobin concentration (MCHC). **Microcytic anemia** is

**TABLE 33-1****Morphologic Classification of Anemia**

<b>Morphologic Type of Anemia</b>	<b>Underlying Abnormality</b>	<b>Clinical Syndromes and Causes</b>	<b>Treatment</b>
<b>Macrocytic (MCV &gt; 94; MCHC &gt; 31)</b>			
Megaloblastic	Vitamin B <sub>12</sub> deficiency Folic acid deficiency	Pernicious anemia Nutritional megaloblastic anemias, sprue, and other malabsorption syndromes	Vitamin B <sub>12</sub> Folic acid
	Inherited disorders of DNA synthesis Drug-induced disorders of DNA synthesis	Orotic aciduria Chemotherapeutic agents, anticonvulsants, oral contraceptives	Treatment based on the nature of the disorder Discontinue offending drug and administer folic acid
Nonmegaloblastic	Accelerated erythropoiesis Increased membrane surface area	Hemolytic anemia	Treatment of underlying disease Treatment of underlying disease
<b>Hypochromic Microcytic (MCV &lt; 80; MCHC &lt; 31)</b>			
	Iron deficiency	Chronic loss of blood, inadequate diet, impaired absorption, increased demands	Ferrous sulfate and correction of underlying cause
	Disorders of globin synthesis Disorders of porphyrin and heme synthesis Other disorders of iron metabolism	Thalassemia Pyridoxine-responsive anemia	Nonspecific Pyridoxine
<b>Normochromic Normocytic (MCV 82-92; MCHC &gt; 30)</b>			
	Recent blood loss	Various	Transfusion, iron, correction of underlying condition
	Overexpansion of plasma volume	Pregnancy	Restore homeostasis
	Hemolytic diseases	Overhydration	Treatment based on the nature of the disorder
	Hypoplastic bone marrow	Aplastic anemia	Transfusion
	Infiltrated bone marrow	Pure red blood cell aplasia Leukemia, multiple myeloma, myelofibrosis	Androgens Chemotherapy
	Endocrine abnormality	Hypothyroidism, adrenal insufficiency	Treatment of underlying disease
	Chronic disorders		Treatment of underlying disease
	Renal disease	Renal disease	Treatment of underlying disease
	Liver disease	Cirrhosis	Treatment of underlying disease

Modified from Wintrobe MM et al: Clinical hematology, ed 8, Philadelphia, 1981, Lea & Febiger.

DNA, Deoxyribonucleic acid; MCHC, Mean corpuscular hemoglobin concentration: concentration of hemoglobin expressed in grams per deciliter (g/dL); MCV, mean corpuscular volume: volume of one red blood cell expressed in femtoliters (fL).

characterized by smaller-than-normal erythrocytes and less circulating hemoglobin, as in iron deficiency anemia and thalassemia.

Most anemias are caused by a lack of nutrients required for normal erythrocyte synthesis, principally iron, vitamin B<sub>12</sub>, and folic acid. These anemias that result from an

inadequate intake of iron, protein, certain vitamins (B<sub>12</sub>, folic acid, pyridoxine, and ascorbic acid), copper, and other heavy metals are called *nutritional anemias*. Other anemias result from conditions such as hemorrhage, genetic abnormalities, chronic disease states, or drug toxicity, and have varying degrees of nutritional consequence.

## IRON-RELATED BLOOD DISORDERS

Iron status can range from overload to deficiency and anemia. Routine measurement of iron status is necessary because approximately 6% of Americans have a negative iron balance, approximately 10% have a gene for positive balance, and approximately 1% have iron overload. Deviations from normal iron status are summarized in Box 33-1. Iron overload disease develops in persons with stage II positive balance after years of iron overload have caused progressive damage to tissues and organs (Figure 33-1).

Iron status has a variety of indicators. Serum ferritin is an iron apoferritin complex, one of the chief storage forms of iron. Serum ferritin levels are in equilibrium with body iron stores. Very early (stage I) positive iron balance may best be recognized by measuring **total iron-binding capacity (TIBC)**, the capacity of transferrin to take on or become saturated with iron. Conversely, measurement of serum or plasma ferritin levels may best reveal early (stage I or II) negative iron balance, although serum TIBC may be as good an indicator (see Chapter 8). **Transferrin saturation** is the measure of the amount of iron bound to transferrin and is a gauge of iron supply to the tissues; the percent saturation = serum iron/TIBC × 100.

### Iron-Deficiency Anemia

**Iron-deficiency anemia** is characterized by the production of small (microcytic) erythrocytes and a diminished level of

#### BOX 33-1

#### Altered Iron Status

**Stages I and II negative iron balance** (i.e., iron depletion): In these stages iron stores are low and there is no dysfunction. In stage I negative iron balance, reduced iron absorption produces moderately depleted iron stores. Stage II negative iron balance is characterized by severely depleted iron stores. More than 50% of all cases of negative iron balance fall into these two stages. When persons in these two stages are treated with iron, they never develop dysfunction or disease.

**Stages III and IV negative iron balance** (i.e., iron deficiency): Iron deficiency is characterized by inadequate body iron, dysfunction, and disease. In stage III, dysfunction is not accompanied by anemia, but anemia does occur with stage IV.

**Stages I and II positive iron balance:** Stage I positive iron balance usually lasts for several years with no accompanying dysfunction. Supplements of iron or vitamin C promote progression to dysfunction or disease, whereas iron removal prevents progression to disease.

circulating hemoglobin. This microcytic anemia is actually the last stage of iron deficiency, and it represents the end point of a long period of iron deprivation.

### Pathophysiology

There are many possible causes of iron-deficiency anemia (see *Pathophysiology and Care Management Algorithm: Iron Deficiency Anemia*). The condition can arise from:

1. Inadequate dietary intake secondary to a poor diet without supplementation
2. Inadequate absorption resulting from diarrhea, achlorhydria, intestinal disease such as celiac disease, atrophic gastritis, partial or total gastrectomy, or drug interference
3. Inadequate utilization secondary to chronic gastrointestinal disturbances
4. Increased iron requirement for growth of blood volume, which occurs during infancy, adolescence, pregnancy, and lactation
5. Increased excretion because of excessive menstrual blood (in females); hemorrhage from injury; or chronic blood loss from a bleeding ulcer, bleeding hemorrhoids, esophageal varices, regional enteritis, ulcerative colitis, parasitic or malignant disease
6. Defective release of iron from iron stores into the plasma and defective iron use caused by a chronic inflammation or other chronic disorder

With few exceptions, iron-deficiency anemia in adult men is the result of blood loss. Large losses of menstrual blood can cause iron deficiency in women, many of whom are unaware that their menses are unusually heavy.

Because anemia is the last manifestation of chronic, long-term iron deficiency, the symptoms reflect a malfunction of a variety of body systems. Inadequate muscle function is reflected in decreased work performance and exercise tolerance. Neurologic involvement is manifested by behavioral changes such as fatigue, anorexia, and pica, especially **pago-phagia** (ice eating). Abnormal cognitive development in children suggests iron deficiency before it has developed into overt anemia.

Growth abnormalities, epithelial disorders, and a reduction in gastric acidity are also common. A possible sign of early iron deficiency is reduced immunocompetence, particularly defects in cell-mediated immunity and the phagocytic activity of neutrophils, which may lead to frequent infections. **Restless legs syndrome (RLS)** with leg pain or discomfort may result from a lack of iron in the brain; this alters dopamine production and movement. Besides iron deficiency, kidney failure, Parkinson disease, diabetes, rheumatoid arthritis, or pregnancy can aggravate RLS (National Heart, Blood and Lung Institute, 2010).

As iron-deficiency anemia becomes more severe, defects arise in the structure and function of the epithelial tissues,

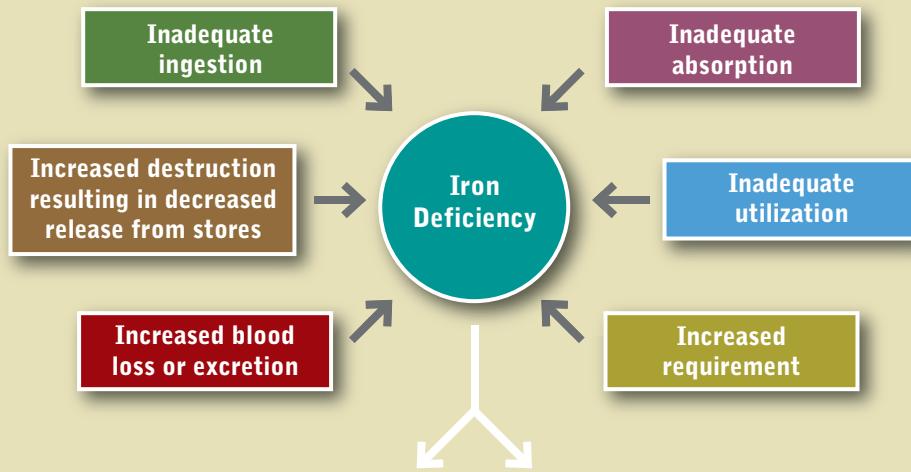

## PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

### Iron Deficiency Anemia

**Etiology**

**Pathophysiology**

**Management**

#### Stages of Deficiency

- Stage 1:** Moderate depletion of iron stores  
No dysfunction
- Stage 2:** Severe depletion of iron stores  
No dysfunction
- Stage 3:** Iron deficiency  
Dysfunction
- Stage 4:** Iron deficiency  
Dysfunction and anemia

#### Clinical Findings

- Early**
  - Inadequate muscle function
  - Growth abnormalities
  - Epithelial disorders
  - Reduced immunocompetence
  - Fatigue
- Late**
  - Defects in epithelial tissues
  - Gastritis
  - Cardiac failure

#### Medical Management

- Assess for and treat underlying disease
- Oral iron salts
- Oral iron, chelated with amino acids
- Oral sustained-release iron
- Iron-dextran by parenteral administration

#### Nutrition Management

- Increase absorbable iron in diet
- Include vitamin C at every meal
- Include meat, fish, or poultry at every meal
- Decrease tea and coffee consumption

especially of the tongue, nails, mouth, and stomach. The skin may appear pale, and the inside of the lower eyelid may be light pink instead of red. Mouth changes include atrophy of the lingual papillae, burning, redness, and in severe cases a completely smooth, waxy, and glistening appearance of the tongue (glossitis). Angular stomatitis may also occur, as may a form of dysphagia. Gastritis occurs frequently and may result in achlorhydria. Fingernails can become thin and flat,

and eventually **koilonychia** (spoon-shaped nails) may be noted (Figure 33-2).

Progressive, untreated anemia results in cardiovascular and respiratory changes that can eventually lead to cardiac failure. Some behavioral symptoms respond to iron therapy before the anemia is cured, suggesting they may be the result of tissue depletion of iron-containing enzymes rather than from a decreased level of hemoglobin.

	(IRON EXCESS)*		(IRON INSUFFICIENCY)			
	POSITIVE BALANCE	NORMAL	DEPLETION		DEFICIENCY	
Iron stores	EXCESS	Normal				
Circulating iron

Transferrin saturation (%)†	>60	>45	35 ± 15	30	30	<15
Sideroblasts (%)	40-60	40-60	40-60	40-60	40-60	<10
RBC protoporphyrin	30	30	30	30	30	100
Erythrocytes	Normal	Normal	Normal	Normal	Normal	Normal
Serum transferrin receptors	Normal	Normal	Normal	Normal-High	High	Very high
Ferritin-iron (haloferritin) (ng/ml)§	Very high	High	Normal	Normal-Low	Low	Very low
						Microcytic/hypochromic

\*Randall Lauffer of Harvard and Joe McCord of University of Colorado–Denver hold that *any* storage iron is excessive because of its potential to promote excessive free radical generation. (Herbert V et al: Most free radical injury is iron related, *Stem Cells* 12:289, 1994.)

†Inflammation reduces transferrin (and the plasma iron on it), because transferrin is a reverse acute-phase reactant.

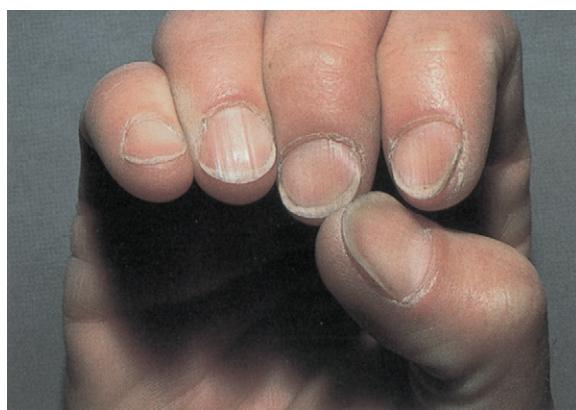

‡Inflammation produces elevated ferritin, because ferritin protein is an acute-phase reactant.

§Ferritin-iron is unaffected by inflammation, so it is reliable when ferritin, transferrin, and plasma iron are not.

Dallman (pediatrician) definition of negative balance: less absorbed than excreted.

Herbert (internist) definition of negative balance: less absorbed than needed.

**FIGURE 33-1** Sequential stages of iron status. *IBC*, Iron-binding capacity; *RBC*, red blood cell; *RE*, reticuloendothelial cells. (Copyright Victor Herbert, 1995.)

**FIGURE 33-2** Fingernails with cuplike depressions (koilonychia) are a sign of iron deficiency in adults. (From Callen JP et al: Color atlas of dermatology, Philadelphia, 1993, Saunders.)

## Diagnosis

A definitive diagnosis of iron-deficiency anemia requires more than one method of iron evaluation; **ferritin**, iron and transferrin are the most useful. The evaluation should also include an assessment of cell morphology. By itself, hemoglobin concentration is unsuitable as a diagnostic tool in cases of suspected iron-deficiency anemia for three reasons: (1) it is affected only late in the disease, (2) it cannot distinguish iron deficiency from other anemias, and (3) hemoglobin values in normal individuals vary widely.

After absorption, iron is transported by plasma **transferrin**—a  $\beta_1$ -globulin (protein) that binds iron derived from the gastrointestinal tract, iron storage sites, or hemoglobin breakdown—to the bone marrow (hemoglobin synthesis), endothelial cells (storage), or placenta (fetal needs). Transferrin molecules are generated on the surface of RBCs in response to the need for iron. With iron deficiency, so many **transferrin receptors** are on the cell surface looking for iron that some of them break off and float in the serum. Their presence is an early measurement of developing iron deficiency; a higher quantity of **soluble serum transferrin receptors (STFRs)** means greater deficiency of iron. Progressive stages of iron deficiency can be evaluated by measurements, as shown in Table 33-2.

**Protoporphyrin** is the iron-containing portion of the respiratory pigments that combines with protein to form hemoglobin or myoglobin. The zinc protoporphyrin (ZnPP)/heme ratio is measured to assess iron deficiency. However, this ZnPP/heme ratio and hemoglobin levels are affected by chronic infection and other factors that can

**TABLE 33-2**

### Biochemical Evaluation of Iron Deficiency

Measure	Comment
Quantity of serum or plasma ferritin	The most sensitive indicator of negative iron balance
Quantity of serum or plasma iron	
Quantity of total circulating transferrin	
Percent saturation of circulating transferrin	This measures the iron supply to the tissues. It is calculated by dividing serum iron by the TIBC; levels less than 16% are considered inadequate for erythropoiesis.
Percent saturation of ferritin with iron	
Quantity of STFR	STFR measures early iron deficiency.

STFR, Soluble serum transferrin receptor; TIBC, total iron-binding capacity.

produce a condition that mimics iron-deficiency anemia when, in fact, iron is adequate.

## Medical Management

Treatment of iron-deficiency anemia should focus primarily on the underlying cause, although this is often difficult to determine. The goal is repletion of iron stores.

**Oral Supplementation.** The chief treatment for iron-deficiency anemia involves oral administration of inorganic iron in the ferrous form. Although the body uses both ferric and ferrous iron, the reduced ferrous is easier on the gut and better absorbed. At a dose of 30 mg, absorption of ferrous iron is three times greater than if the same amount were given in the ferric form. Chelated forms of iron (combined with amino acids) are more bioavailable than nonchelated iron. Chelated iron is less affected by phytate, oxalate, phosphate, and calcium (all iron absorption inhibitors). Chelated iron causes less gastrointestinal disturbances than elemental iron because it is needed in lower doses when it is absorbed into mucosal cells (Ashmead, 2001).

Iron is best absorbed when the stomach is empty; however, under these conditions it tends to cause gastric irritation. Gastrointestinal side effects can include nausea, epigastric discomfort and distention, heartburn, diarrhea, or constipation. If these side effects occur, the patient is told to take the iron with meals instead of on an empty stomach; however, this sharply reduces the absorbability of the iron. Gastric irritation is a direct result of the high quantity of free ferrous iron in the stomach.

Health professionals usually prescribe oral iron for 3 months (three times daily) to treat iron deficiency. Depending on the severity of the anemia and the patient's tolerance, the daily dose of elemental iron should be 50 to 200 mg for adults and 6 mg/kg of body weight for children. Ascorbic acid greatly increases both iron absorption and gastric irritation through its capacity to maintain iron in the reduced state.

Absorption of 10 to 20 mg of iron per day permits RBC production to increase to approximately three times the normal rate and, in the absence of blood loss, hemoglobin concentration to rise at a rate of 0.2 g/dL daily. Increased **reticulocytosis** (an increase in the number of young RBCs) is seen within 2 to 3 days after iron administration, but affected persons may report subjective improvements in mood and appetite sooner. The hemoglobin level will begin to increase by day 4. Iron therapy should be continued for 4 to 5 months, even after restoration of normal hemoglobin levels, to allow for repletion of body iron reserves.

**Parenteral Iron-Dextran.** If iron supplementation fails to correct the anemia, (1) the patient may not be taking the medication as prescribed; (2) bleeding may be continuing at a rate faster than the erythroid marrow can replace blood cells; or (3) the supplemental iron is not being absorbed, possibly as a result of malabsorption secondary to steatorrhea, celiac disease, or hemodialysis. In these circumstances parenteral administration of iron in the form of iron-dextran may be necessary. Although replenishment of

iron stores by this route is faster, it is more expensive than, and not as safe as oral administration.

### Medical Nutrition Therapy

In addition to iron supplementation, attention should be given to the amount of absorbable dietary iron consumed. A good source of iron contains a substantial amount of iron in relation to its calorie content and contributes at least 10% of the recommended dietary allowance (RDA) for iron. Liver; kidney; beef; dried fruits; dried peas and beans; nuts; green leafy vegetables; and fortified whole-grain breads, muffins, cereals, and nutrition bars are among the foods that rank highest in iron content (see Appendix 54). It is estimated that 1.8 mg of iron must be absorbed daily to meet the needs of 80% to 90% of adult women and adolescent boys and girls.

**Bioavailability of Dietary Iron.** Because typical Western diets generally contain 6 mg/1000 kcal of iron, the bioavailability of iron in the diet is more important in correcting or preventing iron deficiency than the total amount of dietary iron consumed. The rate of absorption depends on the iron status of the individual, as reflected in the level of iron stores. The lower the iron stores, the greater the rate of iron absorption. Individuals with iron-deficiency anemia absorb approximately 20% to 30% of dietary iron compared with the 5% to 10% absorbed by those without iron deficiency.

**Form of Iron.** **Heme iron** (approximately 15% of which is absorbable) is the organic form in meat, fish, and poultry, and is known as the **meat-fish-poultry (MFP) factor**. It is much better absorbed than nonheme iron. **Nonheme iron** can be found in MFP, as well as in eggs, grains, vegetables, and fruits, but it is not part of the heme molecule. The absorption rate of nonheme iron varies between 3% and 8%, depending on the presence of dietary enhancing factors, specifically ascorbic acid and meat, fish, and poultry. Ascorbic acid is not only a powerful reducing agent, but it also binds iron to form a readily absorbed complex. The mechanism by which the MFP factor potentiates the absorption of nonheme iron in other foodstuffs is unknown.

**Inhibitors.** Iron absorption can be inhibited to varying degrees by factors that chelate iron, including carbonates, oxalates, phosphates, and phytates (unleavened bread, unrefined cereals, and soybeans). Factors in vegetable fiber may inhibit nonheme iron absorption. If taken with meals, tea and coffee can reduce iron absorption by 50% through the formation of insoluble iron compounds with tannin. Iron in egg yolk is poorly absorbed because of the presence of phosphitin.

## IRON OVERLOAD

Excess iron is stored as ferritin and hemosiderin in the macrophages of the liver, spleen, and bone marrow. The body has a limited capacity to excrete iron. Approximately 1 mg of iron is excreted daily through the gastrointestinal tract, urinary tract, and skin. To maintain a normal iron balance, the daily obligatory loss must be replaced by the

absorption of heme and nonheme food iron. Persons with iron overload excrete increased amounts of iron, especially in the feces, to compensate partially for the increased absorption and higher stores.

Excessive iron intake usually stems from accidental incorporation of iron into the diet from environmental sources. In developing countries the iron overload can result from eating foods cooked in cast-iron cooking vessels or contaminated by iron-containing soils. In developed countries it likely results from excessive intake of iron-supplemented foods or multivitamin and mineral supplementation.

Uncommon disorders associated with iron overload or toxicity include thalassemias, sideroblastic anemia, chronic hemolytic anemia, ineffective erythropoiesis, transfusional iron overload (secondary to multiple blood transfusions), porphyria cutanea tarda, aplastic anemia, and alcoholic cirrhosis. **Aplastic anemia** is a normochromic-normocytic anemia accompanied by a deficiency of all the formed elements in the blood; it can be caused by exposure to toxic chemicals, ionizing radiation, and medications, although the cause is often unknown.

Brain iron increases with age, is higher in men, and is abnormally elevated in neurodegenerative diseases, including Alzheimer disease and Parkinson disease (Bartzokis et al., 2010). Several gene variants affect iron metabolism and may contribute to early onset of these conditions.

### Hemochromatosis

**Hemochromatosis** is the most common form of iron overload that causes progressive hepatic, pancreatic, cardiac, and other organ damage. People with this condition absorb three times more iron from their food than those without hemochromatosis. This disease, associated with the HFE gene, is often underdiagnosed. Persons who have two affected genes (homozygotes) will die of iron overload unless they donate blood frequently. Otherwise, the excessive iron absorption continues unabated.

Asians and Pacific Islanders have the highest levels of iron in their blood of all racial and ethnic groups, but they have the lowest prevalence of the gene mutation found with the typical form of hemochromatosis (Adams et al., 2005). The Hemochromatosis and Iron Overload Screening Study notes that non-Hispanic whites have the highest prevalence of the C282Y mutation of the hereditary iron (HFE) gene, followed by Native Americans, Hispanics, blacks, Pacific Islanders, and Asians.

In women, monthly menses slow the associated organ damage until after menopause (Adams et al., 2005). Men are particularly susceptible to hemochromatosis because they have no physiologic mechanisms for losing iron such as menstruation, pregnancy, or lactation.

### Pathophysiology

**Hepcidin** is a peptide synthesized in the liver that functions as the principal regulator of systemic iron homeostasis. It regulates iron transport from iron-exporting tissues into plasma. Hepcidin deficiency underlies most known forms of

hereditary hemochromatosis (Nemeth and Ganz, 2006). Hepcidin inhibits the cellular efflux of iron by binding to and inducing the degradation of **ferroprotein**, the sole iron exporter in iron-transporting cells. Hepcidin controls plasma iron concentration and tissue distribution of iron by inhibiting intestinal iron absorption, iron recycling by macrophages, and iron mobilization from hepatic stores.

Hepcidin synthesis is increased by iron loading and decreased by anemia and hypoxia. Its synthesis is also greatly increased during inflammation, trapping iron in macrophages, decreasing plasma iron concentrations, and causing iron-restricted erythropoiesis that is characteristic of anemia of chronic disease. There is evidence that the mutation of the HFE gene leading to hemochromatosis is also associated with increased levels of gastrin in the stomach, leading to increased levels of gastric acid and thus increased absorption of iron (Smith et al., 2006).

In hemochromatosis iron absorption is enhanced, resulting in a gradual, progressive accumulation of iron. Most affected persons do not know they have it. In its early stages iron overload may result in symptoms similar to iron deficiency such as fatigue and weakness; later it can cause chronic abdominal pain, aching joints, impotence, and menstrual irregularities.

A progressive, positive iron balance may result in a variety of serious problems, including hepatomegaly, skin pigmentation, arthritis, heart disease, hypogonadism, diabetes mellitus, and cancer. Individuals with abnormally high iron levels are more likely to develop cancer of the colon. Iron is a prooxidant that can be used for tumor cell growth and proliferation. There also seems to be increased risk for age-related macular degeneration and Alzheimer disease because of the oxidant effect of iron overload (Connor and Lee, 2006; Dunaief, 2006).

## Assessment

If an iron overload is suspected, the following screening tests should be performed: serum ferritin level (storage iron), serum iron concentration, TIBC, and percent of transferrin saturation ( $[\text{serum iron}/\text{TIBC}] \times 100$ ). Iron overload may be present if the percent of transferrin saturation is greater than 50 in women and 60 in men, and if the serum iron level is greater than 180 mg/dL. Deoxyribonucleic acid (DNA) testing, using blood or cheek cell samples, is also available for early detection of hemochromatosis. Liver biopsy is the gold standard for the diagnosis of iron overload.

## Medical Management

The patient with iron overload may simultaneously be anemic as a result of damage to the bone marrow, an inflammatory disorder, cancer, internal bleeding, or chronic infection. Iron supplements should not be taken until the cause is known.

For patients with significant iron overload, weekly phlebotomy for 2 to 3 years may be required to eliminate all

excess iron. Treatment for iron overload may also involve iron depletion with intravenous desferrioxamine-B, a chelating agent that is excreted by the kidneys, or with calcium disodium ethylenediaminetetraacetic acid (EDTA). Mortality is preventable if excess body iron is removed by phlebotomy therapy before hepatic cirrhosis develops. Patients diagnosed as having hemochromatosis should inform all blood relatives so they can be evaluated.

## Medical Nutrition Therapy

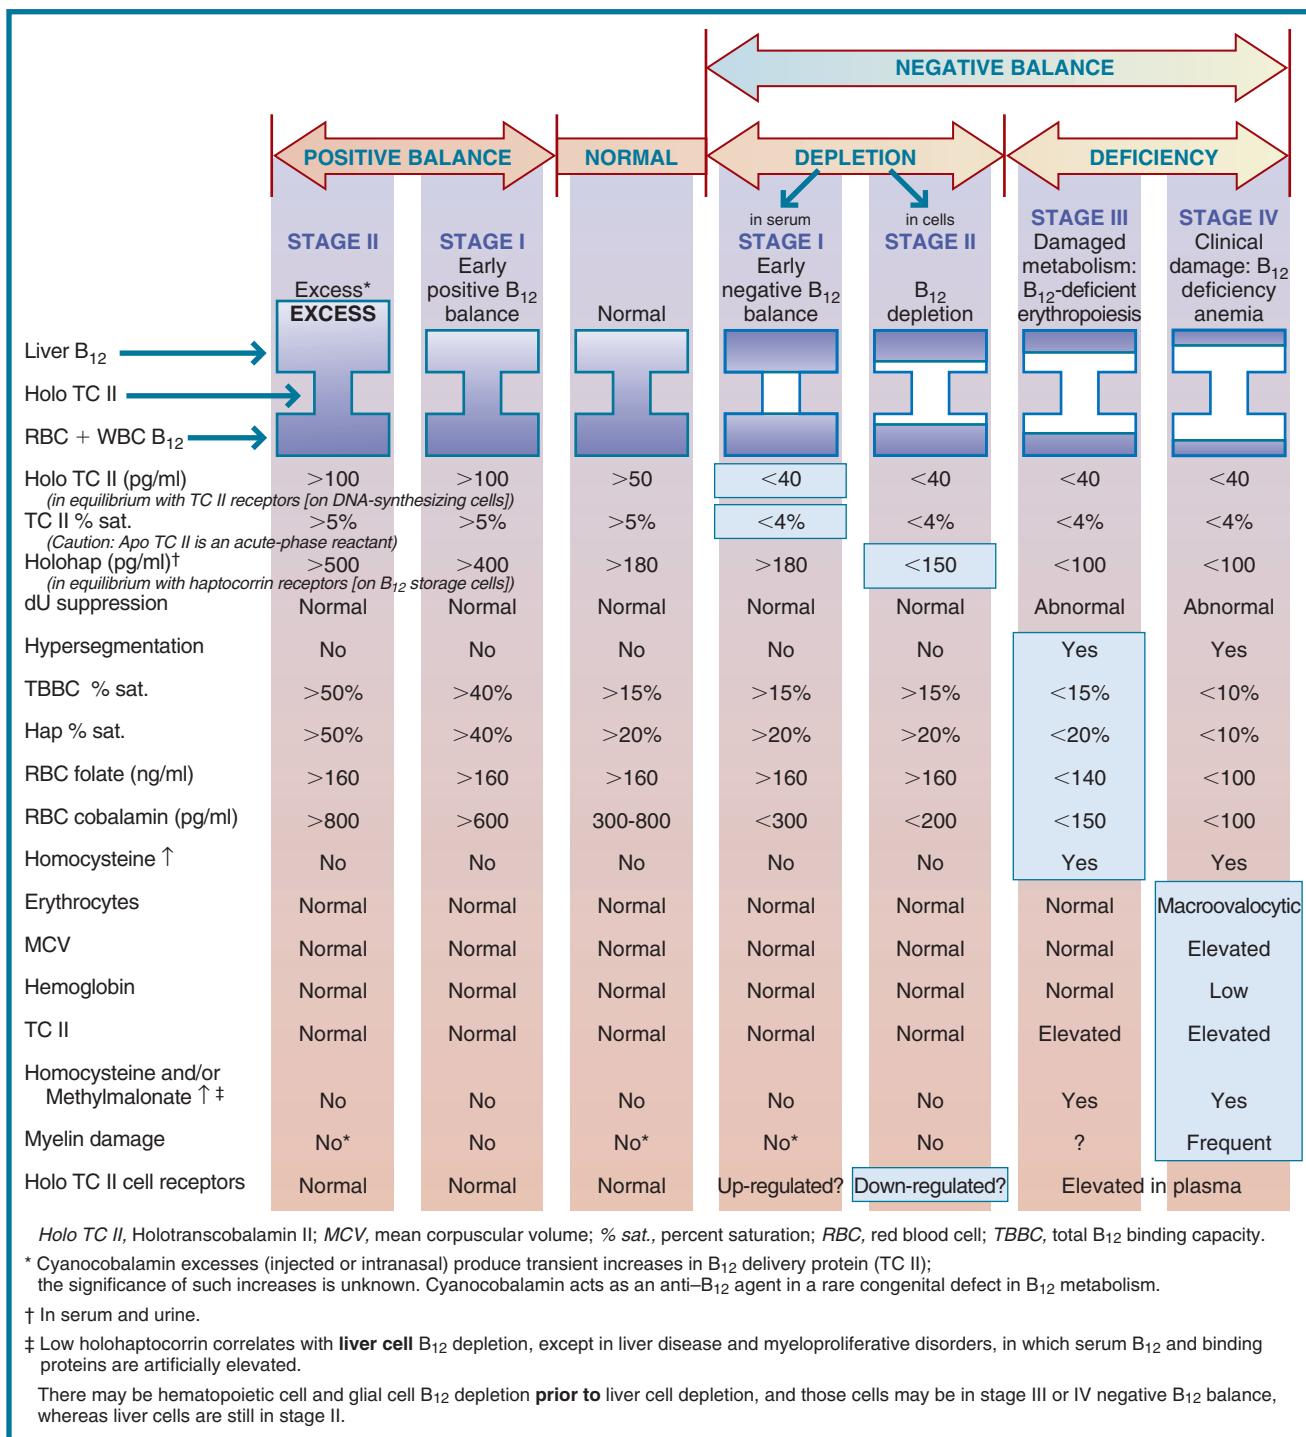

Individuals with iron overload should ingest less heme iron from meat, fish, and poultry compared with nonheme iron from plant foods. Persons with iron overload should also avoid alcohol and vitamin C supplements because both enhance iron absorption. In addition, vitamin C supplements may cause release of harmful free radical-generating excess iron from body stores.

Affected persons should avoid foods that are highly fortified with iron (i.e., many breakfast cereals, fortified “energy” or sports bars, and many meal-replacement drinks or shakes that are fortified with vitamins and minerals). They should also avoid iron supplements or multiple vitamin and mineral supplements that contain iron. The dietary requirement for iron should not be exceeded, and perhaps the intake of iron should be less in some persons. The dietary reference intakes (DRIs) for iron are summarized on the inside front cover. The RDA for women in their childbearing years is 18 mg; for pregnant women, 27 mg; and the RDA for adult men and women 51 years of age and older is 8 mg.

## MEGALOBLASTIC ANEMIAS

**Megaloblastic anemia** reflects a disturbed synthesis of DNA, which results in morphologic and functional changes in erythrocytes, leukocytes, platelets, and their precursors in the blood and bone marrow. This anemia is characterized by the presence of large, immature, abnormal, RBC progenitors in the bone marrow; 95% of cases are attributable to folic acid or vitamin B<sub>12</sub> deficiency. Two disorders of cobalamin metabolism arise from mutations of the methionine synthase and methionine synthase reductase genes; these disorders feature both megaloblastic anemia and neurologic manifestations.

Both vitamins are essential to the synthesis of nucleoproteins. Hematologic changes are the same for both; however, the folic acid deficiency is the first to appear. Normal body folate stores are depleted within 2 to 4 months in individuals consuming folate-deficient diets. By contrast, vitamin B<sub>12</sub> stores are depleted only after several years of a vitamin B<sub>12</sub>-deficient diet. In persons with vitamin B<sub>12</sub> deficiency, folic acid supplementation can mask B<sub>12</sub> deficiency (Figure 33-3). In correcting the anemia, the vitamin B<sub>12</sub> deficiency may remain undetected, leading to the irreversible neuropsychiatric damage that is only corrected with B<sub>12</sub> supplementation (see Chapters 3 and 8).

**FIGURE 33-3** Sequential stages of vitamin B<sub>12</sub> status. (From Herbert V: Staging vitamin B<sub>12</sub>. In Ziegler EE, Filer LJ, editors: Present knowledge in nutrition, ed 7, Washington, DC, 1996, International Life Sciences Institute Press.)

## Folic Acid Deficiency Anemia

### Etiology

Folic acid deficiency anemia is associated with tropical sprue, can affect pregnant women, and occurs in infants born to mothers with folic acid deficiency. Folic acid deficiency in early pregnancy can also result in an infant with a neural tube defect (see Chapter 16). Prolonged

inadequate diets, faulty absorption and use of folic acid, and increased requirements resulting from growth are believed to be the most frequent causes. Other causes include gluten-induced enteropathy (childhood and adult celiac disease), idiopathic steatorrhea, nontropical sprue and drugs (anti-convulsants, barbiturates, cycloserine, ethanol, sulfasalazine, cholestyramine and metformin), and amino acid excess (glycine and methionine).

Because alcohol interferes with the folate enterohepatic cycle, most alcoholics have a negative folate balance or a folate deficiency. Alcoholics constitute the only group that generally has all six causes of folic acid deficiency simultaneously: inadequate ingestion, absorption, and use with increased excretion, requirement, and destruction of folic acid. **Box 33-2** describes the causes of folate deficiency.

Folate absorption takes place in the small intestine. Enzyme conjugases (e.g., pteroylpolyglutamate hydrolase, the folate conjugase), found in the brush border of the small intestine, hydrolyze the polyglutamates to monoglutamates and reduce them to dihydrofolate and tetrahydrofolic acid (THFA) in the small intestinal epithelial cells (enterocytes). From the enterocytes these forms are transported to the circulation, where they are bound to protein and transported as methyl THFA into the cells of the body.

In the absence of vitamin B<sub>12</sub>, 5-methyl THFA, the major circulating and storage form of folic acid, is metabolically inactive. To be activated the 5-methyl group is removed, and THFA is cycled back into the folate pool, where it functions as the main 1-carbon-unit acceptor in mammalian biochemical reactions. THFA may then be converted to the coenzyme form of folate required to convert deoxyuridylate to thymidylate, which is necessary for DNA synthesis.

## BOX 33-2

### Causes of Folate Deficiency

#### Inadequate Ingestion

Poor diet (lack of or overcooked fruits and vegetables), vitamin B<sub>12</sub> or vitamin C deficiency, chronic alcoholism

#### Inadequate Absorption

Gluten-induced enteropathy or celiac disease, tropical sprue, drug interactions, congenital defects

#### Inadequate Utilization

Antagonists, anticonvulsants, enzyme deficiency, both vitamin B<sub>12</sub> and vitamin C deficiency, chronic alcoholism, excess glycine and methionine

#### Increased Requirement

Extra tissue demand, infancy, increased hematopoiesis, increased metabolic activity, Lesch-Nyhan syndrome, drugs

#### Increased Excretion

Vitamin B<sub>12</sub> deficiency, liver disease, kidney dialysis, chronic exfoliative dermatitis

#### Increased Destruction

Dietary oxidants

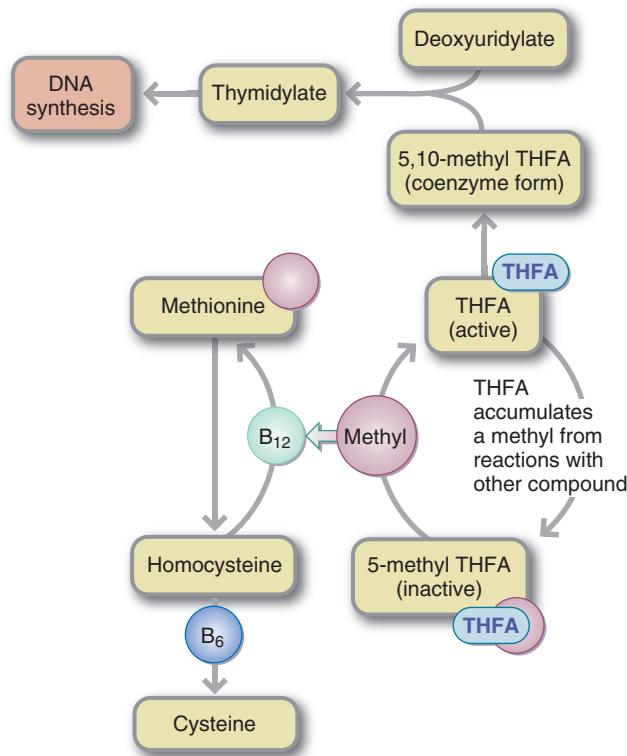

Modified from Herbert V, Das KC: Folic acid and vitamin B<sub>12</sub>. In Shils ME et al., editors: Modern nutrition in health and disease, ed 8, vol 1, Philadelphia, 1994, Lea & Febiger.

**MTHFR Allele.** A genetic defect found in 10% of whites is the methylenetetrahydrofolate reductase (MTHFR) deficiency. (See Chapters 5 and 8.) The allele is problematic in pregnancy, and may contribute to miscarriages, anencephaly, or neural defects. Because MTHFR irreversibly reduces 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate, its deficiency may result in developmental delay, motor and gait dysfunction, seizures, neurologic impairment, extremely high levels of homocysteine, clotting disorders, and other conditions.

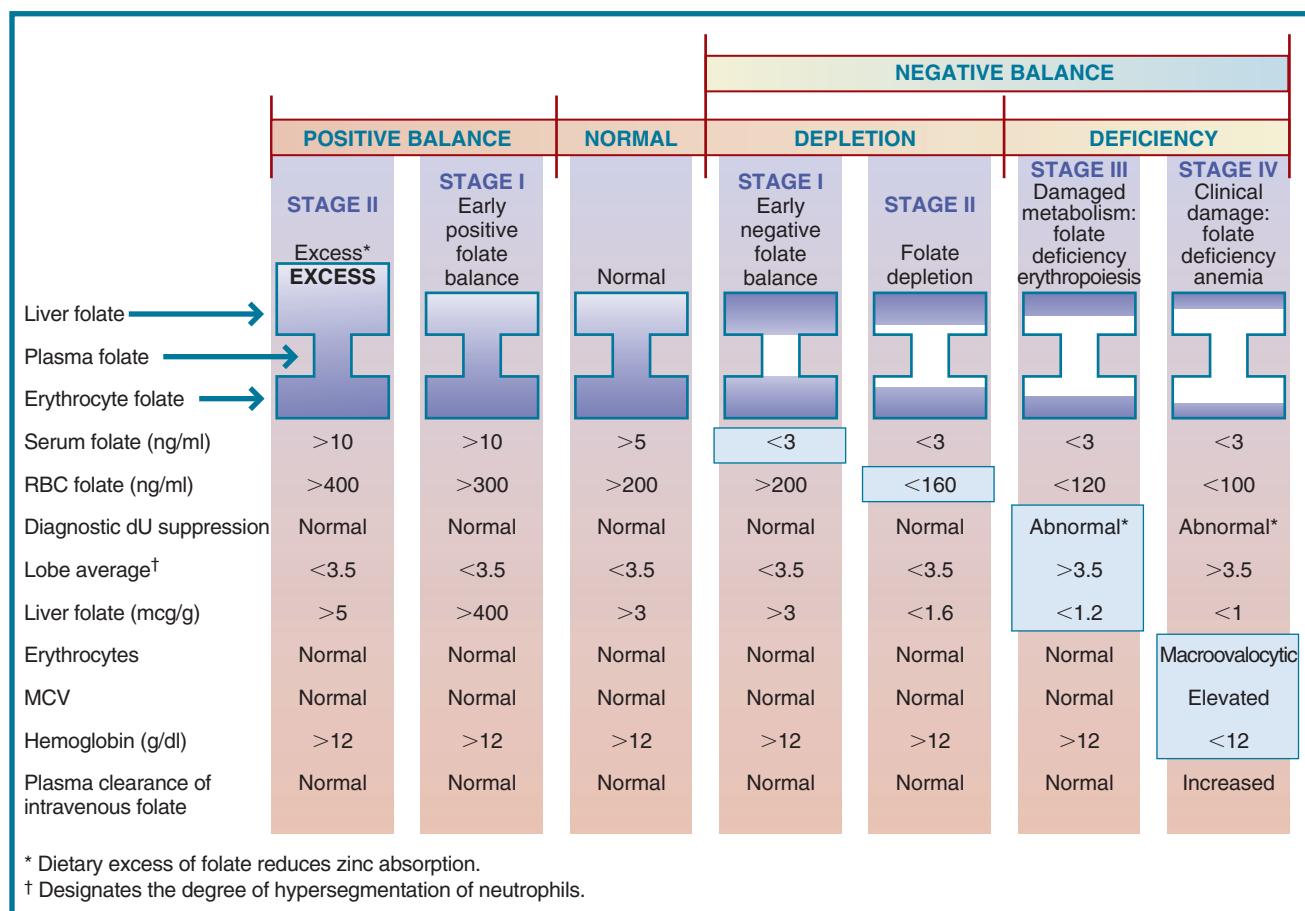

**Methylfolate Trap.** Vitamin B<sub>12</sub> deficiency can result in a folic acid deficiency by causing folate entrapment in the metabolically useless form of 5-methyl THFA (Figure 33-4). The lack of vitamin B<sub>12</sub> to remove the 5-methyl unit means that metabolically inactive methyl THFA is trapped. It cannot release its 1-carbon methyl group to become THFA, the basic 1-carbon carrier that picks up 1-carbon units from one molecule and delivers them to another. Hence a functional folic acid deficiency results.

#### Pathophysiology

Folate deficiency develops in four stages: two that involve depletion, followed by two marked by deficiency (Figure 33-5):

**FIGURE 33-4** Methylfolate trap. A deficiency of vitamin B<sub>12</sub> can result in a deficiency of folic acid because folate is trapped in the form of 5-methyltetrahydrofolate (5-methyl THFA), which cannot be converted to THFA and methyl groups donated by the vitamin B<sub>12</sub>-dependent pathway. *DNA*, Deoxyribonucleic acid.

**FIGURE 33-5** Sequential stages of folate status. *dU*, Deoxyuridine; *MCV*, mean corpuscular volume; *RBC*, red blood cell. (From Herbert V: Folic acid. In Shils ME, Olson JA, Shike M, editors: *Modern nutrition in health and disease*, ed 9, Philadelphia 1998, Lea & Febiger.)

Stage 1: Characterized by early negative folate balance (serum depletion to less than 3 ng/mL).

Stage 2: Characterized by negative folate balance (cell depletion), with a decrease in erythrocyte folate levels to less than 160 ng/mL.

Stage 3: Characterized by damaged folate metabolism, with folate-deficient erythropoiesis. This stage is characterized by slowed DNA synthesis, manifested by an abnormal diagnostic deoxyuridine (*dU*) suppression test correctable in vitro by folates, granulocyte nuclear hypersegmentation, and macroovalocytic red cells.

Stage 4: Characterized by clinical folate-deficiency anemia, with an elevated MCV and anemia.

Because of their interrelated roles in the synthesis of thymidylate in DNA formation, a deficiency of either vitamin  $B_{12}$  or folic acid results in a megaloblastic anemia. The immature nuclei do not mature properly in the deficient state; and large (macrocytic), immature (megaloblastic) RBCs are the result. The common clinical signs of folic acid

deficiency include fatigue, dyspnea, sore tongue, diarrhea, irritability, forgetfulness, anorexia, glossitis, and weight loss.

### Assessment

Normal body folate stores are depleted within 2 to 4 months on a folate-deficient diet, resulting in a macrocytic, megaloblastic anemia with a decreased number of erythrocytes, leukocytes, and platelets. Folate-deficiency anemia is manifested by very low serum folate (<3 ng/mL) and RBC folate levels of less than 140–160 ng/mL. Whereas a low serum folate level merely diagnoses a negative balance at the time the blood is drawn, an red cell folate (RCF) level measures actual body folate stores and thus is the superior measurement for determining folate nutriture. To differentiate folate deficiency from vitamin  $B_{12}$  deficiency, levels of serum folate, RCF, serum vitamin  $B_{12}$ , and vitamin  $B_{12}$  bound to transcobalamin II (TCII) can be measured simultaneously using a radioassay kit. Also diagnostic for folate deficiency is an elevated level of formiminoglutamic acid in the urine, as well as the *dU* suppression test in bone marrow cells or peripheral blood lymphocytes. See Chapter 8.

## Medical Management

Before treatment is initiated, it is important to diagnose the cause of the megaloblastosis correctly. Administration of folate will correct megaloblastosis from either folate or vitamin B<sub>12</sub> deficiency, but it can mask the neurologic damage of vitamin B<sub>12</sub> deficiency, allowing the nerve damage to progress to the point of irreversibility.

A dosage of 1 mg of folate taken orally every day for 2 to 3 weeks replenishes folate stores. Maintaining repleted stores requires an absolute minimum oral intake of 50 to 100 mcg of folic acid daily. When folate deficiency is complicated by alcoholism or other conditions that suppress hematopoiesis, increase folate requirements, or reduce folate absorption, therapy should remain at 500 to 1000 mcg daily. Symptomatic improvement, as evidenced by increased alertness, cooperation, and appetite, may be apparent within 24 to 48 hours, long before hematologic values revert to normal, a gradual process that takes approximately a month.

## Medical Nutrition Therapy

After the anemia is corrected, the patient should be instructed to eat at least one fresh, uncooked fruit or vegetable or to drink a glass of fruit juice daily. One cup of orange juice supplies approximately 135 mcg of folic acid (see Appendix 46 for a list of foods). Fresh, uncooked fruits and vegetables are good sources of folate because folate can easily be destroyed by heat. In 1998 the Food and Drug Administration required that grains be fortified with folic acid. The DRIs for folate are RDAs and are summarized on the inside front cover of this text. The RDA for adults is 400 mcg daily. The Dietary Guidelines for Americans recommend that women of childbearing age who may become pregnant and those in their first trimester of pregnancy consume adequate synthetic folic acid (600 mcg/day) from fortified foods and supplements in addition to consuming a variety of foods containing folate.

## Vitamin B<sub>12</sub> Deficiency and Pernicious Anemias

**Intrinsic factor (IF)** is a glycoprotein in the gastric juice that is necessary for the absorption of dietary vitamin B<sub>12</sub>. Secreted by parietal cells of the gastric mucosa, IF is necessary for the absorption of exogenous vitamin B<sub>12</sub>. Ingested vitamin B<sub>12</sub> is freed from protein by gastric acid and gastric and intestinal enzymes. The free vitamin B<sub>12</sub> attaches to salivary R-binder, which has a higher affinity for the vitamin than does IF. An acid pH (2.3) is needed, such as that found in the healthy stomach.

The release of pancreatic trypsin into the proximal small intestine destroys R-binder and releases vitamin B<sub>12</sub> from its complex with R-protein. With an alkaline pH (6.8) in the intestine, IF binds the vitamin B<sub>12</sub>. The vitamin B<sub>12</sub>-IF complex is then carried to the ileum. In the ileum, with the presence of ionic calcium (Ca<sup>2+</sup>) and a pH (>6), the complex attaches to the surface vitamin B<sub>12</sub>-IF receptors on the ileal

cell brush border. Here, the vitamin B<sub>12</sub> is released and attaches to **holotranscobalamin II (holo TCII)**. Holo TCII is vitamin B<sub>12</sub> attached to the β-globulin, the major circulating vitamin B<sub>12</sub> delivery protein. Like IF, holo TCII plays an active role in binding and transporting vitamin B<sub>12</sub>. The TCII-vitamin B<sub>12</sub> complex then enters the portal venous blood.

Other binding proteins in the blood include haptocorrin, also known as *transcobalamin I (TCI)* and *transcobalamin III (TCIII)*. These are α-globulins, larger macromolecular-weight glycoproteins that make up the R-binder component of the blood. Unlike IF, the R-proteins are capable of binding not only vitamin B<sub>12</sub> itself but also to many of its biologically inactive analogs. Although approximately 75% of the vitamin B<sub>12</sub> in human serum is bound to haptocorrin and roughly 25% is bound to TCII, only TCII is important in delivering vitamin B<sub>12</sub> to all the cells that need it. After transport through the bloodstream, TCII is recognized by receptors on cell surfaces. Patients with haptocorrin abnormalities have no symptoms of vitamin B<sub>12</sub> deficiency. Those lacking TCII rapidly develop megaloblastic anemia. Vitamin B<sub>12</sub> is excreted in urine.

## Pathophysiology

**Pernicious anemia** is a megaloblastic, macrocytic anemia caused by a deficiency of vitamin B<sub>12</sub>, most commonly from a lack of IF. Rarely, vitamin B<sub>12</sub> deficiency anemia occurs in strict vegetarians whose diet contains no vitamin B<sub>12</sub> except for traces found in plants contaminated by microorganisms capable of synthesizing vitamin B<sub>12</sub>. Other causes include antibody to IF in saliva or gastric juice; small intestinal disorders affecting the ileum such as celiac disease, idiopathic steatorrhea, tropical sprue, cancers involving the small intestine; drugs (paraaminosalicylic acid, colchicine, neomycin, metformin, antiretrovirals); and long-term ingestion of alcohol or calcium-chelating agents (Table 33-3).

## Stages of Deficiency

As a result of normal enterohepatic circulation (i.e., excretion of vitamin B<sub>12</sub> and analogs in bile and resorption of vitamin B<sub>12</sub> in the ileum), it generally takes decades for strict vegetarians who are not receiving vitamin B<sub>12</sub> supplementation to develop a vitamin B<sub>12</sub> deficiency. Serum B<sub>12</sub>, homocysteine, and methylmalonic acid levels are not as effective as predictors of B<sub>12</sub>-responsive neurologic disorders; patients with unexplained leukoencephalopathy should be treated proactively because even long-standing deficits may be reversible (Graber et al., 2010).

Stage 1: Early **negative vitamin B<sub>12</sub> balance** begins when vitamin B<sub>12</sub> intake is low or absorption is poor, depleting the primary delivery protein, TCII. A low TCII (<40 pg/mL) may be the earliest detectable sign of a vitamin B<sub>12</sub> deficiency (Serefhanoglu et al., 2008). This is a vitamin B<sub>12</sub> predeficiency stage.

**TABLE 33-3****Causes of Vitamin B<sub>12</sub> Deficiency**

Inadequate ingestion	Poor diet resulting from a vegan diet and lack of supplementation, chronic alcoholism, poverty
Inadequate absorption	Gastric disorders, small intestinal disorders, competition for absorption sites, pancreatic disease, HIV or AIDS
Inadequate utilization	Vitamin B <sub>12</sub> antagonists, congenital or acquired enzyme deficiency, abnormal binding proteins
Increased requirement	Hyperthyroidism, increased hematopoiesis
Increased excretion	Inadequate vitamin B <sub>12</sub> binding protein, liver disease, renal disease
Increased destruction	Pharmacologic doses of ascorbic acid by antioxidants

AIDS, Acquired immune deficiency syndrome; HIV, human immunodeficiency virus.

Stage 2: Vitamin B<sub>12</sub> depletion shows a low B<sub>12</sub> on TCII and a gradual lowering of B<sub>12</sub> in haptocorrin (holohap <150 pg/mL), the storage protein.

Stage 3: Damaged metabolism and vitamin B<sub>12</sub>-deficient erythropoiesis includes an abnormal dU suppression, hypersegmentation, a decreased TIBC and holohap percent saturation, a low RCF level (<140 ng/mL), and subtle neuropsychiatric damage (impaired short-term and recent memory).

Stage 4: Clinical damage occurs, including vitamin B<sub>12</sub> deficiency anemia; includes all preceding parameters, including macroovalocytic erythrocytes, elevated MCV, elevated TCII levels, increased homocysteine (see Chapter 34) and methylmalonic acid levels, and myelin damage. Leukoencephalopathy and autonomic dysfunction occur with very low serum B<sub>12</sub> levels (<200 pg/mL); psychiatric changes, neuropathy, and dementia may also occur (Graber et al., 2010).

### Clinical Findings

Pernicious anemia affects not only the blood but also the gastrointestinal tract and the peripheral and central nervous systems. This distinguishes it from folic acid deficiency anemia. The overt symptoms, which are caused by inadequate myelinization of the nerves, include paresthesia (especially numbness and tingling in the hands and feet), diminution of the senses of vibration and position, poor muscular coordination, poor memory, and hallucinations. If the deficiency is prolonged, the nervous system damage may be irreversible, even with initiation of vitamin B<sub>12</sub> treatment.

*Helicobacter pylori* causes peptic ulcer disease and chronic gastritis. Both conditions are associated with hypochlorhydria, reduced production of IF by epithelial cells in the stomach, vitamin B<sub>12</sub> malabsorption, and pernicious anemia. There is also a correlation between autoimmune gastritis and pernicious anemia. More than 90% of patients with pernicious anemia have parietal cell antibodies (PCAs) and 50% to 70% have elevated IF antibodies. Serum vitamin B<sub>12</sub> levels of the *H. pylori*-infected patients are significantly lower than that of uninfected patients (Sarari et al., 2008).

A study on *H. pylori* infection and autoimmune type atrophic gastritis examined serum markers for gastric atrophy (pepsinogen I, pepsinogen I/II, and gastrin) and autoimmunity. Positive serum autoimmune markers (IF antibodies and PCA) suggest that *H. pylori* contributes to autoimmune gastritis and pernicious anemia (Veijola et al., 2010).

Vitamin B<sub>12</sub> deficiency is an important modifiable risk factor for osteoporosis in both men and women. Adults with vitamin B<sub>12</sub> levels below 148 pg/mL have a lower average bone mineral density and greater risk for osteoporosis (Tucker and Mayer, 2005).

Reduced vitamin B<sub>12</sub> status and elevated homocysteine concentrations are common. These alterations are problematic among vegans (Elmadfa and Singer, 2009). B<sub>12</sub>-folate-homocysteine interactions aggravate heart disease and may lead to adverse pregnancy outcomes (Moreiras et al., 2009).

### Diagnosis

Vitamin B<sub>12</sub> stores are depleted after several years without vitamin B<sub>12</sub> intake. A low holo-TCII value (<40 pg/mL) is a sign of early B<sub>12</sub> deficiency. Radioassays measure more than one component within the same biologic medium. The Becton-Dickinson SimulTRAC Radioassay Kit measures the levels of serum vitamin B<sub>12</sub> and serum folate simultaneously in a single test tube.

Other laboratory tests that may be helpful in diagnosing a vitamin B<sub>12</sub> deficiency and determining its cause include measurements of unsaturated B<sub>12</sub> binding capacity, IF antibody (IFAB), the Schilling test, the dU suppression test, and tests to determine serum homocysteine and serum methionine levels (see Chapter 8). The IFAB and Schilling urinary excretion tests can determine whether the deficiency is caused by a lack of IF. The IFAB assay is performed on a patient's serum, whereas the Schilling test requires that the patient first swallow radioactive B<sub>12</sub> alone and then a second time with IF.

The vitamin B<sub>12</sub> assay is performed on the patient's urine after both steps of the Schilling test are completed. Patients with pernicious anemia excrete very little vitamin B<sub>12</sub> during the first step because little or no vitamin B<sub>12</sub> is absorbed. However, during the second step the urinary excretion

becomes almost normal because more vitamin B<sub>12</sub> is absorbed with the addition of the IF. Vitamin B<sub>12</sub> deficiency secondary to malabsorption syndrome is manifested by a decrease in urinary excretion of B<sub>12</sub> that remains unchanged with IF administration.

### Medical Management

Treatment usually consists of an intramuscular or subcutaneous injection of 100 mcg or more of vitamin B<sub>12</sub> once per week. After an initial response is elicited, the frequency of administration is reduced until remission can be maintained indefinitely with monthly injections of 100 mcg. Very large oral doses of vitamin B<sub>12</sub> (1000 mcg daily) are also effective, even in the absence of IF, because approximately 1% of vitamin B<sub>12</sub> will be absorbed by diffusion. Initial doses should be increased when vitamin B<sub>12</sub> deficiency is complicated by debilitating illness such as infection, hepatic disease, uremia, coma, severe disorientation, or marked neurologic damage. A response to treatment is evidenced by improved appetite, alertness, and cooperation, followed by improved hematologic results, as manifested by marked reticulocytosis within hours of an injection.

### Medical Nutrition Therapy

A high-protein diet (1.5 g/kg of body weight) is desirable both for liver function and for blood regeneration. Because green leafy vegetables contain both iron and folic acid, the diet should contain increased amounts of these foods. Meats (especially beef and pork), eggs, milk, and milk products are particularly rich in vitamin B<sub>12</sub> (see Appendix 46).

For those individuals prescribed metformin for treatment of diabetes, 10% to 30% have reduced vitamin B<sub>12</sub> absorption. Metformin negatively affects the calcium-dependent membrane and the B<sub>12</sub>-IF complex by decreasing the absorbability by the ileal cell surface receptors. Increased intake of calcium reverses the vitamin B<sub>12</sub> malabsorption (see Chapter 9).

The Dietary Guidelines for Americans recommend that people older than age 50 consume vitamin B<sub>12</sub> in its crystalline form (i.e., fortified cereals or supplements) to overcome the effects of atrophic gastritis. The DRIs for B<sub>12</sub> are RDAs and are summarized on the inside front cover. The RDA for adult men and women is 2.4 mcg daily.

## OTHER NUTRITIONAL ANEMIAS

### Anemia of Protein-Energy Malnutrition

Protein is essential for the proper production of hemoglobin and RBCs. Because of the reduction in cell mass and thus oxygen requirements in protein-energy malnutrition (PEM), fewer RBCs are required to oxygenate the tissue. Because blood volume remains the same, this reduced number of RBCs with a low hemoglobin level (**hypochromic**, normocytic anemia), which can mimic an iron-deficiency anemia, is actually a physiologic (nonharmful) rather than harmful anemia. In acute PEM, the loss of active tissue mass may be greater than the reduction in the number of RBCs, leading

to polycythemia. The body responds to this RBC production, which is not a reflection of protein and amino acid deficiency but of an oversupply of RBCs. Iron released from normal RBC destruction is not reused in RBC production but is stored, so that iron stores are often adequate. Iron-deficiency anemia can reappear with rehabilitation when RBC mass expands rapidly.

The anemia of PEM may be complicated by deficiencies of iron and other nutrients and by associated infections, parasitic infestation, and malabsorption. A diet lacking in protein is usually deficient in iron, folic acid, and, less frequently, vitamin B<sub>12</sub>. The nutrition counselor plays an important role in assessing recent and typical dietary intake of these nutrients.

### Copper-Deficiency Anemia

Copper and other heavy metals are essential for the proper formation of hemoglobin. Ceruloplasmin, a copper-containing protein, is required for normal mobilization of iron from its storage sites to the plasma. In a copper-deficient state, iron cannot be released; this leads to low serum iron and hemoglobin levels, even in the presence of normal iron stores. Other consequences of copper deficiency suggest that copper proteins are needed for use of iron by the developing erythrocyte and for optimal functions of the erythrocyte membrane (see Chapter 3). The amounts of copper needed for normal hemoglobin synthesis are so minute that they are usually amply supplied by an adequate diet; however, copper deficiency may occur in infants who are fed cow's milk or a copper-deficient infant formula. It may also be seen in children or adults who have a malabsorption syndrome or who are receiving long-term total parenteral nutrition that does not supply copper.

### Sideroblastic (Pyridoxine-Responsive) Anemia

**Sideroblastic anemia** is characterized by a derangement in the final pathway of heme synthesis, leading to a buildup of iron-containing immature RBCs. It has four primary characteristics: (1) microcytic and hypochromic RBCs; (2) high serum and tissue iron levels (causing increased transferrin saturation); (3) the presence of an inherited defect in the formation of δ-aminolevulinic acid synthetase, an enzyme involved in heme synthesis (pyridoxal-5-phosphate is necessary in this reaction); and (4) a buildup of iron-containing immature RBCs (sideroblasts, for which the anemia is named). The iron that cannot be used for heme synthesis is stored in the mitochondria of immature RBCs. These iron-laden mitochondria do not function normally, and the development and production of RBCs become ineffective. The symptoms are those of both anemia and iron overload. The neurologic and cutaneous manifestations of vitamin B<sub>6</sub> deficiency are not observed. The anemia responds to the administration of pharmacologic doses of pyridoxine and thus is referred to as **vitamin B<sub>6</sub> (pyridoxine)-responsive anemia**, to distinguish it from anemia caused by a dietary vitamin B<sub>6</sub> deficiency.

Treatment consists of a therapeutic trial dose of 50 to 200 mg daily of pyridoxine or pyridoxal phosphate, which

is 25 to 100 times the RDA. If the anemia responds to one or the other, pyridoxine therapy is continued for life. However, the anemia is only partially corrected; a normal hematocrit value is never regained. Patients respond to this treatment to varying degrees, and some may achieve near-normal hemoglobin levels.

Acquired sideroblastic anemias such as those attributable to drug therapy (isoniazid, chloramphenicol), copper deficiency, hypothermia, and alcoholism are not responsive to vitamin B<sub>6</sub> (pyridoxine) administration.

## Vitamin E-Responsive Hemolytic Anemia

**Hemolytic anemia** occurs when defects in RBC membranes lead to oxidative damage and eventually to cell lysis.

This anemia is caused by shortened survival of mature RBCs. Vitamin E, an antioxidant, is involved in protecting the membrane against oxidative damage, and one of the few signs noted in vitamin E deficiency is early hemolysis of RBCs (see Chapter 3). Vitamin E-responsive hemolytic anemia in neonates is discussed in Chapter 43.

# NONNUTRITIONAL ANEMIAS

## Anemia of Pregnancy

A physiologic anemia is the anemia of pregnancy, which is related to increased blood volume and usually resolves with the end of the pregnancy; however, demands for iron during pregnancy are also increased so that inadequate iron intake may also play a role (see Chapter 16 for further discussion).

## Anemia of Chronic Disease

Anemia of chronic disease occurs from inflammation, infection, or malignancy because there is decreased RBC production, possibly as a result of disordered iron metabolism. Ferritin levels are normal or increased, but serum iron levels and TIBC are low. It is important that this form of anemia, which is mild and normocytic, not be mistaken for iron-deficiency anemia; iron supplements should not be given. Recombinant erythropoietin therapy usually corrects this anemia. See Chapters 6 and 39.

## Sickle Cell Anemia

### Pathophysiology

**Sickle cell anemia (SCA)**, a chronic hemolytic anemia also known as *hemoglobin S disease*, affects 1 of 600 African Americans in the United States as a result of homozygous inheritance of hemoglobin S. This results in defective hemoglobin synthesis, which produces sickle-shaped RBCs that get caught in capillaries and do not carry oxygen well. The disease is usually diagnosed toward the end of the first year of life.

In addition to the usual symptoms of anemia, SCA is characterized by episodes of pain resulting from the

occlusion of small blood vessels by the abnormally shaped erythrocytes. The occlusions frequently occur in the abdomen, causing acute, severe abdominal pain. The hemolytic anemia and vasoocclusive disease result in impaired liver function, jaundice, gallstones, and deteriorating renal function. The constant hemolysis of erythrocytes increases iron stores in the liver; however, iron-deficiency anemia and SCA can coexist. Iron overload is less common and is usually a problem only in those who have received multiple blood transfusions.

Typically serum homocysteine levels are elevated, which may be due to low concentrations of vitamin B<sub>6</sub>. Children with SCA were found to have these lower vitamin B<sub>6</sub> levels despite B<sub>6</sub> intakes comparable to those of unaffected children.

### Medical Management

No specific treatment exists for SCA other than relieving pain during a crisis, keeping the body oxygenated, and possibly administering an exchange transfusion. It is important that SCA not be mistaken for iron-deficiency anemia, which can be treated with iron supplements, because iron stores in the patient with SCA secondary to transfusions are frequently excessive.

Zinc can increase the oxygen affinity of both normal and sickle-shaped erythrocytes. Thus zinc supplements may be beneficial in managing sickle cell disease, especially because decreased plasma zinc is common in children with the SS genotype sickle cell disease and is associated with decreased linear and skeletal growth, muscle mass, and sexual maturation. Zinc supplementation (as little as 10 mg daily) may also prevent the deficit in growth that appears in these children (Zemel et al., 2007). Because zinc competes with copper for binding sites on proteins, the use of high doses of zinc may precipitate copper deficiency.

### Medical Nutrition Therapy

Children with SCA and their families should receive instruction about how they can develop a well-balanced food plan providing enough calories and protein for growth and development. Their dietary intake may be low because of the abdominal pain characteristic of the disease. They also have increased metabolic rates, leading to a need for a higher caloric intake. This hypermetabolism is probably due to a constant inflammation and oxidative stress (Akohoue et al., 2007; Hibbert et al., 2005). Therefore their diets must be high enough in calories to meet these needs and must provide foods high in folate and the trace minerals zinc and copper (see Appendix 58 for sources of these minerals). In addition, they may be low in vitamins A, C, D, and E, folate, calcium and fiber. The diet should be high in folate (400 to 600 mcg daily) because the increased production of erythrocytes needed to replace the cells being continuously destroyed also increases folic acid requirements.

When assessing the nutrition status of patients with SCA, the questions related to the use of vitamin and mineral supplements, the consumption of alcohol (which increases iron absorption), and sources of protein (animal sources

being high in both zinc and iron) in the diet must be given special attention. A multivitamin and mineral supplement containing 50% to 150% of the RDA for folate, zinc, and copper (not iron) is recommended.

Dietary fluid and sodium intake influence the risk for vasoocclusive events in SCA; increasing fluid intake and limiting high-sodium foods should be discussed (Fowler et al., 2010). Intake of 2 to 3 quarts of water daily is recommended. Finally, it is important to remember that patients with sickle cell disease may require higher than RDA amounts of protein.

If it is necessary for the diet to be low in absorbable iron, the diet should emphasize vegetable proteins. Iron-rich foods, such as liver, iron-fortified formula, iron-fortified cereals, and iron-fortified energy bars are excluded. Substances such as alcohol and ascorbic acid supplements, both of which enhance iron absorption should be avoided. However, it is important to remember that iron deficiency may be present in some patients with SCA owing to repeated phlebotomies, excessive transfusions, or hematuria secondary to renal papillary necrosis. This should be assessed, and the diet adjusted appropriately.

### Hypochromic Microcytic Transient Anemia (Sports Anemia)

Increased RBC destruction, along with decreased hemoglobin, serum iron, and ferritin concentrations, may occur at the initiation and early stages of a vigorous training program. Once called *march hemoglobinuria*, this anemia was believed to arise in soldiers as a result of mechanical trauma incurred by erythrocytes (RBCs) during long marches. The RBCs in the capillaries are compressed every time the foot lands until they burst, releasing hemoglobin. It was thought that a similar situation existed in runners, especially long-distance runners; however, it is now thought that it is a physiologic anemia (i.e., a transient problem of blood volume and dilution) (see Chapter 24 for further discussion).

Athletes who have hemoglobin concentrations below those needed for optimal oxygen delivery may benefit from consuming nutrient and iron-rich foods; ensuring that their diets contain adequate protein; and avoiding tea, coffee, antacids, H<sub>2</sub>-blockers, and tetracycline, all of which inhibit iron absorption. No athlete should take iron supplements unless true iron deficiency is diagnosed based on a complete blood cell count with differential, serum ferritin level, serum iron level, TIBC, and percent saturation of iron-binding capacity. Athletes who are female, vegetarian, involved in endurance sports, or entering a growth spurt are at risk for iron-deficiency anemia and therefore should undergo periodic monitoring.

### Thalassemias

**Thalassemias** ( $\alpha$  and  $\beta$ ) are severe inherited anemias characterized by microcytic, hypochromic, and short-lived RBCs resulting from defective hemoglobin synthesis, which affects mostly persons in the Mediterranean region. The ineffective erythropoiesis leads to an increase in plasma volume, progressive splenomegaly, and bone marrow expansion with the

### CLINICAL SCENARIO

Dana is a 30-year-old mother of a 2-year-old and is now planning to become pregnant with her second child. Struggling to lose the last 10 pounds from her first pregnancy, her diet of choice over this past year has been a version of the low-carbohydrate diet. Dana's food intake lacks variety and balance. She is low on fruits, vegetables, and grains. She complains of diarrhea, loss of appetite, weakness, and irritability. Her blood work reveals a normal hemoglobin level but a low serum folate level. She has scheduled an appointment to see you.

#### Nutrition Diagnostic Statement

Inadequate B vitamin intake related to consumption of very low-carbohydrate diet as evidenced by low serum folate level.

#### Nutrition Care Questions

1. What are the risks of following a low-carbohydrate diet, especially before pregnancy?
2. What folate-containing, nutrient-dense foods could be included in her diet that would be beneficial to her pending pregnancy?
3. What supplements, if any, and in what amounts, would you recommend to Dana?
4. Which websites can you refer Dana to for her to learn more about the role of folate and neural tube defects?
5. What information do you need to gather before developing a plan for Dana? Of what would this plan consist?

result of facial deformities, osteomalacia, and bone changes. Ultimately there is increased iron absorption and progressive iron deposition in tissues, resulting in oxidative damage. The accumulation of iron causes dysfunction of the heart, liver, and endocrine glands. Because these patients require transfusions to stay alive, they must also have regular chelation therapy to prevent the damaging buildup of iron that can occur. Impaired growth in children accompanying thalassemia major can be partially corrected by increasing caloric intake.

# Medical Nutrition Therapy for Cardiovascular Disease

### KEY TERMS

3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA)  
angina  
angiography  
apolipoproteins  
atheroma  
atherogenesis  
atherosclerotic heart disease (ASHD)  
atherothrombosis  
bile acid sequestrant  
blood pressure  
cardiac cachexia  
cardiac catheterization  
cardiovascular disease (CVD)  
C-reactive protein (CRP)  
chylomicron  
coronary heart disease (CHD)  
diastolic blood pressure (DBP)  
Dietary Approaches to Stop Hypertension (DASH)  
dyslipidemia  
dyspnea  
edema  
essential hypertension  
familial combined hyperlipidemia (FCHL)  
familial dysbetalipoproteinemia  
familial hypercholesterolemia (FH)  
fatty streak  
foam cells

heart failure (HF)  
high-density lipoprotein (HDL)  
homocysteine  
hypercholesterolemia  
hypertension  
hypertriglyceridemia  
intermediate-density lipoprotein (ILD)  
ischemia  
left ventricular hypertrophy (LVH)  
lipoprotein  
low-density lipoprotein (LDL)  
metabolic syndrome  
myocardial infarction (MI)  
nitric oxide  
orthopnea  
plaque  
prehypertension  
renin-angiotensin system (RAS)  
secondary hypertension  
statins  
stroke  
syncope  
systolic blood pressure (SBP)  
Therapeutic Lifestyle Changes (TLC) Diet  
thrombus  
*Trans*-fatty acids  
very-low-density lipoprotein (VLDL)  
xanthoma

Sections of this chapter were written by Debra Krummel, PhD, RD for the previous edition of this text.

**Cardiovascular disease (CVD)** is a group of interrelated diseases that include coronary heart disease (CHD), atherosclerosis, hypertension, ischemic heart disease, peripheral vascular disease, and heart failure (HF). These diseases are interrelated and often coexist. An estimated 81,100,000 adult Americans (one in three) have one or more types of CVD (Box 34-1).

CVD remains the number one killer of both men and women in the United States; one of every 2.9 deaths is attributed to CVD. In 2010 it is estimated that 1.26 million Americans had a new or recurrent coronary attack. Every 25 seconds an American suffers a coronary event and about every minute someone will die from one (American Heart Association [AHA], 2010). The lifetime risk for CVD in American men is two in three and for women is one in two (AHA, 2010).

Of all causes of death, CHD, cancer, and stroke are the leaders (AHA, 2010). **Coronary heart disease (CHD)** involves the narrowing of small vessels that oxygenate the heart muscle. **Myocardial infarction (MI)**, or **ischemia**, in one or more of the coronary arteries with tissue damage, is the main form of heart disease responsible for CVD deaths. Heart disease and stroke cause the most deaths in both sexes of all ethnic groups, increasing with age. Until the age of 65 years, black men have the highest rates of CHD deaths; thereafter white men have the highest rates. Black women have higher rates than white women at all ages. Among whites older than age 18, 12.1% have CVD. In the same age group 10.2% of African Americans have heart disease and in Hispanics the incidence is 8.1%. The incidence in adult Native Americans is 12.1%, in Native Hawaiians or other Pacific Islanders it is 19.7 %, and in Asians it is 5.2%. This chapter discusses the incidence, pathophysiologic findings, prevention, and treatment of each of the CVDS.

## ATHEROSCLEROSIS AND CORONARY HEART DISEASE

**Atherogenesis** is the process leading to development of atherosclerosis. It is a chronic, local, inflammatory response to risk factors, such as high levels of low-density lipoprotein

### BOX 34-1

#### Types and Incidence of Cardiovascular Disease in the United States

Hypertension: 74,500,000  
 Coronary heart disease: 17,600,000  
 Myocardial infarction: 8,500,000  
 Angina pectoris: 10,200,000  
 Heart failure: 5,800,000  
 Stroke: 6,400,000

Because of comorbidities, it is not possible to add these numbers together to reach a total (AHA, 2010).

(LDL) cholesterol, that are injurious to the arterial wall (Badimon et al., 2006; Heinecke, 2006 et al.). Hence lesion formation, progression, and eventual **plaque** rupture result from the release of inflammatory cytokines. Proinflammatory (e.g., tumor necrosis factor-alpha [TNF- $\alpha$ ], interleukin [IL]-6, and C-reactive protein [CRP]) and antiinflammatory cytokines (e.g., IL-9, IL-10) are the key proteins that must be balanced to prevent plaque rupture and subsequent clinical events (Tegui and Mallat, 2006).

### Pathophysiology

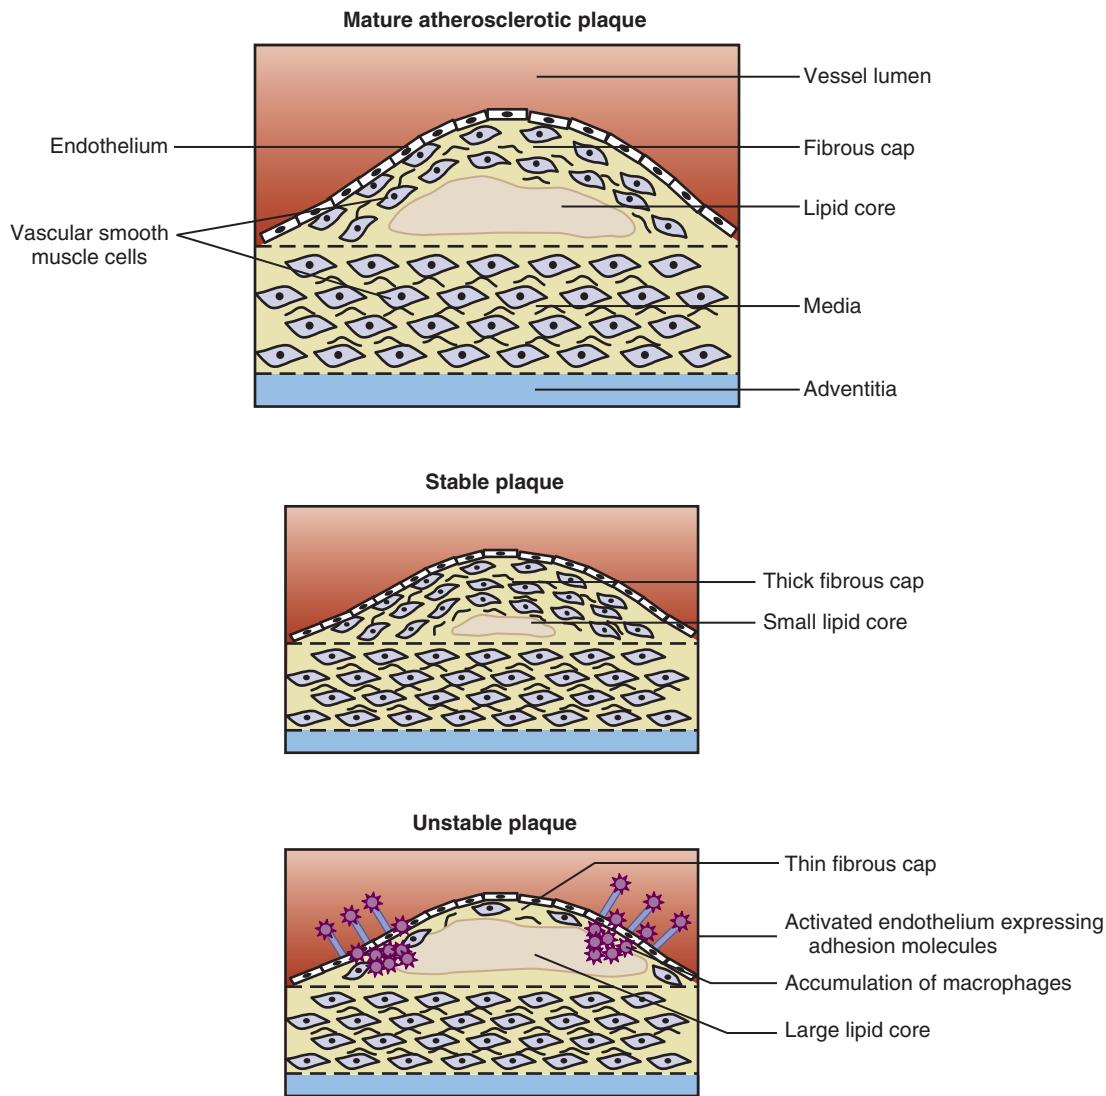

**Atherosclerotic heart disease (ASHD)** involves narrowing and loss of elasticity in the blood vessel wall caused by accumulation of plaque. Plaque forms when inflammation stimulates a response by phagocytic white blood cells (monocytes). Once in the tissue, monocytes evolve into macrophages that ingest oxidized cholesterol, and become **foam cells** and then **fatty streaks** in these vessels. Intracellular microcalcification occurs, forming deposits within the vascular smooth muscle cells of the surrounding muscular layer (Figure 34-1).

A protective fibrin layer (**atheroma**) forms between the fatty deposits and the artery lining. Atheromas produce enzymes that cause the artery to enlarge over time, thus compensating for the narrowing caused by the plaque. This “remodeling” of the shape and size of the blood vessel may result in an aneurysm. Atheromas can rupture or break off, forming a **thrombus**, where they attract blood platelets and activate the clotting system in the body. This response can result in a blockage and restricted blood flow.

Only high-risk or vulnerable plaque forms thrombi. Vulnerable plaque are lesions with a thin fibrous cap, few smooth muscle cells, many macrophages (inflammatory cells), and a large lipid core (Figure 34-2). Arterial changes begin in infancy and progress asymptotically throughout adulthood if the person has risk factors, is susceptible to arterial thrombosis, or has a genetic susceptibility (Naghavi et al., 2006) (Figure 34-3). Consequently, atherosclerosis is a “silent” disease because many individuals are asymptomatic until the first, often fatal, MI.

The clinical outcome of impaired arterial function arising from atherosclerosis depends on the location of the impairment. In the coronary arteries atherosclerosis causes **angina** or chest pain, MI, and sudden death; in the cerebral arteries it causes **strokes** and transient ischemic attacks; and in the peripheral circulation it causes intermittent claudication, limb ischemia, and gangrene (Figure 34-4). Thus atherosclerosis is the underlying cause of many forms of CVD.

Cholesterol is delivered into cell walls by **low-density lipoprotein (LDL)**, especially smaller particles. To attract and stimulate the macrophages, the cholesterol must be released from the LDL particles and oxidized, a key step in the ongoing inflammatory process. Additionally, macrophages must move excess cholesterol quickly into **high-density lipoprotein (HDL)** particles to avoid becoming foam cells and dying. **Dyslipidemia** refers to a blood lipid profile that increases the risk of developing atherosclerosis.

**FIGURE 34-1** The structure of mature, stable, and unstable plaque. (From Rudd JHF et al: Imaging of atherosclerosis—can we predict plaque rupture? *Trends Cardiovasc Med* 15:17, 2005.)

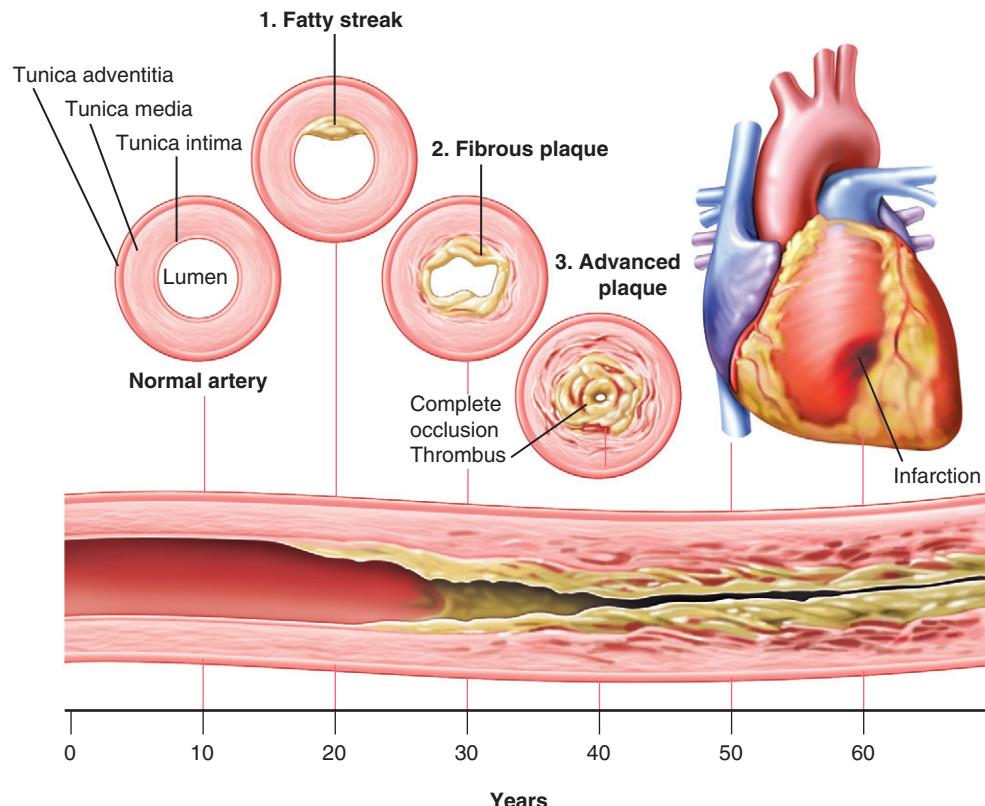

Typically it is a condition in which LDL levels are elevated and HDL levels are low. Three important biochemical measurements in CVD include lipoproteins, total cholesterol, and triglycerides.

### Lipoproteins

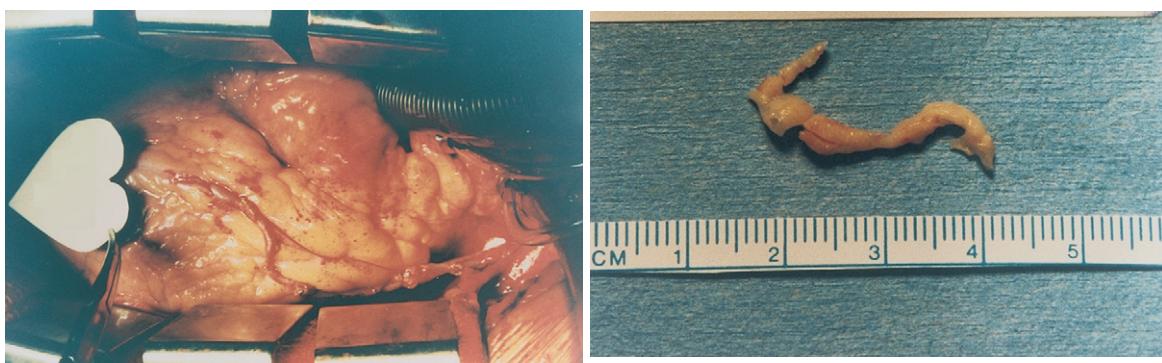

Because lipid is not water soluble, it is carried in the blood bound to protein. These complex particles, called **lipoproteins**, vary in composition, size, and density. Lipoproteins measured in clinical practice—chylomicrons, very-low-density lipoprotein (VLDL), low-density lipoproteins (LDL), and high-density lipoproteins (HDL)—consist of varying amounts of triglyceride, cholesterol, phospholipid, and protein. Each class of lipoprotein actually represents a continuum of particles. The ratio of protein to fat determines the density; thus particles with higher levels of protein are the most dense (e.g., HDLs have more protein than LDLs). The physiologic role of lipoprotein includes

transporting lipid to cells for energy, storage, or use as substrate for synthesis of other compounds such as prostaglandins, thromboxanes, and leukotrienes.

The largest particles, **chylomicrons**, transport dietary fat and cholesterol from the small intestine to the liver and periphery. Once in the bloodstream, the triglycerides within the chylomicrons are hydrolyzed by lipoprotein lipase (LPL), located on the endothelial cell surface in muscle and adipose tissue. **Apolipoproteins** carry lipids in the blood and also control the metabolism of the lipoprotein molecule. Apo C-II, one of the apolipoproteins, is a cofactor for LPL. When approximately 90% of the triglyceride is hydrolyzed, the particle is released back into the blood as a remnant. The liver metabolizes these chylomicron remnants, but some deliver cholesterol to the arterial wall and thus are considered atherogenic. Consumption of high-fat meals produces more chylomicrons and remnants. When fasting plasma studies are done, chylomicrons are normally absent.

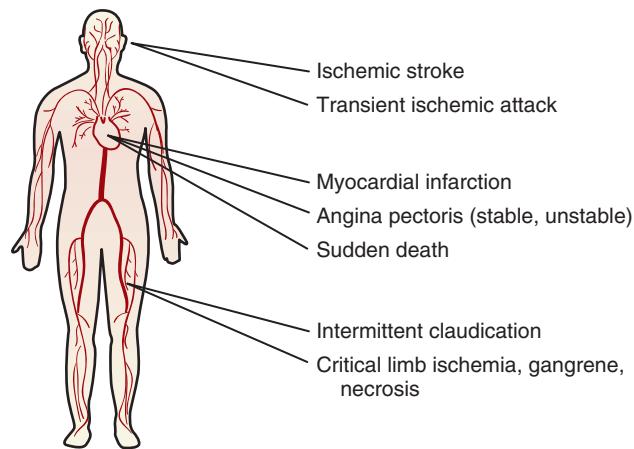

**FIGURE 34-2** Natural progression of atherosclerosis. (From Harkreader H: *Fundamentals of nursing: caring and clinical judgment*, Philadelphia, 2007, Saunders.)

**FIGURE 34-3** Plaque that can be surgically removed from the coronary artery. (Photographs courtesy Ronald D. Gregory and John Riley, MD.)

**Very-low-density lipoprotein (VLDL)** particles are synthesized in the liver to transport endogenous triglyceride and cholesterol. Triglyceride accounts for 60% of the VLDL particle. The large, buoyant VLDL particle is believed to be nonatherogenic. Vegetarian and low-fat diets increase the formation of large VLDL particles. Smaller VLDL particles (i.e., remnants) are formed from triglyceride hydrolysis by LPL. Normally these remnants, called

**intermediate-density lipoproteins (IDLs)**, are atherogenic and are taken up by receptors on the liver or converted to LDLs. In **metabolic syndrome**, the remnants are atherogenic (Olufadi and Byrne, 2006). Some of the smaller LDL particles stay in the blood, are oxidized, and are then taken into the arterial wall. Clinically, a total triglyceride level is a measurement of the triglycerides carried on both the VLDL and the IDL remnants.

**FIGURE 34-4** Major clinical manifestations of atherothrombotic disease. (From Viles-Gonzalez JF et al: Atherothrombosis: a widespread disease with unpredictable and life-threatening consequences, *Eur Heart J* 25:1197, 2004.)

LDL is the primary cholesterol carrier in blood, formed by the breakdown of VLDL. After LDL formation, 60% is taken up by LDL receptors on the liver, adrenals, and other tissues. The remainder is metabolized via nonreceptor pathways. Both the number and activity of these LDL receptors are major determinants of LDL cholesterol levels in the blood. Apo B-100 (apo B) constitutes 95% of the apolipoproteins in LDL. Persons with a high triglyceride level usually have high apo B levels, giving these particles a longer time to deposit lipid in the arterial wall (Marcovina and Packard, 2006). High LDL cholesterol is specifically associated with atherosclerosis.

HDL particles contain more protein than any of the other lipoproteins, which accounts for their metabolic role as a reservoir of the apolipoproteins that direct lipid metabolism. Apo A-I, the main apolipoprotein in HDL, is an antiinflammatory, antioxidant protein that also helps to remove cholesterol from the arterial wall to the liver (Barter and Rye, 2006). Numerous groups promote evaluation of apo A-I or the ratio of apo B to apo A-I to determine risk and treatment (Marcovina and Packard, 2006; Walldius and Jungner, 2006). The lower the ratio, the lower the CHD risk. Both apo C and apo E on HDL are transferred to chylomicrons. Apo E helps receptors metabolize chylomicron remnants and also inhibits appetite (Gotoh et al., 2006). Therefore high HDL levels are associated with low levels of chylomicrons; VLDL remnants; and small, dense LDLs. Subsequently, high HDL implies lower atherosclerotic risk, except in patients with **familial hypercholesterolemia (FH)** who can have a triglyceride-enriched HDL<sub>3</sub> fraction that is proatherogenic (Ottestad et al., 2006).

### Total Cholesterol

A total cholesterol measurement captures cholesterol contained in all lipoprotein fractions: 60% to 70% is carried on LDL, 20% to 30% on HDL, and 10% to 15% on VLDL.

Studies have consistently shown that a high serum cholesterol level (specifically high LDL cholesterol) is one of the key causes of CHD, stroke, and mortality.

### Triglycerides

The triglyceride-rich lipoproteins include chylomicrons, VLDLs, and any remnants or intermediary products formed in metabolism. Of these triglyceride-rich lipoproteins, chylomicrons and VLDL remnants are known to be atherosgenic because they activate platelets, the coagulation cascade, and clot formation (Olufadi and Byrne, 2006). All contain the apo B lipoprotein. Fasting triglyceride levels are classified as normal (<150 mg/dL), borderline high (150 to 199 mg/dL), high (200 to 499 mg/dL), and very high (<500 mg/dL) (National Cholesterol Education Program [NCEP], 2002).

Patients with familial dyslipidemias have high triglyceride levels (**hypertriglyceridemia**). Triglycerides in the very high range place the patient at risk for pancreatitis. These patients usually have hyperchylomicronemia and require diets very low in fat (i.e., 10% to 15% of calories derived from fat) and medications. Triglyceride measurements are now considered along with glucose intolerance, hypertension, low HDL cholesterol, and high LDL cholesterol as part of the metabolic syndrome.

## GENETIC HYPERLIPIDEMIAS

The study and identification of the genes responsible for the familial forms of hyperlipidemia have provided insight into the roles of enzymes, apolipoproteins, and receptors on cells involved in lipid metabolism. Several forms of hyperlipidemia have strong genetic components and are described here.

### Familial Hypercholesterolemia

FH (type IIa hyperlipidemia) is a monogenetic disorder that is seen around the world, with an estimated 10,000,000 people being affected. It is major risk factor for CHD; 85% of men and 50% of women with FH will have a coronary event before the age of 65 years unless the **hypercholesterolemia** is successfully treated (Civeira, 2004). Defects in the LDL receptor gene cause FH; 800 mutations have been identified and screening is possible (Lombardi et al., 2006). Early detection is critical. Treatment with statin drugs improves arterial function and structure (Masoura, 2011). Ultrasound of the Achilles tendon for **xanthomas** (cholesterol deposits from LDL) correctly identifies the majority of FH patients.

### Polygenic Familial Hypercholesterolemia

Polygenic FH is the result of multiple gene defects. The apo E-4 allele is common in this form. The diagnosis is based on two or more family members having LDL cholesterol levels above the 90th percentile without any tendon xanthomas. Usually these patients have lower LDL cholesterol levels than patients with the nonpolygenic form, but they

remain at high risk for premature disease. The treatment is lifestyle change in conjunction with cholesterol-lowering drugs.

### Familial Combined Hyperlipidemia

**Familial combined hyperlipidemia (FCHL)** is a disorder in which two or more family members have serum LDL cholesterol or triglyceride levels above the 90th percentile. Several lipoprotein patterns may be seen in patients with FCHL. These patients can have (1) elevated LDL levels with normal triglyceride levels (type IIa), (2) elevated LDL levels with elevated triglyceride levels (type IIb), or (3) elevated VLDL levels (type IV). Often these patients have the small, dense LDL associated with CHD. Consequently all forms of FCHL cause premature disease; approximately 15% of patients who have an MI before the age of 60 have FCHL. The defect in FCHL is hepatic overproduction of apo B-100 (VLDL) or a defect in the gene that produces hepatic lipase, the liver enzyme involved in triglyceride removal from the bloodstream. Patients with FCHL usually have other risk factors such as obesity, hypertension, diabetes, or metabolic syndrome. If lifestyle measures are ineffective, treatment includes medication. Patients with elevated triglyceride levels also need to avoid alcohol.

### Familial Dysbetalipoproteinemia

**Familial dysbetalipoproteinemia** (type III hyperlipoproteinemia) is relatively uncommon. Catabolism of VLDL and chylomicron remnants is delayed because apo E-2 replaces apo E-3 and apo E-4. For dysbetalipoproteinemia to be seen, other risk factors such as older age, hypothyroidism, obesity, diabetes, or other dyslipidemias such as FCHL must be present. Total cholesterol levels range from 300 to 600 mg/dL, and triglyceride levels range from 400 to 800 mg/dL. This condition creates increased risk of premature CHD and peripheral vascular disease. Diagnosis is based on determining the isoforms of apo E. Treatment involves weight reduction, control of hyperglycemia and diabetes, and dietary restriction of saturated fat and cholesterol. If the dietary regimen is not effective, drug therapy is recommended.

### Medical Diagnosis

Noninvasive tests such as electrocardiograms, treadmill stress tests, thallium scans, and echocardiography are used initially to establish a cardiovascular diagnosis. A more definitive, invasive test is **angiography (cardiac catheterization)**, in which a dye is injected into the arteries and radiographic images of the heart are obtained. Most narrowing and blockages from atherosclerosis are readily apparent on angiograms; however, neither smaller lesions nor lesions that have undergone remodeling are visible.

Magnetic resonance imaging scans show the smaller lesions and can be used to follow atherosclerosis progression or regression following treatments. To predict MI or stroke, measuring the intimal thickness of the carotid artery may be used. Intracoronary thermography helps to determine the presence of vulnerable plaque.

Finally, the calcium in atherosclerotic lesions can be assessed. Electron beam computed tomography can measure calcium in the coronary arteries; persons with a positive scan are far more likely to have a future coronary event than those with a negative scan. Despite these findings, atherosclerosis imaging in asymptomatic individuals is a controversial public health topic because of the costs associated with screening (O'Malley, 2006; Raggi, 2006).

Approximately two thirds of cases of acute coronary syndromes (unstable angina and acute MI) happen in arteries that are minimally or mildly obstructed. This illustrates the role of thrombosis in clinical events. In the ischemia of an infarction, the myocardium or other tissue is deprived of oxygen and nourishment. Whether the heart is able to continue beating depends on the extent of the musculature involved, the presence of collateral circulation, and the oxygen requirement.

### Prevention and Management of Risk Factors

The identification of risk factors for atherosclerosis, CHD, and stroke has been a landmark achievement. The primary prevention of these disorders involves the assessment and management of the risk factors in the asymptomatic person. Persons with multiple risk factors are the target population, especially those with modifiable factors (Box 34-2).

Risk factor reduction has been shown to reduce CHD in persons of all ages. Approximately one quarter of the decline in CHD is attributable to improved treatment; more than half is from the reduction in risk factors. Many coronary events could be prevented with adoption of a healthy lifestyle (eating a heart-healthy diet, exercising regularly, managing weight, and not using tobacco) and adherence to lipid and hypertension drug therapy (Chiuve et al., 2006). The Framingham Study, conducted over several decades, has given much useful information to researchers (see *Focus On: Framingham Heart Study*). An algorithm also used to screen for risk factors is shown in Figure 34-5.

In the medical model, primary prevention of CHD and stroke involves altering similar risk factors toward a healthy patient profile. For ischemic stroke, atherosclerosis is the underlying disease. Therefore optimal lipid levels, as determined by the National Cholesterol Education Program (NCEP) for hypercholesterolemia, are also the target levels to prevent stroke. Guidelines for cholesterol management were released as the *Third Report of the Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel or ATP III)*. In the past the recommended dietary approach was a Step I and Step II diet, but this has been replaced by the **Therapeutic Lifestyle Changes (TLC) Diet**. Updates of the NCEP guidelines are due by the fall of 2011.

Although the National Heart, Lung and Blood Institute created the NCEP, the American Heart Association (AHA) has endorsed it. AHA suggests that primary prevention of CHD should begin in children older than age 2 (Gidding et al., 2009). Dietary recommendations for children are a bit more liberal than those for adults. Activity is emphasized in maintaining ideal body weight. Early

## © FOCUS ON

### Framingham Heart Study

Since 1948 various leading investigators (Dr. Joseph Mountain, Dr. Thomas Dawber, Dr. William Kannel, and Dr. William Castelli) have been studying the population (28,000) of Framingham, Massachusetts, to determine the prevalence and incidence of cardiovascular disease and factors related to its development. This is the largest epidemiologic study of cardiovascular disease in the world. Initial study participants ( $n = 5209$ ) were healthy adults between 30 and 62 years of age. The study continues today, looking at the children and grandchildren of the original cohort. Through this cohort study, the concept of risk factors and thus prevention was born. Modifiable risk factors not only predict disease in healthy adults but also contribute to the disease process in those who have atherosclerotic disease. The seven major risk factors identified by the Framingham study are age, sex, blood pressure, total and high-density lipoprotein cholesterol, smoking, glucose intolerance, and left-ventricular hypertrophy (Opie et al., 2006).

#### Milestones of the Framingham Study

- 1960 Cigarette smoking found to increase the risk of heart disease.
- 1961 Cholesterol level, blood pressure, and electrocardiogram abnormalities found to increase the risk of heart disease.
- 1967 Physical activity found to reduce the risk of heart disease, and obesity found to increase the risk of heart disease.
- 1970 High blood pressure found to increase the risk of stroke.

- 1976 Menopause found to increase the risk of heart disease.
- 1978 Psychosocial factors found to affect heart disease.
- 1988 High levels of high-density lipoprotein cholesterol found to reduce risk of death.
- 1994 Enlarged left ventricle (one of two lower chambers of the heart) found to increase the risk of stroke.
- 1996 Progression from hypertension to heart failure described.
- 2006 Genetic Research Study begins to identify genes underlying cardiovascular diseases in 9000 participants from three generations.
- 2008 Discovery and publication of four risk factors that raise probability of developing precursor of heart failure; new 30-year risk estimates developed for serious cardiac events.
- 2009 Researchers find parental dementia may be linked to poor memory in middle-aged adults.

In 1971 the offspring study was begun to measure the influence of heredity and environment on the offspring of the original cohort. The younger group appears to be more health conscious because they have lower rates of smoking, lower blood pressures, and lower cholesterol levels than their parents at the same age. The Generation III Cohort Study of the grandchildren is presently underway.

Data from <http://www.framingham.com/heart/timeline.htm>. Accessed March 19, 2011.

## BOX 34-2

### Cardiovascular Disease Risk Factors

#### Major Risk Factors

- Hypertension
- Age (older than 45 years for men, 55 years for women)
- Diabetes mellitus
- Estimated glomerular filtration rate <60 mL/min
- Microalbuminuria
- Family history of premature cardiovascular disease (men <55 years of age, or women <65 years of age)

#### Modifiable Cardiovascular Risk Factors

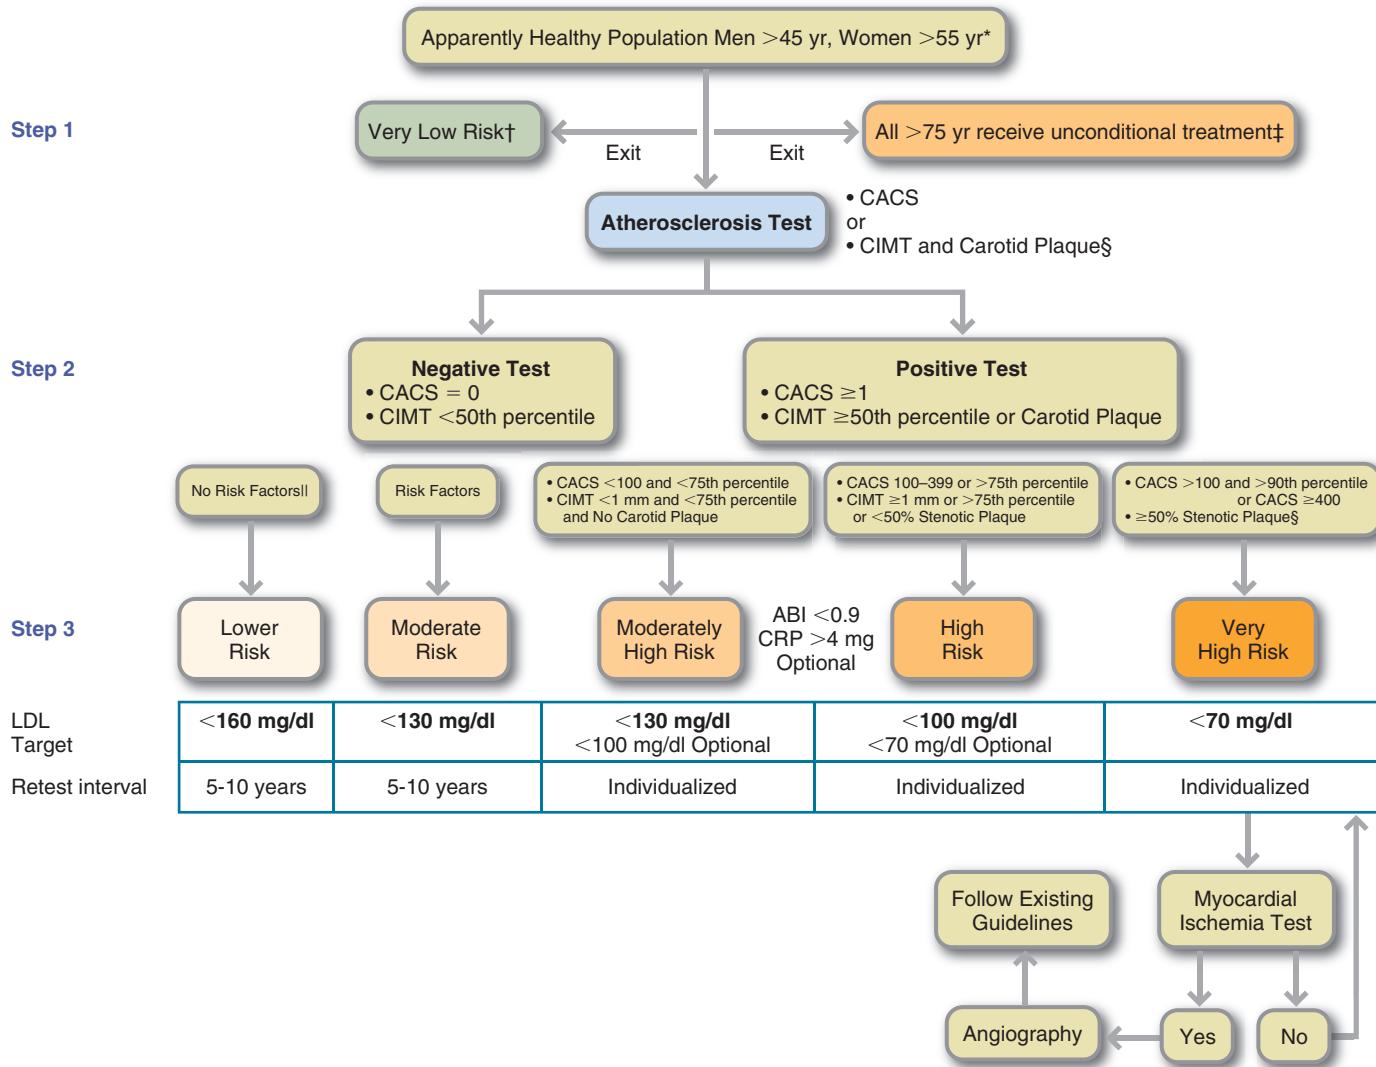

- Lipoprotein profile
- Low-density lipoprotein cholesterol, elevated
  - Total triglycerides, elevated
  - High-density lipoprotein (HDL) cholesterol, low
- Inflammatory markers
- Fibrinogen
- C-reactive protein

#### Lifestyle Risk Factors

- Tobacco use, particularly cigarettes
- Physical inactivity
- Poor diet
- Stress
- Insufficient sleep
- Excessive alcohol consumption

#### Related Conditions

- Hypertension
- Obesity (body mass index >30 kg/m<sup>2</sup>)
- Metabolic syndrome (including reduced HDL, elevated triglycerides, abdominal obesity)
- Modified from National Institutes of Health, National Heart, Lung, and Blood Institute National High Blood Pressure Education Program: The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure, NIH Publication No. 04-5230, August 2004.

**FIGURE 34-5** Flow chart of the first Screening for Heart Attack Prevention and Education (SHAPE) Guideline. *ABI*, Ankle-brachial index; *CACS*, coronary artery calcium score; *CIMT*, carotid intima-media thickness; *CRP*, C-reactive protein; *LDL*, low-density lipoprotein.

\*No history of angina, heart attack, stroke, or peripheral arterial disease.

†Population age older than 75 years is considered high risk and must receive therapy without testing for atherosclerosis.

‡Must not have any of the following: total cholesterol level 200 mg/dL (5.18 mmol/L), blood pressure higher than 120/80 mm Hg, diabetes mellitus, smoking, family history of coronary heart disease, or the metabolic syndrome.

§Pending the development of standard practice guidelines.

¶High cholesterol, high blood pressure, diabetes, smoking, family history of coronary heart disease, or the metabolic syndrome.

\*\*For stroke prevention, follow existing guidelines. (From *Vulnerable plaque to vulnerable patient. Part III: Executive summary of the screening for heart attack prevention and education [SHAPE] task force report*, Am J Cardiol 98[2A]:2H, 2006.)

screening for dyslipidemia is recommended for children with a family history of hypercholesterolemia or CHD. Goals for total cholesterol levels for 2- to 19-year-olds are shown in Table 34-1.

For adults, a desirable lipoprotein profile is a total cholesterol level of less than 200 mg/dL, LDL cholesterol less than 130 mg/dL, HDL cholesterol greater than 40 mg/dL, and triglyceride level less than 150 mg/dL (NCEP, 2002). An LDL cholesterol level less than 100 mg/dL is rec-

ommended for persons with two or more risk factors (high-risk patients). See Fig. 34-5 for AHA recommendations.

### Inflammatory Markers

Increasing knowledge about the role of inflammation in CVD gives credence to the use of inflammatory markers to indicate the presence of atherosclerosis in asymptomatic individuals or the extent of atherosclerosis in patients with symptoms. Several markers have been suggested (Box 34-3),

**TABLE 34-1****Cholesterol Levels for 2- to 19-Year-Olds**

Levels	Total Cholesterol (mg/dL)	LDL-C (mg/dL)
Acceptable	<170	<110
Borderline	170-199	110-129
High	≥200	≥130

Modified from Fletcher B et al: Managing abnormal blood lipids: a collaborative approach, Circulation 112:3184, 2005.

LDL-C, Low-density lipoprotein cholesterol.

**BOX 34-3****Inflammatory Markers for Cardiovascular Risk**

Genetic markers: angiotensin II receptor type-1 polymorphism

Oxidized low-density lipoprotein cholesterol

Adhesion molecules

Selectins

Free fatty acids

Cytokines

Interleukin-1

Interleukin-6

Tumor necrosis factor- $\alpha$

Acute-phase reactants

Fibrinogen

C-reactive protein

Serum amyloid A

White blood cell count

Erythrocyte sedimentation rate

Derived from Fung MM et al: Early inflammatory and metabolic changes in association with AGTR1 polymorphisms in prehypertensive subjects, Am J Hypertens 23 September 2010. [Epub ahead of print]; Pearson TA et al: Markers of inflammation and cardiovascular disease: application to clinical and public health practice: a statement for healthcare professionals from the Centers for Disease Control and Prevention and the American Heart Association, Circulation 107:499, 2003.

atherogenesis or is just a marker of vascular damage. Blood thrombogenicity increases with high LDL cholesterol and in diabetes. To date the most widely studied preventive factor for thrombogenesis is the use of aspirin; 75 mg/day of aspirin reduces total CHD, nonfatal MI, and CVD events but does not have any effect on stroke or cardiovascular mortality (Bartolucci and Howard, 2006).

**C-Reactive Protein.** **C-reactive protein (CRP)** is synthesized in the liver as the acute-phase response to inflammation. Thus in a normal individual without infection or inflammation, CRP levels are very low <0.6 mg/dL. Because atherogenesis is an inflammatory process, CRP has been shown to be elevated (>3 mg/dL) in people with angina, MI, stroke, and peripheral vascular disease; the elevated levels are independent of other risk factors (Scirica et al., 2006). CRP has been found in arterial atherosoma and therefore is now considered both a risk factor and a causal agent for **atherothrombosis** (Scirica et al., 2006).

CRP levels are categorized for risk as low (<1 mg/L); average (2 to 3 mg/L) and high (>3 mg/L) after the average of two measurements are taken at least 2 weeks apart (American Heart Association, 2010). Because CRP is a general measure of inflammation, it is not specific to the heart or vascular system and therefore an increased level requires further investigation to determine the source of the inflammation.

Few studies have investigated the effects of dietary variables on CRP, but higher intakes of fruits and vegetables tend to lower CRP levels. For instance, the “Daniel Fast” has shown improvement in multiple cardiovascular indicators, including CRP. This is a 21-day diet without animal products and preservatives that highlights fruits, vegetables, whole grains, legumes, nuts, and seeds (Bloomer et al., 2010). Dietary intervention trials are needed.

**Homocysteine.** **Homocysteine**, an amino acid metabolite of methionine, is a risk factor. It was first observed that children who were deficient in cystathione B synthase, the essential enzyme for breakdown of homocysteine, had premature atherosclerosis in some veins. Although the original homocysteine hypothesis for atherothrombotic disease has fallen out of favor, prior studies did not comprehensively adjust for confounding factors. Indeed, elevated total homocysteine (tHcy) independently increases the odds of stroke, especially in younger individuals (Towfighi et al., 2010). Tests for folate alleles in susceptible individuals are useful, giving vitamins B<sub>6</sub>, B<sub>12</sub>, and methylated folate when needed.

**Modifiable Lifestyle Factors**

The AHA supports diet and lifestyle recommendations to reduce risk of CVD, shown in **Box 34-4**.

**Poor Diet Quality**

It is known that diet is the predominant environmental cause of coronary atherosclerosis and that diet modification unequivocally can reduce risk of CHD. Not surprisingly, caloric intake increased by approximately 300 kcal between 1985 and 2000 (Thom et al., 2006). A major environmental,

and research continues to look at the effects of diet on these biomarkers (Esposito and Giugliano, 2006). A recent study showed that the plasma levels of  $\omega$ -3 fatty acids were inversely associated with the inflammatory markers CRP, IL-6, fibrinogen, and homocysteine (Kalogeropoulos, 2010). In addition, genetic factors also play a role.

**Fibrinogen.** Most MIs are the result of an intracoronary thrombosis. Prospective studies have shown that plasma fibrinogen is an independent predictor of CHD risk. Factors associated with an elevated fibrinogen are smoking, diabetes, hypertension, obesity, sedentary lifestyle, elevated triglycerides, and genetic factors. More clinical trials are needed to determine if fibrinogen is involved in

**BOX 34-4****American Heart Association Lifestyle Goals for Risk Reduction**

- Consume an overall healthy diet.
- Aim for a healthy body weight.
- Aim for recommended levels of low-density lipoprotein cholesterol, high-density lipoprotein cholesterol, and triglycerides.
- Aim for a normal blood pressure.
- Aim for a normal blood glucose level.
- Be physically active.
- Avoid use of and exposure to tobacco products.

From Lichtenstein AH et al: Diet and lifestyle recommendations revision 2006: a scientific statement from the American Heart Association Committee, Circulation 114:83, 2006. Reprinted with permission. Circulation. 2006; 114:82-96. © American Heart Association, Inc.

dietary contributor to obesity is the increase in portion sizes that has occurred during the last 20 years. Most Americans consume less than the recommended amount of fiber (Anderson, 2009); only 22% of adults consume five servings of fruits and vegetables daily. Nutrition diagnoses common in this population include the following (Brindle, 2006):

- Excessive energy intake
- Excessive fat intake (saturated)
- Inadequate vitamin intake (e.g., B-complex)
- Inadequate mineral intake (e.g., potassium, calcium)
- Inadequate intake of bioactive substances (e.g., stanols or sterols)
- Excessive alcohol intake
- Food- and nutrition-related knowledge deficit
- Undesirable food choices
- Limited adherence to nutrition-related recommendations
- Inadequate physical activity
- Obesity or overweight

**Physical Inactivity**

Physical inactivity and a low level of fitness are independent risk factors for CHD. Physical activity is associated with CVD, independent of the common cardiometabolic risk factors of obesity, serum lipids, serum glucose and hypertension, in both men and women (McGuire, 2009). Despite public health recommendations to increase activity levels, 40% of Hispanic women, 34% of black women, 32% of American Indian and Alaskan Native women, and 22% of white women reported no leisure-time physical activity in the *Behavioral Risk Factor Surveillance System survey* (2007). Approximately 20% of all men were inactive. With the high prevalence of obesity, physical activity is a high priority. Physical activity lessens CHD risk by retarding atherogenesis, increasing vascularity of the myocardium, increasing fibrinolysis, increasing HDL cholesterol,

improving glucose tolerance and insulin sensitivity, aiding in weight management, and reducing blood pressure.

**Stress**

Stress activates a neurohormonal response in the body that results in increased heart rate, blood pressure, and cardiac excitability. The stress hormone angiotensin II is released following stimulation of the sympathetic nervous system (SNS); exogenous infusion of angiotensin II accelerates the formation of plaque (Mehta and Griendling, 2007). The INTERHEART study found that the effect of stress is comparable to that of hypertension.

**Tobacco Use**

The increased risk of CVD and stroke from cigarette smoking has been recognized for more than 40 years, with definitive evidence presented in several Surgeon General reports. Smoking is the number one cause of preventable death in the United States; 35% of deaths from tobacco use are from CVD (Thom et al., 2006). Smoking is synergistic with other risk factors (i.e., the risk of CHD is much higher with multiple risk factors) and directly influences acute coronary events, including thrombus formation, plaque instability, and arrhythmias (abnormal heart rhythm). Thus tobacco causes subclinical atherosclerosis. Women who smoke and use oral contraceptives have 10 times the risk of developing CHD than women who do not smoke and who do not use contraceptives. Risk also increases with the number of cigarettes smoked each day; low-tar brands do not reduce the risk. Furthermore, any exposure, including second-hand smoke, increases the risk (Thom et al., 2006).

**Controllable Risk Factors****Diabetes**

Diabetes is both a disease and a risk factor. The prevalence of diabetes mirrors that of obesity in the United States. Since 1990, a 61% increase in the prevalence of diabetes has been observed, and it is becoming more prevalent in obese children (Thom et al., 2006). Any form of diabetes increases the risk for CHD, with occurrence at younger ages. Most people with diabetes die from CVD. Similarly, 75% of people with diabetes have more than two risk factors for CHD (McCollum et al., 2006). Some of the increased risk for CHD seen in diabetic patients is attributable to the concurrent presence of other risk factors, such as dyslipidemia, hypertension, and obesity. Thus diabetes is now considered a CHD risk factor (see Chapter 31).

**Hypertension**

Hypertension is a significant risk factor for CHD, stroke, and HF.

**Metabolic Syndrome**

Since the early findings of the Framingham study, it has been known that a clustering of risk factors markedly increases the risk of CVD. See Chapter 22 for an in-depth discussion of metabolic syndrome.

## Obesity

Obesity has now reached epidemic levels in children and adults in many developed countries. Body mass index (BMI) and CHD are positively related; as BMI goes up, the risk of CHD also increases. The prevalence of overweight and obesity is the highest that it has ever been in the United States; 65% of adults are overweight, and 31% are obese (Blumenthal et al., 2010). Obesity rates vary by race and ethnicity in women. Non-Hispanic black women have the highest prevalence, followed by Mexican-American women, American Indians and Alaskan natives, and non-Hispanic whites. In men the rates of obesity vary from 25% to 28% of the population. The epidemic of obesity and diabetes could reverse the downward trend in CHD mortality if it is not soon controlled, especially given the increasing rates seen in children and adolescents (Thompson et al., 2007) (see Chapter 22).

Carrying excess adipose tissue greatly affects the heart through the many risk factors that are often present: hypertension, glucose intolerance, inflammatory markers (IL-6, TNF- $\alpha$ , CRP), obstructive sleep apnea, prothrombotic state, endothelial dysfunction, and dyslipidemia (small LDL, increased apo B, low HDL, high triglyceride levels) (Poirier et al., 2006). Many inflammatory proteins are now known to come from the adipocyte (Berg, Scherer, 2006). These concurrent risk factors may help to explain the high morbidity and mortality rates observed in people who are obese.

Weight distribution (abdominal versus gynoid) is also predictive of CHD risk, glucose tolerance, and serum lipid levels. Central adiposity has also been strongly related to markers of inflammation, especially CRP. Therefore a waist circumference of less than 35 inches for women and 40 inches for men is recommended.

Small weight losses (10 to 20 lb) can improve LDL cholesterol, HDL cholesterol, triglycerides, high blood pressure, glucose tolerance, and CRP levels, even if an ideal BMI is not achieved. Weight loss has also been correlated with lower CRP levels. However, to restore vascular function, the amount of weight that must be lost, the time of weight maintenance, or the amount of improvement in endothelial function that lessens cardiovascular events is still unknown.

## Nonmodifiable Risk Factors

### Age and Sex

With increasing age, higher mortality rates from CHD are seen in both genders. However, gender is a factor for the assessment of risk. The incidence of premature disease in men 35 to 44 years of age is three times as high as the incidence in women of the same age. Therefore being older than 45 years of age is considered a risk factor for men (NCEP, 2002). For women the increased risk comes after the age of 55 years, which is after menopause for most women. Overall the increased risk for CHD parallels increase in age.

## Family History and Genetics

A family history of premature disease is a strong risk factor, even when other risk factors are considered. A family history is considered to be positive when MI or sudden death occurs before the age of 55 years in a male first-degree relative or the age of 65 in a female first-degree relative (parents, siblings, or children). The presence of a positive family history, although not modifiable, influences the intensity of risk factor management.

## Menopausal Status

Endogenous estrogen confers protection against CVD in premenopausal women, probably by preventing vascular injury. Loss of estrogen following natural or surgical menopause is associated with increased CVD risk. Rates of CHD in premenopausal women are low except in women with multiple risk factors. During the menopausal period total cholesterol, LDL cholesterol, and triglyceride levels increase; HDL cholesterol level decreases, especially in women who gain weight.

## Medical Nutrition Therapy

Medical nutrition therapy (MNT), which includes discussion of physical activity, is the primary intervention for patients with elevated LDL cholesterol (Box 34-5). Physicians are encouraged to refer patients to registered dietitians (RDs) to help patients meet goals for therapy based on LDL cholesterol levels.

With diet, exercise, and weight reduction, patients can often reach serum lipid goals and reduce body inflammation. The complexity of changes, number of changes, and motivation of the patient will dictate how many patient visits it will take for the adherent client to be successful.

An initial visit of 45 to 90 minutes followed by two to six visits of 30 to 60 minutes each with the RD is recommended (American Dietetic Association [ADA] Evidence Library, 2006). Consequently these interventions are tried before drug therapy and also continue during pharmacologic treatment to enhance effectiveness of the medication (see *Pathophysiology and Care Management Algorithm: Atherosclerosis*).

### Therapeutic Lifestyle Changes

The TLC dietary pattern is used for primary and secondary prevention of CHD; its updated version can be found in Table 34-2. The AHA recommends diet and lifestyle changes to reduce CVD risk in all people older than the age of 2 (Lichtenstein et al., 2006). Recommendations include saturated fat less than 7% of calories and total fat content 25% to 35% of calories.

Consuming 30% to 35% of calories from fat while maintaining a low saturated fatty acid (SFA) and *trans*-fatty acid intake is the dietary pattern recommended for individuals with insulin resistance or metabolic syndrome. This higher fat intake, emphasizing polyunsaturated fatty acids (PUFAs) and monounsaturated fatty acids (MUFA), can lower triglycerides, and raise HDL cholesterol and lower LDL cholesterol without exacerbating blood glucose levels.

Planned MNT requires a 3- to 6-month time frame. Lowering SFAs and trans-fats is the first level of behavior change. The TLC diet is followed for 6 weeks. At visit two the LDL response is evaluated and therapy is intensified if warranted. Adjuncts such as plant sterols and stanols, and fiber are incorporated into education at the second visit (dietary compliance must be monitored during this period). At visit three, metabolic syndrome treatment begins if target LDL is not reached. Once the maximum LDL reduction

has occurred, management of metabolic syndrome or the cluster of risk factors becomes the target for MNT interventions.

Increasing physical activity, decreasing energy intake, and weight loss are critical for normalizing multiple risk factors. Behavioral strategies for weight management and cardiovascular risk reduction have been provided in Box 34-6. Learning outcomes for the client include planning meals that fit the TLC plan, reading food labels, modifying recipes, preparing or purchasing appropriate foods, and choosing healthier choices when dining out.

Along with the TLC dietary pattern, the Dietary Approaches to Stop Hypertension (DASH) pattern, discussed later in this chapter, is also very appropriate for CVD prevention and treatment. These dietary patterns emphasize grains, cereals, legumes, vegetables, fruits, lean meats, poultry, fish, and nonfat dairy products.

Because animal fats provide approximately two thirds of the SFAs in the American diet, these foods are limited. High-fat choices are omitted, but low-fat choices can be included. Similarly with dairy products, nonfat choices are recommended. Meat is limited to 5 oz/day. Lean meats are high in protein, zinc, and iron; thus if patients wish to consume meat, a 5-oz portion or less can be fit into the dietary plan if other low SFA choices are made. Eggs are restricted to four per week; however, eggs do not contribute to high cholesterol levels in the same way as other animal protein. Most people should add the recommended two servings of fatty fish per week.

For highly motivated patients who want to avoid drug therapy, sometimes very-low-fat diets are effective for reaching blood lipid goals. These diets can also be used as an adjunct to drug therapy for secondary prevention and possible regression of lesions. Such diets contain minimum

**TABLE 34-2**

### Therapeutic Lifestyle Change Dietary Pattern

Nutrient	Recommended Intake
Total fat	25%-35% of total calories
Saturated fat	Less than 7% of total calories
<i>Trans</i> -fatty acids	Zero or as low as possible
Polyunsaturated fat	Up to 10% of total calories
Monounsaturated fat	Up to 20% of total calories
Carbohydrate <sup>†</sup>	50% to 60% of total calories, especially from whole grains, fruits and vegetables
Fiber	25-30 g/day (soluble forms such as psyllium at 10-25 g)
Plant sterols	2 g/day
Protein	Approximately 15% of total calories
Cholesterol	Less than 200 mg/day
Total calories (energy)	Balance energy intake and expenditure to maintain desirable body weight/prevent weight gain. Daily energy expenditure should include at least moderate physical activity of approximately 200 kcal/day).

Updated by authors in 2010 from National Heart, Lung, and Blood Institute: Detection, evaluation, and treatment of high blood cholesterol in adults (adult treatment panel III), Final report, U.S. Department Of Health and Human Services, NIH Publication No. 02-5215, Bethesda, Md, September 2002.

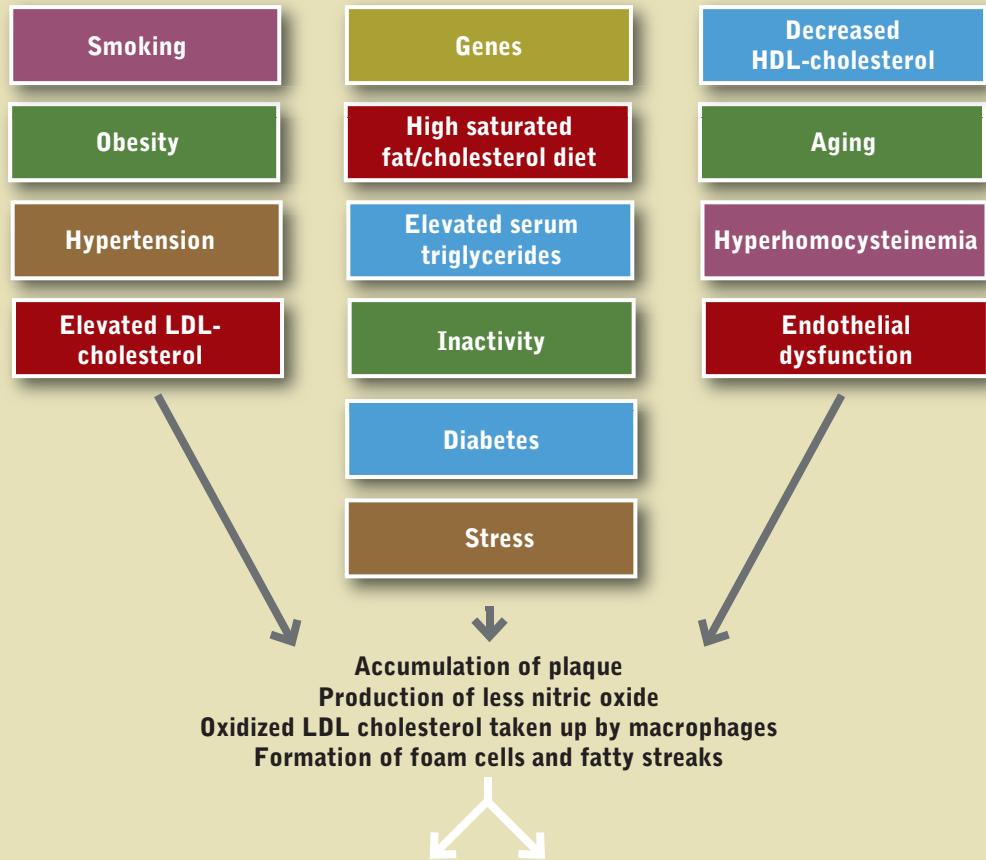

<sup>†</sup>Refined carbohydrates should be limited.

## PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

### Atherosclerosis

**Etiology**

**PATHOPHYSIOLOGY**

#### Clinical Findings

- Elevated serum total cholesterol
- Elevated LDL cholesterol
- Elevated serum triglycerides
- Elevated C-reactive protein
- Low HDL-cholesterol

#### Nutrition Assessment

- BMI evaluation
- Waist circumference; waist to hip ratio (WHR)
- Dietary assessment for:  
SFA, *trans*-fatty acids, ω-3 fatty acids, fiber, sodium, alcohol, and refined carbohydrates

**MANAGEMENT**

#### Medical Management

- Bile acid sequestrants
- HMG CoA reductase inhibitors (statins)
- Triglyceride-lowering medication
- Blood pressure—lowering medication
- Medication for glucose management
- Percutaneous coronary intervention (PCI)
  - Balloon
  - Stent
- Coronary artery bypass graft (CABG)
- Antiplatelet Therapy

#### Nutrition Management

- TLC dietary pattern—7% kcal from SFA
- AHA dietary pattern—7% kcal from SFA
- DASH dietary pattern
- Weight reduction if needed
- Increase dietary fiber to 25–30 g/day or more
- Add stanols and sterols (2–3 g/day) in multiple doses
- Add ω-3 fats
- Add fruits and vegetables for antioxidants
- Reduce dietary cholesterol—<200 mg/day
- CoQ<sub>10</sub> for those on statin drugs

**BOX 34-6**

### American Heart Association Diet Recommendations for Cardiovascular Disease Risk Reduction

- Balance calorie intake and physical activity to achieve or maintain a healthy body weight.
- Consume a diet rich in vegetables and fruits.
- Choose whole-grain, high-fiber foods.
- Consume fish, especially oily fish, at least twice a week.
- Limit intake of saturated fat to <7% of energy, *trans*-fat to <1% of energy, and cholesterol to <300 mg/day by:
  - Choosing lean meats and vegetable alternatives.
  - Selecting fat-free (skim), 1%-fat, and low-fat dairy products.
  - Minimizing intake of partially hydrogenated fats.
- Minimize intake of beverages and foods with added sugars.
- Choose and prepare foods with little or no salt.
- Consume alcohol in moderation.
- When eating food that is prepared outside of the home, follow the American Heart Association Diet and Lifestyle Recommendations.

Modified from Lichtenstein AH et al: Diet and lifestyle recommendations revision 2006: a scientific statement from the American Heart Association Committee, Circulation 114:83, 2006. Reprinted with permission. Circulation. 2006;114:82-96. © American Heart Association, Inc.

amounts of animal products; thus SFA (<3%), cholesterol (<5 mg/day), and total fat (<10%) intakes are very low. The emphasis is on low-fat grains, legumes, fruits, vegetables, and nonfat dairy foods. Because egg whites are allowed, the plan is a lacto-ovo-vegetarian regimen.

For more than 40 years epidemiologic studies, experimental studies, and clinical trials have shown that numerous dietary risk factors affect serum lipids, atherogenesis, and CHD. To ensure nutritional adequacy, consulting with an RD is recommended. Key discussion points follow.

**Saturated Fatty Acids.** The predominant sources of SFAs in the American diet are animal foods (meat and dairy). SFAs are restricted because they have the most potent effect on LDL cholesterol, which rises in a dose-response fashion when increasing levels of SFAs are consumed. In the National Health and Nutrition Examination Survey (NHANES) IV, the mean consumption of SFAs was 11% of kilocalories, versus the goal of less than 7% of energy. SFAs raise serum LDL cholesterol by decreasing LDL receptor synthesis and activity. Regardless of form, all fatty acids lower fasting triglycerides if they replace carbohydrate in the diet.

**Trans-fatty Acids.** **Trans-fatty acids** (stereoisomers of the naturally occurring *cis*-linoleic acid) are produced in the hydrogenation process used in the food industry to increase shelf life of foods and to make margarines, made from oil, firmer. Most *trans*-fatty acids intake comes from partially

hydrogenated vegetable oils. These fatty acids are limited because they raise LDL cholesterol (Basu et al., 2006). No more than 1% of calories (approximately 1-3 g/day) should come from *trans*-fatty acids (Lichtenstein et al., 2006).

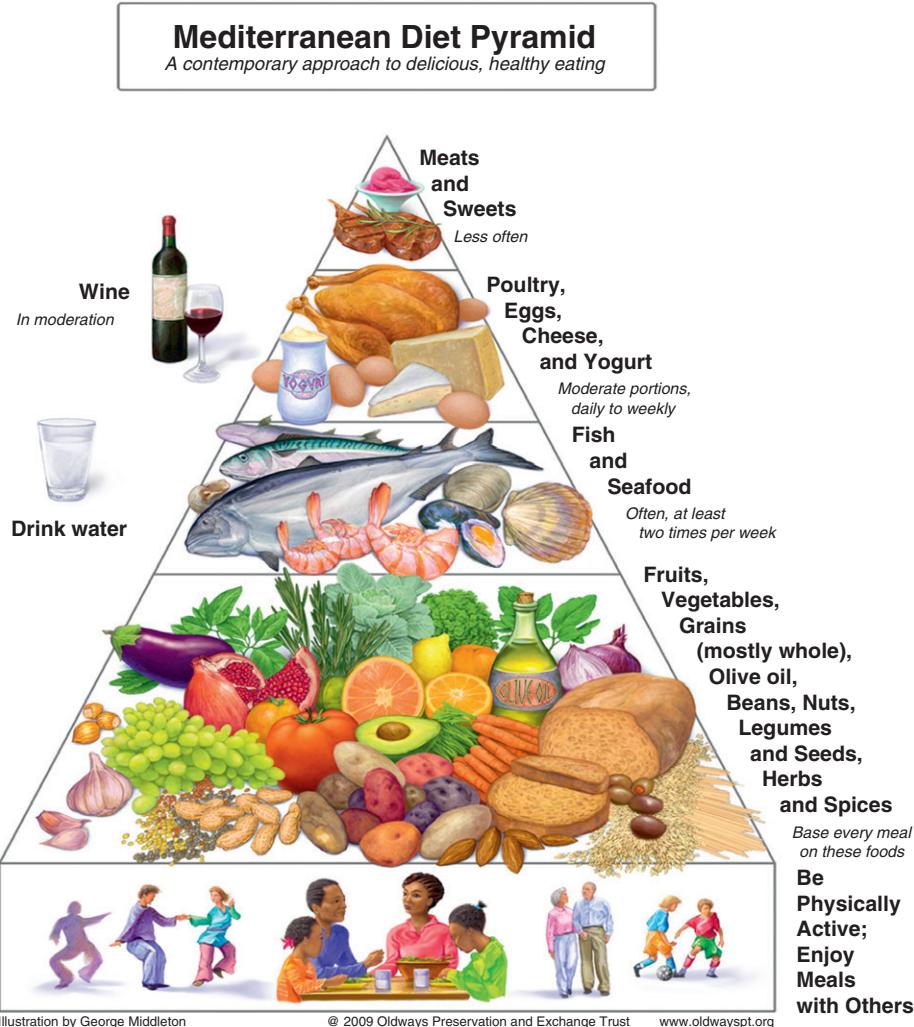

**Monounsaturated Fatty Acids.** Oleic acid (C18:1) is the most prevalent MUFA in the American diet. Substituting oleic acid for carbohydrate has almost no appreciable effect on blood lipids. However, replacing SFAs with MUFA (as would happen when substituting olive oil for butter) lowers serum cholesterol levels, LDL cholesterol levels, and triglyceride levels to about the same extent as PUFAs. The effects of MUFA on HDL cholesterol depend on the total fat content of the diet. When intakes of both MUFA (>15% of total kilocalories) and total fat (>35% of kilocalories) are high, HDL cholesterol does not change or increases slightly compared with levels with a lower-fat diet. Oleic acid as part of the Mediterranean diet (Figure 34-6) has been shown to have antiinflammatory effects.

In epidemiologic studies, high-fat diets of people in Mediterranean countries have been associated with low blood cholesterol levels and CHD incidence. Among other factors, the main fat source is olive oil, which is high in MUFA. This observation led to many studies on the benefits of high-fat and high-MUFA diets. A Mediterranean-type step I diet may reduce recurrent CVD by 50% to 70% and has been shown to positively affect lipoprotein levels in high-risk populations (Carter et al., 2010). This diet emphasizes fruits, root vegetables (carrots, turnips, potatoes, onions, radishes), leafy green vegetables, breads and cereals, fish, foods high in  $\alpha$ -linolenic acid (flax, canola oil), vegetable oil products (salad dressing and other products made with nonhydrogenated oils), and nuts and seeds (walnuts and flaxseed).

Red wine is considered a key part of the Mediterranean diet. Resveratrol, a polyphenolic compound, is found in the skin of red grapes. Resveratrol in large quantities appears to lower blood pressure by increasing nitric oxide levels. Its role in smaller quantities found in the 1-2 glasses of red wine recommended in the Mediterranean diet is not yet clear (Carter, 2010). Grape juice is another good source of resveratrol.

**Polyunsaturated Fatty Acids.** The essential fatty acid linoleic acid (LA) is the predominant PUFA consumed in the American diet; its effect depends on the total fatty acid profile of the diet. When added to study diets, large amounts of LA diminish HDL serum cholesterol levels. High intakes of  $\omega$ -6 PUFAs may exert adverse effects on the function of vascular endothelium or stimulate production of proinflammatory cytokines. Thus a low ratio of  $\omega$ -6: $\omega$ -3 PUFAs is recommended (Basu et al., 2006; Gebauer et al., 2006). Replacing PUFAs for carbohydrate in the diet results in a decline in serum LDL cholesterol. When SFAs are replaced with PUFAs in a low-fat diet, LDL and HDL cholesterol levels are lowered. Overall, eliminating SFAs is twice as effective in lowering serum cholesterol levels as increasing PUFAs.

**FIGURE 34-6** The Traditional Healthy Mediterranean Diet Pyramid. (Courtesy Oldways Preservation and Exchange Trust, [www.oldwayspt.org](http://www.oldwayspt.org).)

**Omega-3 Fatty Acids.** The main  $\omega$ -3 fatty acids (eicosapentaenoic acid [EPA] and docosahexaenoic acid [DHA]) are high in fish oils, fish oil capsules, and ocean fish. Many studies have shown that eating fish is associated with a decreased CVD risk. The recommendation for the general population for fish consumption is to eat fish high in  $\omega$ -3 fatty acids (salmon, tuna, mackerel, sardines) at least twice a week (Psota et al., 2006). For patients who have CVD, 1 g of EPA and DHA combined is recommended from fish if possible but, if not, then from supplements (Lichtenstein et al., 2006). Patients who have hypertriglyceridemia need 2 to 4 g of EPA and DHA per day for effective lowering. Omega-3 fatty acids lower triglyceride levels by inhibiting VLDL and apo B-100 synthesis, thereby decreasing postprandial lipemia.

An  $\omega$ -3 fatty acid from vegetables,  $\alpha$ -linolenic acid (ALA), has antiinflammatory effects. CRP levels are reduced when patients consume 8 g of ALA daily (Basu et al., 2006). Omega-3 fatty acids are cardioprotective because they interfere with blood clotting and alter prostaglandin synthesis. Omega-3 fat stimulates production of **nitric oxide**, a substance that stimulates relaxation of the blood vessel wall (vasodilation). Unfortunately, high intakes prolong bleeding

time, a common condition among Eskimo populations with high  $\omega$ -3 fat dietary intakes and low incidence of CHD.

**Total Fat.** Total fat intakes are related to obesity, which affects many of the major risk factors for atherosclerosis. Also, high-fat diets increase postprandial lipemia and chylomicron remnants, both of which are associated with increased risk of CHD. When fat is reduced in the diet and carbohydrate is the replacement source of calories, triglycerides and HDL levels are affected. Low-fat diets (<25% of total kilocalories from fat) raise triglyceride levels and lower HDL cholesterol levels. However, research on the role of fat in prevention and treatment of CVD is now aimed at moderate-fat diets with a low  $\omega$ -6: $\omega$ -3 fat ratio that includes MUFA, such as from nuts. Nuts are part of a heart-healthy diet; a 37% lower risk of CHD in those consuming nuts at least four times a week has been noted (Kelly and Sabate, 2006).

**Dietary Cholesterol.** Dietary cholesterol raises total cholesterol and LDL cholesterol but to a lesser extent than SFAs. The AHA and TLC dietary patterns contain no more than 200 mg of cholesterol each day. There is a threshold beyond which addition of cholesterol to the diet has minimal effects. When cholesterol intakes reach 500 mg/day, only

small increments in blood cholesterol occur. Cholesterol responsiveness also varies widely among individuals. Some people are hypo-responders (i.e., their plasma cholesterol level does not increase after dietary cholesterol challenge), whereas others are hyper-responders (i.e., their plasma cholesterol level responds more strongly than expected to a cholesterol challenge). Hyper-responders may have the apo E-4 allele and poor rates of conversion of cholesterol to bile acids, which causes elevated LDL cholesterol. Feeding cholesterol to animals enriches lipoproteins, which are atherogenic beyond just the rise in serum cholesterol. The effect of dietary cholesterol on inflammatory factors has been inconsistent (Basu et al., 2006).

**Fiber.** High intake levels of dietary fiber are associated with significantly lower prevalence of CHD and stroke (Anderson, 2009). The AHA, TLC, and DASH dietary patterns emphasize fruits, vegetables, legumes, and whole grains, so they contain adequate fiber to lower LDL cholesterol. In particular, the soluble fibers in pectins, gums, mucilages, algal polysaccharides, and some hemicelluloses lower LDL cholesterol. The quantity of fiber needed to produce the lipid-lowering effect varies by food source; higher quantities of legumes are needed than of pectin or gums. Proposed mechanisms for the hypocholesterolemic effect of soluble fiber include the following: (1) the fiber binds bile acids, which lowers serum cholesterol as it repletes the bile acid pool; and (2) bacteria in the colon ferment the fiber to produce acetate, propionate, and butyrate, which inhibit cholesterol synthesis. The role of fiber, if any, on inflammatory pathways is not well established (Erkkila and Lichtenstein, 2006). Minerals, vitamins, and antioxidants that are components of a high-fiber diet further enrich the diet.

Insoluble fibers such as cellulose and lignin have no effect on serum cholesterol levels. Of the total recommended fiber intake (25 to 30 g daily for adults), approximately 6 to 10 g should be from soluble fiber. This level is easy to achieve with the recommended five or more servings of fruits or vegetables per day and six or more servings of grains (if whole grains and high-fiber cereals are chosen).

**Antioxidants.** Two dietary components that affect the oxidation potential of LDL cholesterol are the level of LA in the particle and the availability of antioxidants. Vitamins C, E, and β-carotene at physiologic levels have antioxidant roles in the body. Vitamin E is the most concentrated antioxidant carried on LDLs, the amount being 20 to 300 times greater than any other antioxidant. A major function of vitamin E is to prevent oxidation of PUFAs in the cell membrane. The AHA does not recommend vitamin E supplementation for CVD prevention. However, RRR-α-tocopherol, the natural form of vitamin E, shows promise as an antiinflammatory agent (Basu et al., 2006). Foods with concentrated amounts of catechins have been found to improve vascular reactivity. Red grapes, red wine, tea (especially green tea), chocolate, and olive oil should be in any preventive eating plan (Kay et al., 2006).

**Stanols and Sterols.** Since the early 1950s plant stanols and sterols isolated from soybean oils or pine tree oil have been known to lower blood cholesterol by inhibiting absorption of dietary cholesterol. When esterified and made into margarines, 2 to 3 g/day may lower cholesterol up to 20%. ATP-III includes stanols as part of dietary recommendations for lowering LDL cholesterol in adults. Because these esters can also affect the absorption of and cause lower β-carotene, α-tocopherol, and lycopene levels, further safety studies are needed for use in normocholesterolemic individuals, children, and pregnant women.

**Weight Loss.** Weight loss improves endothelial function measured using different methods (Brook, 2006). In a group of patients with extreme obesity (BMI = 52), flow-mediated dilation, which is an estimate of endothelial function, improved after the patients lost a mean of 23 kg (Williams et al., 2005). Overall, it is not known how much weight has to be lost, how long the effect lasts, and whether the improvement in endothelial function reduces coronary events (Brook, 2006).

## Medical Management

### Pharmacologic Management

Determination of drug therapy depends on risk category and attainment of the LDL cholesterol goal. Many drugs are available for LDL lowering (see Chapter 9). Regardless of the drug used or category of risk, the TLCs underpin all treatment. The classes of drugs include the following: (1) **bile acid sequestrants** such as cholestyramine (adsorbs bile acids); (2) nicotinic acid; (3) **statins**, or **3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA)** reductase inhibitors, which inhibit the rate-limiting enzyme in cholesterol synthesis; (4) fibric acid derivatives; and (5) probucol. Classes 1, 2, and 3 have been the first choices for treatment.

### Medical Intervention

Medical interventions such as percutaneous coronary intervention (PCI) are now performed in patients with asymptomatic ischemia or angina. PCI, previously known as *percutaneous transluminal coronary angioplasty*, is a procedure that uses a catheter with a balloon that, once inflated, breaks up plaque deposits in an occluded artery. Coronary stenting involves a wire mesh tube inserted to hold an artery open; it can release medication that prevents clotting (Thom et al., 2006).

PCI is often possible because of earlier detection of blockages. The most common problem with PCI is restenosis of the artery. A recent study examined more than 2200 patients, half of whom received intervention of medication and lifestyle changes such as quitting smoking, exercise, and nutrition, and half of whom received lifestyle changes as well as angioplasty. After 5 years it was observed that the number who had heart attacks, was hospitalized, or died because of their heart problems was virtually identical in both groups. Angioplasty did not appear to provide an additional benefit versus lifestyle changes combined with medication (Boden et al., 2007).

Because PCI is performed with the patient under local anesthesia in a cardiac catheterization laboratory, recovery is quicker than with coronary artery bypass graft (CABG) surgery. In CABG surgery, an artery from the chest is used to redirect blood flow around a diseased vessel. Candidates for CABG usually have more than two occluded arteries. CABG surgeries have decreased since 1995 because more PCI procedures are being done. These surgeries improve survival time, relieve symptoms, and markedly improve the quality of life for patients with CHD. However, CABG does not cure atherosclerosis; the new grafts are also susceptible to atherogenesis. Consequently restenosis is common within 10 years of surgery. Risk factor modification, including at a minimum TLCs and probably more aggressive dietary changes, is needed to stop progression.

In the postoperative period CABG patients, like others undergoing major surgery, are in a catabolic state; therefore adequate nutritional intake via oral routes is essential. Patients with complications may be at risk for developing cardiac cachexia, which is often associated with HF. Patients are usually discharged with the TLC, AHA, or DASH dietary pattern.

## HYPERTENSION

**Hypertension** is persistently high arterial **blood pressure**, the force exerted per unit area on the walls of arteries. To be defined as hypertension, the **systolic blood pressure (SBP)**, the blood pressure during the contraction phase of the cardiac cycle, has to be 120 mm Hg or higher; or the **diastolic blood pressure (DBP)**, the pressure during the relaxation phase of the cardiac cycle, has to be 80 mm Hg or higher; this is reported as more than 120/80 mm Hg. If an individual has a blood pressure of 120 mm Hg and a DBP of 80 mm Hg, this is read as a blood pressure of 120/80.

In the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure, hypertension is classified in stages, based on the risk of developing CVD (Table 34-3). Individuals diagnosed with **prehypertension** have a SBP between 120 and 139 mm Hg or a DBP between 80 and 89 mm Hg, and they are at high risk for developing hypertension and CVD. Stage 1 hypertension (140 to 159/90 to 99 mm Hg) is the most prevalent level seen in adults; this is the group most likely to have a MI or stroke. The defining point for hypertension is arbitrary because any level of elevated blood pressure is associated with increased incidence of CVD and renal disease. Therefore normalization of blood pressure is important for all stages of hypertension.

Hypertension is a common public health problem in developed countries. In the United States one in three adults has high blood pressure (AHA, 2010). Untreated hypertension leads to many degenerative diseases, including HF, end-stage renal disease, and peripheral vascular disease. It is often called a “silent killer” because people with hypertension can be asymptomatic for years and then have a fatal stroke or heart attack. Although no cure is available,

hypertension is easily detected and usually controllable. Some of the decline in CVD mortality during the last two decades has been attributed to the increased detection and control of hypertension. The emphasis on lifestyle modifications has given diet a prominent role in both the primary prevention and management of hypertension.

Of those persons with high blood pressure, 90% to 95% have **essential hypertension** (hypertension of unknown cause) or primary hypertension. The cause involves a complex interaction between poor lifestyle choices and gene expression. Lifestyle factors that have been implicated include poor diet (i.e., high sodium, low fruit and vegetable intake), smoking, physical inactivity, stress, and obesity. Vascular inflammation has also been implicated (Savioa and Schiffriin, 2007). Many genes play a role in hypertension; most relate to the renal or neuroendocrine control of blood pressure. Evaluations of 2.5 million genotyped polymorphisms have identified CYP17A1, CYP1A2, FGFS, SH2B3, MTHFR, ZNF652, and PLCD3 genes in hypertensive individuals, primarily of European or Asian ancestry (Newton-Cheh et al., 2009). Hypertension that arises as the result of another disease, usually endocrine, is referred to as **secondary hypertension**. Depending on the extent of the underlying disease, secondary hypertension can be cured.

## Prevalence and Incidence

Approximately 74 million American adults age 20 and older have hypertension or are taking antihypertensive medication (AHA, 2010). Prevalence rates for hypertension have remained somewhat stable during the last 8 years, but are still almost double the *Healthy People 2010* goal; more than 30% of the adult U.S. population has high blood pressure (Egan et al., 2010). Non-Hispanic black adults have a higher age-adjusted prevalence of hypertension (43% of men; 44.8% of women) than non-Hispanic whites (34.3% of men; 31.1% of women), Mexican-Americans (25.9% of men; 31.6% of women), or Native Americans (25.3% men and women) (AHA, 2010, AHA, 2007). The prevalence of high blood pressure in blacks is one of the highest rates seen anywhere in the world. Because blacks develop hypertension earlier in life and maintain higher blood pressure levels, their risk of fatal stroke, heart disease, or end-stage kidney disease is higher than in whites (AHA, 2010).

A person of any age can have hypertension. Approximately 16% of boys and 9% of girls have elevated blood pressure (Ostchega et al., 2009). With aging, the prevalence of high blood pressure increases (Figure 34-7). Before the age of 45 more men than women have high blood pressure, and after age 65 the rates of high blood pressure among women in each racial group surpass those of the men in their group (AHA, 2010). Because the prevalence of hypertension rises with increasing age, more than half the older adult population (>65 years of age) in any racial group has hypertension. Although lifestyle interventions targeted to older persons may reduce the prevalence of hypertension, early intervention programs provide the greatest long-term

**TABLE 34-3****Classification and Management of Blood Pressure for Adults Ages 18 Years or Older**

	Classification*		Management*			Initial Drug Therapy	
	Systolic BP (mm Hg)*	Diastolic BP (mm Hg)*	Lifestyle Modification	Without Compelling Indication	With Compelling Indications		
Normal	<120	and	<80	Encourage	No antihypertensive drug indicated	Drugs for compelling indications <sup>†</sup>	
Prehypertension	120-139	or	80-89	Yes	Thiazide-type diuretics for most; may consider ACE inhibitor, ARB, $\beta$ -blocker, CCB, or combination	Drugs for compelling indications	
Stage 1 hypertension	140-159	or	90-99	Yes	Two-drug combination for most (usually thiazide-type diuretic and ACE inhibitor or ARB or $\beta$ -blocker or CCB) <sup>‡</sup>	Other antihypertensive drugs (diuretics, ACE inhibitor, ARB, $\beta$ -blocker, CCB) as needed	
Stage 2 hypertension	$\geq 160$	or	$\geq 100$	Yes	Two-drug combination for most (usually thiazide-type diuretic and ACE inhibitor or ARB or $\beta$ -blocker or CCB) <sup>‡</sup>	Drugs for compelling indications

potential for reducing overall blood pressure-related complications (Gidding et al., 2009).

The relationship between blood pressure and risk of CVD events is continuous, independent of other risk factors. The higher the blood pressure, the greater the chance of target organ damage, including left ventricular hypertrophy (LVH), HF, stroke, chronic kidney disease, and retinopathy (ADA, 2009). As many as 30% of adults with hypertension have treatment-resistant hypertension, which means that their blood pressure remains high despite the use of three or more antihypertensive drugs from different classes (Calhoun et al., 2008). Treatment-resistant hypertension puts an individual at greater risk of target organ damage. Older age and obesity are two of the strongest risk factors associated with the condition. Identification and reversal of lifestyle factors contributing to treatment resistance, along with diagnosis and appropriate treatment of secondary causes and use of effective multidrug regimens are essential treatment strategies.

Adults with diabetes have CVD death rates two to four times higher than adults without diabetes (American Diabetes Association, 2007). Consequently, national guidelines have set the target blood pressure goal for antihypertensive therapy for individuals with diabetes at 130/80 mm Hg, lower than that recommended for the general population. With the increased prevalence of diabetes, this is an important public health problem to address.

Although hypertensive patients are often asymptomatic, hypertension is not a benign disease. Cardiac, cerebrovascular, and renal systems are affected by chronically elevated blood pressure (Table 34-4). High blood pressure was the

primary or a contributory cause in 326,000 of the 2.4 million U.S. deaths in 2006 (AHA, 2010). Between 1996 and 2006 the age-adjusted death rate from hypertension increased by 19.5%; overall deaths from hypertension increased by 48%. Death rates from hypertension are approximately 3.2 times higher in blacks than in whites (AHA, 2010). Hypertension is a major contributing factor to atherosclerosis, stroke, renal failure, and MI. Factors associated with a poor prognosis in hypertension are shown in Box 34-7.

**Pathophysiology**

Blood pressure is a function of cardiac output multiplied by peripheral resistance (the resistance in the blood vessels to the flow of blood). Thus the diameter of the blood vessel markedly affects blood flow. When the diameter is decreased (as in atherosclerosis) resistance and blood pressure increase. Conversely, when the diameter is increased (as with vasodilator drug therapy), resistance decreases and blood pressure is lowered.

Many systems maintain homeostatic control of blood pressure. The major regulators are the SNS for short-term control and the kidney for long-term control. In response to a fall in blood pressure, the SNS secretes norepinephrine, a vasoconstrictor, which acts on small arteries and arterioles to increase peripheral resistance and raise blood pressure. Conditions that result in overstimulation of the SNS (i.e., certain adrenal disorders or sleep apnea) result in increased blood pressure (Khayat et al., 2009). The kidney regulates blood pressure by controlling the extracellular fluid volume and secreting renin, which activates the **renin-angiotensin system (RAS)** (Figure 34-8). Abnormal blood pressure is usually multifactorial. In most cases of hypertension, peripheral resistance increases. This resistance forces the left ventricle of the heart to increase its effort in pumping blood through the system. With time, LVH and eventually HF can develop.

Common genetic variants of the RAS gene, including angiotensin-converting enzyme (ACE) and angiotensinogen, have shown relationships with hypertension

(Norton et al., 2010). An increased production of these proteins may increase production of angiotensin II, the primary mediator of the RAS, thus increasing blood pressure. Angiotensin II may also trigger low-grade inflammation within the blood vessel wall, a condition that predisposes to hypertension (Savioia and Schiffrin, 2007).

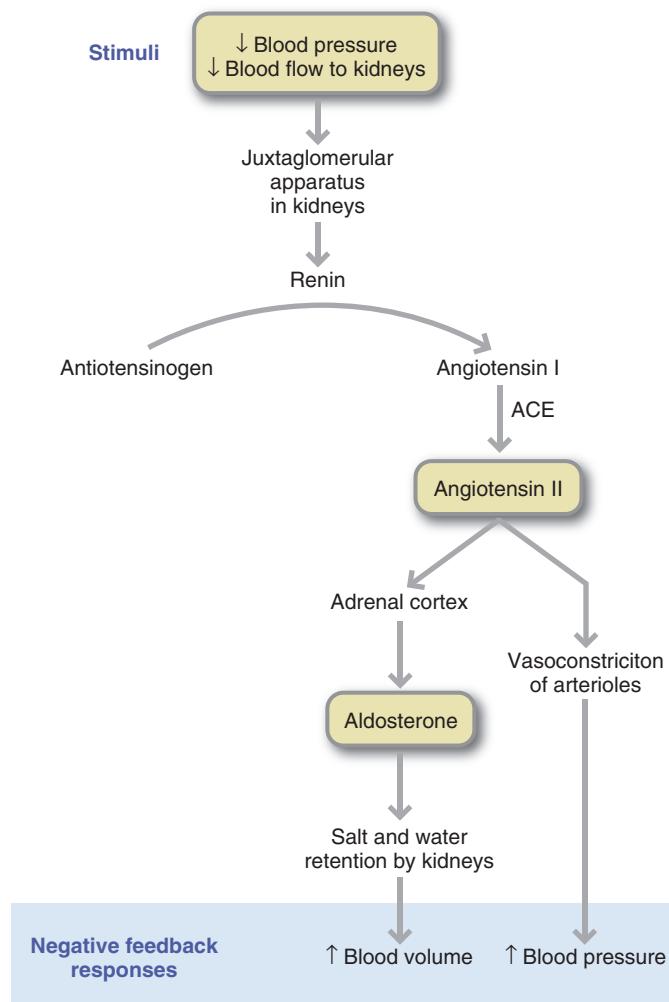

Hypertension often occurs with other risk factors for CVD including visceral (intraabdominal) obesity, insulin resistance, high triglycerides, and low HDL cholesterol levels. The coexistence of three or more of these risk factors leads to metabolic syndrome. It is unclear whether one or more of these risk factors precedes the others or whether they occur simultaneously. Accumulation of visceral fat synthesizes increased amounts of angiotensinogen, which activates the RAS and increases blood pressure (Mathieu et al., 2009). Also, angiotensin II, the primary mediator of the RAS, promotes the development of large dysfunctional adipocytes, which produce increased amounts of leptin and reduced quantities of adiponectin. Higher levels of leptin and lower amounts of circulating adiponectin activate the SNS, a key component of the hypertensive response (Depres, 2006).

### Primary Prevention

Positive changes in hypertension awareness, treatment, and control have occurred during the last several years. Based on analysis of NHANES data from 2007-2008, 81% of people with hypertension are aware that they have it (Egan et al., 2010), up from 72% in 1999-2004. Current hypertension treatment and control rates have also increased; this 50% control rate meets the *Healthy People 2010* objective, and reflects increased awareness, treatment and control of hypertension. In 2008 women, younger adults (aged 18-39 years), and Hispanic individuals had lower rates of blood pressure control compared with men, younger individuals, and non-Hispanic whites. Improving hypertension treatment through targeted intervention programs should have a positive effect on CVD outcomes. Blood pressure treatment guidelines highlight the importance of evaluating patients for the presence of multiple CVD risk factors and individualizing lifestyle modification and drug therapies accordingly.

Primary prevention can improve quality of life and the associated costs. One strategy is to reduce blood pressure in those with prehypertension (above 120/80) but below the cutoff points for stage 1 hypertension. A downward shift of 3 mm Hg in SBP would decrease the mortality from stroke by 8% and from CHD by 5% (Appel, 2006). Persons at highest risk should be strongly encouraged to adopt healthier lifestyles.

Changing lifestyle factors have documented efficacy in the primary prevention and control of hypertension. These factors were systematically reviewed and categorized by the American Dietetic Association (ADA) in 2009 (Table 34-5). A strong recommendation (i.e., high benefit/risk ratio with supporting evidence) is made for reducing intake of dietary sodium and increasing intake of fruits and vegetables. The ADA Practice Guidelines also recommend weight reduction

**FIGURE 34-8** Renin-angiotensin cascade. *ACE*, Angiotensin-converting enzyme. (Reprinted with permission from Fox SI: *Human physiology*, ed 6, New York, 1999, McGraw-Hill.)

**TABLE 34-5****Evidence Analysis Library Recommendations on Blood Pressure and Hypertensive Adults**

<b>Food or Nutrient</b>	<b>Recommendation</b>	<b>Rating</b>
Fruits and vegetables	Fruits and vegetables should be recommended at a level of five to ten servings per day for significant BP reduction.	Strong
Sodium	Sodium intake should be limited to no more than 2300 mg/day; if adherent to this recommendation and BP target not achieved, a further reduction in dietary sodium to 1600 mg/day should be encouraged in combination with a DASH dietary pattern. Approximate SBP reduction range 2-8 mm Hg.	Strong
DASH diet	Individuals should adopt the DASH dietary pattern, which is rich in fruits, vegetables, low-fat dairy, and nuts; low in sodium, total fat, and saturated fat; and adequate in calories for weight management. Approximate SBP reduction range 8-14 mm Hg.	Consensus
Physical activity	Individuals should be encouraged to engage in aerobic physical activity for at least 30 minutes per day on most days of the week, as it reduces SBP. Approximate SBP reduction range 4-9 mm Hg.	Consensus
Weight management	Optimal body weight should be achieved and maintained (BMI 18.5-24.9) to reduce BP. Approximate SBP reduction range 5-20 mm Hg/10 kg.	Consensus
Alcohol	For individuals who can safely consume alcohol, consumption should be limited to no more than two drinks (24 oz beer, 10 oz wine, or 3 oz of 80-proof liquor) per day in most men and to no more than one drink per day in women. Approximate SBP reduction range 2-4 mm Hg.	Consensus
Calcium	The effect of increasing calcium intake with lowered blood pressure is unclear; although some research indicates minimal benefit.	Fair
Magnesium	The effect of increasing magnesium intake with lowered blood pressure is unknown; although some research indicates minimal benefit.	Fair
Omega-3 fatty acids	Studies investigating increased consumption of ω-3 fatty acids have not demonstrated a beneficial effect on BP.	Fair
Potassium	Studies support a modest relationship between increasing intake of potassium and a lower sodium-potassium ratio with lowered blood pressure.	Fair

BMI, Body mass index; BP, blood pressure; DASH, Dietary Approaches to Stop Hypertension; SBP, systolic blood pressure.

Recommendations listed are for those rated by the American Dietetic Association as strong, fair, and consensus; for those with weak ratings consult the American Dietetic Association Evidence Analysis Library for Hypertension (2009) <http://www.adaevidencelibrary.com/topic.cfm?cat=3259>.

if overweight; limiting alcohol intake; adopting a dietary pattern that emphasizes fruits, vegetables, and low-fat dairy products; and increasing physical activity. These recommendations are consensus recommendations based on expert opinion. A fair recommendation is made for increasing dietary potassium, magnesium, and calcium to recommended levels based on the dietary reference intakes (DRI). Evidence is not clear for modifications in dietary fats to lower blood pressure.

### Fats

Although dietary lipids do not seem to affect blood pressure, they strongly affect CVD risk; thus the TLC diet is recommended. Although fatty acids may not directly affect blood pressure, an olive oil-enriched diet may reduce the need for antihypertensive medication. Both the amount and type of fat have been studied with respect to blood pressure. In several large prospective observational studies and clinical

trials, intake of total fat and specific fatty acids had little effect on blood pressure (Cicero et al., 2009). Supplementation with large doses of fish oil (average 3.7 g/day) can give a modest reduction in SBP and DBP, especially in older hypertensive persons.

Fewer vegans have hypertension than omnivores, even though their salt intake is not significantly different. The vegan diet tends to be higher in PUFAs, among other nutrients, and lower in total fat, SFAs, and cholesterol. PUFAs are precursors of prostaglandins, whose actions affect renal sodium excretion and relax vascular musculature. Thus factors other than dietary fat, such as increased potassium levels, appear to lower blood pressure in vegans.

### Protein

Although soy protein may contribute to the lowering of blood pressure, the effect of increased soy food intake on blood pressure remains controversial (ADA, 2009).

## Dietary Patterns Emphasizing Fruits and Vegetables

Several dietary patterns have been shown to lower blood pressure. Vegetarian dietary patterns have been associated with lower SBP in observational studies and clinical trials. Average SBP reductions of 5 to 6 mm Hg have been reported. Specifically, the **Dietary Approaches to Stop Hypertension (DASH)** Diet Study shows that this low-fat dietary pattern (including lean meats and nuts and emphasizing fruits, vegetables, and nonfat dairy products) decreased SBP. The DASH diet is found to be more effective than just adding fruits and vegetables to a low-fat dietary pattern (Appel et al., 2006). Although the DASH diet is safe and currently advocated for preventing and treating prehypertension and hypertension, the diet is high in potassium, phosphorus, and protein, depending on how it is planned. For this reason the DASH diet is not advisable for individuals with end-stage renal disease (Appel et al., 2006).

The OmniHeart Trial examined the effects of three versions of the DASH diet on blood pressure and serum lipids. The diets studied included the original DASH diet, a high-protein version of the DASH diet (25% of energy from protein, approximately half from plant sources), and a DASH diet high in unsaturated fat (31% of calories from unsaturated fat, mostly monounsaturated). Although each diet lowered SBP, substituting some of the carbohydrate (approximately 10% of total calories) in the DASH diet with either protein or monounsaturated fat achieved the best reduction in blood pressure and blood cholesterol (Appel et al., 2006; Miller et al., 2006). This could be achieved by substituting nuts for some of the fruit, bread, or cereal servings.

Because many hypertensive patients are overweight, hypocaloric versions of the DASH diet have also been tested for efficacy in promoting weight loss and blood pressure reduction. A hypocaloric DASH diet versus a low-calorie, low-fat diet produces a greater reduction in SBP and DBP. More recently, the ENCORE study showed that the addition of exercise and weight loss to the DASH diet resulted in greater blood pressure reductions, greater improvements in vascular function, and reduced left ventricular mass compared with the DASH diet alone (Blumenthal et al., 2010).

## Weight Reduction

There is a strong association between BMI and hypertension among men and women in all race or ethnic groups and in most age groups. The risk of developing elevated blood pressure is two to six times higher in overweight than in normal-weight persons (National Institutes of Health [NIH], 2004). Risk estimates from population studies suggest that 30% or more of cases of hypertension can be directly attributed to obesity (AHA, 2010). Weight gain during adult life is responsible for much of the rise in blood pressure seen with aging.

Some of the physiologic changes proposed to explain the relationship between excess body fat and blood pressure are

overactivation of the SNS and RAS and vascular inflammation (Mathieu et al., 2009). Visceral fat in particular promotes vascular inflammation by inducing cytokine release, proinflammatory transcription factors, and adhesion molecules (Savoia and Schiffrin, 2007). Low-grade inflammation occurs in the vasculature of individuals with elevated blood pressure; whether it precedes the onset of hypertension is unclear. Weight loss, exercise, and a Mediterranean-style diet are quite beneficial.

Virtually all clinical trials on weight reduction and blood pressure support the efficacy of weight loss on lowering blood pressure. Reductions in blood pressure can occur without attainment of desirable body weight in most participants. Larger blood pressure reductions are achieved in participants who lost more weight and were also taking antihypertensive medications. This latter finding suggests a possible synergistic effect between weight loss and drug therapy. Although weight reduction and maintenance of a healthy body weight is a major effort, interventions to prevent weight gain are needed prior to midlife. In addition, BMI is recommended as a screening tool in adolescence for future health risk.

## Sodium

Evidence from a variety of studies supports lowering blood pressure and CVD risk by reducing dietary sodium. For example, in the Trials of Hypertension Prevention more than 2400 individuals with moderately elevated blood pressure were randomly assigned to either cut their sodium by 750 to 1000 milligrams per day or to follow general guidelines for healthy eating for 18 months to 4 years. In 10 to 15 years after the studies ended, individuals who cut their sodium experienced a 25% to 30% lower risk of heart attacks, strokes, or other cardiovascular events compared with the group that did not (Cook et al., 2007). Several randomized trials have confirmed these positive effects of sodium reduction on blood pressure and cardiovascular outcomes for normotensive and hypertensive individuals.

The DASH sodium trials tested the effects of three different levels of sodium intake (1500 mg, 2300 mg, and 3300 mg/day) combined with either a typical U.S. diet or the DASH diet in persons with prehypertension or stage 1 hypertension (Appel, 2006). The lowest blood pressures were achieved by those eating the 1500-mg sodium level in the DASH diet. In both the DASH diet and the typical American diet groups, the lower the sodium, the lower the blood pressure. Such data provide the basis for current dietary guidelines to limit sodium intake to 1500 mg/day for those with higher than optimal blood pressure (U.S. Department of Health and Human Services, 2005) (see Chapter 12). For those with normal blood pressure, the Dietary Guidelines for Americans recommend an intake of less than 2300 mg of sodium, the equivalent of 6 grams of salt, each day. This goal is supported by the ADA Practice Guidelines (ADA, 2009) and other organizations.

There is heterogeneity in individual responsiveness to sodium. Some persons with hypertension show a greater

decrease in their blood pressures in response to reduced sodium intake than others. The term *salt-sensitive hypertension* has been used to identify these individuals. *Salt-resistant hypertension* refers to individuals with hypertension whose blood pressures do not change significantly with lowered salt intakes. Salt sensitivity varies, with individuals having greater or lesser degrees of blood pressure reduction. In general, individuals who are more sensitive to the effects of salt and sodium tend to be individuals who are black, obese, and middle-aged or older, especially if they have diabetes, chronic kidney disease, or hypertension. Currently, there are no practical methods for identifying the salt-sensitive individual from the salt-resistant individual.

## Calcium

Higher dairy versus supplemental calcium is associated with lower risk of hypertension (Wang et al., 2008). Analyses of the effects of calcium on blood pressure report modest reductions in SBP and DBP in hypertensive patients (Dickinson, 2006b). Mechanistically, a low calcium intake increases intracellular calcium concentration. This in turn increases 1,25-vitamin D<sub>3</sub> and parathyroid hormone levels, causing calcium influx into vascular smooth muscle cells and greater vascular resistance (Kris-Etherton et al., 2009). Alternatively, peptides derived from milk proteins, especially fermented milk products, may function as ACEs, thereby lowering blood pressure. The DASH trial found that 8-week consumption of a diet high in fruits, vegetables, and fiber; three servings of low-fat dairy products/day; and lower total and saturated fat could lower SBP and DBP by 5.5 and 3 mm Hg greater, respectively, than the control diet. The fruit and vegetable diet without dairy foods results in blood pressure reductions approximately half that of the DASH diet. The ADA Practice Guidelines recommend a diet rich in fruits, vegetables, and low-fat dairy products (versus calcium supplements) for the prevention and management of elevated blood pressure (ADA, 2009). An intake of dietary calcium to meet the DRI is recommended.

## Magnesium

Magnesium is a potent inhibitor of vascular smooth-muscle contraction and may play a role in blood pressure regulation as a vasodilator. High dietary magnesium is often correlated with lower blood pressure (Sontia and Touyz, 2007). Less consistent findings have been reported from trials of magnesium supplementation (Dickinson et al., 2006b). The DASH dietary pattern emphasizes foods rich in magnesium, including green leafy vegetables, nuts, and whole-grain breads and cereals. Overall food sources of magnesium rather than supplemental doses of the nutrient are encouraged to prevent or control hypertension (ADA, 2009).

## Potassium

Higher potassium intakes are usually associated with lower blood pressures, often dose-responsive. Specifically, supplemental doses of potassium in the range of 1900 to

4700 mg/day will lower blood pressure approximately 2 to 6 mm Hg DBP and 2 to 4 mm Hg SBP (Dickinson et al., 2006a). The effects of potassium are greater in those with higher initial blood pressure, in blacks compared with whites, and in those with higher intakes of sodium. Higher potassium intake is also associated with a lower risk of stroke. More significant effects are found for improved diet, aerobic exercise, alcohol and sodium restriction, and fish oil supplements than for potassium supplements (Dickinson et al., 2006a).

The large number of fruits and vegetables recommended in the DASH diet makes it easy to meet the dietary potassium recommendations—approximately 4.7 g/day (ADA, 2009). In individuals with medical conditions that could impair potassium excretion (e.g., chronic renal failure, diabetes, and congestive HF), a lower potassium intake (< 4.7 g/day) is appropriate to prevent hyperkalemia.

## Physical Activity

Less active persons are 30% to 50% more likely to develop hypertension than their active counterparts. Despite the benefits of activity and exercise in reducing disease, many Americans remain inactive. Hispanics (33% men, 40% women), blacks (27% men, 34% women), and whites (18% men, 22% women) all have a high prevalence of sedentary lifestyles (AHA, 2010). Exercise is beneficial to blood pressure. Increasing the amount of low- to moderate-intensity physical activity to 30 to 45 minutes most days of the week is an important adjunct to other strategies.

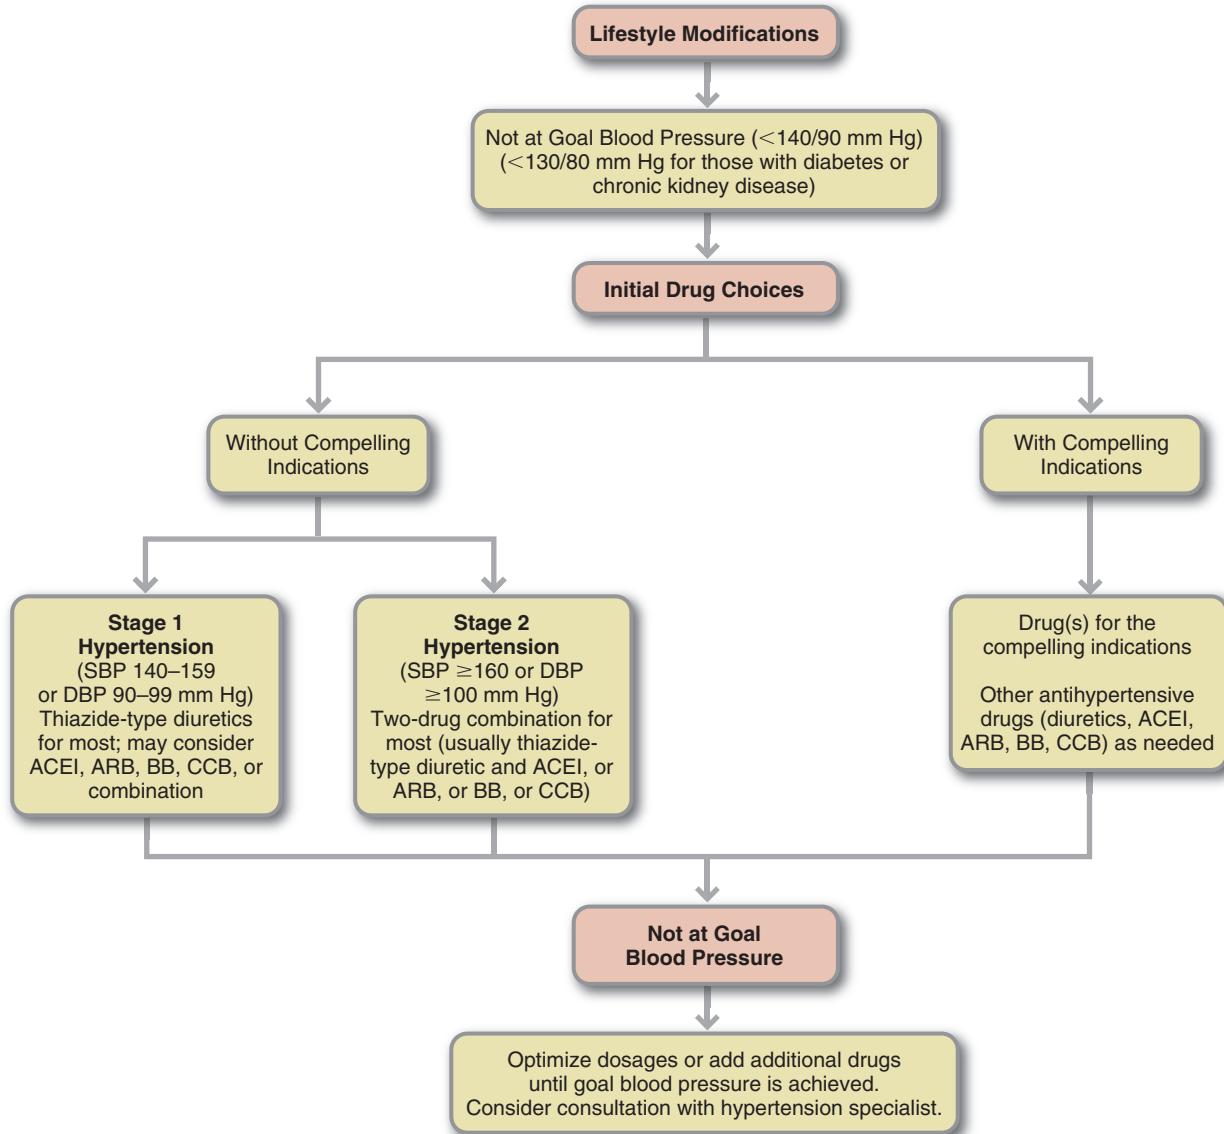

## Alcohol Consumption

Excessive alcohol consumption is responsible for 5% to 7% of the hypertension in the population (Appel et al., 2006). A three drink/day amount (a total of 3 oz of alcohol) is the threshold for raising blood pressure and is associated with a 3-mm Hg rise in SBP. For preventing high blood pressure, alcohol intake should be no more than two drinks per day (24 oz of beer, 10 oz of wine, or 3 oz of 80-proof whiskey) in men, and no more than one drink a day is recommended for lighter-weight men and for women.

## Medical Management

The goal of hypertension management is to reduce morbidity and mortality from stroke, hypertension-associated heart disease, and renal disease. The three objectives for evaluating patients with hypertension are to (1) identify the possible causes, (2) assess the presence or absence of target organ disease and clinical CVD, and (3) identify other CVD risk factors that will help guide treatment. The presence of risk factors and target organ damage determines treatment priority.

Lifestyle modifications are definitive therapy for some and adjunctive therapy for all persons with hypertension. Several months of compliant lifestyle modifications should be tried before drug therapy is initiated. An algorithm for treatment of hypertension is shown in Figure 34-9. Even if lifestyle modifications cannot completely correct the blood

**FIGURE 34-9** Algorithm for treatment of hypertension. *ACEI*, angiotensin-converting enzyme inhibitor; *ARB*, angiotensin-receptor blocker; *BB*,  $\beta$ -blocker; *CCB*, calcium channel blocker; *DBP*, diastolic blood pressure; *SBP*, systolic blood pressure. (From National Institutes of Health, National Heart, Lung and Blood Institute National High Blood Pressure Education Program: *The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure*, NIH Publication No. 04-5230, August 2004).

pressure, they help increase the efficacy of pharmacologic agents and improve other CVD risk factors. Management of hypertension requires a lifelong commitment.

Pharmacologic therapy is necessary for many individuals, especially if blood pressure remains elevated after 6 to 12 months of lifestyle changes. Most patients with hypertension more severe than stage 1 hypertension require drug treatment; however, lifestyle modifications remain a part of therapy in conjunction with medications. The standard treatment for hypertension includes diuretics and  $\beta$ -blockers, although other drugs ( $\beta$ -ACE inhibitors,  $\alpha$ -receptor blockers, and calcium antagonists) are equally effective. All these drugs can affect nutrition status (see Chapter 9).

Diuretics lower blood pressure in some patients by promoting volume depletion and sodium loss. Thiazide diuretics increase urinary potassium excretion, especially in the presence of a high salt intake, thus leading to potassium loss and possible hypokalemia. Except in the case of a potassium-sparing diuretic such as spironolactone or triamterene, additional potassium is usually required.

A number of medications either raise blood pressure or interfere with the effectiveness of antihypertensive drugs. These include oral contraceptives, steroids, nonsteroidal antiinflammatory drugs, nasal decongestants and other cold remedies, appetite suppressants, cyclosporine, tricyclic antidepressants, and monoamine-oxidase inhibitors (see Chapter 9 and Appendix 31).

## Medical Nutrition Therapy

The appropriate course of nutrition therapy for managing hypertension should be guided by data from a detailed nutrition assessment. Weight history; leisure-time physical activity; and assessment of dietary sodium, alcohol, saturated fat, and other patterns (e.g., intake of fruits, vegetables, and low-fat dairy products) are essential components of the medical and diet history. Nutrition assessment should include evaluation of the individual in the following specific domains to determine nutrition problems and diagnoses: food and nutrient intake; knowledge, beliefs, and attitudes; behavior; physical activity and function; and appropriate biochemical data. Following are the components of the current recommendations for managing elevated blood pressure. See [Table 34-6](#) for a list of approaches sometimes used.

### Energy Intake

For each kilogram of weight lost, reductions in SBP and DBP of approximately 1 mm Hg are expected. Hypertensive patients who weigh more than 115% of ideal body weight should be placed on an individualized weight-reduction program that focuses on both hypocaloric dietary intake and exercise (see [Chapter 22](#)). A modest caloric reduction is associated with a significant lowering of SBP and DBP, and LDL cholesterol levels. Hypocaloric diets that include a low-sodium DASH dietary pattern have produced more significant blood pressure reductions than low-calorie diets emphasizing only low-fat foods. Another benefit of weight loss on blood pressure is the synergistic effect with drug therapy. Weight loss should be an adjunct to drug therapy because it may decrease the dose or number of drugs necessary to control blood pressure.

### DASH Diet

The DASH diet is used for both preventing and controlling high blood pressure (see [Appendix 33](#)). Successful adoption of this diet requires many behavioral changes: eating twice the average number of daily servings of fruits, vegetables, and dairy products; limiting by one-third the usual intake of beef, pork, and ham; eating half the typical amounts of fats, oils, and salad dressings; and eating one-quarter the number of snacks and sweets. Lactose-intolerant persons may need to incorporate lactase enzyme or use other strategies to replace milk. Assessing patients' readiness to change and engaging patients in problem solving, decision making, and goal setting are behavioral strategies that may improve adherence ([Appel et al., 2006](#)).

The high number of fruits and vegetables consumed on the DASH diet is a marked change from typical patterns of Americans. To achieve the 8 to 10 servings, two to three fruits and vegetables should be consumed at each meal. Importantly, because the DASH diet is high in fiber, gradual increases in fruit, vegetables, and whole-grain foods should be made over time. Slow changes can reduce potential short-term gastrointestinal disturbances associated with a high-fiber diet such as bloating and diarrhea. The DASH pattern

is in the current AHA nutrition guidelines ([Appel et al., 2006](#)). Servings for different calorie levels are shown in [Appendix 33](#).

### Salt Restriction

The Dietary Guidelines for Americans recommend that young adults consume less than 2400 mg of sodium per day. People with hypertension, blacks, and middle-age and elderly people—almost half the population—are advised to consume no more than 1500 mg/day ([U.S. Department of Agriculture \[USDA\], 2005](#)). The DASH-Sodium trial showed that people consuming diets of 1.5 g/day of sodium had greater blood pressure benefits than those with higher intakes. Lower-sodium diets were also shown to maintain low blood pressure over time and enhance the efficacy of certain blood pressure-lowering medications. Although it may be advisable for individuals with elevated blood pressure to restrict sodium to adequate intake (AI) levels, adherence to diets containing less than 2 g/day of sodium is very difficult to achieve.

In addition to advice to select minimally processed foods, dietary counseling should include instruction on reading food labels for sodium content, avoidance of discretionary salt in cooking or meal preparation (1 tsp salt = 2400 mg sodium), and use of alternative flavorings to satisfy individual taste. The DASH eating plan is rich in fruits and vegetables, which are naturally lower in sodium than many other foods.

Because most dietary salt comes from processed foods and eating out, changes in food preparation and processing can help patients reach the sodium goal. Sensory studies show that commercial processing could develop and revise recipes using lower sodium concentrations and reduce added sodium without affecting consumer acceptance. The food industry has begun this effort to reduce sodium in the American diet. See *Focus On: Sodium and the Food Industry*.

### Potassium-Calcium-Magnesium

Consuming a diet rich in potassium has been shown to lower blood pressure and blunt the effects of salt on blood pressure in some individuals ([Appel et al., 2006](#)). The recommended intake of potassium for adults is 4.7 g/day ([National Academies of Science, Institute of Medicine, 2004](#)). Potassium-rich fruits and vegetables include leafy green vegetables, fruits, and root vegetables. Examples of such foods include oranges, beet greens, white beans, spinach, bananas, and sweet potatoes. Although meat, milk, and cereal products contain potassium, the potassium from these sources is not as well-absorbed as that from fruits and vegetables ([USDA, 2005](#)).

Increased intakes of calcium and magnesium may have blood pressure benefits, although there is not enough data at present to support a specific recommendation for increasing levels of intake ([ADA, 2009](#)). Rather, recommendations suggest meeting the AI intake for calcium and the recommended dietary allowance for magnesium from food sources rather than supplements. The DASH diet plan encourages

## Sodium and the Food Industry

**M**ost foods sold in supermarkets and restaurants are high in salt. The dramatic differences in sodium from brand to brand suggest that many companies could easily achieve significant reductions without sacrificing taste. According to the Center for Science in the Public Interest (Lieberman, 2010), processed foods and restaurant foods contribute approximately 80% of the sodium in Americans' diets; 10% comes from salt added during cooking at home or at the table; the remaining 10% is naturally occurring. Americans now consume approximately 4000 mg of sodium per day—about twice the recommended amount. To help address this problem, the National Academy of Science and Institute of Medicine (2010) issued a report calling for urgent government action

to reduce salt in packaged and restaurant foods. The report recommends five strategies to reduce sodium levels in America's food supply. The primary strategy is to set a mandatory national sodium level standard for foods. The interim strategy is voluntary reduction of sodium content in foods by food manufacturers. Supporting strategies are for government agencies, public health and consumer organizations, and the food industry to administer activities to support both the reduction of sodium in the food supply and consumers' intake of sodium. Federal agencies are recommended to improve the data collection, monitoring, and surveillance of sodium intake measurement, salt taste preference, and sodium content of foods.

foods that would be good sources of both nutrients, including low-fat dairy products, dark green leafy vegetables, beans, and nuts.

### Lipids

Current recommendations for lipid composition of the diet are recommended to help control weight and decrease the risk of CVD. Omega-3 fatty acids are not highlighted, because their consumption does not appear to lower blood pressure (ADA, 2009). However, the research continues.

### Alcohol

The diet history should contain information about alcohol consumption. Alcohol intake should be limited to no more than two drinks daily in men, which is equivalent to 2 oz of 100-proof whiskey, 10 oz of wine, or 24 oz of beer. Women or lighter-weight men should consume half this amount.

### Exercise

Moderate physical activity, defined as 30 to 45 minutes of brisk walking on most days of the week, is recommended as an adjunct therapy in hypertension. Overweight or obese hypertensive patients should strive for 300 to 500 kcal expended in exercise per day or 1000 to 2000 kcal/week to promote weight loss or weight control. Because exercise is strongly associated with success in weight-reduction and weight-maintenance programs, any increase in activity level should be encouraged. Daily moderate-intensity physical activity lasting 60 to 90 minutes is recommended for individuals trying to maintain a new lower weight after having lost weight (USDA, 2005).

### Treatment of Hypertension in Children and Adolescents

The prevalence of primary hypertension among children in the United States is increasing in concert with rising obesity

rates and increased intakes of high-calorie, high-salt foods (Mitsnefes, 2006). Hypertension tracks into adulthood and has been linked with carotid intimal-medial thickness, LVH, and fibrotic plaque formation. Secondary hypertension is more common in preadolescent children, mostly from renal disease; primary hypertension caused by obesity or a family history of hypertension is more common in adolescents (Luma and Spiotta, 2006). In addition, it has been noted that intrauterine growth retardation leads to hypertension in childhood (Shankaran, 2006).

High blood pressure in youth is based on a normative distribution of blood pressure in healthy children. Hypertension is defined as an SBP or DBP of greater than the 95th percentile for age, sex, and height. The designation for prehypertension in children is SBP or DBP of greater than the 90th percentile. Therapeutic lifestyle changes are recommended as an initial treatment strategy for children and adolescents with prehypertension or hypertension. These lifestyle modifications include regular physical activity, avoiding excess weight gain, limiting sodium, and consuming a DASH-type diet.

Weight reduction is considered the primary therapy for obesity-related hypertension in children and adolescents. Unfortunately, sustained weight loss is difficult to achieve in this age group. The Framingham Children's Study showed that children with higher intakes of fruits, vegetables (a combination of four or more servings per day), and dairy products (two or more servings per day) had lower SBP compared with those with lower intakes of these foods. Couch and colleagues (2008) showed that adolescents with prehypertension and hypertension could achieve a significant reduction in SBP in response to a behaviorally oriented nutrition intervention emphasizing the DASH diet. Because adherence to dietary interventions may be particularly challenging among children and teenagers, innovative nutrition intervention approaches that address the unique needs and

**TABLE 34-6****Complementary and Alternative Approaches to Lowering Blood Pressure**

<b>Common Name</b>	<b>Scientific Name</b>	<b>Effect on BP and Mechanism of Action</b>	<b>Side Effects and Risks</b>
Coenzyme Q <sub>10</sub>	Ubiquinone	Decreases SBP and DBP via a direct effect on the vascular endothelium and smooth muscle.	May cause gastrointestinal discomfort, nausea, flatulence, and headaches.
Vitamin C and Vitamin E taken in combination as supplement	Ascorbic Acid α-tocopherol	Decreases SBP and DBP, decreases arterial stiffness, and improves endothelial function by improving antioxidant status.	Vitamin E supplementation alone may increase BP.
Vitamin D	1,25-Dihydroxy vitamin D <sub>3</sub>	Decreases SBP via suppression of renin expression and vascular smooth muscle cell proliferation.	Hypercalcemia may occur depending on level of supplementation.
Fish oil	Omega-3 polyunsaturated fatty acid	At very high doses in hypertensive individuals, SBP and DBP reductions may occur by increasing the endothelium-dependent vasodilatory response; it may also increase the bioavailability of NO in the vascular wall.	May cause gastrointestinal discomfort, belching, bad breath and altered taste.
Garlic	Allium sativum	Reduces SBP and DBP in individuals with hypertension via vasodilation resulting from activation of potassium channels; may also be due to activation of NOS.	May cause bad breath and body odor.
Resveratrol	Trans-3,4',5-trihydroxystilbene	Reduces systolic BP in animals via enhanced NOS expression in the aorta.	Unknown
Mistletoe	<i>Viscum album</i>	Reduces systolic BP in animals via a sympathetic mechanism.	Unknown
Hawthorn berry	<i>Crataegus oxyacantha</i> , <i>Crataegus monogyna</i>	Exerts a mild, gradual BP lowering effect. The mechanism is unclear.	Unknown
Mulberry	<i>Morus alba</i>	Reduces SBP and DBP in animals. The mechanism is unclear.	Unknown
Roselle	<i>Hibiscus sabdariffa</i>	Lowers SBP in pre- and mildly hypertensive adults via calcium channel activation.	None
Dogbane plant	<i>Rauwolfia serpentine</i>	Reduces SBP by depleting catecholamines and serotonin from central and peripheral synapses.	None
Quercetin	3,3',4',5,7-pentahydroxyflavone	Reduced SBP via a direct vasodilator effect; also may cause an increase in the bioavailability and biological activity of NO.	May cause joint discomfort with long-term use and gastrointestinal upset unless taken with meals. May increase estradiol and reduce the effectiveness of other forms of estrogen.

circumstances of this age-group are important considerations in intervention design (see Chapters 18 and 19).

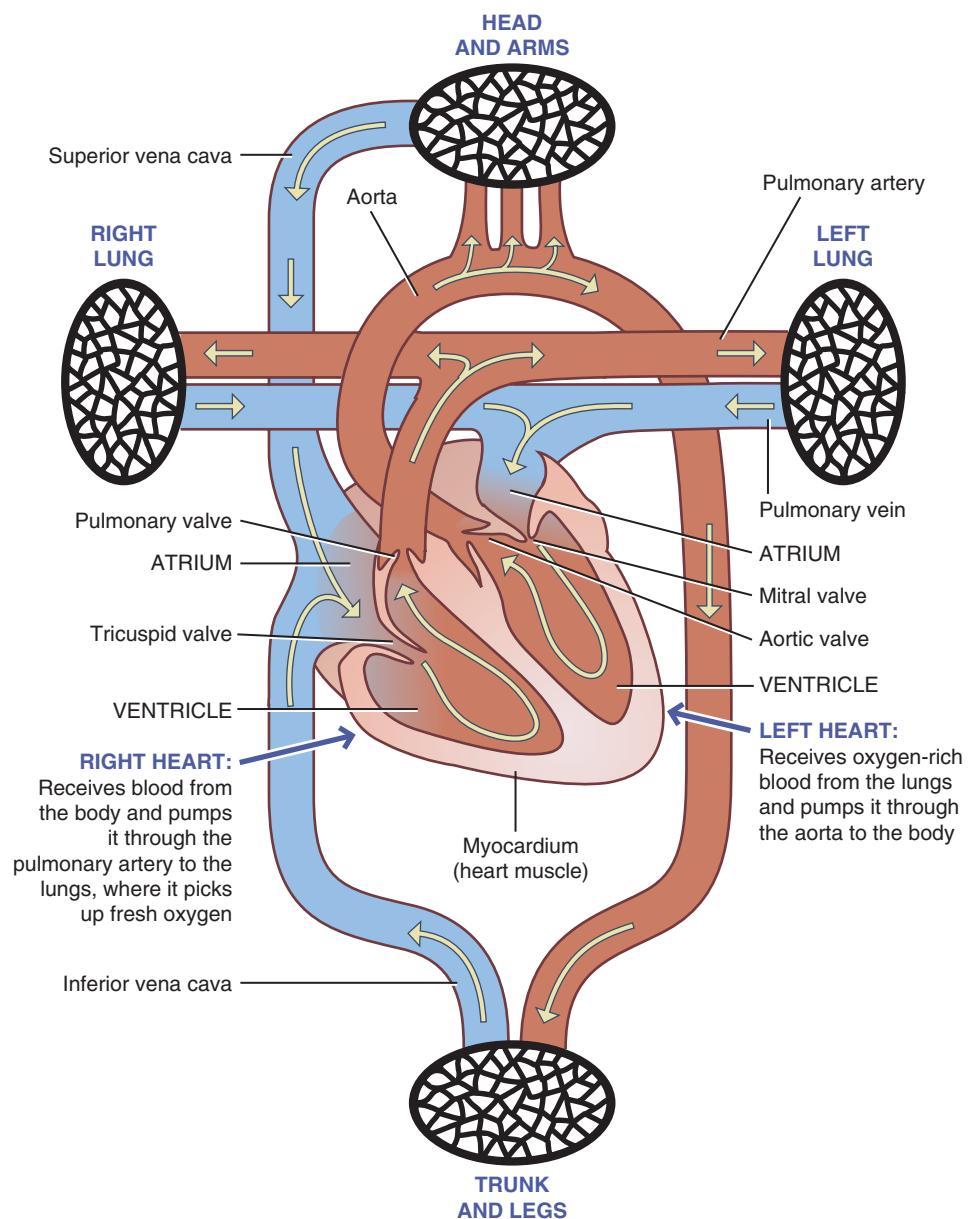

### Treatment of Blood Pressure in Older Adults

More than half of the older population has hypertension; this is not a normal consequence of aging. The lifestyle modifications discussed previously are the first step in treatment of older adults, as with younger populations. The Trial of Nonpharmacologic Interventions in the Elderly study found that losing weight (8 to 10 lb) and reducing sodium intake (to 1.8 g/day) can lessen or eliminate the need for drugs in obese, hypertensive older adults. Although losing weight and decreasing sodium in older adults are very effective in lowering blood pressure, knowing how to facilitate these changes and promote adherence remains an obstacle for health professionals.

Blood pressure should be controlled regardless of age, initial blood pressure level, or duration of hypertension (NIH, 2004). Severe sodium restrictions are not adopted because these could lead to volume depletion in older patients with renal damage. Drug treatment in the older adult is supported by very strong data.

## HEART FAILURE

Normally the heart pumps adequate blood to perfuse tissues and meet metabolic needs (Figure 34-10). In **heart failure (HF)**, formerly called *congestive heart failure*, the heart cannot provide adequate blood flow to the rest of the body, causing symptoms of fatigue, shortness of breath (**dyspnea**), and fluid retention. Diseases of the heart (valves, muscle, blood vessels) and vasculature can lead to HF (see *Pathophysiology*

**FIGURE 34-10** Structure of the heart pump.

*and Care Management Algorithm: Heart Failure).* HF can be right-sided, left-sided, or can affect both sides of the heart. It is further categorized as *systolic failure* when the heart cannot pump, or eject, blood efficiently out of the heart or *diastolic failure*, meaning the heart cannot fill with blood as it should.

HF is a major public health problem that affects more than 5 million Americans. The prevalence of HF increases with age. HF affects almost 10 per 1,000 population after age 65 (AHA, 2010). Black women have the highest rates of HF, followed by black men, Mexican-American men, white men, white women, and Mexican-American women (Thom et al., 2006). The incidence of new cases of HF has risen during the last 20 years because of an aging population, the increased number of people being saved from a MI, and the increase in obesity. In 2006 the overall death rate for HF was 89.2 per 100,000 population (AHA, 2010). The death rate per 100,000 for white men was 103.7, black men 105.9, white women 80.3, and black women 84.4. Unlike other CVDs, the number of people being discharged with an HF diagnosis rose from 877,000 in 1996 to 1,106,000 in 2006 (AHA, 2010).

### Pathophysiology

The progression of HF is similar to that of atherosclerosis because there is an asymptomatic phase when damage is silently occurring (stages A and B) (Figure 34-11). HF is initiated by damage or stress to the heart muscle either of acute MI or insidious (hemodynamic pressure or volume overloading) onset. See Table 34-7 for classifications of HF.

The progressive insult alters the function and shape of the left ventricle such that it hypertrophies in an effort to sustain blood flow, a process known as *cardiac remodeling*. Symptoms do not usually arise until months or years after cardiac remodeling begins. Many compensatory mechanisms from the SNS, RAS, and cytokine system are activated to restore homeostatic function. Proinflammatory cytokines, such as TNF- $\alpha\alpha$ , IL-1, and IL-6 are increased in

blood and the myocardium and have been found to regulate cardiac remodeling.

Another substance, B-natriuretic peptide (BNP), is secreted by the ventricles in response to pressure and is predictive of the severity of HF and mortality at any level of BMI (Horwitz et al., 2006). Patients are asymptomatic during these first two stages. BNP is often highly elevated in patients with HF (greater than 100 pg/mL is abnormal, and some patients have levels over 3000 pg/mL). Nesiritide (recombinant human BNP) provides symptomatic and hemodynamic improvement in acute decompensated HF and is now standard procedure (Arora et al., 2006).

Eventually overuse of compensatory systems leads to further ventricle damage, remodeling, and worsening of symptoms (stage C). HF patients have elevated levels of norepinephrine, angiotensin II, aldosterone, endothelin, and vasopressin; all of these are neurohormonal factors that increase the hemodynamic stress on the ventricle by causing sodium retention and peripheral vasoconstriction. These neurohormones and the proinflammatory cytokines contribute to disease progression; hence current studies focus on inhibition of these undesirable pathways and promotion of desirable ones.

For the final stages of HF, there is a subjective scale used to classify symptoms based on the degree of limitation in daily activities (Table 34-8). The severity of symptoms in this classification system is weakly related to the severity of left ventricular dysfunction; therefore treatment encompasses both improving functional capacity and lessening progression of the underlying disease.

**TABLE 34-8**

### Skeletal Muscle Changes in Heart Failure

**TABLE 34-7**

### Classifications of Heart Failure

Class I	No undue symptoms associated with ordinary activity and no limitation of physical activity
Class II	Slight limitation of physical activity; patient comfortable at rest
Class III	Marked limitation of physical activity; patient uncomfortable at rest
Class IV	Inability to carry out physical activity without discomfort; symptoms of cardiac insufficiency or chest pain at rest

## PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

### Heart Failure

**Etiology**

#### Clinical Findings

- Shortness of breath
- Fatigue
- Fluid retention
- Peripheral vasoconstrictor
- Elevated B-natriuretic peptide
- Mental confusion
- Memory loss
- Anxiety
- Insomnia
- Syncope and headache
- Dry cough

#### Nutrition Assessment

- Anorexia
- Nausea, abdominal pain and feeling of fullness
- Constipation
- Malabsorption
- Malnutrition
- Cardiac cachexia
- Hypomagnesemia
- Hyponatremia

#### Medical Management

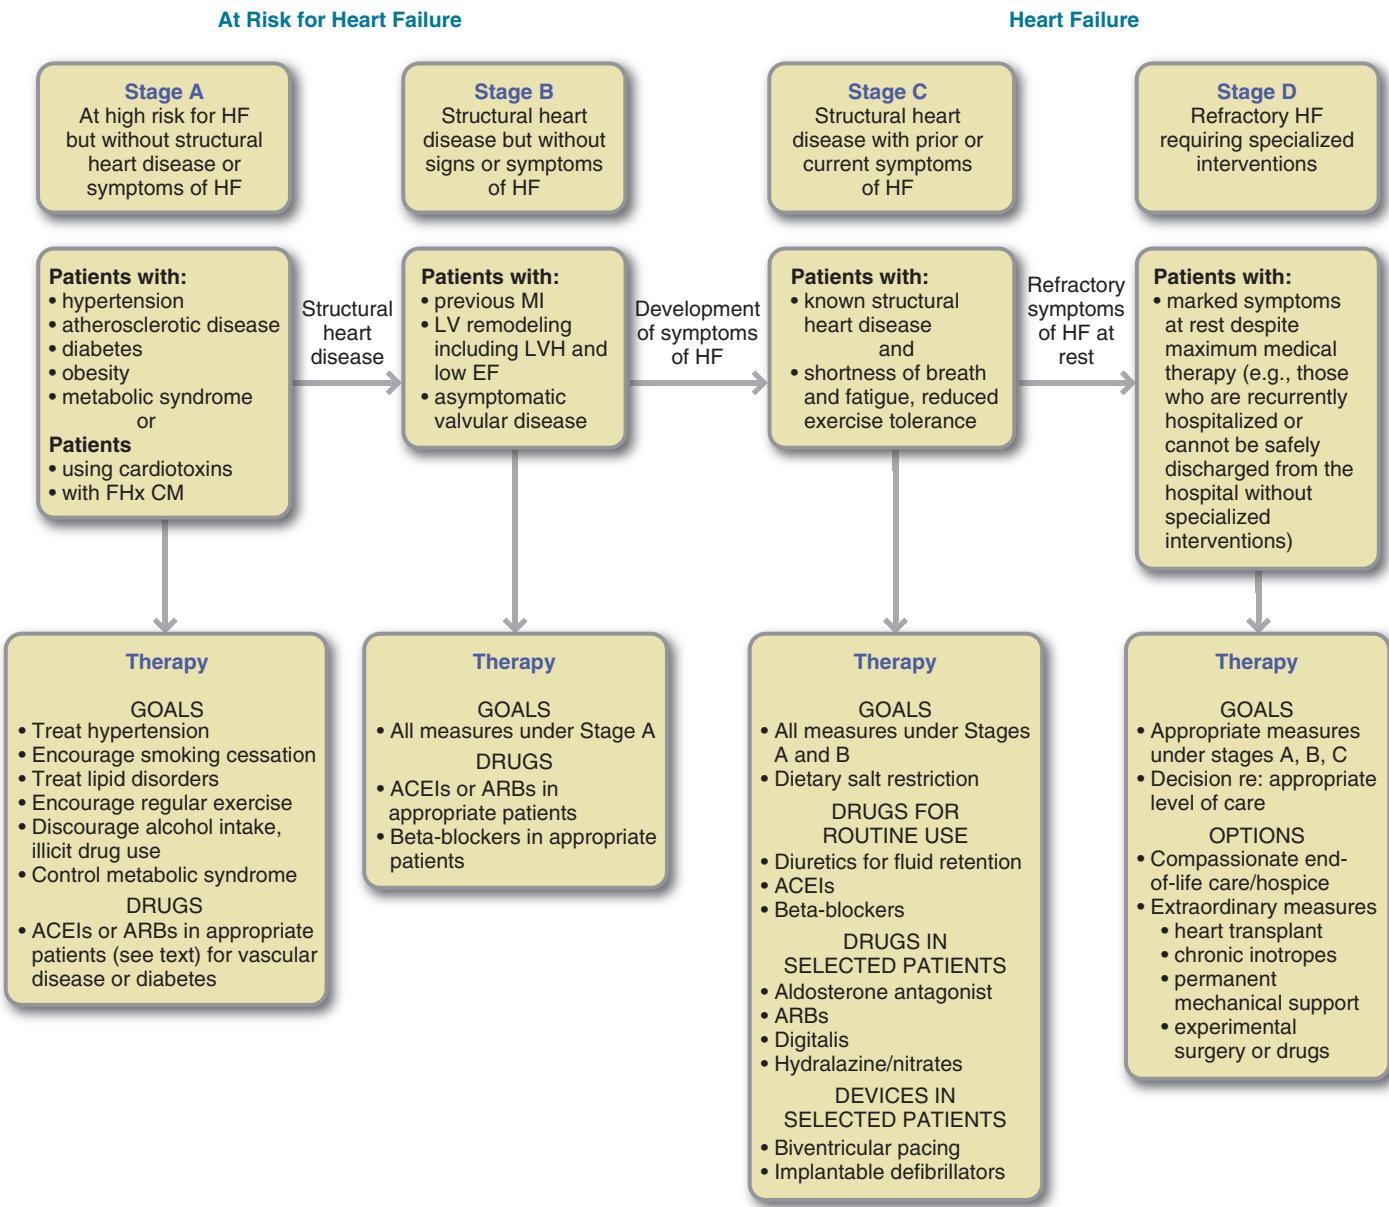

- ACE inhibitors
- Angiotensin receptor blockers
- Aldosterone blockers
- $\beta$ -blockers
- Digoxin
- Vasodilators
- Implantable defibrillator
- Heart transplant

#### Nutrition Management

- Diet low in saturated fat, *trans* fat, cholesterol
- Restricted sodium diet— $<2$  gm/day
- Increased use of whole grains, fruits, vegetables
- Limit fluid to 2 L per day
- Lose to or maintain appropriate weight
- Magnesium supplementation
- Thiamin supplementation
- Increase physical activity as tolerated
- Avoid tobacco
- Avoid alcohol

**Pathophysiology**

**Management**

**FIGURE 34-11** Stages of heart failure and recommended therapy by stage. ACEI, Angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; CM, cardiomyopathy; EF, ejection fraction; FHx, family history; HF, heart failure; IV, intravenous; MI, myocardial infarction; LV, left ventricular; LVH, left ventricular hypertrophy. (Source: Hunt SA et al: ACC/AHA 2005 guideline update for the diagnosis and management of chronic heart failure in the adult: a report of the American College of Cardiology/American Heart Association Task Force, *J Am Coll Cardiol* 46: e1, 2005.)

In HF the heart can compensate for poor cardiac output by (1) increasing the force of contraction, (2) increasing in size, (3) pumping more often, and (4) stimulating the kidneys to conserve sodium and water. For a time this compensation maintains near-normal circulation, but eventually the heart can no longer maintain a normal output (decompensation). Advanced symptoms can develop in weeks or months, and sudden death can occur at any time.

Three symptoms—fatigue, shortness of breath, and fluid retention—are the hallmarks of HF. Shortness of breath on exertion, or effort intolerance, is the earliest symptom. This

shortness of breath gets worse and occurs at rest (**orthopnea**) or at night (paroxysmal nocturnal dyspnea). Fluid retention can manifest as pulmonary congestion or peripheral edema. Evidence of hypoperfusion includes cool forearms and legs, sleepiness, declining serum sodium level caused by fluid overload and worsening renal function.

Decreased cranial blood supply can lead to mental confusion, memory loss, anxiety, insomnia, **syncope** (loss of oxygen to the brain causing brief loss of consciousness), and headache. The latter symptoms are more common in older patients and often are the only symptoms; this can lead to a

delay in diagnosis. Often the first symptom in older adults is a dry cough with generalized weakness and anorexia.

**Cardiac cachexia** is the end result of HF in 10% to 15% of patients. It is defined as involuntary weight loss of at least 6% of nonedematous body weight during a 6-month period (Springer et al., 2006). Unlike normal starvation, which is characterized by adipose tissue loss, this cachexia is characterized by a significant loss of lean body mass. This decrease in lean body mass further exacerbates HF because of the loss of cardiac muscle and the development of a heart that is soft and flabby. In addition, there are structural, circulatory, metabolic, inflammatory, and neuroendocrine changes in the skeletal muscle of patients with HF (Delano and Moldawer, 2006). Differences between younger and older patients are listed in Table 34-9.

Cardiac cachexia is a serious complication of HF with a poor prognosis and high mortality rate. Symptoms that reflect inadequate blood supply to the abdominal organs include anorexia, nausea, a feeling of fullness, constipation, abdominal pain, malabsorption, hepatomegaly, and liver tenderness. All of these contribute to the high prevalence of malnutrition observed in hospitalized patients with HF. Lack of blood flow to the gut leads to loss of bowel integrity; bacteria and other endotoxins may enter the bloodstream and cause cytokine activation. Proinflammatory cytokines such as TNF- $\alpha$  and adiponectin are highest in patients with cardiac cachexia. An increased level of TNF- $\alpha$  is associated with a lower BMI, smaller skinfold measurements, and decreased plasma total protein levels, indicative of a catabolic state.

Adiponectin levels are high in HF and are a marker for wasting and a predictor of mortality. As with TNF- $\alpha$ , adiponectin levels are also inversely correlated with BMI. Treatments for muscle wasting are being explored (Springer et al., 2006).

**TABLE 34-9**

### Heart Failure in Middle Age versus Older Adulthood

	Middle Age	Older Adulthood
Prevalence	<1%	≈10%
Sex	Men > Women	Women > Men
Cause	CAD	Hypertension
Clinical features	Typical	Atypical
LVEF	Reduced	Normal
Comorbidities	Few	Multiple
RCTs	Many	Few
Therapy	Evidence-based	Empiric
Physician treating HF	Cardiologist	Primary care

From Rich MW: Office management of heart failure in the elderly, Am J Med 118:342, 2005.

CAD, Coronary artery disease; HF, heart failure; LVEF, left ventricular ejection fraction; RCT, randomized clinical trial.

### Risk Factors

The Framingham Study (see *Focus On: Framingham Heart Study*) showed the risk factors for HF were hypertension, diabetes, CHD, and **left ventricular hypertrophy (LVH)** (enlargement of the left ventricle of the heart). Antecedent hypertension is present in 75% of HF cases (AHA, 2010). Individuals who have diabetes mellitus and ischemic heart disease more frequently develop HF compared with patients without diabetes (Rosano et al., 2006). Diabetes is an especially strong risk factor for HF in women. The prevalence of both hypertension and diabetes increases with age, making the elderly particularly vulnerable to HF. Another large cohort study of older adults (70 to 79 years) showed that waist circumference and percentage of body fat were the strongest predictors of who would develop HF (Nicklas et al., 2006). Numerous changes in cardiovascular structure and function also place the elderly at high risk for developing HF (Box 34-8).

### Prevention

Because long-term survival rates for persons with HF are low, prevention is critical. HF is categorized into four stages ranging from persons with risk factors (stage A—primary prevention) to persons with advanced HF (stage D—severe disease). For stages A and B the aggressive treatment of underlying risk factors and diseases such as dyslipidemia, hypertension, and diabetes is critical to prevent structural damage to the myocardium and the appearance of HF symptoms. Such prevention has been very effective. Even patients who experience an MI can reduce the risk of HF with anti-hypertensive therapy.

For stages C and D, secondary prevention strategies to prevent further cardiac dysfunction are warranted. These strategies include the use of ACE inhibitors (first line of therapy), angiotensin receptor blockers, aldosterone blockers,  $\beta$ -blockers, and digoxin. Early detection, correction of

### BOX 34-8

#### Principal Effects of Aging on Cardiovascular Structure and Function

- Increased vascular stiffness
  - Increased myocardial stiffness
  - Decreased  $\beta$ -adrenergic responsiveness
  - Impaired mitochondrial ATP production
  - Decreased baroreceptor responsiveness
  - Impaired sinus node function
  - Impaired endothelial function
  - Net Effect: Marked reduction in cardiovascular reserve
- From Rich MW: Office management of heart failure in the elderly, Am J Med 118:342, 2005.
- ATP, Adenosine triphosphate.

asymptomatic left ventricular dysfunction, and aggressive management of risk factors are needed to lower the incidence and mortality of HF.

New research is studying the effects of cardiotonic steroids, including marinobufagenin, a group of hormones found in plasma and urine of patients with HF, MI, and chronic renal failure (Tian et al., 2010). If there are preventive measures, studies will identify them.

## Medical Management

Therapy recommendations correspond to the stage of HF. For patients at high risk of developing HF (stage A), treatment of the underlying conditions (hypertension, dyslipidemia, thyroid disorders, arrhythmias), avoidance of high-risk behaviors (tobacco, excessive alcohol, illicit drug use), and lifestyle changes (weight reduction, exercise, reduction of sodium intake, heart-healthy diet) are recommended. All these recommendations are carried through the other stages. In addition, an implantable defibrillator, which shocks the heart when it stops, can be placed in patients at risk of sudden death. Pharmacologic treatment of HF is the hallmark of therapy with progressive stages. The last stage also includes surgically implanted ventricular-assist devices, heart transplantation, and continual intravenous therapy.

The short-term goals for the treatment of HF are to relieve symptoms, improve the quality of life, and reduce depression if it is present. The long-term goal of treatment is to prolong life by lessening, stopping, or reversing left ventricular dysfunction. Medical management is tailored to clinical and hemodynamic profiles with evidence of hypoperfusion and congestion. In some cases surgical procedures are needed to alleviate the HF caused by valvular disease; medical management is limited in these instances.

Initial management of HF includes a restricted sodium diet (less than 2000 mg daily) and regular activity, as symptoms permit. Bed rest is no longer recommended except for those with acute failure. The heart becomes deconditioned with less exercise, whereas with regular exercise capacity can be increased. Standard fluid restrictions are to limit total fluid intake to 2 L (2000 mL) daily. When patients are severely decompensated, a more restrictive fluid intake (1000 to 1500 mL daily) may be warranted for adequate diuresis. A sodium-restricted diet should be maintained despite low-sodium blood levels because in this case the sodium has shifted from the blood to the tissues. Serum sodium appears low in a patient who is fluid overloaded because of dilution; diuresis improves the levels by decreasing the amount of water in the vascular space.

An ACE inhibitor is the first line of pharmacologic treatment for HF. As the stages progress, a  $\beta$ -blocker or angiotensin receptor blocker may be added. In Stages C and D selected patients may also take a diuretic, aldosterone antagonists, digitalis, and vasodilators (e.g., hydralazine). Basically these medications reduce excess fluid, dilate blood vessels, and increase the strength of the heart's contraction. Several of these medications have neurohormonal benefits along with their primary mechanism of action. For example, ACE inhibitors (e.g., captopril, enalapril) not only inhibit

the RAS (see Chapter 36) but also improve symptoms, quality of life, exercise tolerance, and survival. Similarly, spironolactone has both diuretic and aldosterone-blocking functions that result in reduced morbidity and mortality in patients. Most of these medications can affect nutrition status (see Chapter 9 and Appendix 31).

## Medical Nutrition Therapy

The RD provides MNT, which includes assessment, establishing a nutrition diagnosis, and interventions (education, counseling). As part of a multidisciplinary team (physician, pharmacist, psychologist, nurse, and social worker), the RD positively affects patient outcomes. Reduced readmission to the hospital, fewer days in the hospital, improved compliance with restricted sodium and fluid intakes, and improved quality of life scores are the goals in HF patients.

Nutrition screening for HF in older adults can help prevent disease progression and improve disease management, overall health, and quality-of-life outcomes. The first step in screening is determination of body weight. Altered fluid balance complicates assessment of body weight in the patient with HF. Weights should be taken before eating and after voiding at the same time each day. A dry weight (weight without edema) should be determined on the scale at home. Patients should record daily weights and advise their care providers if weight gain exceeds more than 1 lb a day for patients with severe HF, more than 2 lb a day for patients with moderate HF, and more than 3 to 5 pounds with mild HF. Restricting sodium and fluids along with diuretic therapy may restore fluid balance and prevent full-blown HF.

Dietary assessments in HF patients reveal that more than half have malnutrition, usually related to the cardiac cachexia mentioned earlier. Negative energy balance and negative nitrogen balances can be noted. In overweight patients caloric reduction must be carefully monitored to avoid excessive and rapid body protein catabolism. Nutrition education to promote behavior change is a critical component of MNT. The benefits of MNT should be communicated to patients.

The total diet must be addressed in patients with HF because underlying risk factors are often present; dietary changes to modify these risk factors are an important component of MNT. For dyslipidemia or atherosclerosis, a heart-healthy diet low in SFAs, *trans*-fatty acids, and cholesterol and high in fiber, whole grains, fruits, and vegetables is recommended. For persons with hypertension, the DASH diet is recommended. Both of these dietary patterns emphasize lower-sodium foods and higher intake of potassium. Total energy expenditure is higher in HF patients because of the catabolic state, adequate protein and energy should be provided.

## Salt Restriction

**Edema** in patients with decompensated HF results from impaired cardiac function. Inadequate blood flow to the kidneys leads to aldosterone and vasopressin (antidiuretic hormone) secretion. Both these hormones act to conserve

fluid, thus trying to restore blood flow. Aldosterone promotes sodium resorption, and vasopressin promotes water conservation in the distal tubules of the nephron. Sodium and fluid thus accumulate in the tissues. Even asymptomatic patients with mild HF and no edema can retain sodium and water if consuming a high-salt diet.

The degree of restriction depends on the individual. For the healthy elderly population (older than 71 years), the AI is 1200 mg (50 mmol)/day. Recommendations for HF patients vary between 1200 and 2400 mg/day. For patients taking large doses of lasix (80 mg/day), a sodium intake of less than 2 g/day is recommended to optimize the effects of the diuretic. Severe restrictions (500 mg/day) are unpalatable and nutritionally inadequate. See *Focus On: Sodium and Salt Measurement Equivalents*.

Adherence to sodium restrictions can be problematic for many individuals, and individualized instruction is recommended. Ethnic differences in sodium consumption must be considered. Some cultures have traditional diets that are very high in sodium such as Kosher and Asian diets. In some cases regional cooking, like in some areas in the southern United States, depends heavily on salt.

Positive outcomes (i.e., decreased urinary sodium excretion, less fatigue, less frequent edema) have been observed in HF patients receiving MNT. The type of sodium restriction prescribed should be the least restrictive diet that will still achieve the desired results. The first step is to minimize or eliminate the use of table salt and high-sodium foods (Box 34-9) (see Appendix 37 for further explanation of the sodium-restricted diet).

Poor adherence to low-sodium diets occurs in part as a result of lack of knowledge about sodium and lower-sodium

food choices by the patient, and perception that the diet interferes with the social aspects of eating. Lack of cooking skills or adequate cooking facilities is another obstacle because it leads patients to eat premade foods that tend to be high in salt. Memory loss, severe fatigue, and economic issues are all challenges to following a low-sodium diet. In addition, food labels, although informative, may be hard for many patients or their caregivers to comprehend (Box 34-10).

### Alcohol

In excess, alcohol contributes to fluid intake and raises blood pressure. Many cardiologists recommend avoiding alcohol. Chronic alcohol ingestion may lead to cardiomyopathy and HF (Li and Ren, 2006). Although heavy drinking should be discouraged, moderate drinking may lower the risk of HF through beneficial effects of alcohol on coronary artery disease. Quantity, drinking patterns, and genetic factors influence the relationship between alcohol consumption and HF (Djousse and Gaziano, 2008). If alcohol is consumed, intake should not exceed one drink per day for women and two drinks per day for men. A drink is equivalent to 1 oz of alcohol (1 oz of distilled liquor), 5 oz of wine, or 12 oz of beer.

### BOX 34-9

#### Top Ten Categories of High-Sodium Foods

1. Smoked, processed, or cured meats and fish (e.g., ham, bacon, corned beef, cold cuts, hot dogs, sausage, salt pork, chipped beef, pickled herring, anchovies, tuna, and sardines)
2. Tomato juices and tomato sauce, unless labeled otherwise
3. Meat extracts, bouillon cubes, meat sauces, \*MSG, and taco seasoning
4. Salted snacks (potato chips, tortilla chips, corn chips, pretzels, salted nuts, popcorn, and crackers)
5. Prepared salad dressings, condiments, relishes, ketchup, Worcestershire sauce, barbecue sauce, cocktail sauce, teriyaki sauce, soy sauce, commercial salad dressings, salsa, pickles, olives, and sauerkraut
6. Packaged mixes for sauces, gravies, casseroles, and noodle, rice, or potato dishes; macaroni and cheese; stuffing mix
7. Cheeses (processed and cheese spreads)
8. Frozen entrees and pot pies
9. Canned soup
10. Foods eaten away from home

\*MSG, Monosodium glutamate.

Note: Reading labels is most important; some brands are lower in sodium than others.

### FOCUS ON

#### Sodium and Salt Measurement Equivalents

**S**odium chloride is approximately 40% (39.3%) sodium and 60% chloride. To convert a specified weight of sodium chloride to its sodium equivalent, multiply the weight by 0.393. Sodium is also measured in milliequivalents (mEq). To convert milligrams of sodium to mEq, divide by the atomic weight of 23. To convert sodium to sodium chloride (salt), multiply by 2.54. Millimoles (mmol) and milliequivalents (mEq) of sodium are the same. For example:

$$\begin{aligned} 1 \text{ tsp of salt} &= \text{approximately } 6 \text{ g NaCl} = 6096 \text{ mg NaCl} \\ 6096 \text{ mg NaCl} \times 0.393 &= 2396 \text{ mg Na (approximately}} \\ &\quad 2400 \text{ mg)} \end{aligned}$$

$$2396 \text{ mg Na}/23 = 104 \text{ mEq Na}$$

$$1 \text{ g Na} = 1000 \text{ mg}/23 = 43 \text{ mEq or mmol}$$

$$1 \text{ tsp of salt} = 2400 \text{ mg or } 104 \text{ mEq Na}$$

**BOX 34-10****Food Labeling Guide for Sodium**

Sodium-free	Less than 5 mg per standard serving; cannot contain any sodium chloride
Very low sodium	35 mg or less per standard serving
Low sodium	140 mg or less per standard serving
Reduced sodium	At least 25% less sodium per standard serving than in the regular food
Light in sodium	50% less sodium per standard serving than in the regular food
Unsalted, without added salt, or no salt added	No salt added during processing; the product it resembles is normally processed with salt
Lightly salted	50% less added sodium than is normally added; product must state "not a low-sodium food" if that criterion is not met

Data from U.S. Food and Drug Administration: Scouting for sodium and other nutrients important to blood pressure, FDA Consumer Publication No. 95-2284, 1995.

**Caffeine**

Until now caffeine has been considered detrimental to patients with HF because it contributes to irregular heartbeats. However, a study in the Netherlands suggests that moderate intake of either tea or coffee reduces CHD risk; tea actually reduces CHD deaths (deKonig Gans, 2010). Researchers in the United States followed 130,054 men and women and found that those who reported drinking four or more cups of coffee each day had an 18% lower risk of hospitalization for heart rhythm disturbances. Those who reported drinking one to three cups each day had a 7% reduction in risk (Klatsky, 2010). The antioxidant effects of coffee and tea may be beneficial.

**Calcium**

Patients with HF are at increased risk of developing osteoporosis because of low activity levels, impaired renal function, and prescription drugs that alter calcium metabolism (Zittermann et al., 2006). Cachectic HF patients have lower bone mineral density and lower calcium levels than HF patients without cachexia (Anker, 2006). Caution must be used with calcium supplements because they may aggravate cardiac arrhythmias. Before transplant, most HF patients only have subtle changes in bone.

**Coenzyme Q<sub>10</sub>**

Levels of coenzyme Q<sub>10</sub> (CoQ<sub>10</sub>) are often lower in HF patients; it is postulated that repletion can prevent oxidative stress and further myocardial damage (Sanders, 2006). However, in two randomized control trials in patients with class III and IV symptoms, CoQ<sub>10</sub> had limited benefit (Levy and Kohlhaas, 2006). Routine supplementation is not

recommended by the AHA at this time. However, HF is known to be associated with key deficiencies of micronutrients that are required for cardiac function and further studies are needed (Soukoulis, 2009). It should be noted that patients on statins (HMG-CoA reductase inhibitors) may have a different reason to consider supplementation. HMG-CoA reductase inhibitors are a class of cholesterol lowering drugs that are known to interfere with synthesis of CoQ<sub>10</sub> (see Chapter 9).

**D-Ribose**

D-ribose is a component of ATP for cellular metabolism and energy production. Myocardial ischemia lowers cellular energy levels, integrity, and function. The failing heart is energy-starved. D-ribose is being tested to correct this deficient cellular energy as a naturally occurring carbohydrate (Shecterle et al., 2010).

**Energy**

The energy needs of patients with HF depend on their current dry weight, activity restrictions, and the severity of the HF. Overweight patients with limited activity must achieve and maintain an appropriate weight that will not stress the myocardium. For the obese patient, hypocaloric diets (1000 to 1200 kcal daily) reduce the stress on the heart and facilitate weight reduction. However, the nutrition status of the obese patient must be assessed to ensure that the patient is not malnourished. In patients with severe HF, energy needs are increased by 30% to 50% more than basal level as a result of the increased energy expenditure of the heart and lungs; 31 to 35 kcal/kg of body weight is often used as the starting point for determining caloric requirements. Patients with cardiac cachexia may require further increases in energy to 1.6 to 1.8 times the resting energy expenditure for nutritional repletion.

**Fats**

Fish consumption and fish oils rich in ω-3 fatty acids can lower elevated triglyceride levels, prevent atrial fibrillation, and perhaps even reduce mortality rates in HF patients (Roth and Harris, 2010). Intake of at least 1 g daily of ω-3 fatty acids from either oily fish or fish-oil supplements can be safely recommended. Interestingly, recent evidence suggests that high saturated fat feeding in mild to moderate HF preserves contractile function and prevents the switch from fatty acid to glucose metabolism, thus serving a cardioprotective role (Chess et al., 2009; Christopher et al., 2010).

**Feeding Strategies**

Patients with HF often tolerate small, frequent feedings better than larger, infrequent meals because the latter are more tiring to consume, can contribute to abdominal distension, and markedly increase oxygen consumption. All these factors tax the already stressed heart. Caloric supplements can help to increase energy intake; however, this intervention may not reverse this form of malnutrition (Anker et al., 2006).

## Folate, Vitamin B<sub>6</sub>, and Vitamin B<sub>12</sub>

High dietary intakes of folate and vitamin B<sub>6</sub> have been associated with reduced risk of mortality from HF and stroke in some populations (Cui et al., 2010). Elevated tHcy levels should be lowered when possible.

## Magnesium

Magnesium deficiency is common in patients with HF as a result of poor dietary intake and the use of diuretics, including furosemide. As with potassium, the diuretics used to treat HF increase magnesium excretion. Magnesium deficiency aggravates changes in electrolyte concentration by causing a positive sodium and negative potassium balance. Because deficient magnesium status is associated with poorer prognosis, blood magnesium levels should be measured in HF patients and treated accordingly. Magnesium supplementation (800 mg/day) produces small improvements in arterial compliance (Fuentes et al., 2006). Poor dietary intake of magnesium has been associated with elevated CRP, a product of inflammation. Hypermagnesemia may be found in some cases of renal failure, HF, and high doses of furosemide.

## Thiamin

Patients with HF are at risk for thiamin deficiency because of poor food intake; use of loop diuretics, which increases excretion; and advanced age. Thiamin deficiency is diagnosed using erythrocyte thiamin pyrophosphate levels in 33% of HF patients (Hanninen et al., 2006). Loop diuretics can deplete body thiamin and cause metabolic acidosis. Thiamin status should be assessed in HF patients on loop diuretics, and appropriate supplementation recommended if necessary. Thiamin supplementation (e.g., 200 mg/day) can improve left ventricular ejection fraction (fraction of blood pumped out of the ventricles with each heart beat) and symptoms.

## Vitamin D

Patients with a polymorphism of the vitamin D receptor gene have higher rates of bone loss than HF patients without this genotype. Vitamin D may improve inflammation in HF patients (Vieth and Kimball, 2006). In a double-blind, randomized, placebo-controlled trial, supplementation with vitamin D (50 mcg or 2000 international units of vitamin D<sub>3</sub> per day) for 9 months increased the antiinflammatory cytokine IL-10 and decreased the proinflammatory factors in HF patients (Schleithoff et al., 2006). As a steroid hormone, vitamin D regulates gene expression and inversely regulates renin secretion (Meems et al., 2010). However, it remains unclear if vitamin D supplementation is truly needed in HF patients.

## CARDIAC TRANSPLANTATION

Cardiomyopathies represent a heterogeneous group of diseases that often lead to progressive HF; types include dilated

cardiomyopathy, hypertrophic cardiomyopathy, restrictive cardiomyopathy, and arrhythmogenic right ventricular cardiomyopathy (Wexler et al., 2009). Cardiac transplantation is the only cure for refractory, end-stage HF. Because the number of donor hearts is limited, careful selection of recipients with consideration of the likelihood for adherence to lifelong therapeutic regimen and their quality of life is imperative (D'Amico, 2005). Nutrition support before and after transplantation is crucial to decrease morbidity and mortality. Thus the nutrition care of the heart transplant patient can be divided into three phases: pretransplant, immediate posttransplant, and long-term posttransplant.

## Pretransplant Medical Nutrition Therapy

A comprehensive nutrition assessment of the pretransplant patient should include a history, physical and anthropometric assessment, and biochemical testing. Recommended lifestyle changes prior to transplantation include restricting alcohol consumption, losing weight, exercising, quitting smoking, and eating a low-sodium diet (Wexler et al., 2010). Extremes in body weight (<80% or >140% of ideal body weight) increase the patient's risk for infection, diabetes, morbidity, and higher mortality. Pretransplant comorbidities such as hyperlipidemia and hypertension also reduce survival rates. If oral intake is inadequate, an enteral feeding should be tailored to the nutritional and comorbid conditions of the patient.

## Immediate Posttransplant Nutrition Support

The nutritional goals in the acute posttransplant patient are to (1) provide adequate protein and calories to treat catabolism and promote healing, (2) monitor and correct electrolyte abnormalities, and (3) achieve optimal blood glucose control (Hasse, 2001). In the immediate posttransplant period nutrient needs are increased, as is the case after any major surgery. Protein needs are increased because of steroid-induced catabolism, surgical stress, anabolism, and wound healing.

Patients progress from clear liquids to a soft diet given in small, frequent feedings. Enteral feeding may be appropriate in the short term, especially if complications arise. Nutrient intake is often maintained by using liquid supplements and foods of high caloric density, especially in patients with poor appetite. Weight gain to an ideal weight is the nutritional goal for patients who were cachectic before transplant. The increase in cardiac function helps to halt the presurgical cachectic state. Hyperglycemia can be exacerbated by the stress of the surgery and the immunosuppressive drug regimen. Dietary adjustments can be made to aid in glucose control (see Table 34-10).

## Long-Term Posttransplant Nutrition Support

Comorbid conditions that often occur after transplantation include hypertension, excessive weight gain, hyperlipidemia,

**TABLE 34-10****Short-Term Posttransplant Nutrient Recommendations**

<b>Nutrient</b>	<b>Recommendations</b>	<b>Comment</b>
Protein	1.5-2.0 g/kg	Protein catabolism is increased due to because of surgery and corticosteroids.
Calories	130%-150% of REE	Protein is required for wound healing; infection prevention; and losses from drains, wounds, etc.
Carbohydrate	50%-70% of nonprotein calories	Upper range for underweight patients; lower range for overweight patients.
Lipid	30%-50% of nonprotein calories	Medications may cause hypoglycemia; treat with sliding-scale insulin.
Fluid	1 mL/calorie	Higher range is recommended only when hyperglycemia is severe and not under control with insulin alone.
Sodium	2-4 g/day	Monitor output from urine, drains, etc.
Phosphorus, magnesium, bicarbonate	Individualize	Restrict if edema is present.
		Monitor biochemical parameters.

From Hasse JM: Nutrition assessment and support of organ transplant recipients, JPEN 25(3):120, 2001.

REE, Resting energy expenditure.

**CLINICAL SCENARIO**

Tom is a 55-year-old single man with hypertension (blood pressure 145/92), high low-density lipoprotein cholesterol (241) and low high-density lipoprotein cholesterol (38). He reports that he often eats in his car so he frequents fast-food restaurants. He works long hours and, other than gardening on the weekends, he does not exercise. He is 5'10" and 220 lbs. His breakfast is usually a cheese-egg biscuit, white toast with butter, bacon, and coffee without milk or cream. Lunch is a fried luncheon meat sandwich with mayonnaise, potato chips, and a piece of fruit pie with ice cream. Dinner is often fried chicken, mashed potatoes with gravy, creamed vegetables, and some type of whipped cream dessert.

Using the following list, what are Tom's nutritional diagnoses? Which should be the top priority?

**Nutrition Diagnostic Term**

Excessive energy intake  
Excessive intake of fats

Excessive alcohol intake  
Inadequate fiber intake  
Inadequate calcium intake  
Inadequate magnesium intake  
Inadequate potassium intake  
Excessive sodium intake  
Overweight or obesity  
Food- and nutrition-related knowledge deficit  
Undesirable food choices  
Physical inactivity

**Nutrition Care Questions**

Which interventions would be most beneficial for Tom?  
What signs and symptoms would you want to monitor and evaluate?

osteoporosis, and infection. Hypertension is managed by diet, exercise, and medications. Minimizing excessive weight gain is important because patients who become obese after transplantation are at higher risk for rejection and lower rates of survival.

Increases in total LDL cholesterol and triglycerides are a consequence of immunosuppressive drug therapy and increase the risk of HF after transplantation. Along with a heart-healthy diet, patients also need a lipid-lowering drug regimen to normalize blood lipids. Statins are recommended in the early and long-term postoperative periods. Because

of their LDL-lowering effect, stanols or sterols may be helpful to reduce statin dosages (Goldberg et al., 2006).

Before transplantation, patients are likely to have osteopenia because of their lack of activity and cardiac cachexia. After transplantation, patients are susceptible to steroid-induced osteoporosis. Patients require optimal calcium and vitamin D intake to slow bone loss; weight-bearing exercise and antiresorptive drug therapy are often necessary. Infection must be avoided because of the necessity of lifelong use of immunosuppressive drugs. Food safety should be discussed.

## CHAPTER 35

Donna H. Mueller, PhD, RD, FADA, LDN

# Medical Nutrition Therapy for Pulmonary Disease

### KEY TERMS

acute respiratory distress syndrome  
asthma  
bronchopulmonary dysplasia (BPD)  
chronic bronchitis  
chronic lung disease of prematurity (CLD)  
chronic obstructive pulmonary disease (COPD)  
cor pulmonale  
cystic fibrosis (CF)  
distal intestinal obstruction syndrome (DIOS)  
dyspnea  
elastase  
emphysema

hypercapnia  
osteopenia  
pancreatic enzyme replacement therapy (PERT)  
pancreatic insufficiency (PI)  
pulmonary aspiration  
pulmonary function tests  
pulse oximetry  
respiratory quotient (RQ)  
spirometry  
surfactant  
sweat test  
tachypnea  
tuberculosis (TB)

During fetal life, from birth to maturity and throughout adulthood, the pulmonary system is intertwined with nutrition. An optimal pulmonary system enables the body to obtain the oxygen needed to meet its cellular demands for energy from macronutrients, and to remove metabolic byproducts. Optimal nutrition permits the proper growth and development of the respiratory organs, supporting structures of the skeleton and muscles, and related nervous, circulatory, and immunologic systems. Overall, a person's nutritional well being and proper metabolism of nutrients are essential for the formation, development, growth, maturity, and protection of healthy lungs and associated processes throughout life.

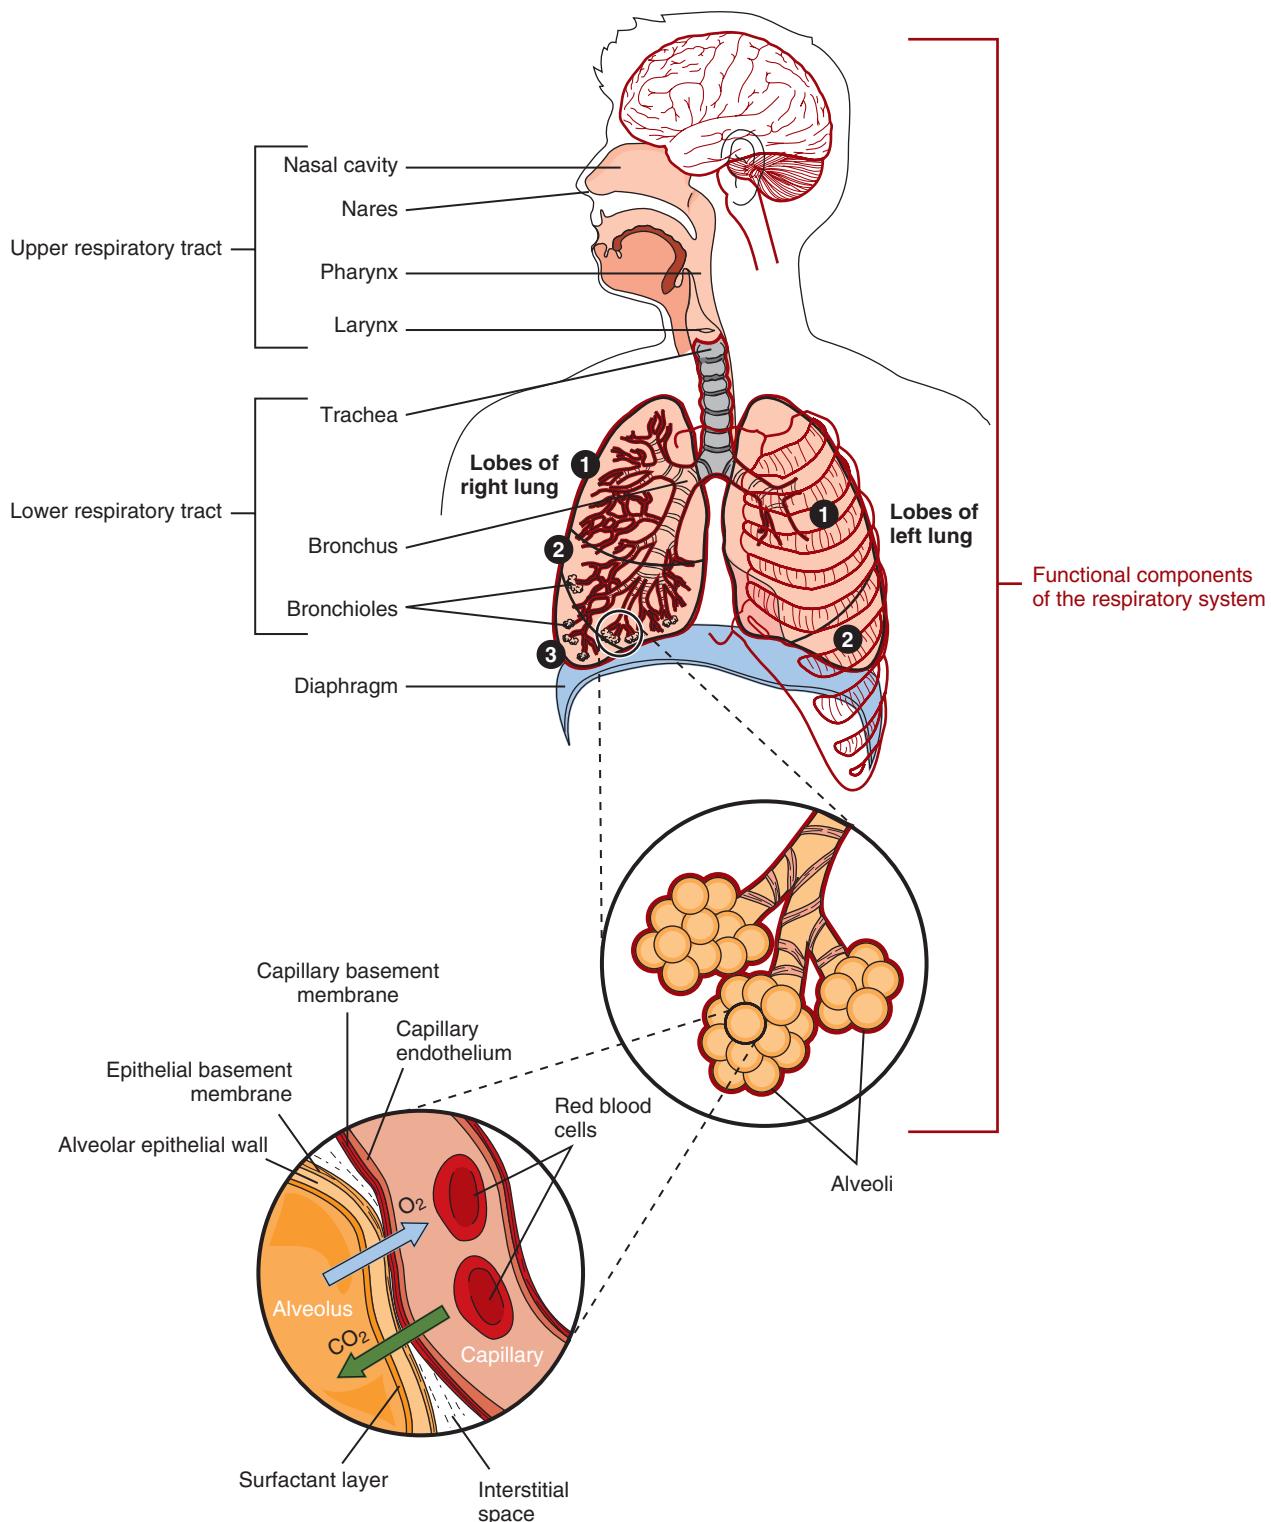

### THE PULMONARY SYSTEM

The respiratory structures include the nose, pharynx, larynx, trachea, bronchi, bronchioles, alveolar ducts, and alveoli (Figure 35-1). Supporting structures include the skeleton

and the muscles (e.g., the intercostal, abdominal, and diaphragm muscles). Within a month after conception, pulmonary structures are recognizable. The pulmonary system grows and matures during gestation and childhood. No new alveoli are produced after approximately age 20. As aging occurs there is a loss of lung capillaries and the lungs lose elasticity.

Gas exchange is the major function of the pulmonary system (Figure 35-2). The lungs enable the body to obtain the oxygen needed to meet its cellular metabolic demands and to remove the carbon dioxide ( $\text{CO}_2$ ) produced by these processes. Healthy nerves, blood, and lymph are needed to supply oxygen and nutrients to all tissues. The lungs also filter, warm, and humidify inspired air.

The lungs have several metabolic functions. For example, they help regulate the body's acid-base balance. The body's pH partially is maintained by the proper balance of  $\text{CO}_2$  and  $\text{O}_2$ . The lungs synthesize arachidonic acid, that ultimately may be converted to prostaglandins or leukotrienes,

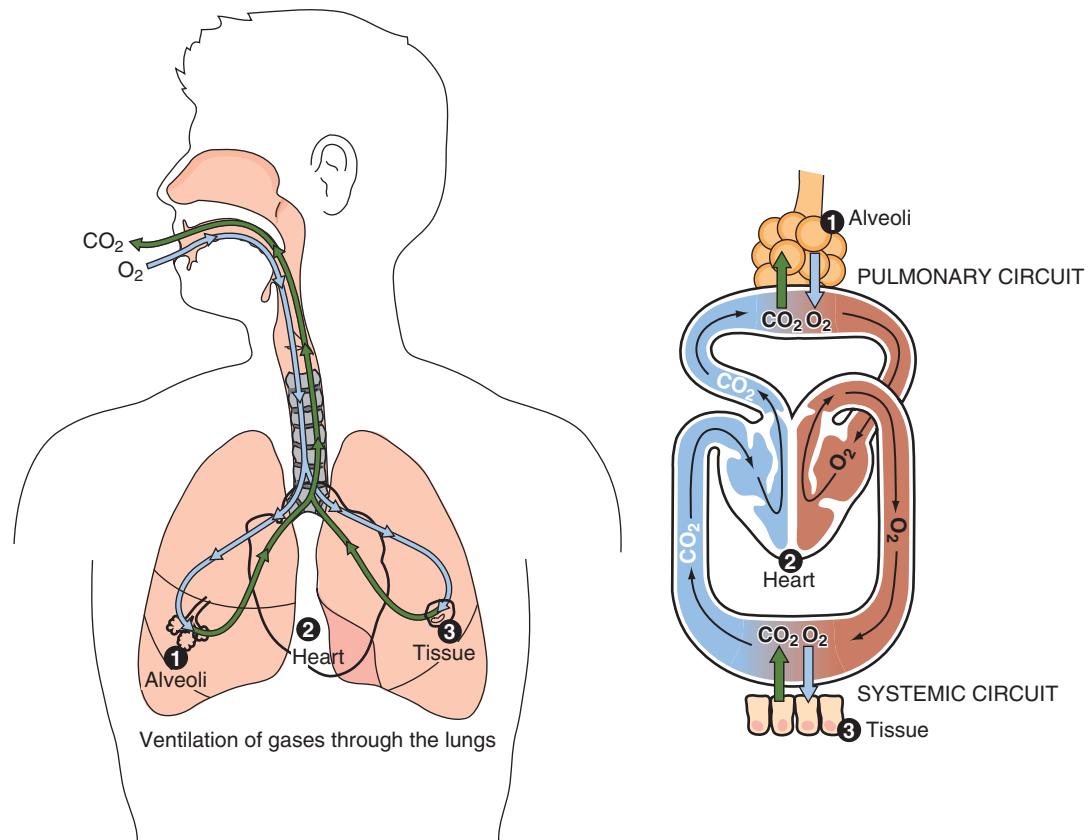

**FIGURE 35-1** The anatomy of the pulmonary system is highly complex and interdependent.

a possible cause of bronchoconstriction in asthma. The lungs convert angiotension I to angiotensin II by the angiotension-converting enzyme (ACE) found mainly in the numerous capillary beds of the lungs. Angiotensin II increases blood pressure.

The alveolar cells secrete **surfactant**, a compound synthesized from proteins and phospholipids that serves to

maintain the stability of pulmonary tissue by reducing the surface tension of fluids that coat the lung.

The lungs are an important part of the body's immune defense system because inspired air is laden with particles and microorganisms. Mucus keeps the airways moist and traps the particles and microorganisms from inspired air. Most cells that line the trachea, bronchi, and bronchioles

**FIGURE 35-2** The major function of the respiratory tract is to provide the oxygen for cellular metabolism and to remove the carbon dioxide that is produced but not needed.

have cilia. These constantly beating cilia sweep the particles upward toward the pharynx so they can enter the gastrointestinal tract. Each time a person swallows, the particle- and microorganism-containing mucus passes into the digestive tract. The epithelial surface of the alveoli contains macrophages. By the process of phagocytosis, these alveolar macrophages engulf inhaled inert materials and microorganisms and digest them.

### Medical Treatment

Pulmonary system disorders may be categorized as *primary*, such as tuberculosis (TB), bronchial asthma, and cancer of the lung; or *secondary* when associated with cardiovascular disease, obesity, human immunodeficiency virus (HIV) infection, sickle cell disease, and scoliosis. Conditions may also be acute or chronic. Examples of acute conditions include aspiration pneumonia, airway obstruction from foods like peanuts, and allergic anaphylaxis from consumption of shellfish. Examples of chronic conditions include cystic fibrosis (CF) and lung cancer.

The assessment of pulmonary status generally starts with physical examination using percussion and auscultation. These bedside techniques provide important information to the clinician on breathing. Numerous diagnostic and monitoring tests such as imaging procedures, arterial blood gas determinations, sputum cultures, and biopsies can also be employed. Signs and symptoms of pulmonary disease include

**FIGURE 35-3** A pulse oximeter is an inexpensive and non-invasive instrument used to monitor a person's blood oxygen level. (From Potter PA, Perry AG: *Fundamentals of nursing*, ed 7, St. Louis, 2009, Mosby.)

cough, early satiety, anorexia, weight loss, **dyspnea** (shortness of breath), and fatigue.

**Pulmonary function tests** are used to diagnose or monitor the status of lung disease; they are designed to measure the ability of the respiratory system to exchange oxygen and CO<sub>2</sub>. **Pulse oximetry** is one such test. A small device called a *pulse oximeter*, which uses light waves to measure the oxygen saturation of arterial blood, is placed on the end of the finger (Figure 35-3). Normal for a young, healthy person is 95%

to 99%. **Spirometry** is another common pulmonary function test. This involves breathing into a spirometer that gives information on lung volume and the rate at which air can be inhaled and exhaled.

## Medical Nutrition Therapy in Pulmonary Disease

Individualized nutrition assessment, diagnosis, and intervention, followed by routine monitoring and evaluation, are integral components of care for each patient with pulmonary disease. Concomitant assessment of the cardiovascular, renal, neurologic, and hematologic systems is important because diseases often produce complications affecting pulmonary anatomy, physiologic findings, and biochemistry. Nutrition assessment precedes any nutrition intervention or medical treatment, unless the treatment is emergent.

### Effect of Malnutrition on the Pulmonary System

The relationship between malnutrition and respiratory disease has long been recognized. Malnutrition adversely affects lung structure, elasticity, and function; respiratory muscle mass, strength, and endurance; lung immune defense mechanisms; and control of breathing. For example, protein and iron deficiencies result in low hemoglobin levels which diminish the oxygen-carrying capacity of the blood. Low levels of calcium, magnesium, phosphorus, and potassium compromise respiratory muscle function at the cellular level. Hypoproteinemia contributes to the development of pulmonary edema by decreasing colloid osmotic pressure, allowing body fluids to move into the interstitial space. Decreased levels of surfactant contribute to the collapse of alveoli, thereby increasing the work of breathing. The supporting connective tissue of the lungs is composed of collagen, which requires ascorbic acid for its synthesis. Normal airway mucus is a substance consisting of water, glycoproteins, and electrolytes, and thus requires adequate nutritional intake.

Pulmonary disease substantially increases energy requirements. This factor explains the rationale for including body composition and weight parameters in medical, surgical, pharmacologic, and nutrition research studies. Weight loss from inadequate energy intake is significantly correlated with a poor prognosis in persons with pulmonary diseases. Malnutrition leading to impaired immunity places any patient at high risk for developing respiratory infections. Malnourished patients with pulmonary disease who are hospitalized are likely to have lengthy stays and are susceptible to increased morbidity and mortality.

The complications of pulmonary diseases or their treatments can make adequate intake and digestion difficult. Absorption and metabolism of most nutrients are affected. As pulmonary disease progresses, several conditions may interfere with food intake and overall nutrition status. For example, abnormal production of sputum, vomiting, **tachypnea** (rapid breathing), hemoptysis, thoracic pain, nasal polyps, anemia, depression, and altered taste secondary to medications are often present. Weight loss, low body mass index (BMI), and other adverse effects are listed in Box 35-1.

## BOX 35-1

### Adverse Effects of Lung Disease on Nutrition Status

#### **Increased Energy Expenditure**

Increased work of breathing  
Chronic infection  
Medical treatments (e.g., bronchodilators, chest physical therapy)

#### **Reduced Intake**

Fluid restriction  
Shortness of breath  
Decreased oxygen saturation while eating  
Anorexia resulting from chronic disease  
Gastrointestinal distress and vomiting

#### **Additional Limitations**

Difficulty preparing food due to fatigue  
Lack of financial resources  
Impaired feeding skills (for infants and children)  
Altered metabolism  
Food-drug interaction

## ASPIRATION

**Pulmonary aspiration** involves the movement of food or fluid into the lungs, which can result in pneumonia or even death. Besides liquids, foods that are most easily aspirated include those that have a round shape such as nuts, popcorn, hard candy, and hot dog pieces; or chunks of inadequately chewed foods such as meat or raw vegetables. Infants and toddlers are at increased risk for aspiration, as are older adults and persons with oral, upper gastrointestinal, neurologic, or muscular abnormalities. In addition, close attention must be given to people receiving enteral tube feedings (see Chapter 14). Because the primary reason for aspiration pneumonia is excessive lung secretions, pulmonary treatments and suctioning are critical to preventing aspiration.

## ASTHMA

**Asthma**, a disease of bronchial hyperresponsiveness and airway inflammation, has increased in prevalence during the last three decades. The syndrome appears to result from complex interactions among genetic, immunologic, and environmental factors. It is characterized by (1) increased mucus secretion that can obstruct the airways, (2) inflammation and swelling, and (3) smooth muscle tightening that results in smaller airways. Asthma is characterized by airflow obstruction and is a leading cause of hospitalization and death worldwide (DHHS, 2010; Stevenson and Birrell, 2010).

## Pathophysiology

Genetic attributes, environmental exposures, and gene-environmental interactions all play a role in asthma. Respiratory infections caused by viruses, *Chlamydophila* or *Mycoplasma*, have been hypothesized to have significant roles in the pathogenesis (Guilbert and Denlinger, 2010). Host immunity is also critical. A healthy diet during pregnancy and during the early years, and prolonged breastfeeding may decrease the risk of asthma in childhood. In children genetically at high risk of asthma, being overweight at age 1 year is often associated with a decreased risk of asthma and better lung function at ages 6 and 8 years; however, being overweight beyond infancy may confer a higher risk for asthma (Zhang et al., 2010). Thus obesity should be avoided after the toddler stage.

## Medical Treatment

Asthma is categorized as *allergic (extrinsic)* and *nonallergic (intrinsic)*. Allergic asthma is more common and is generally triggered by inhalation of pollen, pet dander, air pollution, cigarette smoke, or other inhalants. Nonallergic asthma may be triggered by factors such as ear infections, stress, viruses, and exercise. Asthmatic symptoms may be aggravated by exposure to allergens such as shrimp or sulfites (see Chapter 27); rhinoviruses; and botanicals such as citronella in insect repellents, rusty-leaved rhododendron in natural honeys, and strawberry leaf in herbal teas.

Eosinophilic airway inflammation is commonly observed; therefore removal of potential triggers and known sensitizers is an important measure. A life-threatening situation with flat airways, known as *status asthmaticus*, can result without proper intervention. Corticosteroid therapy is often prescribed, but chronic use may place the individual at risk for osteopenia, bone fractures, or steroid-induced hyperglycemia. New research proposes use of sublingual immunotherapy and other novel treatments (Peden and Bush, 2011.)

## Medical Nutrition Therapy

Food and individual nutrients have possible roles in the treatment of asthma. Examples include soy,  $\omega$ -3 fatty acids and  $\omega$ -6 fatty acids (decreasing the production of bronchoconstrictive leukotrienes), antioxidant nutrients (protecting the airway tissues from oxidative stress), vitamin D (a molecular antiinfective nutrient), magnesium (a smooth-muscle relaxant and antiinflammatory agent), and methylxanthine bronchodilators such as caffeine (Baines et al., 2009; Barros, et al., 2008; Bede, et al., 2008; Kalhan, et al., 2008; Kazaks, et al., 2010; Lindemann, 2009; Schubert, et al., 2009). The dilemma for the nutrition care provider is the paucity of evidence-based research to support practice procedures (Allan and Devereux, 2011; Kealoha, 2009; Raviv and Smith, 2010; Sorkness, 2009). Scientific nutrition studies aimed at producing evidence-based results are desperately needed.

One illustration is the often-asked question: “Does milk cause an increase in mucus production in asthma?” A

literature review found no cause-and-effect relationship, and avoiding dairy foods could lead to inadequate intake of nutrients (Wüthrich et al., 2005). However, until scientists clearly demonstrate the biologic foundations of people’s perceptions, clinicians will be asked the question and be expected to determine the proper course of treatment.

Nutrition assessment and therapy must take into account routinely prescribed medications. These include bronchodilators that relax the airway smooth muscle and antiinflammatory agents that suppress airway inflammation. Pulmonary patients experience side effects such as dry mouth and throat, nausea, early satiety, vomiting, diarrhea, increased serum glucose levels, sodium retention, hypokalemia, hand tremors, headache, and dizziness. Another possible side effect of medications or chronic coughing is gastroesophageal reflux. Chronic steroid use causes bone demineralization. Bone density tests should be part of the nutritional assessment when these drugs are chronically used (see Chapter 9).

Nutrition therapy should include individual evaluation for environmental or food triggers and strategies for their avoidance if necessary. In addition, there is need for a diet of wholesome foods to provide optimal energy and balance of nutrients; proper ratio of  $\omega$ -3 and  $\omega$ -6 fatty acids and phytonutrients; correction of diagnosed energy and nutrient deficiencies or excesses; careful attention to medication-food-nutrient interactions; frequent monitoring to maintain healthy pulmonary status; and education of the patient, family, and community (American Academy of Allergy, Asthma, and Immunology, 2005).

## CHRONIC LUNG DISEASE OF PREMATURITY AND BRONCHOPULMONARY DYSPLASIA

**Chronic lung disease of prematurity (CLD) and bronchopulmonary dysplasia (BPD)** are closely related. Newborn lungs appear unable to respond to adverse situations. Immature lungs often cannot synthesize surfactant that permits inflation for gas exchange.

## Pathophysiology

CLD and BPD are the result of incomplete recovery from lung injury during the neonatal period. CLD and BPD occur most frequently in infants who are extremely premature or of low birth weight (see Chapter 43). Other risk factors include perinatal infection, meconium aspiration, tracheoesophageal fistula, and generalized infections. Signs and symptoms of CLD and BPD include hypercapnia, tachypnea, wheezing, dyspnea, recurrent respiratory infections, **cor pulmonale** (right ventricular enlargement and heart failure), and a characteristic radiographic appearance of the lungs.

## Medical Treatment

Because the pathophysiologic conditions of CLD and BPD are incompletely understood, medical treatment and

**FIGURE 35-4** Demonstration of how to gastrostomy feed a baby with bronchopulmonary dysplasia.

nutrition intervention are empirically based and often have limited scientific rationale (Van Marter, 2009). Infants with severe disease often require prolonged intensive medical care, provided by an interdisciplinary team. Figure 35-4 shows student members of the interdisciplinary team practicing tube feeding a simulated infant with BPD. Therapies such as parenteral nutrition or enteral tube feedings, mechanical ventilation, supplemental oxygen, and medications may be required long after discharge from the hospital.

### Medical Nutrition Therapy

Because of the fragile nature of affected infants, careful and consistent nutrition assessment is imperative. Infant growth is followed closely because it is a major outcome indicator of medical and nutrition therapy. Because lung size is stature-dependent, linear growth is important for the growth of healthy lung tissue and for the resolution of the condition. Observations of growth patterns of infants with CLD and BPD suggest that these infants have delayed growth, thereby requiring careful assessment of both respiratory and nutrition status (Box 35-2).

Possible reasons for growth failure among infants include increased energy needs combined with inadequate dietary intake, gastroesophageal reflux, emotional deprivation, and chronic hypoxia. Growth should be evaluated and compared with that of other infants of the same postconceptional age (see Chapter 43). Infants with CLD and BPD have special short- and long-term nutritional requirements related to both their prematurity and their pulmonary status. The general goals of nutrition care are to supply adequate nutrient intakes, promote linear growth, maintain fluid balance, and develop age-appropriate feeding skills. Meeting energy and nutrient needs is a major challenge in the care of infants and toddlers with BPD.

### BOX 35-2

#### Components of Nutrition Assessment for Infants with Bronchopulmonary Dysplasia

##### History

- Birth weight
- Gestational age
- Medical history
- Nutrition history
- Previous growth pattern

##### Medical Status

- Respiratory status
- Oxygen saturation
- Use of medications
- Emesis
- Stool pattern
- Urine output
- Urine specific gravity
- Ventilator dependency

##### Nutrition-Biochemical Measures

- Anthropometrics
  - Weight
  - Length
  - Growth percentiles
  - Head circumference
- Biochemical
  - Hemoglobin
  - Hematocrit
  - Serum electrolytes
  - C-reactive protein
  - Transthyretin

##### Feeding History

- Volume of intake
- Frequency of feedings
- Behavior during feedings
- Formula composition
- Use of solid foods
- Developmental feeding milestones
- Swallowing difficulty
- Gastroesophageal reflux

##### Environmental Concerns

- Parent-child interaction
- Home facilities
- Access to safe food supply
- Community resources
- Economic resources
- Access to food and nutrients

## Energy

Increased energy needs are well recognized in infants with CLD and BPD. Resting energy expenditure for infants with CLD and BPD has been documented to be 25% to 50% greater than that in age-matched controls. Energy needs also vary during the course of the disease. In the acute phase, when infants are kept in controlled temperature environments, are fed parenterally, remain relatively inactive, and are not growing or are growing slowly, energy requirements may be 50 to 85 kcal/kg daily. In contrast, during the convalescent phase, when infants are growing rapidly, being fed orally, and using additional energy for temperature regulation, activity, and the work of breathing, they may require 120 to 130 kcal/kg or more daily.

## Macronutrients

Protein intake should be within the advised range for infants of comparable postconceptional age. As the caloric density of the diet is increased by the addition of fat and carbohydrate, protein should provide 7% or more of total calories because lesser amounts may be inadequate for growth.

Additions of fat or carbohydrate are made to formula only after it has been concentrated to 24 kcal/oz to keep protein at an acceptable level. See Box 43-2 in Chapter 43. Fat provides essential fatty acids (EFAs) and helps meet energy demands when tolerance for fluid and CO<sub>2</sub> load is limited. Excessive amounts of carbohydrate increase the **respiratory quotient (RQ)** (the ratio of CO<sub>2</sub> expired to the volume of oxygen inspired) and the output of CO<sub>2</sub>. This would seem to make the work of breathing more difficult; however, the clinical application of manipulating nutrient mix to change RQ is controversial. Ongoing calculation of the proportions of the macronutrients related to respiratory status are major considerations in any nutritional evaluation.

## Fluid

To maintain fluid balance, infants with CLD and BPD may require fluid restriction, sodium restriction, and diuretics, all of which have nutritional implications. When fluid intake is restricted, the use of parenteral lipids or calorically dense enteral feedings may help the infant meet energy needs. When calorically dense formulas are used (>24 kcal/oz), the adequacy of fluid intake and urinary output must be monitored closely.

## Vitamins and Minerals

Adequate supplies of all vitamins and minerals are essential. Special attention is focused on those related to prematurity, infections, oxygen therapy, and drug-nutrient interactions. Adequate vitamin K is essential for bone development and should be monitored, especially when colon microflora are insufficient for the synthesis of this vitamin. Vitamin A is essential because of its role in the proper development and maintenance of the epithelial cells of the respiratory tract. In fact, some reports support the conclusion that vitamin A (either as an oral or intramuscular supplement) prevents or fully treats CLD and BPD, whereas others reject that conclusion (Darlow, 2007; Van Marter, 2009).

Mineral intake and retention should be monitored and supplemented as needed to maintain normal levels. Determination of mineral requirements is complicated by lack of adequate stores as a result of prematurity (e.g., iron, zinc, and calcium), growth delay, and the multiple medications prescribed for infants and toddlers with CLD and BPD. Medications may include diuretics, bronchodilators, antibiotics, cardiac antiarrhythmics, and corticosteroids. Collectively, these medications are associated with increased urinary loss of minerals, especially chloride, potassium, and calcium. Additional chloride losses may occur in infants with chronic CO<sub>2</sub> retention and respiratory acidosis because of metabolic correction for the acidosis. Deficiencies of chloride or potassium are associated with muscle weakness and impaired growth (see Chapter 7). For infants sensitive to sodium loads, lower-sodium formulas can be used, and the sodium content of medications, water, and foods must be considered (see Chapter 34).

Infants with CLD and BPD are at risk for **osteopenia** (inadequate bone mineralization). Besides limited nutrient intake, other risk factors include inadequate stores of calcium and phosphorus related to prematurity, intermittent respiratory acidosis, chronic use of certain medications, and insufficient physical activity. See Chapter 25.

## Feeding Strategies

Feeding difficulties frequently occur among infants with CLD and BPD. Risk factors include a history of unpleasant oral experiences (e.g., intubation, frequent suctioning, or recurrent vomiting), a history of parenteral and enteral nutrition, delayed introduction of solids, and discomfort or choking associated with eating solids. Infants may tire easily while breast-feeding or bottle-feeding. Useful approaches that facilitate feeding acceptance include providing a pleasant and calm mealtime environment, providing oral stimulation during tube feedings, using consistent and appropriate feeding techniques, and gradually introducing progressive texture and flavor changes.

Barriers to adequate intake include anorexia, fatigue, poor coordination of breathing and swallowing, and inability to suck. To meet energy needs, calorically dense formulas, small and frequent feedings, use of a soft nipple, and nasogastric or gastrostomy tube feedings may be needed. Gastroesophageal reflux is also common and may result in vomiting with expulsion of feedings, which leads to inadequate nutritional intake. Treatment includes upright positioning, medications such as antacids or histamine H<sub>2</sub>-receptor antagonists, and thickening of formula. In severe cases surgical fundoplication may be necessary.

## CHRONIC OBSTRUCTIVE PULMONARY DISEASE

**Chronic obstructive pulmonary disease (COPD)** is characterized by slow, progressive obstruction of the airways. COPD may be subdivided into two categories: **emphysema** (type I), which is characterized by abnormal, permanent

enlargement and destruction of the alveoli; and **chronic bronchitis** (type II), in which there is a productive cough with inflammation of the bronchi and other lung changes. Tobacco smoking or continual contact with second-hand smoke are the primary causative factors. Environmental air pollution (including cooking in a confined, unventilated space) and genetic susceptibility are other possible causal factors.

### Pathophysiology

Patients with emphysema are thin and often cachectic. They are generally older and have mild hypoxemia but normal hematocrit values. Cor pulmonale (right ventricular enlargement and failure of the heart) develops late in the course of the disease. Conversely, patients with chronic bronchitis are of normal weight and, indeed, are often overweight. Hypoxemia is prominent in these patients, hematocrit values are increased, and cor pulmonale develops early.

### Medical Treatment

Medical and surgical treatment approaches for persons with COPD are codified and periodically updated based on the latest research ([Global Initiative for Chronic Obstructive Lung Disease, 2009](#)). The four goals for effective management are to (1) assess and monitor disease, (2) reduce risk factors, (3) maintain stable COPD, and (4) manage any exacerbations. Early, accurate diagnosis is key to treatment. Once the disease progresses, in addition to pulmonary rehabilitation programs and oxygen therapy, numerous medications are prescribed, mainly bronchodilators, glucocorticosteroids, and mucolytic agents, along with antibiotics to treat infections. Surgical treatments for advanced COPD, including lung transplantation, may be options for some patients.

### Medical Nutrition Therapy

Medical nutrition therapy (MNT) for people with COPD has been evaluated and recommendations have been made. ([American Dietetic Association, 2010](#)). The primary goals of nutrition care for patients with COPD are to facilitate nutritional well being, maintain an appropriate ratio of lean body mass to adipose tissue, correct fluid imbalance, manage drug-nutrient interactions, and prevent osteoporosis.

After fluid status, energy is a primary consideration. Because maintaining energy balance is crucial for combating this progressive disorder, accurate evaluation of both energy intake and energy expenditure is essential. On the energy intake side, decreased food intake is common. Morning headache and confusion from **hypercapnia** (excessive CO<sub>2</sub> in the blood) may interfere with food preparation or intake. Other pertinent assessments focus on blood oxygen saturation, fatigue, anorexia, difficulty chewing and swallowing from dyspnea, constipation from low-fiber food selections, or diarrhea. Diarrhea occurs from impaired peristalsis, secondary to lack of oxygen to the gastrointestinal tract.

On the other hand, energy expenditure is generally elevated because of airflow obstruction, thus increasing the energy needs from the increased work of breathing. Gas

diffusing capacity, CO<sub>2</sub> retention, respiratory inflammation, and biochemical mediators such as hormones and cytokines also affect energy expenditure. Common outcomes are reduced respiratory and skeletal muscle strength and endurance along with increased muscle fatigability, altered pulmonary accessory muscle function, and increased susceptibility to infections. Malnourished patients with COPD, including those diagnosed with pulmonary cachexia, have a worse prognosis than those who are well nourished ([King, 2008](#)).

Nutritional depletion may be evidenced clinically by low body weight for height and reduced triceps fatfold measurements. Decreases in lean body mass may occur, even when actual weight appears stable. Calculation of BMI may be insufficient to detect alterations. Instead, determination of body composition helps to differentiate lean muscle mass from adipose tissue and overhydration from dehydration. In patients with cor pulmonale and the resultant fluid retention, weight maintenance or gain from fluid may camouflage actual wasting of lean body mass. Thus for patients retaining fluids, careful interpretation of both anthropometric measurements and biochemical indicators of nutrition status is necessary, especially because the latter are depressed by hemodilution (see [Chapters 6 and 8](#)).

The medication profile should be assessed for food and nutrient interactions. Examples of drugs with potential nutritional implications are bronchodilators, expectorants, and corticosteroids (see [Chapter 9](#)).

### Energy

Meeting energy needs can be difficult. For patients participating in pulmonary inpatient or outpatient rehabilitation programs, adjusted energy requirements depend on the intensity and frequency of exercise therapy. Actual energy needs may be increased or decreased ([Weekes, 2009](#)). It is crucial to remember that energy balance and nitrogen balance are intertwined. Consequently, maintaining optimal energy balance is essential to preserving visceral and somatic proteins. Preferably, indirect calorimetry should be used to determine energy needs and to prescribe and monitor the provision of sufficient, but not excessive calories ([American Dietetic Association, 2010](#)). When energy equations are used for prediction of needs, increases for physiologic stress must be included. Caloric needs may vary significantly from one person to the next, and even in the same individual (see [Chapter 2](#)).

### Macronutrients

In stable COPD, requirements for water, protein, fat, and carbohydrate are determined by the underlying lung disease, oxygen therapy, medications, weight status, and any acute fluid fluctuations. Attention to the metabolic side effects of malnutrition and the role of individual amino acids is necessary ([Baldi, 2010](#)). Determination of a specific patient's macronutrient needs is made on an individual basis, with close monitoring of outcomes.

Sufficient protein of 1.2 to 1.7 g/kg of dry body weight is necessary to maintain or restore lung and muscle strength, as well as to promote immune function. A balanced ratio of

protein (15% to 20% of calories) with fat (30% to 45% of calories) and carbohydrate (40% to 55% of calories) is important to preserve a satisfactory RQ from substrate metabolism use (see Chapter 2). Repletion but not overfeeding is particularly critical in patients with compromised ability to exchange gases as excess feeding of calories results in CO<sub>2</sub> that must be expelled. Other concurrent disease processes such as cardiovascular or renal disease, cancer, or diabetes mellitus affect the total amounts, ratios, and kinds of protein, fat, and carbohydrate prescribed.

### Vitamins and Minerals

As with macronutrients, vitamin and mineral requirements for individuals with stable COPD depend on the underlying pathologic conditions of the lung, other concurrent diseases, medical treatments, weight status, and bone mineral density. For people continuing to smoke tobacco, additional vitamin C is necessary. Research indicates that people who smoke approximately one pack of cigarettes per day appear to require approximately 16 mg more ascorbate per day, whereas those who smoke two packs need approximately 32 mg more than the recommended dietary allowance.

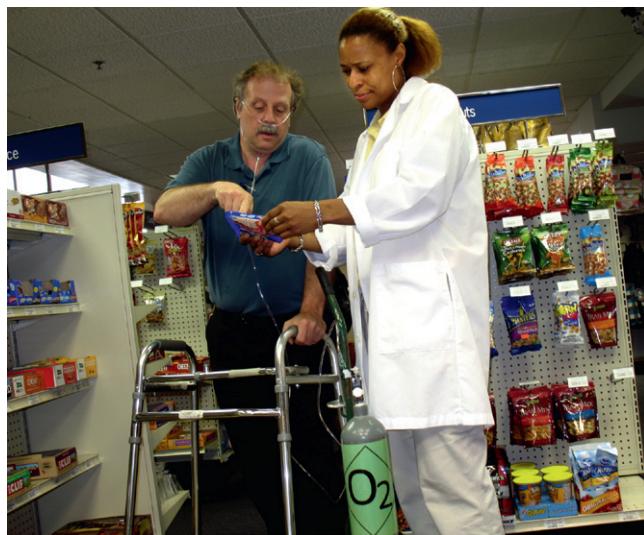

The role of minerals such as magnesium and calcium in muscle contraction and relaxation may be important for people with COPD. Intakes at least equivalent to the dietary reference intake (DRI) should be provided. Depending on bone mineral density test results, coupled with food intake history and glucocorticoid medications use, additional vitamins D and K also may be necessary (see Chapter 25).

Patients with cor pulmonale and subsequent fluid retention require sodium and fluid restriction. Depending on the diuretics prescribed, increased dietary intake of potassium may be required (see Chapter 9).

### Feeding Strategies

Interdisciplinary team involvement is paramount. A modified oral diet is usually preferred. Adequate exercise, fluids, and easily-chewed dietary fiber enhance gastrointestinal motility. When abdominal bloating is a problem, limitation of foods associated with gas formation may help (see Chapter 29).

Patients and their families benefit from specific suggestions for enhancing appetite, promoting oral intake, and lessening fatigue when cooking or eating. Some suggestions are resting before meals, eating small portions of nutrient-dense foods, and planning medications and breathing treatments around mealtimes. For many patients using oxygen at mealtimes, eating slowly, chewing foods well, and engaging in social interaction all can enhance food intake, nutrient metabolism, and enjoyment of the experience. To prevent aspiration, special caution must be given to proper sequencing of breathing with swallowing as well as to proper sitting posture during eating. Patients with disease-related physical limitations may require assistance with food shopping, meal preparation, and linkage with community resources such as congregate meal programs or home-delivered meals (Fig. 35-5).

**FIGURE 35-5** An individual with chronic obstructive pulmonary disease and oxygen being shown how to read a label.

Enteral tube feeding can be used to increase total caloric and nutrient intake for some patients with COPD. Decisions to implement this method of nutrition support should take into consideration the goal of the nutrition therapy, the ability of the caregivers, the attitude of the patient, and the cost (see Chapter 14).

## CYSTIC FIBROSIS

**Cystic fibrosis (CF)** is a complex multisystem disorder that is inherited in an autosomal-recessive fashion. The underlying genetic basis of the disease has been identified, with more than 1400 mutations noted. CF remains one of the most common lethal genetic disorders in the white population, and it is expressed in other population groups as well. Approximately 2% to 5% of white populations are heterozygotes, with a CF incidence of 1:3500 live births.

CF was once thought to be only a pediatric disease, but the number of people surviving to or being diagnosed at 18 years or older is approximately 42%. Survival has dramatically improved because of scientific advancements and improvements in diagnostic and treatment procedures, including nutrition. The median age of patients is approximately 37 years. Many women with CF have delivered healthy infants, and some have chosen to breastfeed their unaffected infants.

### Pathophysiology

Expression of the CF gene is largely restricted to epithelial cells. In CF, almost all exocrine glands are affected and secrete abnormally thick, tenacious mucus that obstructs glands and ducts in various organs. The clinical features are dominated by involvement of the respiratory tract, sweat and salivary glands, intestine, pancreas, liver, and reproductive tract. Pulmonary complications include acute

and chronic bronchitis, bronchiectasis, pneumonia, atelectasis, and peribronchial and parenchymal scarring. Infection with *Staphylococcus aureus* and *Pseudomonas aeruginosa* is typical. Pneumothorax and hemoptysis are common. In advanced stages, cor pulmonale or infection with *Burkholderia cepacia* may be present, signifying a poor prognosis.

## Medical Treatment

Several methods are available for diagnosing CF. For families with previously identified CF, prenatal analysis may be possible. Several countries and most states in the United States conduct routine neonatal screening for the disease. Genotyping is available and is a routine procedure. The most reliable clinical diagnostic test, known as the **sweat test**, is performed by pilocarpine iontophoresis.

CF can have a profound effect on the digestive system. Infants born with meconium ileus have the diagnosis of probable CF until differentiated from other causes. Approximately 85% to 90% of persons with CF have **pancreatic insufficiency (PI)**, in which plugs of thick mucus reduce the quantity of digestive enzymes released from the pancreas into the small intestine. The resultant enzyme insufficiency causes maldigestion of food and malabsorption of nutrients. Decreased bicarbonate secretion can further reduce digestive enzyme activity. Decreased bile acid resorption contributes to fat malabsorption.

**Distal intestinal obstruction syndrome (DIOS)**, recurrent intestinal impaction, sometimes occurs in children and adults. Prevention of DIOS involves intake of adequate enzymes, fluids, and dietary fiber and regular exercise; treatment includes adding stool softeners, laxatives, hyperosmolar enemas, or intestinal lavage.

The presence of excessive mucus lining the small intestinal tract may interfere with nutrient absorption by the microvilli. Gastrointestinal complications include bulky, foul-smelling stools; cramping and intestinal obstruction; rectal prolapse; and liver involvement. As the disease progresses, damage to the endocrine portion of the pancreas causes impaired glucose tolerance and development of CF-related diabetes mellitus (Moran, 2010). Pancreatic enzyme replacement therapy is essential (see *Focus On: PERT Therapy*).

## Medical Nutrition Therapy

Because of the numerous intricate manifestations and complications, nutritional requirements and care must be individually determined for each patient. MNT must be coordinated with other treatments, including a variety of different kinds of medicines and chest physical therapy. The goals of nutrition care in CF are to control maldigestion and malabsorption, provide adequate nutrients, promote optimal growth or maintain weight for height, support pulmonary function, and prevent nutritional deficiencies. Individuals at especially high risk include infants, children, adolescents, and pregnant or lactating women, even when they are medically stable. They should have a nutrition assessment. Comprehensive MNT for people with CF has been evaluated scientifically, with recommendations

## ◎ FOCUS ON

### PERT Therapy

**Pancreatic enzyme replacement therapy (PERT)** is the first step taken to correct maldigestion and malabsorption. The microspheres, designed to withstand the acidic environment of the stomach, release enzymes in the duodenum, where they digest protein, fat, and carbohydrate. The quantity of enzymes to be taken with food depends on the degree of pancreatic insufficiency; the quantity of food eaten; the fat, protein, and carbohydrate content of food consumed; and the type of enzymes used. Enzyme dosage per meal or snack is adjusted empirically to control gastrointestinal symptoms, including steatorrhea, and to promote growth appropriate for age. Following the manufacturer's directions about storage and administration of a particular brand of enzyme is important to emphasize. If gastrointestinal symptoms cannot be controlled, enzyme dosage, patient adherence, and enzyme type should be reevaluated. Fecal **elastase** (protein-digesting enzyme secreted by the pancreas and involved in hydrolysis of peptide bonds), fecal fat, or nitrogen balance studies may help to evaluate the adequacy of enzyme supplementation.

published (Michel, 2009; Stallings, 2008). Periodic updated practice guidelines are available online from the various international CF organizations and should be consulted for the latest information.

Maldigestion and malabsorption, as well as the progressive complications of the disease, make it difficult to meet increased nutrient needs. Factors interfering with adequate intake and retention of nutrients include dyspnea, coughing and cough-induced vomiting, gastrointestinal discomfort, anorexia during episodes of infection, possible impaired sense of smell and taste, and glucosuria. Growth retardation and difficulty maintaining desired weight for height are common problems. Before diagnosis, infants with CF often demonstrate growth failure. With treatment, growth generally improves. When energy and nutrient intakes are adequate, growth nearly appropriate for age usually can be achieved (Leonard, 2010) (see *Pathophysiology and Care Management Algorithm: Cystic Fibrosis*).

As lung disease progresses, growth velocity in children and weight for height in adults may decline. The long-term relationship between nutrition support, growth, and survival is not known; however, improved nutrition status on a long-term basis continues to be suggested as a contributing factor to increased survival. Adults have similar medical, surgical, psychosocial, and nutrition assessment concerns, but they also have regular adult life issues. Thus they require nutrition information delivered by different educational approaches than those used with children (Morton, 2009; Watson, 2008).

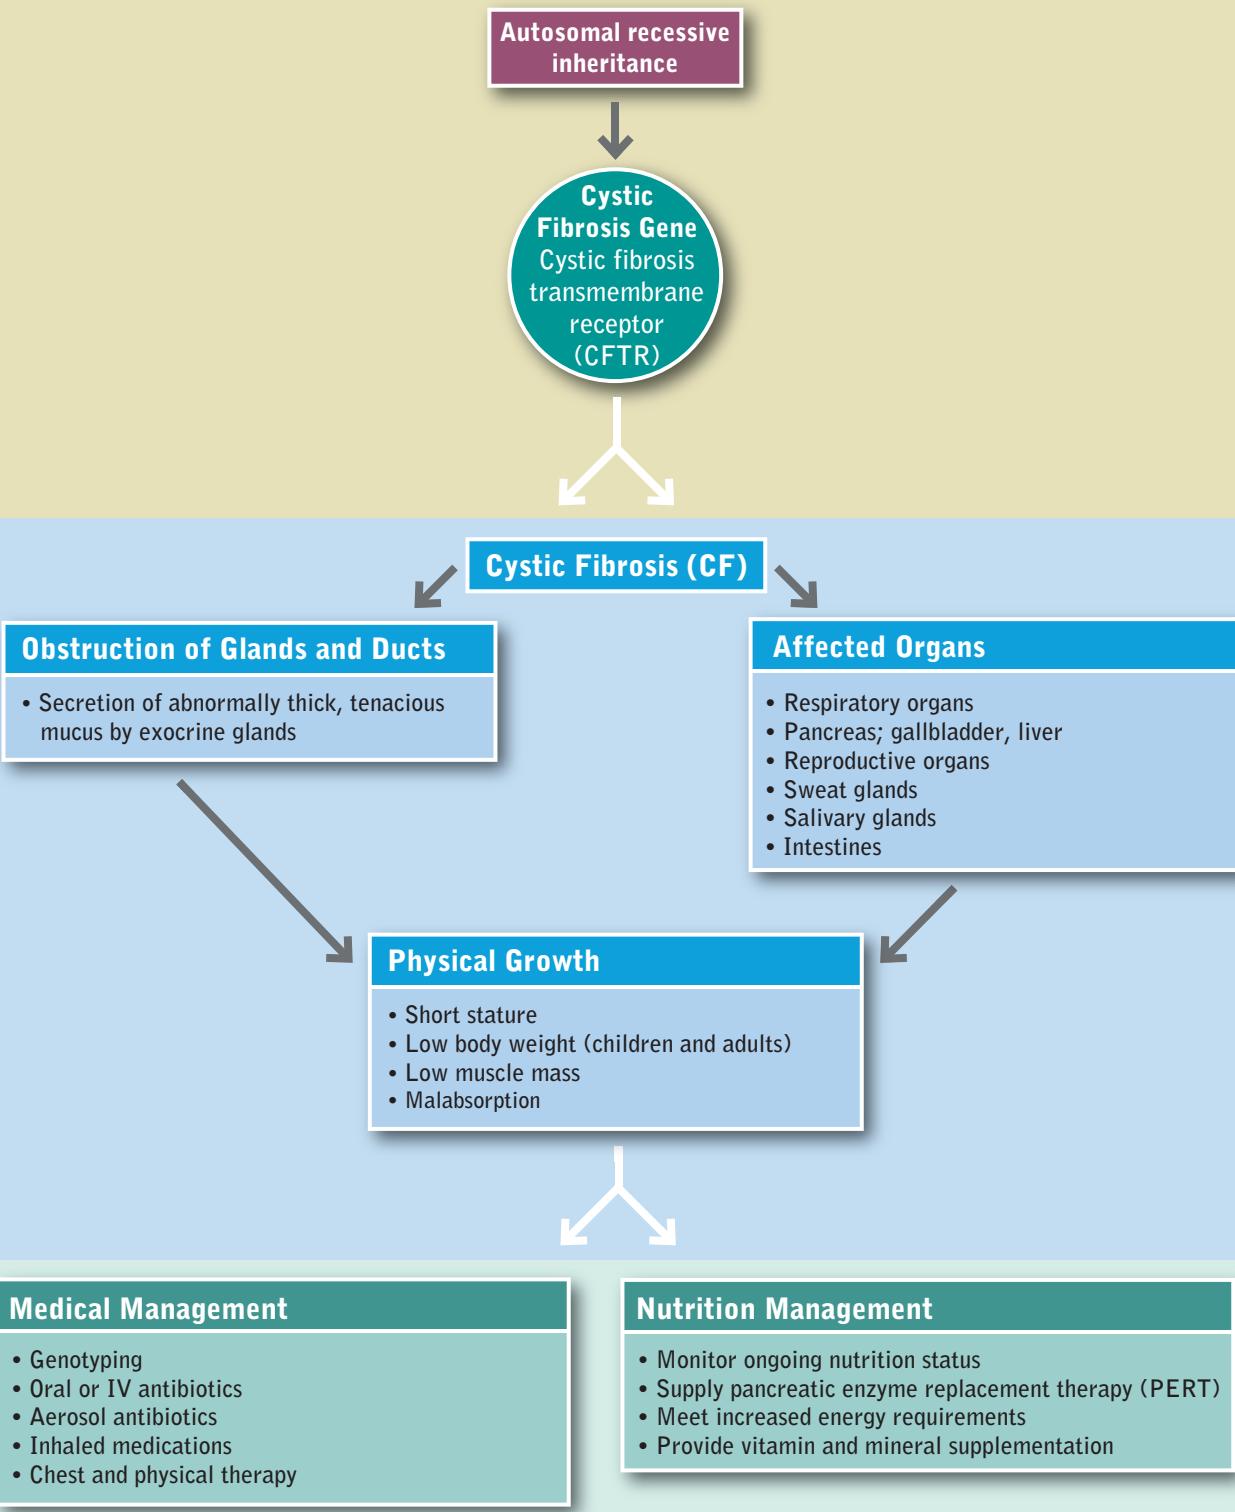

## PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

### Cystic Fibrosis

**ETIOLOGY**

**PATHOPHYSIOLOGY**

**MANAGEMENT**

## Macronutrients

Energy needs vary widely from individual to individual, even in the same individual throughout the course of life based on gender, age, basal metabolic rate, physical activity, respiratory infection, severity of lung disease, and severity of malabsorption. When laboratory methods to determine energy requirements are unavailable, equations for calculating caloric recommendations are convenient to use (Magoffin, 2008). Patients with CF should not be encouraged to decrease their activity levels, but rather to increase their energy intake instead. Relatively healthy children with CF usually are able to maintain normal growth and energy stores when they eat a high-energy, moderate-fat diet complemented with sufficient pancreatic enzyme replacement therapy (PERT).

Dietary protein levels are increased in CF as a result of malabsorption; however, when energy needs are adequately met, individuals with CF generally can meet their protein needs. At least 15% to 20% of the total calories consumed as proteins or the appropriate DRI for protein for the individual's gender, age, and height is suggested.

Fat intake should provide 35% to 40% or more of total kilocalories as tolerated. Dietary fat helps to provide the required energy, EFAs (i.e., linoleic acid and linolenic acid), and fat-soluble vitamins. Moreover, fat limits the volume of food required to meet energy demands and improves the palatability of the diet. Indications of fat intolerance include an increase in the number of stools, greasy stools, or abdominal cramping.

EFA deficiencies may be present, even among patients who are treated adequately with pancreatic enzymes to control malabsorption (Strandvik, 2010). Although clinical signs of EFA deficiency are rare, blood and tissue lipid levels may be abnormal (Aldamiz-Echievarria, 2009). Even if the visible signs of EFA deficiency (e.g., the typical skin lesions) are not noticeable, the clinician should consider routinely testing for abnormal blood lipid profiles. In addition, at-risk patients need to be encouraged to include sources of EFAs (e.g., canola, flaxseed, soybean, or corn oil, or fish) as part of their daily fat intake.

As the disease progresses, changes in carbohydrate intake may be necessary. Lactose intolerance may become evident (see Chapter 29), and pancreatic endocrine involvement may require carbohydrate adjustments.

## Vitamins and Minerals

With pancreatic enzyme replacement, the water-soluble vitamins appear to be adequately absorbed in patients with CF. Requirements under normal conditions can usually be met by diet plus a standard age-appropriate multivitamin and mineral supplement; however, monitoring individual variations is important.

Even with pancreatic enzyme supplementation, fat-soluble vitamins usually remain inadequately absorbed. Low serum concentrations of vitamin A despite increased hepatic stores have been documented in CF, suggesting impaired mobilization and transport of the vitamin from the liver. Decreased

levels of vitamin D metabolites have also been observed. This is one of several factors that may be related to the decreased bone mineral content seen in populations with CF. Low vitamin E levels have been associated with hemolytic anemia and abnormal neurologic findings. Individuals with CF may be at risk for vitamin K deficiency secondary to long-term use of antibiotics or liver disease, as well as malabsorption. Thus vitamin regimens should be adjusted based on routine serum monitoring of the individual.

Mineral intake should meet the gender and age recommendations according to the DRI. Special attention must be given to some of the minerals. Sodium requirements for infants, children, and adults are increased in CF because of increased losses in sweat. When sodium intake is inadequate, lethargy, vomiting, and dehydration may occur. Adequate salt is consumed by most children and adults who eat a typical North American diet with processed foods; however, supplemental salt is required under some conditions. Infants require extra salt because of the low-sodium content of breast milk, formula, and infant foods (Coates et al., 2009). Children and adults need additional salt during periods of fever, hot weather, or physical exertion. Table salt or proprietary electrolyte replacement solutions are used.

Other minerals are not routinely supplemented, although mineral status should be evaluated on an individual basis. Decreased bone mineralization starts during childhood and must be assessed and addressed (Haworth, 2010). Low iron stores and low magnesium levels have been described in CF. Plasma zinc levels may be low in cases of moderate to severe malnutrition.

## Feeding Strategies

Diet modification focuses on meeting the increased nutritional requirements of CF. Along with adequate dietary modification, positive eating behaviors must be established (Stark et al., 2010). Parent educational materials are available online from the Cystic Fibrosis Foundation. For infants with CF and their families, the immunologic and psychosocial benefits of breast-feeding are well established, and breast-feeding should be encouraged. For the infant with pancreatic insufficiency, enzyme microspheres can be added to a small amount of baby food or placed directly in the infant's mouth. Supplementation with high-calorie formula may be necessary to meet growth goals. For formula-fed infants, standard formulas (20–27 kcal/oz) given with supplemental enzymes are usually adequate.

For children and adults, intake can be enhanced by regular and enjoyable mealtimes, larger food portions at meals, extra snacks, and foods selected for high-nutrient density. Homemade or proprietary nutritional supplements such as fortified beverages and puddings also can help the individual with CF attain nutritional goals.

Supplementation by feeding tube is an alternative for those unable to meet nutritional needs by the oral route. Formulas are provided by continuous infusion through a nasogastric, gastrostomy, or jejunostomy tube, often while the person sleeps. Elemental (predigested) and nonelemental formulas with enzymes may be effective. See Chapter 14.

Intensive supplementation has been associated with improved weight gain, slowed decline in pulmonary function, decreased incidence of respiratory infection, and improved sense of well being. Although the short-term benefits of supplementation have been well documented, nutrition status is likely to regress when supplementation is discontinued. The long-term effect of intensive supplementation on the course of the disease has not been determined. Parenteral nutrition is best used for short-term support in patients with clearly evident needs such as those recuperating from gastrointestinal surgery.

## LUNG CANCER

The primary sites of lung cancer are usually the bronchi, with subsequent metastasis to other organs such as the bone, brain, liver, or skin. As new screening technologies become commonplace, early detection and diagnosis should improve.

### Pathophysiology

Lung cancer is often associated with persistent tobacco smoking for many years, but other inhaled pollutants may initiate the malignant condition.

### Medical Treatment

Currently the medical treatment of lung cancer involves radiation therapy, chemotherapy, and surgery, which are accompanied by various nutritional side effects. Patients with lung cancer experience the added stress of respiratory fatigue and diminished lung residual capacity. Smoking cessation sessions are part of most wellness programs and offer ideal settings for nutrition education.

### Medical Nutrition Therapy

In cigarette smokers, food components and specific nutrients have been investigated as either preventive or therapeutic modalities for lung cancer. High-dose  $\beta$ -carotene supplements may have a negative effect, whereas increased consumption of fruits and vegetables may be beneficial (Hercberg, 2005). The possible role of whole foods or their various components, or botanicals, in lung cancer initiation, promotion, or treatment receives worldwide attention (Lambert et al., 2005).

Because of the pulmonary constraints in people with lung cancer, purchasing and preparing foods may be overwhelming tasks. Eating may become an unpleasant activity because of severe pain, dyspnea, and dyspepsia. Weight loss, along with associated declines in other anthropometric and laboratory indicators of cancer-related malnutrition, portends a worsening prognosis. Thus, providing foods, beverages, and nutritional supplements in the forms and at the times best tolerated by the patient is essential. Administering oral medications with calorically dense nutritional supplements is another means of supplying needed nutrients (Cranganu and Camporeale, 2009).

## PNEUMONIA

Pneumonia usually occurs as an infection from bacteria, viruses, or fungi, or as a consequence of aspiration of food, fluid, or secretions such as saliva. Aspiration is common in infants, children, and adults who are frail, have frequent coughing spasms, are unable to effectively chew or swallow their foods and beverages, or have inadequate head and neck control during eating.

### Pathophysiology

The infection or foreign material cause the alveoli to become inflamed. These air sacs fill with fluid or pus, which results in symptoms including cough (with phlegm), fever, chills, and labored breathing.

### Medical Nutrition Therapy

The role of vitamin A in treating pneumonia in children yielded conflicting results based on study designs (Mathew, 2010). Because of their role in inflammation and immunity, EFAs in adults were investigated, and showed a possible protective effect against pneumonia by the ingestion of  $\alpha$ -linolenic and linoleic acids (Merchant et al., 2005).

Optimal nutrition status and proper feeding techniques aid in preventing this pulmonary infection. Suggestions for preventing aspiration of secretions or food and fluids are in Chapter 41 and Appendix 35. Once pneumonia occurs, the goals of nutrition care are to provide adequate fluids and energy. Small, frequent meals of nourishing foods usually are better tolerated, coupled with proper positioning during eating.

## RESPIRATORY FAILURE

Respiratory failure (RF) occurs when the pulmonary system is unable to perform its functions. The causes may be traumatic, surgical, or medical. Multiple organ dysfunction syndrome (see Chapter 39) is the term used to denote abnormal interaction among the organ systems, culminating in relentless dysfunction of all organ systems.

### Pathophysiology

**Acute respiratory distress syndrome** is a common complication of critical illness. Ultimately, in RF from any cause, the patient requires oxygen provided through a nasal cannula or by mechanical ventilator support for varying lengths of time and at various levels of oxygen.

### Medical Treatment

Central factors in failure to wean from oxygen support or mechanical ventilation are respiratory muscle weakness and retention of CO<sub>2</sub>. The prognosis is precarious for patients with underlying chronic pulmonary disease such as CF or emphysema, or for those who are otherwise medically compromised, malnourished, or older. Lung transplantation (or cardiopulmonary transplantation) may be a viable option for some patients.

## Medical Nutrition Therapy

Nutritional needs vary widely within this group of patients, depending on the underlying disease process, prior nutrition status, and the patient's age. Hypercatabolism or hypermetabolism may be present.

As with most pulmonary diseases, body composition fluctuation is the hallmark nutrition assessment indicator for persons with RF. Most patients become severely underweight. Thus a series of accurate anthropometric measurements is crucial during the entire course of treatment, sometimes spanning the patient's lifetime (see Chapter 6). When at all possible, more accurate estimations of energy requirements are recommended with the use of indirect calorimetry measurements (see Chapter 2). Accurate interpretation of laboratory results may be confounded by fluid imbalances, medications, and ventilator support. Other nutritionally relevant factors to assess include immunocompetence, chronic mouth breathing, aerophagia, dyspnea, exercise tolerance, and depression.

The goals of nutrition care in patients with RF are to meet basic nutritional requirements, preserve lean body mass, restore respiratory muscle mass and strength, maintain fluid balance, improve resistance to infection, and facilitate weaning from oxygen support and mechanical ventilation by providing energy substrates without exceeding the capacity of the respiratory system to clear CO<sub>2</sub>. Methods to provide nutrition support depend on the underlying disease, whether the patient is acutely or chronically ill, and whether ventilator support is necessary (see Chapter 14).

## Energy

Because of hypercatabolism and hypermetabolism, energy needs are elevated in RF, and sufficient energy must be supplied to prevent the use of the body's own reserves of protein and fat. Energy requirements fluctuate and thus are best determined by continuous individual assessment. To estimate initial caloric requirements using prediction equations, see Chapter 2. Indirect calorimetry is considered the "gold standard" because it is the most accurate estimation of energy needs. Overfeeding in this population is particularly deleterious. By general agreement the most important factor is to provide adequate but not excessive energy.

## Macronutrients

Because the patient with RF may be in negative nitrogen balance, protein should be supplied to restore balance; however, enterally supplied protein does affect the RQ. The basic requirements for carbohydrate and fat as actual nutrients for nourishment are influenced by the underlying organ system decompensation, the patient's respiratory status, and the ventilation methods used. Controversy persists concerning the optimal ratio of protein, fat, and carbohydrate supplied to patients with RF. Protein is calculated as 1.5 to 2 g/kg of dry body weight. Nonprotein calories are evenly divided between fat and carbohydrate. Daily monitoring of each patient's intake is crucial.

Water requirements must be individualized based on the method of oxygen delivery and environmental factors, coupled with knowledge of underlying disease processes and prescribed medications.

## Vitamins and Minerals

Exact requirements for specific vitamins and minerals in RF are unknown. It is assumed that vitamins and minerals need to be supplied at least at the levels of the DRI plus repletion, based on the gender and age of the patient. The intake of vitamins and minerals necessary for anabolism, wound healing, and immunity, and those with antioxidant functions may need to be increased. For example, during anabolism mineral balance must be monitored in an anticipatory manner to prevent the refeeding syndrome (see Chapter 14). Minerals that function as electrolytes need to be monitored closely, especially because of fluid imbalances and the occurrence of respiratory acidosis or alkalosis. As a side effect of medications, potassium, calcium, and magnesium may be lost in the urine.

## Feeding Strategies

Diet composition and food selections should be planned to accommodate the nutritional requirements, individual preferences, and living arrangements of the patient. Some people participate in pulmonary rehabilitation programs. Most patients who are not intubated or who have tracheostomies will be able to meet all or most of their nutritional needs by mouth. Small portions and favorite foods enhance oral food intake. Consumption must be monitored to maintain appropriate calorie levels and a suitable ratio of protein, fat, and carbohydrate.

Provision of adequate oxygen is crucial for proper digestion and absorption of food. Patients receiving inadequate oxygen may complain of anorexia, early satiety, malaise, bloating, and constipation or diarrhea. Intubated patients usually require enteral tube feedings or parenteral feedings. In a hospital setting establishing a nutrition protocol increases the likelihood of appropriate enteral feeding, thus yielding better outcomes such as decreased duration of mechanical ventilation. The use of specially formulated pulmonary proprietary products should be reserved for patients fitting the specified criteria (see Chapter 14). Otherwise effort and expense may not provide the expected results.

## TUBERCULOSIS

Tuberculosis (TB) traditionally was diagnosed among economically disadvantaged population groups (e.g., immigrants, homeless persons, and children) or those living in close quarters (e.g., prisoners, refugees, and armed forces). At high risk are health care workers; residents in assisted living facilities, skilled nursing homes, or hospitals; and people who are immunocompromised such as those with cancer, chronic renal disease, or HIV (see Chapters 36 through 38).

## Pathophysiology

**Tuberculosis (TB)** is a bacterial disease caused by mycobacteria, specifically *Mycobacterium tuberculosis*, *M. bovis*, or *M. africanum*. The disease is spread from inhalation of organisms dispersed as droplets from the sputum of infected persons (the bacteria-laden droplets can float in the air for several hours). TB yields prolonged cytokine production. Increased levels of interferon gamma, interleukin (IL)-10, and IL-6 are accompanied by a modest increase in the levels of cortisol, prolactin, and thyroid hormones and decreased testosterone and dehydroepiandrosterone levels (Bottasso et al., 2009).

TB produces profound abnormalities on the immune system. Although most people infected by the tubercle bacillus (90%) do not develop the disease during their lifetime, when there are coinfections with HIV, malnutrition, or diabetes, the risk of developing active disease increases considerably.

## Medical Treatment

Pharmacologically, this pulmonary infection is treated with multiple medications, especially antibiotics. First-line drugs are isoniazid, rifampicin, ethambutol, and pyrazinamide. Each has drug-food-nutrient interactions (see Chapter 9).

Because tubercle bacilli increasingly are becoming resistant to drug therapy; strains with increased virulence have emerged. New therapies are constantly under review.

## Medical Nutrition Therapy

Signs and symptoms of TB with nutritional relevance include undernutrition, weight loss, night sweats, fatigue, dyspnea, and hemoptysis (Campbell and Bah-Sow, 2006; Villamor et al., 2006). People with chronic infections may need higher caloric intakes. Unless otherwise contraindicated, people with TB routinely require increased energy intake and fluids. Research has not found a role for vitamin A or zinc supplementation specifically, but vitamin C may have merit. Providing access to food and also to high-calorie, high-protein oral supplements is a less expensive, feasible medical option (Abba K, et al., 2008). Many patients require assistance with activities of daily living, such as shopping for food and meal preparation.

Because isoniazid absorption is reduced by food, it should be administered 1 hour before or 2 hours after meals. It depletes pyridoxine (vitamin B<sub>6</sub>) and interferes with vitamin D metabolism, which in turn can decrease absorption of calcium and phosphorus. Patients thus require increased vitamins B<sub>6</sub> and D (Yamshchikov, et al., 2010), and minerals from meals or supplements.

## CLINICAL SCENARIO

Rick is a 63-year-old widower who is a retired commercial carpet installer. He started smoking when he was 15, and he smoked two packs per day until 7 years ago. You have an appointment with Rick during his next session at the Outpatient Pulmonary Rehabilitation Program. Significant findings are weight 124 lb, height 5'4", blood pressure 127/65, heart rate 82, respiratory rate 18, temperature 98.6° F, oxygen saturation 95, carbon dioxide 54, forced vital capacity (FVC) 1.04 (28% predicted), forced expiratory volume in 1 second (FEV1) 0.37 (12% predicted), FEV1/FVC ratio 36, and forced expiratory flow 25%-76% 0.19 (67% predicted). History and physical examination reveal severe dyspnea on exertion, including showering, carrying packages, making the bed, and pushing a vacuum cleaner; orthopnea (two or three pillows); and decreased breath sounds. Prescribed medications include theophylline (300 mg twice daily), prednisone (20 mg once daily in the morning), fluticasone (Flovent; 220 mg, four puffs twice daily), albuterol and ipratropium (Atrovent; two puffs as needed), trimethoprim and sulfamethoxazole (Bactrim DS; 1 tablet every 12 hours), and furosemide (Lasix; as needed). Over-the-counter medications include vitamin C (250 mg twice daily), vitamin E (400 units daily), and calcium (500 mg daily). He had a blood test and his potassium was low; his diet history reveals almost no potassium intake.

### Nutrition Diagnostic Statement

Food-medication interaction related to low potassium intake while on diuretic as evidenced by latest serum potassium.

### Nutrition Care Questions

- What other nutrition assessment information do you need before you see Rick?
- What are the interrelationships between chronic obstructive pulmonary disease, food intake, and nutrient metabolism?
- Are there any food-drug interactions that are a concern for Rick?
- What are the principles of medical nutrition therapy for Rick? Explain the scientific rationale for each.
- Write out a day's schedule to include mealtimes, medication administration times, and activities of daily living. Include the foods you might suggest for fulfilling the nutrition prescription. Verify by performing a computerized nutrient analysis.
- What do you think of Rick's nutrient supplementation program? Would you have Rick change it?
- You are planning a session on nutrition for the clients and their families who participate in the Outpatient Pulmonary Rehabilitation Program. What topics would you cover? What educational techniques would you use?

# Medical Nutrition Therapy for Renal Disorders

### KEY TERMS

acute glomerulonephritis  
acute kidney injury (AKI)  
acute renal failure (ARF)  
adynamic (low turnover) bone disease  
antidiuretic hormone (ADH)  
azotemia  
calciphylaxis  
chronic interstitial nephritis  
chronic kidney disease (CKD)  
continuous renal replacement therapy (CRRT)  
continuous venovenous hemodialysis (CVVHD)  
continuous venovenous hemofiltration (CVVH)  
dialysate  
end-stage renal disease (ESRD)  
erythropoietin (EPO)  
faconi syndrome  
fistula  
glomerular filtration rate (GFR)  
hemodialysis (HD)  
hypercalciuria  
hyperoxaluria  
intradialytic parenteral nutrition (IDPN)  
intraperitoneal nutrition (IPN)  
Kidney Dialysis Outcome Quality Initiative (KDOQI)

kinetic modeling  
Kt/V  
metastatic calcification  
nephritic syndrome  
nephrolithiasis  
nephrotic syndrome  
oliguria  
osteitis fibrosa cystica  
osteomalacia  
peritoneal dialysis (PD)  
phosphate binders  
protein digestibility corrected amino acid score (PDCAAS)  
protein-nitrogen appearance (PNA) rate  
pyelonephritis  
renal failure  
renal osteodystrophy  
renal replacement therapy (RRT)  
renal tubular acidosis (RTA)  
renin-angiotensin mechanism  
syndrome of inappropriate anti-diuretic hormone (SIAH)  
ultrafiltrate  
urea reduction ratio (URR)  
uremia  
vasopressin

### PHYSIOLOGY AND FUNCTION OF THE KIDNEYS

The main function of the kidney is to maintain the balance of fluids, electrolytes, and organic solutes. The normal kidney performs this function over a wide range of

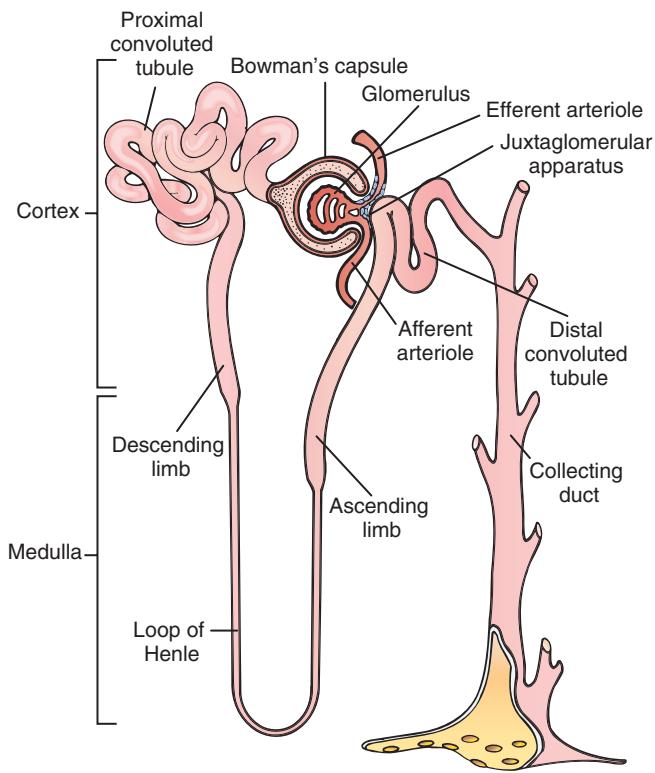

fluctuations in sodium, water, and solutes. This task is accomplished by the continuous filtration of blood with alterations in secretion and reabsorption of this filtered fluid. The kidney receives 20% of cardiac output, filtering approximately 1600 L/day of blood and producing 180 liters of fluid called **ultrafiltrate**. Through active processes of reabsorbing certain components and secreting others,

composition of this ultrafiltrate is changed into the 1.5 L of urine excreted in an average day.

Each kidney consists of approximately 1 million functioning nephrons (Figure 36-1), consisting of a glomerulus connected to a series of tubules. Tubules consist of different segments: the proximal convoluted tubule, loop of Henle, distal tubule, and collecting duct. Each nephron functions independently and contributes to the final urine, although all are under similar control and coordination. If one segment of a nephron is destroyed, that complete nephron is no longer functional.

The glomerulus is a spherical mass of capillaries surrounded by a membrane, Bowman's capsule. The glomerulus produces the ultrafiltrate, which is then modified by the next segments of the nephron. Production of ultrafiltrate is mainly passive and relies on the perfusion pressure generated by the heart and supplied by the renal artery.

The tubules reabsorb the vast majority of components that compose the ultrafiltrate. Much of this process is active and requires a large expenditure of energy in the form of adenosine triphosphate (ATP). The tubule is a unique structure; differences in permeability between the various segments and hormonal responses allow the tubule to produce the final urine, which can vary widely in concentration of electrolytes, osmolality, pH, and volume. Ultimately, this urine is funneled into common collecting tubules and into the renal pelvis. The renal pelvis narrows into a single ureter per kidney, and each ureter carries urine into the bladder, where it accumulates before elimination.

**FIGURE 36-1** The nephron. (Modified from Thibodeau GA, Patton KT: *The human body in health and disease*, ed 4, St Louis, 2005, Mosby.)

The kidney has almost unlimited ability to regulate water homeostasis. Its ability to form a large concentration gradient between its inner medulla and outer cortex allows the kidney to excrete urine as dilute as 50 mOsm or as concentrated as 1200 mOsm. Given a daily fixed solute load of approximately 600 mOsm, the kidney can get rid of as little as 500 mL of concentrated urine or as much as 12 L of dilute urine. Control of water excretion is regulated by **vasopressin (antidiuretic hormone [ADH])**, a small peptide hormone secreted by the posterior pituitary. An excess of relative body water, indicated by a low osmolality, leads to prompt shut-off of all vasopressin secretion. Likewise, a small rise in osmolality brings about marked vasopressin secretion and water retention. However, the need to conserve sodium sometimes leads to a sacrifice of the homeostatic control of water for the sake of volume. See *Focus On: Syndrome of Inappropriate Antidiuretic Hormone*.

The minimum urinary volume capable of eliminating a relatively fixed 600 mOsm of solute is 500 mL, assuming that the kidney is capable of maximum concentration. Urinary volume of less than 500 mL/day is called **oliguria**; it is impossible for such a small urine volume to eliminate all of the daily waste.

The majority of the solute load consists of nitrogenous wastes, primarily the end products of protein metabolism. Urea predominates in amount, depending on the protein content of the diet. Uric acid, creatinine (Cr), and ammonia are present in small amounts. If normal waste products are not eliminated appropriately, they collect in abnormal quantities in the blood, known as **azotemia**. The ability of the kidney to adequately eliminate nitrogenous waste products is defined as **renal function**. Thus **renal failure** is the inability to excrete the daily load of wastes.

The kidney also performs functions unrelated to excretion. One of these involves the **renin-angiotensin mechanism**, a major control of blood pressure. Decreased blood volume causes cells of the glomerulus (the juxtaglomerular apparatus) to react by secreting renin, a proteolytic enzyme.

## © FOCUS ON

### Syndrome of Inappropriate Antidiuretic Hormone

**Syndrome of inappropriate antidiuretic hormone (SIAH)** is seen when there is an excessive amount of antidiuretic hormone released from the pituitary gland. Common causes include head injury, meningitis, cancer, infection, and hypothyroidism. The result is hyponatremia caused by hemodilution. It is characterized by a serum sodium less than 135 mEq/L and a urine sodium concentration greater than 20 mEq/L. If left untreated it can result in seizures and coma. It is treated with fluid restriction, generally less than 1800 mL/day, and may require intravenous sodium administration. Oral sodium supplementation is contraindicated.

Renin acts on angiotensinogen in the plasma to form angiotensin I, which is converted to angiotensin II, a powerful vasoconstrictor and a potent stimulus of aldosterone secretion by the adrenal gland. As a consequence, sodium and fluid are reabsorbed, and blood pressure is returned to normal.

The kidney also produces the hormone **erythropoietin (EPO)**, a critical determinant of erythroid activity in the bone marrow. Deficiency of EPO is the primary cause of the severe anemia present in chronic renal disease.

Maintenance of calcium-phosphorus homeostasis involves the complex interactions of parathyroid hormone (PTH); calcitonin; active vitamin D; and three effector organs: the gut, kidney, and bone. The role of the kidney includes production of the active form of vitamin D—1,25-dihydroxycholecalciferol (1,25-[OH]<sub>2</sub>D<sub>3</sub>)—as well as elimination of both calcium and phosphorus. Active vitamin D promotes efficient absorption of calcium by the gut and is one of the substances necessary for bone remodeling and maintenance. Active vitamin D also suppresses PTH production, which is responsible for mobilization of calcium from bone (see Chapter 25).

## RENAL DISEASES

The manifestations of renal disease are significant. They can be ordered by degree of severity: (1) kidney stones, (2) acute kidney injury (AKI), (3) chronic kidney disease (CKD), and (4) end-stage renal disease (ESRD) (National Kidney Foundation, 2002). Objectives of nutritional care depend on the abnormality being treated.

### Kidney Stones (Nephrolithiasis)

**Nephrolithiasis**, the presence of kidney stones, is a significant health problem in the United States. It is characterized by frequent occurrences between the ages of 30 and 50, predominance in males, and a high recurrence rate. The risk doubles in those with a family history of kidney stones; stone formers often have first-degree relatives with kidney stones. Increased frequency of obesity, diabetes, and metabolic syndrome have resulted in increasing rates of nephrolithiasis among women, decreasing the male/female ratio from 1.7 : 1 to 1.3 : 1 (Zilberman, 2010). One Canadian study found significant differences in occurrence rates among ethnic groups, with highest rates in those of Arabic and West Indian descent and the lowest rates among those of East Asian or African descent (Mente, 2007). However, low urine volume is the single most important risk factor for nephrolithiasis.

### Pathophysiology

Kidney stone formation is a complex process that consists of saturation; supersaturation; nucleation; crystal growth or aggregation; crystal retention; and stone formation in the presence of promoters, inhibitors, and complexors in urine. A typical metabolic evaluation is described in Table 36-1.

Calcium stones are the most common: 60% of stones are calcium oxalate, 10% calcium oxalate and calcium

phosphate, and 10% calcium phosphate. Other stones are 5% to 10% uric acid, 5% to 10% struvite, and 1% cystine.

Obese stone formers excrete increased amount of sodium, calcium, uric acid, and citrate, and have lower urine pH. Obesity is the strongest predictor of stone recurrence in first-time stone formers. As body weight increases, the excretion of calcium, oxalate, and uric acid also increases. Patients with higher body mass index (BMI) have a decrease in ammonia excretion and impaired hydrogen ion buffering (Li et al., 2009). With increasing BMI, uric acid stones become more dominant than calcium oxalate stones, especially in men (Eisner, 2010b).

Uric acid stones are common in the presence of type 2 diabetes. Hyperinsulinemia may also contribute to the development of calcium stones by increasing urinary calcium excretion (Maalouf et al., 2010b). Weight control may be considered one of the preventive modalities and in stone formers, a BMI of 18 to 25 kg/m<sup>2</sup> is recommended.

With malabsorptive bariatric procedures such as Roux-en-Y gastric bypass (RYGB), urolithiasis is higher than in obese controls, probably because of the increased prevalence of hyperoxaluria and hypocitraturia in RYGB patients (Maalouf et al., 2010a). However, restrictive gastric surgery (i.e., gastric banding or sleeve gastrectomy) is not associated with increased risk of kidney stones (Semins et al., 2010).

Agents added intentionally or unintentionally to food or drug products have led to the appearance of new types of stones containing melamine and indinavir (Zilberman, 2010). See Table 36-2.

**Calcium Stones.** One third to one half of patients with calcium stones are hypercalciuric. **Hypercalciuria** describes a value of calcium in excess of 300 mg (7.5 mmol) per day in men, 250 mg (6.25 mmol) per day in women, or 4 mg (0.1 mmol)/kg/day for either in random urine collections of outpatients on unrestricted diets. Causes of hypercalciuria may include primary hyperparathyroidism, sarcoidosis, excess vitamin D intake, hyperthyroidism, glucocorticoid use, or renal tubular acidosis (RTA).

Idiopathic hypercalciuria (IH) seems to have a genetic basis. IH can be triggered by an excessive dietary calcium intake, increased intestinal absorption of calcium that may or may not be vitamin D-mediated, decreased renal tubular reabsorption of calcium, or prolonged bed rest. Increased gut absorption of calcium is noted in essentially all patients with IH. However, urinary calcium is higher than normal at any level of net calcium absorption, suggesting that some of the urine calcium is derived from the bone. When challenged with a very-low-calcium diet, the loss of more calcium in the urine than is in the diet results in abnormal bone mineral wasting. Patients with IH tend toward negative phosphorus balance even on normal intakes. The defective phosphate metabolism may lead to increased 1,25(OH)<sub>2</sub>D<sub>3</sub> levels, and increased intestinal calcium absorption.

Bone loss can be high in patients with IH in whom low calcium intake exaggerates bone loss from increased net acid excretion (NAE). For decades low-calcium diets were recommended to reduce the hypercalciuria in these stone-formers. However, chronic prolonged calcium restriction,

**TABLE 36-1****Baseline Information and Metabolic Evaluation of Urolithiasis**

<b>Information</b>	<b>Description and Data</b>
History of urolithiasis	History of onset, frequency Family history Spontaneous passage or removal Retrieval, analysis of stone Current status with radiologic examination
Medical history, investigation	Hyperparathyroidism Renal tubular acidosis Urinary tract infection Sarcoidosis Hypertension Osteoporosis Inflammatory bowel disease, malabsorption syndrome, intestinal bypass surgery for obesity Metabolic syndrome or insulin resistance Diabetes mellitus Obesity
Blood tests	Serum—calcium, phosphorus, creatinine, uric acid, CO <sub>2</sub> , albumin, parathyroid hormone, Hgb A1c
Urinalysis	Urine analysis with pH Urine culture
24-hr urine collection	Volume, calcium, oxalate, uric acid, sodium Citrate, magnesium, phosphorus Urea Creatinine Qualitative cystine
Medications and vitamins	Thiazide, allopurinol, vitamin C, vitamin B <sub>6</sub> , vitamin D, cod liver oil, calcium carbonate, glucocorticoid therapy, potassium citrate
Occupation history and strenuous exercise	Dermal water losses Dehydration Low urine volume Type of job and activity level
Environment	Hard water area
Dietary evaluation	Intake of calcium, oxalate, animal protein, salt, purines, fructose, potassium Fruits and vegetables (related to urine pH) Herbal products Volume of fluid intake Type of fluids containing citrate, caffeine, phosphoric acid; mineral water; sports drinks

CO<sub>2</sub>, Carbon Dioxide; Hgb A1c, hemoglobin A1c.**TABLE 36-2****Causes and Composition of Renal Stones**

<b>Pathogenetic Causes</b>	<b>Composition of Stone</b>
Hypercalciuria, hyperoxaluria, hyperuricosuria, or hypocitraturia	Calcium oxalate
Primary hyperparathyroidism	Calcium oxalate
Cystinuria	Cystine
Infection	Struvite
Acid urine pH	Uric acid
Hyperuricosuria	Uric acid
Renal tubular acidosis	Calcium phosphate
Alkaline urine pH	Calcium phosphate

Modified from: Asplin JR: Evaluation of a kidney stone patient, Seminars in Nephrol 28(2):99, 2008.

deficient calcium intake, and increased losses from hypercalciuria decrease bone mineral density at the spine and cortical sites. Thus vertebral fracture risk increases fourfold among urolithiasis patients in comparison with the general population.

Undesirable bone resorption may be enhanced by a high protein intake of nondairy origin. An inadequate calcium with high protein intake induces metabolic acidosis, increases calcium excretion, and lowers urinary pH. This acid load inhibits the renal reabsorption of calcium. A reduction in nondairy animal protein may be recommended; see *Clinical Insight: Urinary pH—How Does Diet Affect It?*

Calcium supplements do not have the same protective effect as dietary calcium. A trial of combined calcium–vitamin D supplementation to prevent bone loss and fractures led to higher rates of stone formation in women

(Jackson et al., 2006). If taken as a supplement, timing is important. Calcium supplements taken with meals increase urinary calcium and citrate but decrease urinary oxalate; thus the increase in citrate and decrease in oxalate counterbalance the effects of elevated urinary calcium. Therefore, if used by patients who cannot tolerate dairy products because of lactose intolerance, allergies, or preference, calcium supplements should be taken with meals. Urine calcium should be measured prior to starting the supplement and afterward to see the effect; if urine calcium increases, patients should increase fluid intake to dilute the urine concentration of calcium.

Patients may select 700–800 mg of calcium from dairy choices and consume the rest from nondairy foods to make up the total needed per day, according to age group and dietary reference intake (DRI) recommendations. Calcium

## CLINICAL INSIGHT

### Urinary pH—How Does Diet Affect It?

By Sheila Dean, DSc, RD, LD, CCN, CDE

Dietary intake can influence the acidity or alkalinity of the urine (Berardi, 2008). It has been shown that excessive dietary protein (particularly high in sulfur containing amino acids such as methionine and cysteine), and chloride, phosphorous, and organic acids are the main sources of dietary acid load. When these animal proteins such as meat and cheese, are eaten concomitantly with other acid producing foods, and not balanced out with alkaline producing foods such as fruit and vegetables, there is an increased risk of chronic acidosis. Acidosis (which is not to be confused with acidemia) has been linked to inflammatory related chronic diseases such as urolithiasis, hypertension, insulin resistance, low immune function and osteoporosis (Minich, 2007).

Consequently, when working with higher protein intakes it is important to provide a diet balanced in high alkaline foods. The most abundant alkaline foods are plant based foods; particularly vegetables and fruit abundant in alkalinizing micronutrients such as magnesium, calcium, sodium, and potassium. A more alkaline diet consisting of a higher fruit and vegetable intake is associated with a low potential renal acid load (PRAL) (Remer, 1995) Lower consumption of meat which is also associated with a lower PRAL may thus ameliorate not only the elevated blood pressure of hypertension but also the concurrent excess of morbidity and mortality of the concurrent cardiac, vascular and metabolic aspects of the hypertensive state.

Remer and Manz developed a physiologically based model to calculate the PRAL of selected, frequently consumed foods. By means of these PRAL data, the daily net acid excretion can be calculated, allowing for an accurate prediction of the effects of diet on acid load. This has been a reason to recommend animal protein limited diets, in order to control the dietary source of acids (Kiwull-Schone, 2008). The following food

lists serve as a guide to influencing potential renal acid load (PRAL).

#### Potentially Acidic Foods

**Protein:** meat, fish, fowl, shellfish, eggs, all types of cheese, peanut butter, peanuts

**Fat:** bacon, butternuts, walnuts, pumpkin seeds, sesame seeds, sunflower seeds, creamy salad dressings

**Carbohydrate:** all types of bread including cornbran, oats, macaroni, ricebran, rye, wheat and especially wheat gluten

**Sweets:** gelatin desserts (dry mix with and without aspartame), pudding (instant, dry mix)

#### Potentially Basic or Alkaline Foods

**Fat:** dried beechnuts, dried chestnuts, acorn

**Vegetables:** all types including lentils but especially beets, beet greens, Swiss chard, dandelion greens, kale, leeks, mustard greens, spinach, turnip greens

**Fruit:** all types, especially currants, dates, figs, bananas, dried apricots, apples, prunes, raisins

**Spices/Herbs:** all types, especially fresh dill weed and dried spices/herbs such as spearmint, basil, coriander, curry powder, oregano, parsley

**Sweets:** sorghum syrup, sugar (brown), molasses, cocoa (dry powder)

**Beverages:** coffee

#### Neutral Foods

**Fats:** butter, margarine, oils

**Dairy:** milk

**Vegetables:** corn

**Sweets:** sugar (white), most syrups, honey

**Beverages:** water, tea

should be taken in divided doses, choosing a source with each meal to maximize oxalate binding. Any low-fat dairy choices are good options.

**Oxalate Stones. Hyperoxaluria** (>40 mg of oxalate in urine per day) plays an important role in calcium stone formation and is observed in 10% to 50% of recurrent stone formers. Primary hyperoxaluria is a feature of an autosomal-recessive genetic defect of a hepatic enzyme that results in overproduction of oxalate and a urinary oxalate concentration three to eight times normal. Multiple stones occur in these children, causing renal failure and early death.

Patients with inflammatory bowel diseases or gastric bypass often develop hyperoxaluria because of fat malabsorption. The bile acids produced during the digestive process normally are reabsorbed in the proximal gastrointestinal (GI) tract, but when this fails to occur, bile salts and fatty acids increase colonic permeability to oxalate. The unabsorbed fatty acids also bind calcium to form soaps, decreasing availability of calcium in a soluble form. With less calcium available to bind oxalate in the gut and prevent its absorption, serum oxalate and thus urinary oxalate levels increase.

Urinary oxalate also comes from endogenous synthesis, proportional to lean body mass. Ascorbic acid accounts for 35% to 55%, and glyoxylic acid accounts for 50% to 70% of urinary oxalate. In patients with CKD, excessive vitamin C intake may lead to stone formation. Oxalate synthesis is not increased with a high protein diet (Knight et al., 2009). Because pyridoxine acts as a cofactor in the conversion of glyoxylate to glycine, its deficiency could increase endogenous oxalate production.

The bioavailability of food oxalate and urine oxalate are affected by salt forms of oxalate, food processing and cooking methods, meal composition, and the presence of *Oxalobacter formigenes* in the GI tract (Massey, 2007). Stone-forming patients who lack this bacteria have significantly higher urinary oxalate excretion and stone episodes compared with patients colonized with the bacteria (Hatch and Freel, 2008).

Administration of *Oxalobacter formigenes* as enteric-coated capsules significantly reduces urine oxalate in patients with primary hyperoxaluria. Dietary advice for reducing urinary oxalate should include both use of this probiotic and reduction of dietary oxalate and simultaneous consumption of calcium-rich food or supplement to reduce oxalate absorption (Massey, 2007) (Box 36-1).

**Uric Acid Stones.** Uric acid is an end product of purine metabolism from food, de novo synthesis, and tissue catabolism. Approximately half of the purine load is from endogenous sources and is constant. Exogenous dietary sources provide the other half, accounting for the variation in urinary uric acid. The solubility of uric acid depends on urine volume, the amount excreted, and urine pH (Table 36-3). Uric acid stones form when urine is supersaturated with undissociated uric acid, which occurs at urinary pH less than 5.5.

The most important feature in uric acid stone formers is low urine pH resulting from increased NAE and impaired buffering caused by reduced urinary ammonium excretion.

## BOX 36-1

### Foods to Avoid for a Low Oxalate Diet

- Rhubarb
- Spinach
- Strawberries
- Chocolate
- Wheat bran and whole-grain wheat products
- Nuts (almonds, peanuts, or pecans)
- Beets
- Tea (green, black, iced, or instant)
- High doses of turmeric

Data from Siener R et al: Oxalate content of cereals and cereal products, J Agric Food Chem 54:3008, 2006.

**TABLE 36-3**

### Effect of Urine pH on Stone Formation

pH	State of Urate	Likely Stone Development
<5.5	Undissociated urate	Uric acid stones
5.5-7.5	Dissociated urate	Calcium oxalate stones
>7.5	Dissociated urate	Calcium phosphate stones

The former can be a result of low intake of alkali-producing foods or increased consumption of acid-producing foods. See *Clinical Insight: Urine pH—How Does Diet Affect It?*

Inflammatory bowel disease results in chronically acidic urine, usually from dehydration. GI bicarbonate loss from diarrhea may predispose these patients to uric acid stones. Uric acid stones are also associated with lymphoproliferative and myeloproliferative disorders, with increased cellular breakdown that releases purines and thus increases uric acid load. Diabetes, obesity, and hypertension appear to be associated with nephrolithiasis; diabetes is a common factor in uric acid stone development (Lieske et al., 2006). Besides diabetes management for patients with uric acid lithiasis and hyperuricosuric calcium oxalate stones, dietary purines should also be restricted.

Meat, fish, and poultry are rich in purines and acid ash, and thus should be used in moderation. Foods specifically high in purines should be avoided, including organ meats, anchovies, herrings, sardines, meat-based broth, and gravy (see Box 40-3 in Chapter 40). Dietary noncompliance or persistence of hyperuricosuria warrants use of medication such as allopurinol. Uric acid stones are the only stones amenable to dissolution therapy by urine alkalinization to a pH of 6 to 6.5. Potassium citrate has been used as the therapy of choice. Sodium bicarbonate increases urinary monosodium urate and calcium and should not be used.

**Cystine Stones.** Cystine stones represent 1% to 2% of urinary calculi and are caused by homozygous cystinuria. Cystine stones affect approximately 1 in 15,000 persons in the United States. Whereas normal individuals daily excrete

20 mg or less of cystine in their urine, stone-forming cystinuric patients excrete more than 250 mg/day. Cystine solubility increases when urine pH exceeds 7; therefore an alkaline urine pH must be maintained 24 hours per day, even while the patient sleeps. This is almost always achieved with the use of medication. Fluid intake of more than 4 L daily is recommended to prevent cystine crystallization. Lower sodium intake may be useful in reducing cystine in the urine.

**Melamine and Indinavir Stones.** Kidney stones, ARF, and death have been reported in young children who received melamine-contaminated infant formula. Melamine is an organic base synthesized from urea. When added to liquid milk or milk powder, it deceptively increases the protein content. Melamine precipitates in the distal renal tubules, forming crystals and sandlike stones. Hydration and urine alkalinization help with stone passage.

The treatment of human immunodeficiency virus infection with protease inhibitors has led to the appearance of another previously unknown urinary calculus: indinavir. Hypocitraturia is universal in all patients with indinavir stones as well as decreased solubility in a low urine volume with a low pH. These stones are soft, gelatinous, radiolucent, and are not amenable to basket removal or ureteroscopy. Intravenous (IV) hydration and temporary cessation of indinavir should be the first choice of treatment (Zilberman, 2010).

**Struvite Stones.** Struvite stones are composed of magnesium ammonium phosphate and carbonate apatite. They are also known as triple-phosphate or infection stones. Unlike most urinary stones, they occur more commonly in women than in men, at a ratio of 2:1. They form only in the presence of bacteria such as *Pseudomonas*, *Klebsiella*, *Proteus mirabilis*, and *Urealyticum* that carry urease, a urea-splitting enzyme. Urea breakdown results in ammonia and carbon dioxide ( $\text{CO}_2$ ) production, thus raising urine pH and the level of carbonate. Struvite stones grow rapidly to large staghorn calculi in the renal pelvic area. The mainstay of treatment is extracorporeal shockwave lithotripsy (ECSWL) with adjunctive culture-specific antimicrobial therapy that uses urease inhibitors. The goal is to eliminate or prevent urinary tract infections by regularly screening and monitoring urine cultures.

## Medical Management

Uric acid and struvite stones are the only type amenable to dissolution therapy in the form of ECSWL. Shockwave lithotripsy and endourologic techniques have almost replaced the open surgical procedures of stone removal of 20 years ago. Struvite stones are also treated with adjunctive culture-specific antimicrobial therapy that uses urease inhibitors. Management strategies are now aimed at kidney stone prevention (Asplin, 2008).

## Medical Nutrition Therapy

After corrective treatment, nutrition assessment is needed to determine risk factors for stone recurrence. The risk in both men and women rises with increasing urine calcium and oxalate and decreases with increasing citrate and urine

volume. There is a continuum of risk related to increasing urinary calcium and urinary oxalate. (Curhan and Taylor, 2008). Because urine chemistries change from day to day based on changes in the environment and diet, two 24-hour urine specimens are needed based on a usual diet, one during a week day and one on the weekend. Specific medical nutrition therapy (MNT) is then based on comprehensive metabolic evaluations. Nutrition counseling and metabolic monitoring can be quite effective (Table 36-4).

When a patient passes a stone, it should be determined if it is a new stone or a preexisting one and advisement given accordingly (Asplin, 2008). The effectiveness of any MNT should be monitored with evaluation of subsequent 24-hour urine collections. This gives the nutritionist and patient a measure of the effect of dietary changes. Once diet therapy is initiated, the goal is to prevent new stones from forming and preexisting stones from growing. See *Pathophysiology and Care Management Algorithm: Kidney Stones*.

**Fluid and Urine Volume.** A low urine volume is by far the most common abnormality noted on metabolic evaluation of stone formers, and its correction with a high fluid intake should be the focus in all types of kidney stones. The objective is to maintain urinary solutes in the undersaturated zone to inhibit nucleation; this increases urine volume and reduces solute load. The goal is the amount of urine flow rather than a specified fluid intake. High urine flow rate tends to wash out any formed crystals, and a urine volume of 2 to 2.5 L/day should prevent stone recurrence. Fluid intake should change based on different rates of extrarenal fluid loss that affect rate of urine flow.

Achieving a urine volume of 2 to 2.5 L/day usually requires an intake of 250 mL of fluid at each meal, between meals, at bedtime, and when arising to void at night. Hydration during sleep hours is important to break the cycle of the “most-concentrated” morning urine. Half of this daily 2.5 L should be taken as water. Even higher fluid intake, perhaps as much as 3 L/day, may be necessary to compensate for any GI fluid loss, excessive sweating from strenuous exercise, or an excessively hot or an excessively dry environment, such as a commercial airplane cabin.

Cranberry juice acidifies urine and is useful in the treatment of struvite stones. Black currant juice increases urinary citrate and oxalate and, because of its urine alkalinizing effect, may prevent the occurrence of uric acid stones.

Tea, coffee, beer, and wine have been associated with reduced risk of stone formation. The oxalate content of tea brewed from regular black or green tea is 300–1500  $\mu\text{mol/L}$ . Because of the high oxalate content of tea, it should be taken with generous amounts of added milk; milk appears to reduce oxalate absorption by binding it in the gut lumen as calcium oxalate, making it less absorbable. Herbal teas have much lower oxalate content of 31–75  $\mu\text{mol/L}$  and are an acceptable alternative (Massey, 2007). Soft drinks and colas that contain phosphoric acid should be avoided because of their urine acidifying effect.

**Animal Protein.** Epidemiologic studies find a correlation between improved standard of living, high animal protein intake, and the rising incidence of kidney stones.

**TABLE 36-4****Recommendations for Diet and 24-Hour Urine Monitoring in Kidney Stone Disease**

Diet Component	Intake Recommendation	24-Hour Urine
Protein	Normal intake: avoid excess	Monitor urinary urea
Calcium	Normal intake: 1000 mg if age < 50 years; 1200 mg if age > 50 years	Calcium < 150 mg/L (<3.75 mmol/L)
Oxalate	Divide intake between three or more eating sessions Avoid moderate- to high-oxalate foods initially; further restrict if necessary	Oxalate < 20 mg/L (<220 µmol/L)
Fluid	2.5 L or more; assess type of fluids consumed; provide guidelines	Volume > 2 L/day
Purines	Avoid excessive protein intake; avoid specific high-purine foods	Uric acid < 2 mmol/L (<336 mg/L)
Vitamin C	< 500 mg/day	Monitor urinary oxalate
Vitamin D; cod liver oil	Supplements not recommended	
Vitamin B <sub>6</sub>	40 mg or more per day reduces risk. No recommendation made	
Sodium	<100 mmol/day	Monitor urinary sodium

From: Curhan GC, Taylor EN: 24-h uric acid excretion and the risk of kidney stones, *Kidney Internat* 73:489, 2008.

Meat, fish, poultry eggs, cheese, and grains are the primary contributors of acid; see *Clinical Insight: Urine pH—How Does Diet Affect It?* An adequate-calcium, low animal-protein, low-salt diet (less than 4 g) reduces oxalate excretion more than a traditional low oxalate diet (Nouvenne et al., 2009).

**Oxalate.** Because much less oxalate than calcium exists in urine (ratio 1:5), changes in oxalate concentration have a greater effect than changes in urinary calcium. However, oxalate absorption, which is 3% to 8% of the amount in food, is affected by the amount of dietary calcium. On very low calcium intakes of less than 200 mg/day, oxalate absorption rises; it falls when a higher calcium (1200 mg) is ingested.

Dietary counseling to reduce oxalate absorption is beneficial for stone-forming individuals who have large intakes of high-oxalate foods and who excrete more than 30 mg (350 µmol) of oxalate per day. The American Dietetic Association recommends restriction of oxalate to approximately 60 mg/day. To keep the diet plan simple, the patient is told to avoid those foods that are high in oxalate as the first step.

When these foods are avoided, other foods eaten will often only add up to the 50–60 mg, the daily dietary target. In addition, the patient is advised to add calcium to each meal to bind oxalate. The total calcium intake for the day can be divided between at least three meals or as many eating occasions as possible. It takes 150 mg of calcium to bind 100 mg of oxalate. Patients should include approximately 150 mg calcium in each meal, such as that found in  $\frac{1}{2}$  cup milk, ice cream, pudding, yogurt, or  $\frac{3}{4}$  oz cheese (Marcason, 2006; Massey, 2007).

**Potassium.** Stone formers often have a low to normal potassium intake and high sodium intake. Potassium intake is inversely related to the risk of kidney stones. Estimation

of fruit and vegetable intake should be included in the metabolic evaluation. Stone formers should be encouraged to increase the potassium in their diets by choosing low-oxalate fruit and vegetables many times throughout the day (Domrongkitchaiporn et al., 2006; see Appendix 56). See Box 36-1.

**Magnesium.** Magnesium is a low-molecular-weight inhibitor that forms soluble complexes with oxalate. Like calcium, it inhibits oxalate absorption and may have a role to play in hyperoxaluric patients.

**Phosphate.** Excess urine phosphate contributes to calcium phosphate stone risk, but it is not as important a risk factor as urinary pH, which determines how much phosphate will be in the form of hydrogen phosphate ( $HPO_4^{2-}$ ) (Asplin, 2008). Calcium phosphate stones tend to occur in pregnant women in the second and third trimester of pregnancy.

**Sodium.** The daily amount of sodium chloride in modern diets reaches excessive levels of up to 10 g/day. The amount of sodium in the urine and hypercalciuria are directly correlated because sodium and calcium are reabsorbed at common sites in the renal tubule. Because the risk for nephrolithiasis is significantly higher in hypertensive individuals compared with normotensive individuals, sodium intake should be lowered to less than 2300 mg/day in patients with hypercalciuria (Asplin, 2008; Nouvenne et al., 2009; Straub and Hautmann, 2005). Consumption of a diet modeled on the Dietary Approaches to Stop Hypertension diet reduces the risk for kidney stones (Taylor et al., 2009). See Appendix 33.

**Citrate.** Citrate inhibits urinary stones by forming a complex with calcium in urine. Thus less calcium is available to bind urinary oxalate, which helps prevent the formation of calcium oxalate or calcium phosphate stones. Distal RTA

## PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

### Kidney Stones

**Etiology**

**Pathophysiology**

**Management**

#### Co-Morbidities

- Metabolic syndrome
- Renal tubular acidosis
- Medullary sponge kidney
- Hyperparathyroidism
- Malabsorption syndromes
- Urinary tract infections
- Bariatric surgery (Roux-en-y)

#### Family History

#### Urinary risk factors

- Low urine volume
- Hypercalciuria
- Hyperoxaluria
- Hyperuricosuria
- Hypocitraturia
- Urine pH
- ↑ urine urea

#### Dietary Factors

- Low fluid
- Low calcium
- High oxalate
- High sodium
- Low potassium
- High animal protein
- High fructose
- High vitamin C

#### Kidney Stones

#### Flank pain/Renal colic

Spontaneous  
passage of  
stone

Retrieval of  
stone

Locate stone  
and treat

#### Medical Management

- Identify and treat medical cause
- 24 hour urine collection to identify risk factors
- Stone analysis
- Shockwave lithotripsy
- Surgical, endourologic stone removal
- Antimicrobial therapy
- Pharmacologic treatment

#### Nutrition Management

- Normalize urinary excretion of stone forming solutes
- Achieve daily urine volume >2 litre
- Dietary calcium based on age
- Avoid high oxalate foods
- Lower salt intake
- Moderate animal protein
- Vitamin C not >500 mg/day

is an acidosis accompanied by hypokalemia. RTA, malabsorption syndrome with enteric hyperoxaluria, and excessive meat intake (lower urine pH) are associated with decreased urinary citrate levels.

Many citrate-containing beverages have been tested for their effect on urine. Several diet sodas contain moderate amounts of citrate and malate; malate increases the total alkali load delivered, which augments citraturia (Eisner, 2010a). One commercial sports drink tested in non–stone formers increased urine citrate as much as 170 mg/day, but many sports drinks contain too much fructose and do not increase urinary citrate (Goodman, 2009).

Hypocitraturia is most commonly idiopathic, but may also be caused by acidosis accompanied by hypokalemia, malabsorption syndrome with enteric hyperoxaluria, excessive meat intake, and acid ash (Zuckerman and Assimos, 2009). Half of recurrent calcium stone formers have hypocitraturia (urinary citrate of <300 mg/day), predominantly of dietary origin. Normal daily urinary citrate level should be more than 640 mg/day. Long-term lemonade or lime or lemon juice therapy in hypocitraturic stone formers results in increased urinary citrate levels and decreased stone formation rate (Kang et al., 2007). Mineral water, with its magnesium and bicarbonate content, raises urine pH and stone inhibition.

**Fructose.** Fructose intake has increased approximately 2000% during the past 30 years from a widespread increase in the use of high-fructose corn syrup in foods. Fructose may increase urinary excretion of calcium and oxalate. It is the only carbohydrate known to increase the production of uric acid and its urinary excretion. Fructose may also increase insulin resistance, which is associated with low urine pH. Fructose intake has been positively associated with the risk of incident kidney stones (Taylor, 2008). Increased fruit and vegetable consumption is recommended to increase potassium intake, but because of the fructose content of fruit, there should be even more emphasis on vegetables (Asselman and Verkoelen, 2008).

**Vitamins.** Health benefits from 500 mg of ascorbic acid or more are not substantiated. Thus individuals at risk for calcium oxalate stones are wise to not exceed 500 mg/day (Massey et al., 2005; Moyad et al., 2009). Vitamin B<sub>6</sub> in the form of pyridoxal phosphate is a required cofactor in oxalate metabolism; marginal B<sub>6</sub> status should be avoided. Using 2 to 10 mg/day of vitamin B<sub>6</sub> may reduce urinary oxalate in some calcium oxalate stone formers.

## ACUTE KIDNEY INJURY (ACUTE RENAL FAILURE)

### Pathophysiology

**Acute kidney injury (AKI),** formerly **acute renal failure (ARF),** is characterized by a sudden reduction in **glomerular filtration rate (GFR)**, the amount of filtrate per unit in the nephrons, and altered ability of the kidney to excrete the daily production of metabolic waste. AKI can occur in association with oliguria (decreased output of urine) or normal

TABLE 36-5

### Some Causes of Acute Kidney Injury

Causes	Condition
1. Prerenal inadequate renal perfusion	Severe dehydration Circulatory collapse
2. Intrinsic diseases within the renal parenchyma	Acute tubular necrosis <ul style="list-style-type: none"> <li>• trauma, surgery</li> <li>• septicemia</li> </ul> Ischemic acute tubular necrosis Nephrotoxicity <ul style="list-style-type: none"> <li>• antibiotics, contrast agents, and other drugs</li> </ul> Local reaction to drugs Vascular disorders <ul style="list-style-type: none"> <li>• bilateral renal infarction</li> </ul> Acute glomerulonephritis of any cause <ul style="list-style-type: none"> <li>• poststreptococcal infection</li> <li>• systemic lupus erythematosus</li> </ul>
3. Postrenal urinary tract obstruction	Benign prostatic hypertrophy with urinary retention Carcinoma of the bladder or prostate Retroperitoneal or pelvic cancer Bilateral ureteral stones and obstruction Rhabdomyolysis

urine flow, but it typically occurs in previously healthy kidneys. Duration varies from a few days to several weeks. The causes of AKI are numerous, and can occur simultaneously (Table 36-5). These causes are generally classified into three categories: (1) Inadequate renal perfusion (prerenal), (2) diseases within the renal parenchyma (intrinsic), and (3) urinary tract obstruction (postrenal).

### Medical Management

The ratio of blood urea nitrogen (BUN) to Cr can be used diagnostically to assess the location of damage to the kidney. Depending on where the insult occurs, BUN is increased because of poor filtration, and is more actively reabsorbed. In this situation, with a BUN/Cr ratio greater than 20:1, damage is prerenal (before the kidney). When damage is intrinsic (within the kidney), the BUN/Cr ratio decreases to less than 10:1. Generally, if careful attention is directed at diagnosing and correcting the prerenal or obstructive causes, AKI is short lived and requires no particular nutritional intervention.

Intrinsic AKI can result from causes listed in Table 36-5; of these, a prolonged episode of ischemia leading to ischemic acute tubular necrosis is the most devastating. Typically patients develop this illness as a complication of an

overwhelming infection, severe trauma, surgical accident, or cardiogenic shock. The clinical course and outcome depends mainly on the underlying cause. Patients with AKI caused by drug toxicity generally recover fully after they stop taking the drug. On the other hand, the mortality rate associated with ischemic acute tubular necrosis caused by shock is approximately 70%. Typically these patients are highly catabolic, and extensive tissue destruction occurs in the early stages. Hemodialysis (HD) is used to reduce the acidosis, correct the uremia, and control hyperkalemia.

If recovery is to occur, it generally takes place within 2 to 3 weeks after the insult is corrected. The recovery (diuretic) phase is characterized first by an increase in urine output and later by a return of waste elimination. During this period dialysis may still be required, and careful attention must be paid to fluid and electrolyte balance and appropriate replacement.

### Medical Nutrition Therapy

Nutritional care in AKI is particularly important because the patient not only has uremia, metabolic acidosis, and fluid and electrolyte imbalance, but also usually suffers from physiologic stress (e.g., infection or tissue destruction) that increases protein needs. The problem of balancing protein and energy needs with treatment of acidosis and excessive nitrogenous waste is complicated and delicate. In the early stages of AKI the patient is often unable to eat. Mortality in AKI is high, especially among those who are malnourished (Strejc, 2005). Early attention to nutritional support and early dialysis improves patient survival.

At the onset of AKI, depending on severity, some patients can be treated with medical management, other patients require **renal replacement therapy (RRT)** with standard HD or peritoneal dialysis (PD) to remove wastes and fluids until kidney function returns. In significant AKI, a patient in the intensive care unit (ICU) may require continuous treatments, rather than periodic dialysis. **Continuous renal replacement therapy (CRRT)** is the broad category term that includes a whole host of modalities. Most often used are **continuous venovenous hemofiltration (CVVH)** and **continuous venovenous hemodialysis (CVVHD)**, which use a small ultrafiltration membrane to produce an ultrafiltrate that can be replaced by parenteral nutrition (PN) fluids. This treatment allows parenteral feeding without fluid overload. Less often used are continuous arteriovenous hemofiltration, continuous arteriovenous hemodialysis, and continuous venovenous hemodiafiltration. These modalities differ in the type of blood access used, as well as type of filtration (diffuse versus convective, or both).

**Protein.** The amount of protein recommended is influenced by the underlying cause of AKI and the presence of other conditions. A range of recommended levels can be found in the literature, from 0.5–0.8 g/kg for nondialysis patients to 1–2 g/kg for dialyzed patients. With CRRT protein losses are high, and estimated protein needs increase to 1.5–2.5 g/kg. As the patient's overall medical status stabilizes and improves, metabolic requirements decrease. During this stable period before renal function returns, a minimum

protein intake of 0.8–1 g/kg of body weight should be given. This remains dependent on the patient's overall status and comorbidities and should be evaluated individually.

**Energy.** Energy requirements are determined by the underlying cause of AKI and comorbidity. Energy needs can be measured at the bedside by indirect calorimetry in most ICUs (see Chapter 2). If this equipment is not available, calorie needs should be estimated at 30 to 40 kcal/kg of dry body weight per day. Excessive calorie intake can lead to excess CO<sub>2</sub> production, depressing respiration (see Chapter 35). If PD or CRRT with a glucose containing solution is used, the amount of glucose absorbed can add significantly to the daily energy intake and should be calculated. Large intakes of carbohydrate and fat are needed to prevent the use of protein for energy production. For patients who receive PN, high concentrations of both carbohydrate and lipid can be administered to fulfill these needs as long as respiratory status is monitored.

A high-calorie, low-protein diet may be used in cases in which dialysis or hemofiltration is unavailable. In addition to the usual dietary sources of refined sweets and fats, special high-calorie, low-protein, and low-electrolyte formulas have been developed to augment the diet. However, care must be taken with these products because hyperglycemia is not uncommon as a result of glucose intolerance, and additional insulin is often needed.

**Fluid and Sodium.** During the early (often oliguric) phase of AKI, meticulous attention to fluid status is essential. Ideally fluid and electrolyte intake should balance the net output. With negligible urine output, significant contributions to total body water output include emesis and diarrhea, body cavity drains, and skin and respiratory losses. If fever is present, skin losses can be excessive; whereas if the patient is on humidified air, almost no losses occur. Because of the numerous IV drugs, blood, and blood products necessitated by the underlying disease, the challenge in managing patients at this point becomes how to cut fluid intake as much as possible while providing adequate protein and energy.

Sodium is restricted, based on decreased urinary production. In the oliguric phase when the sodium output is very low, intake should be low as well, perhaps as low as 20 to 40 mg/day. However, limiting sodium is often impossible because of the requirement for many IV solutions (including IV antibiotics, medications for blood pressure, and PN). The administration of these solutions in electrolyte-free water in the face of oliguria quickly leads to water intoxication (hyponatremia). For this reason, all fluid above the daily calculated water loss should be given in a balanced salt solution.

**Potassium.** Most of the excretion of potassium and the control of potassium balance are normal functions of the kidney. When renal function is impaired, potassium balance should be scrutinized carefully. In addition to dietary sources, all body tissues contain large amounts of potassium; thus tissue destruction can lead to tremendous potassium overload. Potassium levels can shift abruptly and need to be monitored frequently. Potassium intake needs to be

**TABLE 36-6****Summary of Medical Nutrition Therapy for Acute Kidney Injury**

Nutrient	Amount
Protein	0.8-1 g/kg IBW increasing as GFR returns to normal; 60% should be HBV protein
Energy	30-40 kcal/kg of body weight
Potassium	30-50 mEq/day in oliguric phase (depending on urinary output, dialysis, and serum K <sup>+</sup> level); replace losses in diuretic phase
Sodium	20-40 mEq/day in oliguric phase (depending on urinary output, edema, dialysis, and serum Na <sup>+</sup> level); replace losses in diuretic phase
Fluid	Replace output from the previous day (vomitus, diarrhea, urine) plus 500 mL
Phosphorus	Limit as necessary

GFR, Glomerular filtration rate; HBV, high biologic value; IBW, ideal body weight; K<sup>+</sup>, potassium; Na<sup>+</sup>, sodium.

individualized according to serum levels (see Appendices 36 and 56). The primary mechanism of potassium removal during AKI is dialysis. Control of serum potassium levels between dialysis administrations rely mainly on IV infusions of glucose, insulin, and bicarbonate, all of which serve to drive potassium into cells. Exchange resins such as sodium polystyrene sulfonate (Kayexalate), which exchange potassium for sodium in the GI tract, can be used to treat high potassium concentrations, but for many reasons these resins are less than ideal. Table 36-6 summarizes MNT for AKI.

## CHRONIC KIDNEY DISEASE

A wide range of kidney lesions are characterized by a slow, steady decline in renal function. A number of the diseases discussed earlier lead to renal failure in some patients, whereas other patients have a benign course without loss of renal function. It is unclear why some patients remain stable with **chronic kidney disease (CKD)** for many months to years while others progress rapidly to renal failure and dialysis. The nature of this progressive loss of function has been the subject of an enormous amount of basic and clinical research during the past several decades and the subject of several excellent reviews (Remuzzi et al., 2006; Wenjun et al., 2009).

### Pathophysiology

Once approximately one half to two thirds of kidney function has been lost, regardless of the underlying disease, progressive further loss of kidney function ensues. This is true even in diseases in which the underlying cause has been eliminated completely, such as in vesicoureteral reflux, cortical necrosis of pregnancy, or analgesic abuse. It is thought that, in response to a decreasing GFR, the kidney undergoes a series of adaptations to prevent this decline. Although in the short term this leads to improvement in filtration rate, in the long term it leads to an accelerated loss of nephrons and progressive renal insufficiency (Remuzzi et al., 2006). The nature of these adaptations involves a change in the hemodynamic characteristics of the remaining glomeruli, specifically leading to increased glomerular pressure. Factors

that increase glomerular pressure tend to accelerate this process, whereas factors that decrease glomerular pressure tend to alleviate it.

Diabetes is the leading risk factor for CKD followed by hypertension. The National Kidney Foundation (NKF) divides CKD into five stages related to the estimated GFR (eGFR) (Table 36-7). Stages 1 and 2 are early stages with markers like proteinuria, hematuria, or anatomic issues. Stages 3 and 4 are considered advanced stages. Stage 5 results in death unless dialysis or transplantation is initiated.

### Medical Management

The prevalence of CKD is now estimated at approximately one in nine adults in the United States, or 20 million Americans. This estimated prevalence of CKD is 11% of the population. Many states now urge clinical laboratories reporting serum Cr to also report the patient's eGFR, the rate at which the kidneys are filtering wastes. The formula, which takes into account the patient's sex, age, race, and Cr, is more accurate than the older Cockcroft-Gault formula sometimes used to calculate Cr clearance (Rigalleau et al., 2006). Patients having their eGFR calculated who have a low number do not necessarily have CKD. They must have repeated values over 3 months apart that are consistently low.

An online eGFR calculator can be found at the NKF site at [http://www.kidney.org/professionals/kdoqi/gfr\\_calculator.cfm](http://www.kidney.org/professionals/kdoqi/gfr_calculator.cfm). With screening tools like the calculated eGFR and a greater awareness of the progressive nature of CKD, more attention has focused on its social, medical, and financial effects. For example, CKD is strongly linked with cardiovascular disease; see *Clinical Insight: Chronic Kidney Disease and Heart Disease—A Deadly Union*.

### Medical Nutrition Therapy

With each level of CKD, a different nutritional therapy may be proposed. The primary objectives of MNT are to manage the symptoms associated with the syndrome (edema, hypoalbuminemia, and hyperlipidemia), decrease the risk of progression to renal failure, and maintain nutritional stores. Patients are primarily treated with statins to correct hyperlipidemia, low-sodium diets, and diuretics (Appel, 2006).

**TABLE 36-7****Stages of Chronic Kidney Disease**

<b>Stage</b>	<b>eGFR</b>	<b>Description</b>
1	90-130 mL/min	Kidney damage, but normal to increased kidney function
2	60-89 mL/min	Mild decrease in kidney function
3	30-59 mL/min	Moderate decrease in kidney function
4	15-29 mL/min	Severe decrease in kidney function
5	Less than 15 mL/min	Kidney failure with treatment necessary, defined as end-stage renal disease

*eGFR*, Estimated glomerular filtration rate.

Patients with an established severe protein deficiency who continue to lose protein may require an extended time of carefully supervised nutritional care. The diet should attempt to provide sufficient protein and energy to maintain a positive nitrogen balance and to produce an increase in plasma albumin concentration and disappearance of edema. In most cases, sufficient intake from carbohydrate and fats are needed to spare protein for anabolism.

Some of the more common nutrition diagnoses in the CKD population include:

- Inadequate mineral intake
- Excessive mineral intake
- Imbalance of nutrients
- Excessive fluid intake
- Impaired nutrient utilization

 **CLINICAL INSIGHT**
**Chronic Kidney Disease and Heart Disease—A Deadly Union**

The presence of chronic kidney disease (CKD) increases the risk category for those with coronary vascular disease (CVD), and exacerbates existing CVD. An alarming fact is that most patients with CKD die from heart disease before they develop end-stage renal disease. Recommendations are that CKD patients should decrease their cardiovascular risks: quit smoking, increase exercise, limit intake of fat, and reach and maintain a normal body weight.

Fortunately, intervention makes a difference. The United States Renal Data System Dialysis M/M Study included 2,264 patients with CKD. More than half had not seen a nephrologist in the year prior to needing dialysis, and a third had their first nephrologist encounter less than 4 months prior to starting dialysis. This late referral to nephrologists resulted in low serum albumin and hematocrit levels. Patients who had seen a nephrologist at least 2 years before dialysis had a decrease in mortality. Thus patients who have CKD and receive early nutrition counseling may postpone the need for dialysis, or come to dialysis better nourished. The expertise of the renal dietitian has been recognized by the Center for Medicare Services, allowing for physician-ordered medical nutrition therapy by registered dietitian providers for Americans with CKD who are not on dialysis.

- Altered nutrition-related laboratory values
- Food-medication interaction
- Food- and nutrition-related knowledge deficit

Depending on the nutrition diagnosis, MNT interventions are adjusted for various intakes of minerals, protein, and fluids.

**Protein.** The recommended dietary protein level for CKD patients has changed over time. Historically, these patients received diets high in protein (up to 1.5 g/kg/day) in an attempt to increase serum albumin and prevent protein malnutrition. However, studies have shown that a reduction of protein intake to as low as 0.8 mg/kg/day may decrease proteinuria without adversely affecting serum albumin. Dietary protein has been championed as a factor that increases glomerular pressure and thus leads to accelerated loss of renal function. Numerous studies in experimental models of moderate renal insufficiency demonstrate a significant decline in this process with protein restriction. Clinical studies demonstrate a role for protein restriction in the management of patients with mild to moderate renal insufficiency to preserve renal function. To allow for optimal protein use, 50% to 60% of the protein should be from

sources of high biologic value (HBV). The description for HBV protein has been expanded to include proteins with a high **protein digestibility corrected amino acid score (PDCAAS)** (see Chapter 3).

A large multicenter trial, Modification of Diet in Renal Disease, attempted to determine the role of protein, phosphorus restriction, and blood pressure control in the progression of renal disease. Thus the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDKD) developed recommendations for the management of patients with progressive renal disease or pre-ESRD. Those recommendations for dietary protein intake in progressive renal failure are 0.8 g/kg/day with 60% HBV for patients whose GFR is greater than 55 mL/min, and 0.6 g/kg/day with 60% HBV for patients whose GFR is 25 to 55 mL/min.

The NKF's **Kidney Dialysis Outcome Quality Initiative (KDOQI)** panel suggests that patients whose GFR is less than 25 mL/min and who have not yet begun dialysis should be maintained on 0.6 g/kg/day of protein and 35 kcal/kg/day. If patients cannot maintain an adequate caloric intake on this protein recommendation, their protein intake should be increased to 0.75 g/kg/day. In both cases approximately 50% of the protein should be of HBV.

The potential benefits of protein restriction in the patient with moderate renal insufficiency must be weighed against the potential hazards of such treatment (i.e., protein malnutrition). If protein is restricted, careful monitoring and anthropometric studies should be carried out periodically as directed by the KDOQI guidelines.

Systemic hypertension, which aggravates the progressive loss of renal function, must be well controlled to produce benefits from protein restriction. Also important in the control of the progression of renal failure in people with diabetes is good blood glucose control. In a national multicenter trial, the Diabetes Control and Complications Trial showed that blood glucose control was more important than protein restriction in delaying the onset of renal failure in individuals who have diabetes (see Chapter 31).

**Energy.** Energy intake should be approximately 35 kcal/kg/day for adults to spare protein for tissue repair and maintenance.

**Sodium.** Edema, the most clinically apparent manifestation, indicates total body sodium overload. Additionally, because of low oncotic pressure from hypoalbuminemia, the volume of circulating blood may be reduced. Attempts to severely limit sodium intake or to use diuretics constantly may cause marked hypotension, exacerbation of coagulopathy, and deterioration of renal function. Therefore control of edema in this group of diseases should be with dietary intake of 2-3 g of sodium daily. The use of elastic full-length support hose may also be beneficial.

**Potassium.** Variability in disease states, individual intakes, and use of medications that may decrease potassium, such as diuretics, make potassium management possible. Many patients in early stage CKD take potassium-wasting diuretics and require supplementation. When urine output drops below 1 L/day, these same patients may require a potassium restriction as the kidney is no longer able to

excrete all potassium ingested. This typically occurs rather late in stage 4 CKD.

**Phosphorus.** The importance of controlling phosphate in patients with early stage disease is often overlooked. Serum phosphorous levels elevate at the same rate as eGFR decreases. Early initiation of phosphate reduction therapies is advantageous for delaying hyperparathyroidism and bone disease. Unfortunately, patients are often asymptomatic during the early phase of hyperparathyroidism and hyperphosphatemia; they may not attend to their modified diets or understand the need to take phosphate binders with meals.

Those with an eGFR of less than 60 should be evaluated for renal bone disease, and benefit from phosphorus restriction. Ongoing monitoring of patient's phosphorus and use of **phosphate binders** is recommended. The diet is typically modified to allow no more than 1000 mg of phosphates daily, a limit that allows approximately 1-2 dairy foods per day. Because of the decrease in protein intake, the control of phosphorus is somewhat easier to manage. Patients who are in later stages of CKD, and intolerant of red meats because of uremic taste alterations, are often able to substitute milk foods for meat and still maintain a limited phosphate intake.

**Lipids.** The important consequence of dyslipidemia is cardiovascular disease. Pediatric patients with frequently relapsing or resistant nephrotic syndrome are at particular risk for premature atherosclerosis. Certain lipid-lowering agents in combination with a cholesterol-lowering diet can reduce total cholesterol, low-density lipoprotein cholesterol, and triglycerides in these patients (see Chapter 34). Lowering protein intake in adult patients may also lower fat and cholesterol intake from animal sources.

**Vitamins.** CKD patients are routinely recommended a water-soluble renal customized vitamin supplement, because restrictions may cause the diet to be inadequate.

## DISEASES OF THE TUBULES AND INTERSTITIUM

To a great extent, the functions of the kidney tubules make them susceptible to injury. The enormous energy requirements and expenditures of the tubules for active secretion and reabsorption often leave this part of the kidney particularly vulnerable to ischemic injuries. Many toxic drugs can destroy or damage various segments of the tubules. The high-solute concentration generated in the medullary interstitium exposes it to damage from oxidants and precipitation of calcium-phosphate product (extraosseous calcification) and favors the sickling of red blood cells in sickle cell anemia. Indeed, a wide variety of diseases or disorders of the tubules and interstitium exist. They share common manifestations and can be considered together with respect to nutritional management.

**Chronic interstitial nephritis** can occur as a result of analgesic abuse, sickle cell disease, diabetes mellitus, or vesicoureteral reflux, and manifests primarily as inability to concentrate the urine and as mild renal insufficiency. A

hereditary disorder of the interstitium, *medullary cystic disease*, also presents with this picture. Dietary management consists of adequate fluid intake, which can require several liters of extra fluid. This is generally quite well tolerated by the patient, except when intercurrent illness occurs.

**Fanconi syndrome** is characterized by an inability to reabsorb the proper amount of glucose, amino acids, phosphate, and bicarbonate in the proximal tubule, thus causing urinary excretion of these substances. Adults with this syndrome present with acidosis, hypokalemia, polyuria, or osteomalacia, whereas children present with polyuria, growth retardation, rickets, and vomiting. No specific medical treatment is available to treat Fanconi syndrome; therefore dietary treatment is the main form of management. Replacement therapy usually consists of large volumes of water and dietary supplements of bicarbonate, potassium, phosphate, calcium, and vitamin D.

**Renal tubular acidosis (RTA)**, a defect in tubular handling of bicarbonate, can be caused by either a defect in the distal tubule (type 1) or a proximal tubular defect (type 2). Distal RTA leads to severe osteomalacia, kidney stones, or even nephrocalcinosis (calcification of the kidney). Distal RTA is treated with small amounts of bicarbonate, 70 to 100 mEq/day, with complete resolution of disease manifestations. Isolated proximal RTA in the adult is a benign disease, which is often made worse with bicarbonate and therefore should not be treated.

**Pyelonephritis**, a bacterial infection of the kidney, does not require extensive dietary management. However, in chronic cases the use of cranberry juice to reduce bacteriuria is useful (Kontiokari et al., 2005; Jepson, 2008). Concentrated tannins or proanthocyanidins in cranberry juice and blueberry juice may inhibit the adherence of *Escherichia coli* bacteria to the epithelial cells of the urinary tract.

## GLOMERULAR DISEASES

The functions of the glomerulus that are important with respect to disease are production of an adequate ultrafiltrate and prevention of certain substances from entering this ultrafiltrate.

### Nephritic Syndrome

#### Pathophysiology

**Nephritic syndrome** incorporates a group of diseases characterized by inflammation of the capillary loops of the glomerulus. These **acute glomerulonephritides** are sudden in onset, brief, and may proceed to complete recovery, development of chronic nephrotic syndrome, or ESRD. The primary manifestation of these diseases is hematuria (blood in the urine), a consequence of the capillary inflammation that damages the glomerular barrier to blood cells. The syndrome is also characterized by hypertension and mild loss of renal function. The most common presentation follows a streptococcal infection and is usually, although not always, self-limiting. Other causes include primary kidney diseases such as immunoglobulin A nephropathy (IgA); hereditary nephritis; and secondary diseases such as systemic

lupus erythematosus (SLE), vasculitis, and glomerulonephritis (GN) associated with endocarditis, abscesses, or infected ventriculoperitoneal shunts.

### Nephrotic Syndrome

#### Pathophysiology

**Nephrotic syndrome** comprises a group of diseases that derive from a loss of the glomerular barrier for protein. Large urinary protein losses lead to hypoalbuminemia with consequent edema, hypercholesterolemia, hypercoagulability, and abnormal bone metabolism. More than 95% of the cases of nephrotic syndrome stem from three systemic diseases: (1) diabetes mellitus, (2) SLE, and (3) amyloidosis; and from four diseases that are primarily of the kidney: (1) minimum change disease (seen only with electron microscopy), (2) membranous nephropathy, (3) focal glomerulosclerosis, and (4) membranoproliferative glomerulonephritis. Although renal function can deteriorate during the course of these diseases, it is not a consistent feature.

## END-STAGE RENAL DISEASE

**End-stage renal disease (ESRD)** reflects the kidney's inability to excrete waste products, maintain fluid and electrolyte balance, and produce hormones. As renal failure slowly progresses, the level of circulating waste products eventually leads to symptoms of uremia (see *Pathophysiology and Care Management Algorithm: Chronic Kidney Disease and End-Stage Renal Disease*). **Uremia** is a clinical syndrome of malaise, weakness, nausea and vomiting, muscle cramps, itching, metallic taste in the mouth, and neurologic impairment that is brought about by an unacceptable level of nitrogenous wastes in the body.

#### Pathophysiology

ESRD can result from a wide variety of different kidney diseases. Currently 90% of patients reaching ESRD have chronic (1) diabetes mellitus, (2) hypertension, or (3) glomerulonephritis. The manifestations are somewhat nonspecific and vary by patient. No reliable laboratory parameter corresponds directly with the beginning of symptoms. However, as a rule of thumb, BUN of more than 100 mg/dL and Cr of 10 to 12 mg/dL are usually quite close to this threshold.

#### Medical Treatment

Once the patient progresses from stage 4 to stage 5 CKD, options for treatment for ESRD include dialysis, transplantation, or medical management progressing to death. Patients do best if they have some control and choice over their options.

#### Dialysis

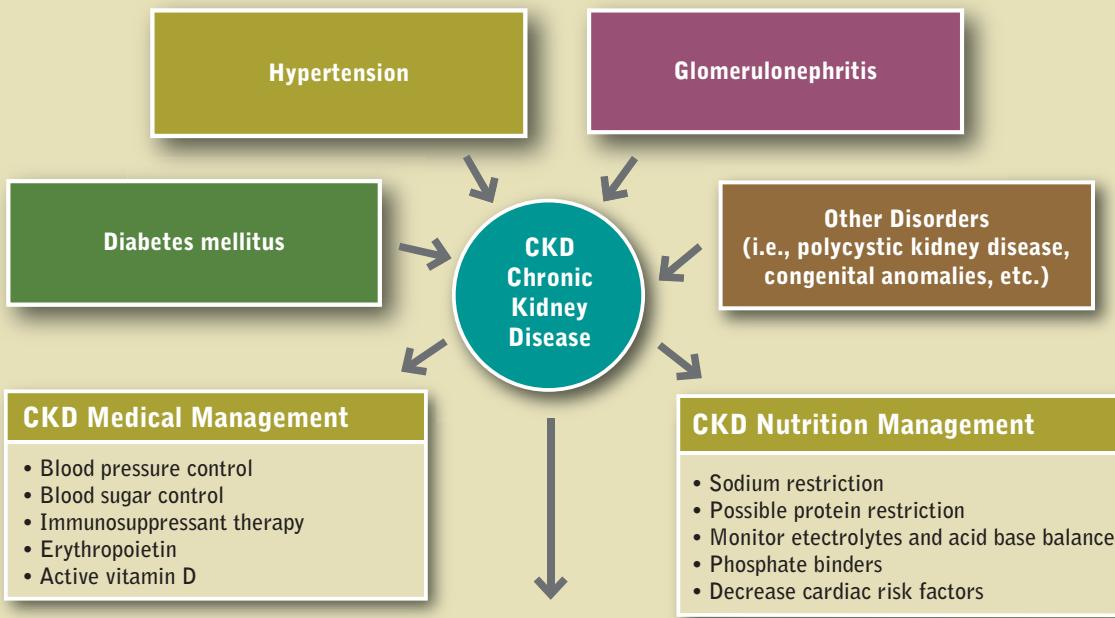

Patients may choose to dialyze in an outpatient dialysis facility or they may prefer HD at home using either conventional daily or nocturnal dialysis. They may choose PD and have a choice of continuous ambulatory peritoneal dialysis (CAPD) or continuous cyclic peritoneal dialysis (CCPD),

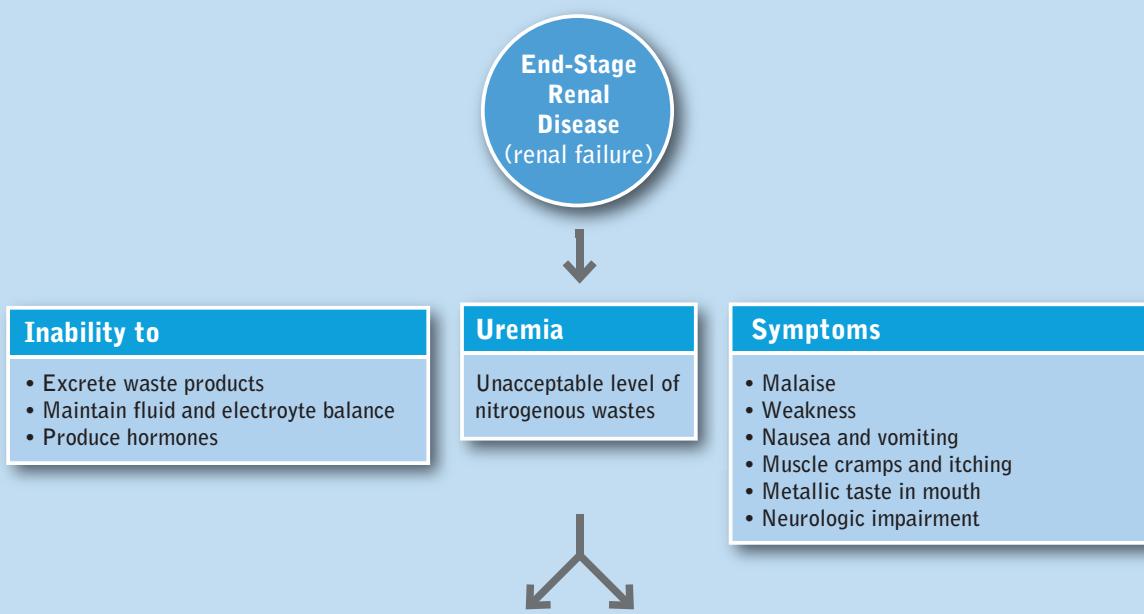

## PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

### Chronic Kidney Disease and End-Stage Renal Disease

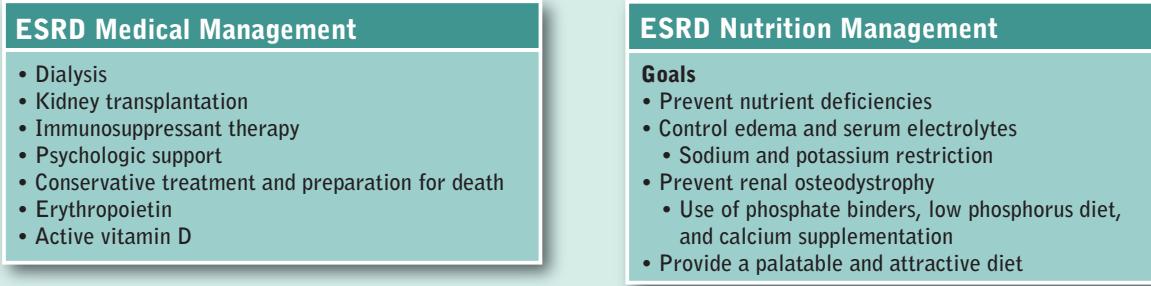

**Etiology**

**Pathophysiology**

**Management**

or combinations of the two. Patients, families, and their physicians together evaluate the therapy that best meets the patient's needs. Factors that come into account in this decision are availability of family or friends to assist with therapy, type of water supply to the home, capability of the patient or involved family (including eyesight and ability to perform sterile technique), previous abdominal surgeries, membrane characteristics of the individual's peritoneal membrane, body size, cardiac status, presence of poor vascular access, desire to travel, and a host of other considerations.

HD requires permanent access to the bloodstream through a **fistula** created by surgery to connect an artery and a vein (Figure 36-2). If the patient's blood vessels are fragile, an artificial vessel called a *graft* may be surgically implanted. Large needles are inserted into the fistula or graft before

each dialysis and removed when dialysis is complete. Temporary access through subclavian catheters is common until the patient's permanent access can be created or can mature; however, problems with infection make these catheters undesirable.

The **hemodialysis (HD)** fluid and electrolyte content is similar to that of normal plasma. Waste products and electrolytes move by diffusion, ultrafiltration, and osmosis from the blood into the dialysate and are removed (Figure 36-3) (Himmelfarb and Ikizler, 2010). Outpatient HD usually requires treatment of 3 to 5 hours three times per week in a dialysis unit (Figure 36-4). Newer therapies can shorten the duration of treatment by increasing its frequency. Patients on these more frequent dialysis therapies have lower mortality rates, approaching that of transplantation. Patients on daily dialysis at home typically have treatments lasting from 2 to 3.5 hours 5 to 6 days a week, whereas some home dialysis patients receive nocturnal dialysis 3 to 6 times a week for 8 hours, while they sleep.

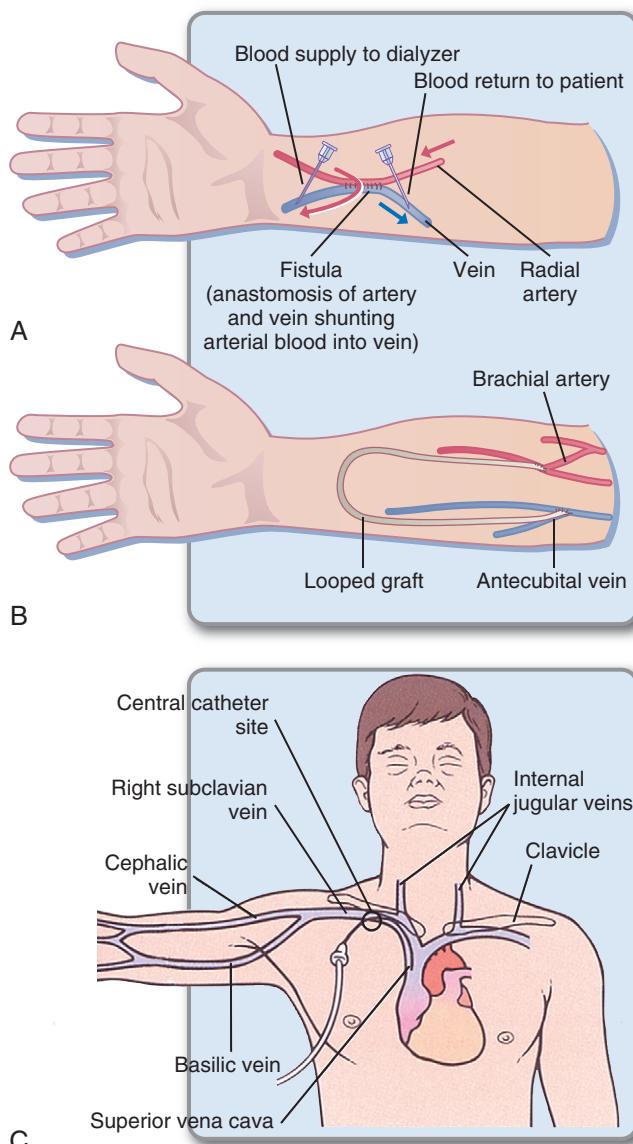

**Peritoneal dialysis (PD)** makes use of the body's own semipermeable membrane, the peritoneum. A catheter is surgically implanted in the abdomen and into the peritoneal cavity. **Dialysate** containing a high-dextrose concentration is instilled into the peritoneum, where diffusion carries waste products from the blood through the peritoneal membrane and into the dialysate; water moves by osmosis. This fluid is then withdrawn and discarded, and new solution is added.

Several types of PD exist. In CAPD, the dialysate is left in the peritoneum and exchanged manually, by gravity. Exchanges of dialysis fluid are done four to five times daily, making it a 24-hour treatment (Figure 36-5). In CCPD, patient treatments are done at night by a machine that does the exchanges. During the day these patients may keep a single dialysate exchange in the peritoneal cavity for extended periods (called a *long dwell*), perhaps the entire day. Several combinations of CAPD and CCPD are possible and are referred to here as *PD*.

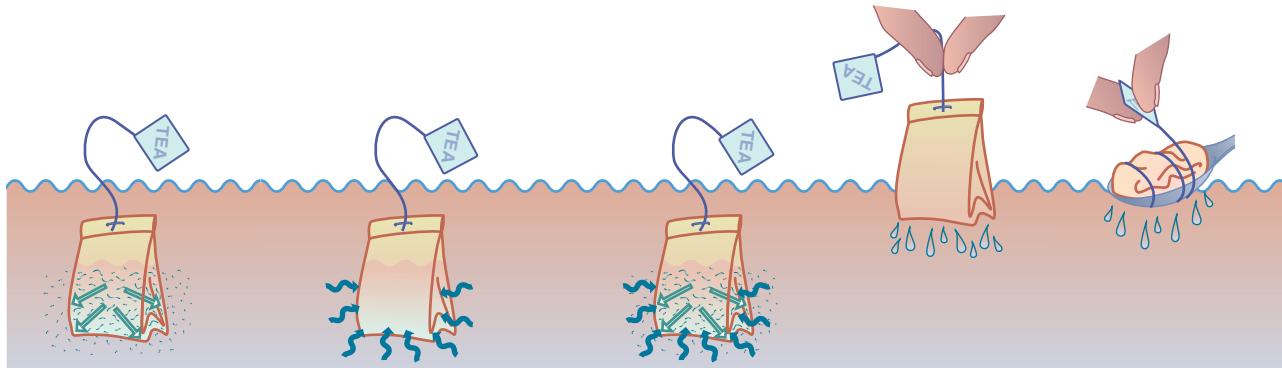

Advantages of PD are avoidance of large fluctuations in blood chemistry, longer residual renal function, and the ability of the patient to achieve a more normal lifestyle. Complications include peritonitis, hypotension that requires fluid and sodium replacement, and weight gain. Tissue weight gain is experienced by most patients as a result of absorbing 400 to 800 calories per day from the glucose in the dialysate. This may be desirable in patients who are underweight, but eventually dietary intake or activity have to be modified to account for the energy absorbed from dialysate. Icodextrin (Extraneal, Baxter) is a long-chain, nonabsorbable sugar available for long dwell times. It offers superior fluid removal (ultrafiltration) without excess dextrose absorption. This can be useful for patients with diabetes and those with excessive tissue weight gain, but can cause other complications and is costly.

### Evaluation of Dialysis Efficacy

**Kinetic modeling** is a method for evaluating the efficacy of dialysis that measures the removal of urea from the patient's

**FIGURE 36-2** Types of access for hemodialysis. **A**, Arteriovenous fistula. **B**, Artificial loop graft. **C**, Subclavian catheter (usually temporary). (From Lewis SL et al: Medical-surgical nursing: assessment and management of clinical problems, ed 7, St Louis, 2007, Mosby.)

**Diffusion**  
is the passage of particles through a semipermeable membrane. Tea, for example, diffuses from a tea bag into the surrounding water.

**Osmosis**  
is the movement of fluid across a semipermeable membrane from a lower concentration of solutes to a higher concentration of solutes. (The water moves into the teabag.)

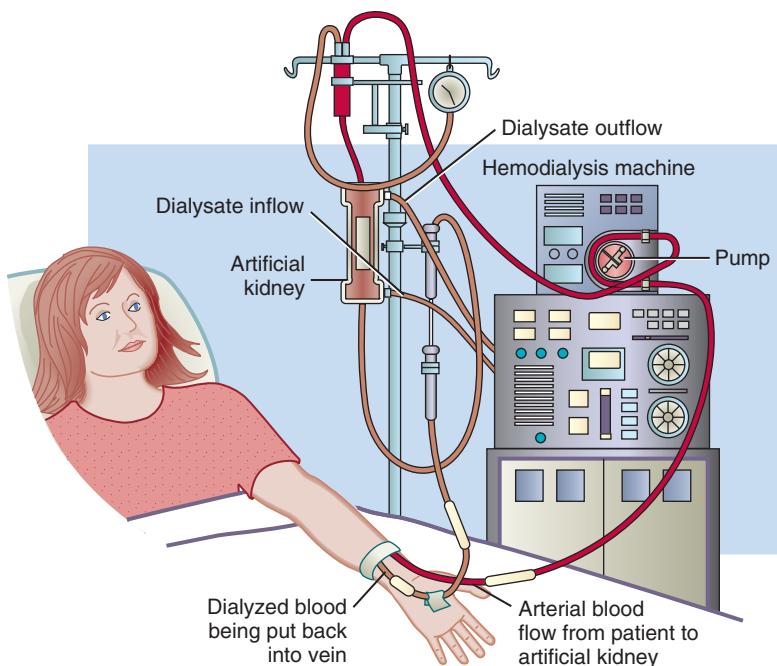

**Diffusion and Osmosis**  
can occur at the same time. (Particles move out and fluid moves in at the same time.)

**Filtration**  
is the passage of fluids through a membrane.

**Ultrafiltration**  
provides additional pressure to squeeze extra fluid through the membrane.

**FIGURE 36-3** Dialysis: how it works. (Modified from Core curriculum for the dialysis technician: a comprehensive review of hemodialysis, AMGEN, Inc.)

**FIGURE 36-4** Hemodialysis. Treatment is usually for 3 to 5 hours, three times per week.

blood over a given period. This formula, often called **Kt/V** (where  $K$  is the urea clearance of the dialyzer,  $t$  is the length of time of dialysis, and  $V$  is the patient's total body water volume), should ideally produce a result higher than 1.4 per HD, or 3.2 per week. These calculations are somewhat complex and are typically calculated using a computer program. A more accurate method for determining adequacy of HD is the **eKt/V** where  $e$  stands for *equilibrated* and takes into account the amount of time it takes for urea to equilibrate across cell membranes after dialysis has stopped. An acceptable **eKt/V** is 1.2 or greater.

Another method to determine effective dialysis treatment is the **urea reduction ratio (URR)**, which looks at the reduction in urea before and after dialysis. The patient is considered well dialyzed when a 65% or greater reduction in the serum urea occurs during dialysis. Unlike **Kt/V**, this calculation can be done quickly at the patient's bedside by the practitioner. The method for calculating the efficacy of PD is somewhat different, but a weekly **Kt/V** of 2 is the goal. The **Kt/V** can be altered by several patient- and dialysis-associated variables. The calculations for **Kt/V** can also be used to determine the patient's **protein-nitrogen**

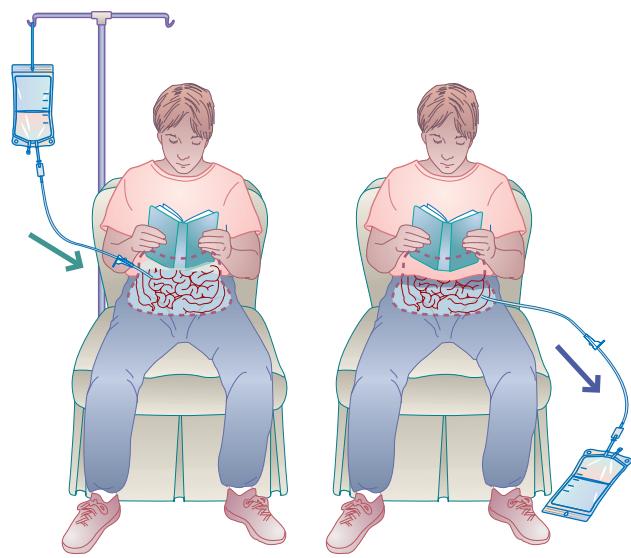

**appearance (PNA) rate**, which is a simplified nitrogen balance test in the dialysis patient. The PNA values should be between 0.8 and 1.4. Patients on short daily HD and nocturnal HD require different calculations to estimate their Kt/V.

## Medical Nutrition Therapy

Goals of medical nutrition therapy in the management of ESRD are intended to:

1. Prevent deficiency and maintain good nutrition status (and, in the case of children, growth) through adequate protein, energy, vitamin, and mineral intake (Table 36-8).
2. Control edema and electrolyte imbalance by controlling sodium, potassium, and fluid intake.
3. Prevent or retard the development of renal osteodystrophy by controlling calcium, phosphorus, vitamin D, and PTH.
4. Enable the patient to eat a palatable, attractive diet that fits his or her lifestyle as much as possible.
5. Coordinate patient care with families, dietitians, nurses, and physicians in acute care, outpatient, or skilled nursing facilities.
6. Provide initial nutrition education, periodic counseling and long-term monitoring of patients.

Table 36-9 presents a guide for teaching patients about their blood values and control of their disease. Because dialysis is done at home or in an outpatient unit, all most all patients with ESRD assume responsibility for their own diets. Most long-term patients know their diets very well (Figure 36-6),

The peritoneal cavity is filled with dialysate, using gravity.

At the end of the exchange, the dialysate is drained into the bag, again using gravity.

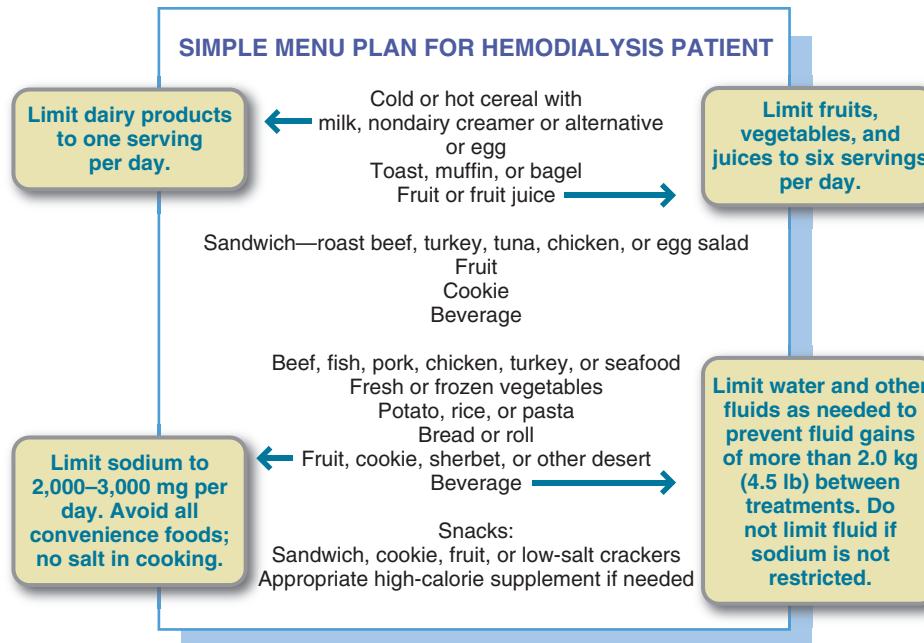

**FIGURE 36-5** Continuous ambulatory peritoneal dialysis; 20-minute exchanges are given four to five times daily every day.

having been instructed many times by renal dietitians at their dialysis units.

## Protein

Dialysis is a drain on body protein, so protein intake must be increased accordingly. Protein losses of 20 to

*Text continued on p. 822*

**FIGURE 36-6** A simple menu plan for a patient on hemodialysis. The diet should allow for less than 4% fluid weight gain between dialyses.

**TABLE 36-8****Nutrient Requirements of Adults with Renal Disease Based on Type of Therapy**

<b>Therapy</b>	<b>Energy</b>	<b>Protein</b>	<b>Fluid</b>	<b>Sodium</b>	<b>Potassium</b>	<b>Phosphorus</b>
Impaired renal function	30-35 kcal/kg IBW	0.6-1.0 g/kg IBW	<i>Ad libitum</i>	Variable, 2-3 g/day or increased to cover losses with diuretics	Variable, usually <i>ad libitum</i> or increased to cover losses with diuretics	0.8-1.2 g/day or 8-12 mg/kg IBW
Hemodialysis	35 kcal/kg IBW	1.2 g/kg IBW	750-1000 mL/day urine output	2-3 g/day	2-3 g/day or 40 mg/kg IBW	0.8-1.2 g/day or <17 mg/kg IBW
Peritoneal dialysis (CAPD)(CCPD)	30-35 kcal/kg IBW	1.2-1.5 g/kg BW	<i>Ad libitum</i> (minimum of 2000 mL/day urine output)	2-4 g/day	3-4 g/day	0.8-1.2 g/day
Transplant, 4-6 weeks after transplant	30-35 kcal/kg IBW	1.3-2 g/kg IBW	<i>Ad libitum</i>	2-3 g/day	Variable; may require restriction with cyclosporine-induced hyperkalemia	Calcium 1.2 g/day No need to limit phosphorus
6 weeks or longer after transplant	To achieve/maintain IBW: • Limit simple CHO • Fat < 35%/cals • Cholesterol < 400 mg/day • PUFA/SFA ratio > 1	1 g/kg BW	<i>Ad libitum</i>	2-3 g/day	Variable	Calcium 1.2 g/day No need to limit phosphorus

Modified from National Kidney Foundation: DOQI clinical practice guidelines for nutrition in chronic renal failure, Am J Kidney Dis 35(suppl 2), 2000; Wiggins K: Guidelines for nutrition care of renal patients, ed 3, Chicago, 2002, American Dietetic Association.  
 CAPD, Continuous ambulatory peritoneal dialysis; CCPD, continuous cyclical peritoneal dialysis; IBW, ideal body weight; PUFA, polyunsaturated fat; SFA, saturated fat.

**TABLE 36-9****Guide to Blood Values in End-Stage Renal Disease Patients**

This guide is to help in understanding laboratory reports. In the following table, the normal values are for people with good kidney function. Acceptable values for dialysis patients are also given. Many things affect blood values. Diet is only one of these. Underlying disease, adequacy of treatment, medications, and complications all may affect laboratory values.

<b>Substance</b>	<b>Normal Values on Dialysis</b>	<b>Normal for People on Dialysis</b>	<b>Function</b>	<b>Diet Changes</b>
Sodium	135-145 mEq/L	135-145 mEq/L	Found in salt and many preserved foods. A diet high in sodium causes thirst. When patients drink too much fluid, it may actually dilute their sodium, and serum levels will appear low. If patients eat too much sodium and do not drink water, sodium may be high. Too much sodium and water raise blood pressure and can cause fluid overload, pulmonary edema, and congestive heart failure.	High: Check fluid status. If high fluid gains, tell patient to eat fewer salty foods. If low fluid gains, make sure patient is gaining about 1.5 kg between dialyses (or < 4% body weight) and is not dehydrated (this is rare).  Low: If high fluid gains, tell patient to eat less salt and fluid. Check fluid status—patient is probably drinking too much fluid. Limit weight gains to less than 4% of body weight between runs, and ask patient to eat fewer salty foods and limit fluid to 3 C plus urine output.
Potassium	3.5-5.5 mEq/L	3.5-5.5 mEq/L	Found in most high-protein foods, milk, fruits, and vegetables. Affects muscle action, especially the heart. High levels can cause the heart to stop. Low levels can cause symptoms such as muscle weakness and atrial fibrillation.	High: Ascertain that no other causes, such as gastrointestinal bleeding, trauma, or medications are creating high potassium values. Tell patient to avoid foods with more than 250 mg/serving and limit daily intake to 2000 mg. Consider lowering potassium in dialysate bath. Recheck blood level next treatment.  Low: Add one high-potassium food/day, and recheck blood level. Consider raising potassium in dialysate bath if diet changes not working.
Urea nitrogen (BUN)	7-23 mg/dL	50-100 mg/dL	Waste product of protein breakdown. Unlike creatinine, this is affected by the amount of protein in the diet. Dialysis removes urea nitrogen.	High: Patient is probably underdialyzed. Check eKt/V. Check npNA.  Low: Underdialysis is also a cause. BUN may decrease if patient not eating because of uremic symptoms. Also decreases with loss of muscle.  Dialysis normally controls creatinine. Low creatinine may indicate good dialysis or low body muscle. Check the clearance of urea during dialysis (Kt/V) to assess dialysis adequacy. If patient losing weight, will break down more muscle, so creatinine may be higher. Patient may need to eat more protein and calories to stop weight loss.
Creatinine	0.6-1.5 mg/dL	Less than 15 mg/dL	A normal waste product of muscle breakdown. This value is controlled by dialysis. Patients have a higher amount because they are not dialyzing 24 hours a day, 7 days a week, as they would with normal kidney function.	

*Continued*

**TABLE 36-9****Guide to Blood Values in End-Stage Renal Disease Patients—cont'd**

<b>Substance</b>	<b>Normal Values</b>	<b>Normal for People on Dialysis</b>	<b>Function</b>	<b>Diet Changes</b>
URR	N/A	Above 65% (or 0.65)	A measure of reduction of urea that occurs during a dialysis treatment. Postdialysis BUN is subtracted and divided by predialysis BUN to give a percentage.	No diet changes, but catabolism or anabolism will affect values, as with Kt/V and equilibrated clearance of urea during dialysis (eKt/V).
eKt/V	N/A	Above 1.2	A mathematical formula that attempts to quantify how well a patient is dialyzed. Represents the clearance of urea by the dialyzer, multiplied by the minutes of treatment, and divided by the volume of water the patient's body holds.	No diet changes. Low: Values below 1.2 are associated with increased morbidity and mortality. High: Higher values are associated with better outcomes.
Kt/V		Above 1.4 for hemodialysis Above 2 for peritoneal dialysis	Not adjusted for urea equilibration. See above.	No diet changes. See above.
nPNA	N/A	0.8-1.4	A calculation used to look at the rate of protein turnover in the body. Assumes patient is not catabolic because of infection, fever, surgery, or trauma. A good indicator of stable patient's protein intake, when combined with dietary history and albumin. The term <i>normalized</i> means that values have been adjusted to the patient's "normal" or ideal weight.	High: Patient may need to decrease protein intake. Have patient consult with nutritionist. Patient may be catabolic. Patient may be eating large amounts of protein. Low: Patient may need to increase protein intake. If patient is putting out urine, a small urine volume can make a big difference in results. Have patient keep a 48-hour urine collection.
Albumin		3.5-5 g/dL (bromcresol green) 3-4.5 g/dL (bromcresol purple)	Good measure of health in dialysis patients. Protein is lost with all dialysis. If albumin is below 2.9, fluid will "leak" from blood vessels into the tissue, thus causing edema. When fluid is in the tissue, it is more difficult to remove with dialysis. Low albumin is closely associated with increased risk of death in dialysis patients.	Low: Increase intake of protein-rich foods: meat, fish, chicken, eggs. A protein supplement may be needed. Intravenous albumin corrects short-term problems with oncotic pressure but does not change serum albumin levels.
Calcium		8.5-10.5 mg/dL	Found in dairy products. Dialysis patients' intakes are usually low. Active vitamin D is needed for absorption. The calcium value multiplied by the phosphorus value should not exceed 59, or patient will get calcium deposits in soft tissue. Because it is bound to albumin, calcium can be falsely lower if albumin is low. Ionized calcium is a more accurate test in this case.	High: Check with doctor if patient is taking calcium supplement or a form of active vitamin D. These should be temporarily stopped. Low: If albumin is low, suggest an ionized calcium drawn. Patient may need a calcium supplement between meals and active vitamin D. Check with physician.

Phosphorus	2.5-4.8 mg/dL	3-6 mg/dL	Found in milk products, dried beans, nuts, and meats. Used to build bones and helps the body produce energy.	Acceptable levels depend on variety of factors, including calcium, PTH levels, and the level of phosphorus in diet. If calcium and PTH levels are normal, a slightly higher-than-normal level of phosphorus is acceptable.	High: Limit milk and milk products to 1 serving/day. Remind patient to take phosphate binders as ordered with meals and snacks. Noncompliance with binders is the most common cause of high phosphorus. Low: Add 1 serving milk product or other high-phosphorus food per day or decrease phosphate binders.
PTH intact (I-PTH)	10-65 pg/mL	200-300 pg/mL	A high level of PTH indicates that calcium is being pulled out of bone to maintain serum calcium levels. This syndrome is called secondary hyperparathyroidism. Leads to osteodystrophy. Pulsed doses of oral or IV vitamin D usually lower PTH.	Patients taking aluminum hydroxide phosphate binders may develop aluminum toxicity, which can cause bone disease and dementia. Value should be checked every 6 months.	High: Check whether patient taking oral or IV active vitamin D. Contact patient's physician regarding therapy. If patient has no symptoms (high phosphorus, bone pain, fractures), treat less aggressively. Low: No treatment available.
Aluminum	0-10 mcg/L	Less than 40 mcg/L		Magnesium is normally excreted in the urine and can become toxic to dialysis patient. High levels may be caused by antacids or laxatives that contain magnesium such as Milk of Magnesia or Maalox.	No dietary changes, except to use nontoxic methods such as fiber to aid in relief of constipation. If magnesium is used as a phosphate binder, levels will need to be checked more often.
Magnesium	1.5-2.4 mg/dL	1.5-2.4 mg/dL		This is the way iron is stored in the liver. If iron stores are low, red blood cell production is decreased.	Low: Iron in food is not well absorbed. Most patients need an IV iron supplement. Patients should not take oral iron at same time as phosphate binders.
Ferritin	Male: 20-350 mcg/L Female: 6-350 mcg/L CO <sub>2</sub>	300-800 mcg/L with EPO; 50 mcg/L without EPO 22-25 mEq/L	300-800 mcg/L with EPO; 50 mcg/L without EPO 22-25 mEq/L	Dialysis patients are often acidotic because they do not excrete metabolic acids in their urine. Acidosis may increase the rate of muscle and bone catabolism.	Low: Review eKtV, BUN, nPNA. Oral sodium bicarbonate may be given to raise CO <sub>2</sub> , but it presents a significant sodium load to patient.
Glucose	65-114 mg/dL	Same for nondiabetic patients Less than 300 mg/dL (patients with diabetes)		Because the kidney metabolizes insulin, low blood sugar levels caused by a longer half-life of insulin are possible. For patients with diabetes: a high blood sugar may increase thirst.	Most people need 6 to 11 servings of breads and starches or cereals per day and 2 to 4 servings of fruit per day to provide energy. Patients with diabetes should avoid concentrated sweets, unless blood sugar level is low.

Developed by Katy G. Wilkens, MS, RD, Northwest Kidney Centers, Seattle, Washington.

BUN, Blood urea nitrogen; CO<sub>2</sub>, carbon dioxide; I/V, intravenous; N/A, not applicable; nPNA, normalized protein nitrogen appearance; PTH, parathyroid hormone; URR, urea reduction ratio.

30 g can occur during a 24-hour PD, with an average of 1 g/hour. Those receiving PD need 1.2 to 1.5 g/kg of body weight. At least 50% should be HBV protein. Patients who receive HD three times per week require a daily protein intake of 1.2 g/kg of body weight. Patients on dialysis who have low albumin levels have much higher mortality rates; thus emphasis is placed on adequate protein intake. Serum BUN and serum Cr levels, uremic symptoms, and weight should be monitored; and the diet should be adjusted accordingly.

In renal failure, prealbumin, which is metabolized by the kidney, is not a good nutritional marker, as values are routinely elevated. Albumin is a limited indicator of protein nutriture, but is routinely used in evaluating ESRD patients' nutritional status. Federal mandates require intervention at levels below 4 g/dL. However, because of the complexity of either acute or chronic inflammation, albumin remains predictive of poor survival in ESRD. Hypoalbuminemia is multifactorial and may be related to poor nutrition, inflammation, or comorbid disease. When interpreting albumin values, it is important to know the laboratory's methodology for measuring serum albumin, because different laboratory techniques give different results in renal failure (see [Table 36-9](#)).

Most patients find it challenging to consume adequate protein because uremia itself causes taste aberrations, notably to red meats. Some patients cannot even tolerate the smell of meat cooking. Often this protein aversion makes it difficult to achieve recommended high biological value protein intake. Patients may tolerate eggs, tofu, and "white" meats better. They can also use spices to hide the taste of meats, or serve animal proteins cold, to minimize the urea taste. Nutritional supplements may be helpful in some patients, and, occasionally, the phosphate restriction may need to be lifted to allow the consumption of dairy products to meet protein needs. As with all the nutritional parameters, meeting patient needs must be individualized.

## Energy

Energy intake should be adequate to spare protein for tissue protein synthesis and to prevent its metabolism for energy ([Byham-Gray, 2006](#)). Depending on the patient's nutrition status and degree of stress, between 25 and 40 kcal/kg of body weight should be provided, with the lower amount for transplantation and PD patients and the higher level for the nutritionally depleted patient. Tools have been developed to allow the renal dietitian to assess the quality of the patient's nutrition status. The Subjective Global Assessment ([Box 6-5](#)) technique has been modified in this population to recognize the basic physiologic and immunologic changes in ESRD.

## Fluid and Sodium Balance

The kidney's ability to handle sodium and water in ESRD must be assessed frequently through measurement of blood pressure, edema, fluid weight gain, serum sodium level, and dietary intake. The vast majority of dialysis patients need to restrict sodium and fluid intakes. Excessive sodium intake

is responsible for increased thirst, increased fluid gain, and resultant hypertension. Even those patients who do not experience these symptoms but produce minimal amounts of urine will benefit from a reduced sodium intake to limit their thirst and prevent large intradialytic fluid gains.

In the patient who is maintained on HD, sodium and fluid intake are regulated to allow for a weight gain of 4 to 5 lb (2 to 3 kg) from increased fluid in the vasculature between dialyses. The goal is a fluid gain of less than 4% of body weight. A sodium intake of 87 to 130 mEq (2 to 3 g) daily and a limit on fluid intake (usually about 750 mL/day plus the amount equal to the urine output) is usually sufficient to meet these guidelines. Only fluids that are liquid at room temperature are included in this calculation. The fluid contained in solid foods is not included in the 750 mL limit. Solid foods in the average diet contribute approximately 500 to 800 mL/day of fluid. This fluid in solid food is calculated to approximately replace the 500 mL/day net insensible water loss.

An 86- to 130-mEq (2- to 3-g) sodium diet requires no salt in cooking; no salt at the table; no salted, smoked, or cured meat or fish; and no salted snack foods, canned soups, or high-sodium convenience foods. In today's increasing convenience food-oriented marketplace, it is estimated that 75% to 90% of sodium intake is consumed in convenience foods, with only 10% to 25% added to foods in cooking or at the table. It is important to remember that the most effective way to reduce the renal patient's thirst and fluid intake is to decrease sodium intake. It is salt intake that drives fluid consumption. [Appendix 37](#) gives the details of a low-sodium meal plan. Many physicians and dietitians believe it is unethical to restrict fluid in patients who are not on a restricted sodium diet, because feelings of thirst become overwhelming to the patient with a high sodium intake.

When educating about fluid balance, the health care provider must teach the patient how to deal with thirst without drinking. Sucking on a few ice chips, cold sliced fruit, or sour candies or using artificial saliva are all good suggestions. In approximately 15% to 20% of patients, hypertension is not alleviated even after meticulous attention to fluid and water balance. In these patients hypertension is usually perpetuated by a high level of renin secretion and requires medication for control.

Although most patients with ESRD retain sodium, a small number may lose it. Examples of conditions with a salt-losing tendency are polycystic disease of the kidney, medullary kidney disease, chronic obstructive uropathy, chronic pyelonephritis, and analgesic nephropathy. To prevent hypotension, hypovolemia, cramps, and further deterioration of renal function, extra sodium may be required. A diet for these types of patients may contain 130 mEq (3 g) or more of sodium per day, which is the amount in a normal diet without added salt. Adding salt or salty foods can satisfy the need for extra sodium. The number of patients who require this higher sodium intake is small, but these patients exemplify the need for individual consideration of the diet prescription and a thorough understanding of the patient's underlying disease and present diet.

Patients receiving frequent dialysis treatments, either daily PD, short daily, or daily nocturnal dialysis may have higher allowance for sodium and fluid, based on an individual evaluation of their dry weight and laboratory values.

## Potassium

Potassium usually requires restriction, depending on the serum potassium level, urine output, medications, and the frequency of HD. The daily intake of potassium for most Americans is 75 to 100 mEq (3 to 4 g). This is usually reduced in ESRD to 60 to 80 mEq (2.3 to 3.1 g) per day and is reduced for the anuric patient on dialysis to 51 mEq (2 g) per day. Some patients (i.e., those on high-flux dialysis or with increased dialysis times or frequencies such as PD, short daily or nocturnal) will be able to tolerate higher intakes. Again, a close monitoring of the patient's laboratory values, K<sup>+</sup> content of the dialysate, and dietary intake is essential.

The potassium content of foods is listed in **Box 7-1** in **Chapter 7**, and in **Appendices 36 and 56**. When counseling HD patients on a low-potassium diet, one should take care to point out that some low-sodium foods contain potassium chloride as a salt substitute rather than sodium chloride. Nutrition labels for products such as salt substitutes, Lite-Salt, and low-sodium herb mixtures must all be checked carefully to be sure they do not contain dangerous levels of potassium. Low-sodium soy sauces, low-sodium soups, and other special dietary products may need particular review by a trained professional. Reviewing such practices not only with the patient but with other people who may be cooking for the patient, such as a church group or neighbors who may use salt substitutes is advisable.

When a thorough diet history does not reveal the reason for elevated serum potassium, other nondietetic sources of potassium should be researched. Examples include poor dialysis adequacy or missed dialysis treatments, too high a concentration of potassium in the dialysate bath, very elevated blood sugar in patients with diabetes, acidosis, constipation, significant GI bleeding, some medications, blood transfusions, major trauma, chemotherapy, or radiation therapy. Occasionally, blood samples are handled improperly, resulting in hemolysis and falsely elevated potassium levels.

## Phosphorus

More than 99% of excess phosphate is excreted in the urine. However, as GFR decreases, phosphorus is retained in the plasma. Because of the large molecular weight of the phosphate molecule, it is not easily removed by dialysis and patients experience net "gain" of about one half of the phosphate they consume daily. Phosphate intake is lowered by restricting dietary sources to 1200 mg/day or less. The difficulty in implementing the phosphorus restriction comes from the necessity for a high-protein diet. High protein foods, such as meats, contain high levels of phosphorus in the form of ATP. Additionally, other sources of protein—dairy products, nuts, and legumes—are also high in phosphorus. Thus high phosphorus foods cannot be eliminated

without restricting protein, creating a challenge to balance intake with dietary intervention alone.

The American diet, which contains highly processed foods, has resulted in increases in both the types and amounts of phosphorus available for absorption, making compliance with a phosphorus restriction more difficult. Naturally occurring phosphate in food is only approximately 60% absorbed. Commonly used phosphate additives such as trisodium phosphate, disodium phosphate, and dicalcium phosphate are nearly 100% absorbed, making the processed diet a likely contributor to elevated phosphorus levels. Dietary intervention should focus on a balance of limiting dairy, nuts, beans, and processed foods while still encouraging enough HBV proteins to meet dietary needs.

Because dietary restrictions alone are not adequate to control serum phosphorus, nearly all patients who undergo dialysis require phosphate-binding medications. Phosphate binders such as calcium carbonate, calcium acetate, sevelamer carbonate and lanthanum carbonate are routinely used with each meal or snack to bind to phosphorus in the gut. These medications bind excess dietary phosphate and transport it through the GI tract for elimination, thus preventing its absorption into the blood. Side effects of taking these medications over long periods are common. Some may cause GI distress, diarrhea, or gas. Severe constipation, leading to intestinal impaction is a potential risk of excessive use of some types of phosphate binders; occasionally this may lead to perforation of the intestine resulting in peritonitis or death. Common medications are listed in **Table 36-10**.

## Calcium and Parathyroid Hormone

In ESRD, the body's ability to maintain phosphorus-calcium balance is complicated by calcium and PTH controls. As GFR decreases, the serum calcium level declines for several reasons. First, decreased ability of the kidney to convert to inactive vitamin D to its active form, 1,25-(OH)<sub>2</sub>D<sub>3</sub> leads to poor GI absorption of calcium. Second, the need for serum calcium increases as serum phosphate levels increase. Both of these causes lead to hypertrophy of the parathyroid gland, which is responsible for calcium homeostasis. The resultant oversecretion of PTH increases resorption of bone to provide a calcium source.

The resulting metabolic bone disease, **renal osteodystrophy**, is essentially one of four types: (1) **osteomalacia**, (2) **osteitis fibrosa cystica**, (3) **metastatic calcification**, or (4) adynamic bone disease. With a deficit of calcium available from dietary absorption, the low calcium level triggers the release of PTH from the parathyroid glands. This acts to increase release of calcium from the bones by stimulating osteoclast activity. This can lead to osteomalacia or bone demineralization, as a result of lack of osteoblast stimulation to replace lost calcium in the bones.

Ongoing low calcium causes the parathyroid glands to continue producing PTH in an attempt to elevate serum calcium levels. In time this leads to secondary hyperparathyroidism, where even the baseline production of PTH by these enlarged glands is enough to cause severe bone

**TABLE 36-10****Common Medications and Nutritional Supplements for Patients with End-Stage Renal Disease**

<b>Phosphate Binders</b>

demineralization (osteitis fibrosis cystica), which is characterized by dull, aching bone pain.

Even though the serum calcium level is elevated in response to PTH, serum phosphate concentration remains high as the GFR falls lower. If the product of serum calcium multiplied by the serum phosphate level is greater than 70, metastatic calcification is imminent. Metastatic calcification occurs when calcium phosphate, removed from bones, is deposited in nonbone cells. This extraskeletal calcification may develop in joints, soft tissue, and vessels.

**Calciphylaxis** occurs when calcium phosphate is deposited in wound tissues with resultant vascular calcification, thrombosis, nonhealing wounds, and gangrene. It is frequently fatal. Clinical management aims to keep the calcium × phosphorus product below 55 by preventing transient

elevations in serum phosphate concentration (National Kidney Foundation, 2003). Phosphorus intake must be controlled to as great a degree as possible to avoid aggravation of the delicate situation posed by hyperparathyroidism, phosphate retention, vitamin D deficiency, and hypocalcemia in renal failure.

Many patients on dialysis suffer from hypocalcemia, despite calcium supplementation. Because of this, the routine drug of choice is active vitamin D, 1,25-(OH)<sub>2</sub>D<sub>3</sub>, available as calcitriol (Rocaltrol and Calcijex). Analogs such as doxercalciferol (Hectorol) and paricalcitol (Zemplar) are also effective in lowering PTH and raising calcium levels, but with less enhancement of gut absorption of calcium than the 1,25 forms. Other mechanisms for controlling PTH include the medication cinacalcet (Sensipar), a calcimimetic

or calcium-imitating drug, which binds to sites on the parathyroid gland and gives the gland a false impression that calcium levels are elevated. The drug is effective in suppressing PTH production and may also lower calcium levels dramatically, with significant consequences. Overall, close monitoring is essential.

In more extreme cases of hyperparathyroidism, use of surgical excision of portions of the parathyroid glands can be used in an attempt to restore balance. This creates the risk of low PTH, and can lead to **adynamic (low turnover) bone disease**, characterized by decreased levels of bone turnover and suppression of both osteoclasts and osteoblasts. This condition is unique to ESRD, in which oversuppression of the parathyroid gland and too much active vitamin D lead to decreased bone formation and fragile bones with very little matrix. Usually diagnosed by a low PTH level, this disease results in a high risk of nonhealing fractures. Oversuppression of the parathyroid gland by use of vitamin D or its analogs can mimic this as well.

Overall the dietary balance of phosphorus, the use of phosphate binders and vitamin D analogs, the removal of phosphate by dialysis, and intense monitoring of laboratory values all contribute to bone management in ESRD.

## Lipid

Atherosclerotic cardiovascular disease is the most common cause of death among patients maintained on long-term dialysis (Bennett et al., 2006). This appears to be a function of both underlying disease (e.g., diabetes mellitus, hypertension, nephrotic syndrome) and a lipid abnormality common among patients with ESRD. The patient with ESRD typically has an elevated triglyceride level with or without an increase in cholesterol. The lipid abnormality likely represents both increased synthesis of very-low-density lipoprotein and decreased clearance as well as increased reliance on animal-based proteins.

Treatment of hyperlipidemia with diet or pharmacologic agents remains controversial. Epidemiologic evidence demonstrating increased incidence of atherosclerotic coronary disease is balanced by studies that demonstrate that patients with clearly defined clinical evidence of atherosclerosis at the initiation of dialysis are at no increased risk for a cardiovascular event. Although routine treatment appears unwarranted, a good case can be made for dietary and pharmacologic treatment of patients with ESRD with underlying lipid disorders and evidence of atherosclerosis. Lipid-lowering drugs, including most statins, may have a significant effect on better management (see Chapter 34).

On the other hand, low cholesterol levels can be a significant predictor of mortality in ESRD. They can indicate poor oral intake, and may be a useful tool in diagnosing malnutrition. Use of lipid-lowering drugs should be monitored and cut back if needed in these patients, particularly if they are underweight or suffering from malnutrition.

## Iron and Erythropoietin

The anemia of chronic renal disease is caused by an inability of the kidney to produce EPO, the hormone that stimulates

the bone marrow to produce red blood cells, an increased destruction of red blood cells secondary to circulating uremic waste products; and blood loss with dialysis or blood sampling. A synthetic form of EPO, recombinant human EPO (rHuEPO), is used to treat this form of anemia. Clinical trials have demonstrated a dramatic improvement in correcting anemia and restoring a general sense of well being (Locatelli F, 2006).

Use of EPO increases red blood cell production 2.5-fold. Almost always accompanying the rise in hematocrit is an increased need for iron that requires IV supplementation. Oral iron alone is not effective in maintaining adequate iron stores in patients who take EPO. Unless a documented allergic reaction exists, almost all patients taking EPO require periodic IV or intramuscular iron. For patients who are allergic to IV iron, several better-tolerated forms are now available as iron dextran (Infed), iron gluconate (Ferlecit), and iron sucrose (Venofer).

Serum ferritin is an accurate indicator of iron status in renal failure. Patients who have received several transfusions and who are storing extra iron may have high serum ferritin levels of 800 to 5000 ng/mL (a normal level is 68 ng/mL for women and 150 ng/mL for men; see Appendix 30). In patients who are receiving EPO, ferritin should be kept above 300 ng/mL but below 800 ng/mL. When ferritin values fall below 100 ng/mL, IV iron is usually given. The percent of transferrin saturation is another useful indicator of iron status in these patients and should be between 25% to 30%.

## Vitamins

Water-soluble vitamins are rapidly lost during dialysis. In general, ascorbic acid and most B vitamins are lost through dialysate at approximately the same rate they would have been lost in the urine (depending on the type and duration of treatment), with the exception of folate, which is highly dialyzable. Patients who still produce urine may be at increased risk of loss of water-soluble vitamins. Folate is recommended to be supplemented at 1 mg/day based on extra losses. Because vitamin B<sub>12</sub> is protein-bound, losses of this B vitamin during dialysis are minimal. Altered metabolism and excretory function, as well as drug administration, also may alter vitamin levels. Little is known about GI absorption of vitamins in uremia, but it may be significantly decreased. Uremic toxins may interfere with the activity of some vitamins, such as inhibition of phosphorylation of pyridoxine and its analogs.

Another cause of decreased vitamin intake in uremia is the restriction of dietary phosphorus and potassium. Water-soluble vitamins are usually abundant in high-potassium foods such as citrus fruits and vegetables and high-phosphorus foods such as milk. Diets for patients on dialysis tend to be low in folate, niacin, riboflavin, and vitamin B<sub>6</sub>. With frequent episodes of anorexia or illness, vitamin intake is decreased further. Whereas levels of water-soluble vitamins decrease as a result of dialysis, replacement of fat-soluble vitamins is not usually required in renal disease.

Several vitamin supplements that fit the needs of the uremic patient or the dialysis patient are now available by prescription: Nephrocaps, Nephplex, Dialyvite, and Renal Caps. An over-the-counter supplement containing the vitamin B complex and vitamin C is often used and can be less expensive than a prescription, but additional supplements of folic acid and pyridoxine may be needed.

Niacin has been found to be helpful in lowering phosphate levels in ESRD patients. It interferes with the sodium-phosphate pump in the GI lumen, causing decreased transport of phosphate, and thus works with a different mechanism than phosphate binders, (Cheng, S, 2006, 2008). It is usually dosed once daily, increasing compliance.

## Nutrition Support in End-Stage Renal Disease

### Enteral Tube Feeding

Patients with ESRD who require enteral tube feeding often do quite well on standard formulas used for most tube-fed patients (see Chapter 14). Patients should receive standard formulas before they try a “specialty” formula because the former are usually less expensive and typically have lower osmolality than the specific renal products. If electrolyte or fluid concerns arise, patients can be changed to one of the formulas now available that are specifically designed for renal patients: Nepro or Novasource Renal. If patients are receiving renal products only, they may develop problems with a low phosphorus or potassium levels as these products are often used in conjunction with oral intake.

### Parenteral Nutrition

PN in ESRD is similar to PN used for other malnourished patients with respect to protein, carbohydrates, and fat, but differs in use of vitamins and minerals. Most researchers agree that vitamin needs for ESRD during PN differ from normal requirements; however, they do not agree on recommendations for individual nutrients. Folate, pyridoxine, and biotin should be supplemented. Vitamin A should not be provided parenterally unless retinol-binding protein is monitored because it is elevated in patients with ESRD. Because there is currently no parenteral vitamin

that is specifically designed for patients with renal failure, a standard vitamin preparation is usually administered. Little information related to parenteral trace mineral supplementation is available. Because most trace minerals, including zinc, chromium, and magnesium, are excreted in the urine, a close monitoring of these minerals in the serum seems to be appropriate.

### Intradialytic Parenteral Nutrition

Malnourished patients with chronic renal failure who are on HD have easy access to PN because of the direct blood access required by the dialysis therapy itself. **Intradialytic PN (IDPN)** can be administered if necessary without additional invasive procedures or need for a separate port. It is typically administered through a connection to the venous side of the extracorporeal circuit during dialysis. Because of the high blood flow rate achieved through use of the surgically created fistula and the high blood pump speeds that are attained, hypertonic glucose and protein can be administered without danger of phlebitis. Lipids may also be administered. Reimbursement issues are complex because IDPN is a supplemental feeding that requires the patient to have at least a functioning GI tract and only supplies an average of 1000 calories every HD treatment (Table 36-11).

Complications are similar to those encountered in usual PN, with the exception of postdialysis hypoglycemia caused by the abrupt ending of the glucose supply. To avoid this problem, glucose administration typically is tapered up and down during the first and last half hour of the 3- to 5-hour treatment. Insulin is given often, and can be given in the bag of the dextrose–amino acid solution, so that the patient does not become hypoglycemic if the infusion must be stopped. Blood sugar levels are typically monitored during the therapy. Some patients may benefit from a complex carbohydrate snack toward the end of the treatment to avoid posttreatment rebound hypoglycemia. Amino acid losses through the dialysate average approximately 10%.

Another method of nutrition support in PD patients is called **intraperitoneal nutrition (IPN)** using a peritoneal dialysate solution that contains amino acids instead of

**TABLE 36-11**

#### Regimen for Intradialytic Parenteral Nutrition Administered During Hemodialysis Therapy

Infusion	Quantity	Calories (kcal)	Volume (mL)
70% dextrose	350 g dextrose <sup>†</sup>	1190	500
15% amino acids	37.5 g protein	Protein should not be counted as calories	250
20% lipid emulsion	50 g fat	450	250
TOTAL		1640	1000*
Monitor serum glucose, sodium, potassium, bicarbonate, phosphate, triglycerides

\*Additional volume may include insulin and vitamins.

<sup>†</sup>3.4 kcal/gm because of hydration in IDPN solution.

dextrose. Typically one bag of this solution is used per day. Some patients experience side effects from this treatment. Reimbursement issues are significant.

### End-Stage Renal Disease in Patients with Diabetes

Because renal failure is a complication of diabetes, approximately 40% to 50% of all new patients starting dialysis have diabetes (Zhang et al., 2005). The need to control blood sugar in these patients requires specialized diet therapy. The diet for diabetes management (see Chapter 31) can be modified for the patient on dialysis. In addition, the diabetic patient on dialysis often has other complications such as retinopathy, neuropathy, gastroparesis, and amputation, all of which can place this patient at high nutritional risk. The NKF has established guidelines for managing diabetes in the presence of CKD (National Kidney Foundation, 2007; Nelson and Tuttle, 2007), which can be accessed at [www.kidney.org](http://www.kidney.org).

Increased osmolality caused by high serum levels of glucose may cause water and potassium to be pulled out of cells, with resultant hyperkalemia. Interpretation of commonly used laboratory values will change when a diabetic patient develops renal failure, because the hemoglobin A1c is affected by the shortened half life of red blood cells in uremia (Rigalleau et al., 2006).

### Chronic Kidney Disease and End-Stage Renal Disease in Children

Although CKD may occur in children at any age, from the newborn infant to the adolescent, it is a relatively uncommon diagnosis. Causal factors in children include congenital defects, anatomic defects (urologic malformations or dysplastic kidneys), inherited disease (autosomal-recessive polycystic kidney disease), metabolic disorders that eventually result in renal failure (cystinosis or methylmalonic aciduria), or acquired conditions or illnesses (untreated kidney infections, physical trauma to kidneys, exposure to nephrotoxic chemicals or medications, hemolytic anemia due to *Escherichia coli* 0157 ingestion, or glomerular nephritis).

As with all children, the major concern is to promote normal growth and development. Without aggressive monitoring and encouragement, the child with renal failure rarely meets his or her nutritional requirements. If the renal disease is present from birth, nutrition support needs to begin immediately to avoid losing the growth potential of the first few months of life. Growth in children with CKD is usually delayed. Although no specific therapy ensures normal growth, factors capable of responding to therapy include metabolic acidosis, electrolyte depletion, osteodystrophy, chronic infection, and protein-calorie malnutrition. Energy and protein needs for children with chronic renal disease are at least equivalent to the DRIs for normal children of the same height and age. If nutrition status is poor, energy needs may be even higher to promote weight gain and linear growth.

Feeding by tube is required in the presence of poor intake, particularly in the critical growth period of the first

2 years of life. Gastrostomy tubes are almost always placed in these children to enhance nutritional intake and facilitate growth. PN is rarely initiated unless the GI tract is nonfunctional. For the nutritional requirements of children with renal failure see the Kidney Disease Outcome Quality Initiative at [www.kdoqi.org](http://www.kdoqi.org).

Control of calcium and phosphorus balance is especially important for maintaining good growth. The goal is to restrict phosphorus intake while promoting calcium absorption with the aid of 1,25-(OH)<sub>2</sub>D<sub>3</sub>. This helps prevent renal osteodystrophy, which can cause severe growth retardation. Use of calcium carbonate formulations to supplement the dietary intake enhances calcium intake while binding excess phosphorus. Persistent metabolic acidosis is often associated with growth failure in infancy. In chronic acidosis the titration of acid by the bone causes calcium loss and contributes to bone demineralization. Bicarbonate may be added to the infant formula to counteract this effect.

Restriction of protein in pediatric diets is controversial. The so-called “protective” effect on kidney function must be weighed against the clearly negative effect of possible protein malnutrition on growth (National Kidney Foundation, 2009). The recommended dietary allowance for protein for age is usually the minimum amount given.

Each child’s diet should be adjusted to his or her food preferences, family eating patterns, and biochemical needs. This is often not an easy task. In addition, care must be taken not to place too much emphasis on the diet to avoid its becoming a manipulative tool and an attention-getting device. Special encouragement, creativity, and attention are required to help the child with CKD consume the necessary energy. When possible, CCPD is given intermittently during the day and continuously at night as it allows liberalization of the diet. The child is more likely to meet nutritional requirements with fewer dietary restrictions and therefore experience better growth. See [www.kidney.org](http://www.kidney.org) for further tips on pediatric renal nutrition support.

Other treatments that help renal disease in children include the use of rHuEPO and recombinant deoxyribonucleic acid-produced human growth hormone. EPO is usually started when the child’s serum hemoglobin falls below 10 g/dL, with a goal of maintaining hemoglobin between 11 and 12 g/dL. Correction of anemia with the use of rHuEPO may increase appetite, intake, and feeling of well being, but it has not been found to affect growth, even with seemingly adequate nutrition support.

### Medical Nutrition Therapy for Transplantation

The nutritional care of the adult patient who has received a transplanted kidney is based mainly on the metabolic effects of the required immunosuppressive therapy. Medications typically used for the long term include azathioprine (Imuran), corticosteroids (e.g., prednisone), calcineurin inhibitors (cyclosporine A, Gengraf, SangCya, Sandimmune], tacrolimus [Prograf, F506]), sirolimus (Rapamune), mycophenolate mofetil (CellCept), and mycophenolic acid (Myfortic). Corticosteroids are associated with accelerated protein catabolism, hyperlipidemia, sodium retention,

weight gain, hyperglycemia, osteoporosis and electrolyte disturbances. Calcineurin inhibitors are associated with hyperkalemia, hypertension, hyperglycemia, and hyperlipidemia. The doses of these medications used after transplantation are decreased over time until a “maintenance level” is reached.

During the first 6 weeks after surgery, a high-protein diet is often recommended (1.2-1.5 g/kg ideal body weight [IBW]) with an energy intake of 30-35 kcal/kg IBW, to prevent negative nitrogen balance. A moderate sodium restriction of 2-3 g/day during this period minimizes fluid retention and helps to control blood pressure (Keven, K. 2006). After recovery, protein intake should be decreased to 1 g/kg IBW, with calorie intake providing sufficient energy to maintain or achieve an appropriate weight for height. A balanced low-fat diet aids in lowering cardiac complications (National Kidney Foundation, 2009). Sodium intakes are individualized based on fluid retention and blood pressure (see Appendix 37).

Hyperkalemia warrants a temporary dietary potassium restriction. Following transplantation, many patients exhibit hypophosphatemia and mild hypercalcemia caused by bone resorption; this is associated with persistent hyperparathyroidism and the effects of steroids on calcium, phosphorus, and vitamin D metabolism. The diet should contain adequate amounts of calcium and phosphorus (1200 mg of each daily) and cholecalciferol (vitamin D<sub>3</sub>, 2000 IU daily). Supplemental phosphorus may also be necessary to correct hypophosphatemia.

Hydration must also be monitored closely after transplantation. Because most kidney recipients required a fluid restriction while on dialysis, they need to be reminded of the importance of maintaining fluid intake after transplant. Typically, patients are encouraged to drink 2 L/day, but their overall needs depend on their urine output.

The majority of transplant recipients have elevated serum triglycerides or cholesterol for a variety of reasons. Intervention consists of medications, calorie restriction for those who are overweight, cholesterol intake limited to less than 300 mg/day, and limited total fat (see Chapter 34). In patients with glucose intolerance, limiting carbohydrates and a regular exercise regimen are appropriate. Tissue weight gain with resultant obesity is common after transplantation. Medication side effects, fewer dietary restrictions, and the lack of physical exercise can all contribute to post-transplant weight gain.

### **Education of Patients with End-Stage Renal Disease**

For effective intervention, it is important to look at the long-range goals for educating the patient with ESRD about his or her nutritional needs. The average patient survives on dialysis 7 to 10 years. Patients with a relatively benign diagnosis may look forward to life spans of 20 to 40 years, particularly if they receive kidney transplants as a part of their treatment. The challenge for the dietitian is educating the patient with a chronic disease who will be primarily responsible for implementing the nutritional recommendations for

the rest of his or her life. Thus intervention for ESRD and that for diabetes share many similarities.

Exchange lists are not always used in educating the patient about a renal diet. Rather a booklet, *The National Renal Diet* available from the American Dietetic Association (see “Useful Websites” later in this chapter), provides information about food sources of nutrients, adapting patients’ usual intakes to meet requirements based on their laboratory values, and reducing the intake of certain foods when blood values rise. A sample diet for the patient receiving dialysis can be found in Appendix 36.

### **Counseling for Patients with End-Stage Renal Disease**

It is incumbent on the registered dietitian (RD) to develop a long-standing rapport with the patient and family and to serve as an ally to help them make the best nutritional choices over an extended period. Understanding the burdens of a complex, challenging, ever-changing diet suggests the transfer of information to the renal patient and family in a workable, flexible, and easily understood manner. Skills for this task are just as challenging, if not more so, than maintaining a patient’s iron status or keeping the patient at a good body weight. Empathy and use of techniques such as motivational interviewing or cognitive behavioral therapy are essential tools.

### **Coordination of Care in End-Stage Renal Disease**

The position of the RD in the care of dialysis patients is unique because it is a federally mandated position. So, too, is the RD’s place on the mandated interdisciplinary health care team that exists within each dialysis unit. The team approach is an important aspect of all health care; however, its importance is magnified in the dialysis team, which consists of the patient, renal nurse, renal social worker, nephrologist, and renal dietitian. Care of these complex, long-term ESRD patients requires the skill and compassion of each member of the health care team working together (Unruh et al., 2005). Advanced levels of practice are available for dietitians who wish to be certified as renal RDs; they can be certified through examination by the American Dietetic Association, and become a Board Certified Specialist in Renal Nutrition.

### **Emergency Diets for Dialysis Patients**

When power outages, flooding, storms, hurricanes, or earthquakes threaten a community, they threaten the most vulnerable people in that community. Patients on HD require power and water sources to do their own treatments at home. If they travel to a dialysis unit, they need access to transportation. Because of poor outcomes in recent natural disasters, the federal government’s ESRD program has specified that patients and care givers must be familiar with alternative nutritional therapies when dialysis is not available because of a natural or manmade emergency. Box 36-2 demonstrates the type of nutrient and practical information that must be considered when patients may be without

**BOX 36-2****Emergency Dialysis Diet Plan**

This plan will work for short periods (5 days or less) when patients cannot dialyze.

The Emergency Diet Plan does not replace dialysis; it should be used only in case of an emergency.

**Guidelines**

1. Limit meat to 3-4 oz/day.
2. Avoid all high-potassium fruits and vegetables.
3. Consume one to two 8-oz cups of fluid per day.
4. Choose low-salt foods.
5. Do not use salt or salt substitute.
6. Use fats and sugars for extra calories.
7. If the power is off for a day, foods in refrigerator should be eaten first.
8. Patients should eat food from the freezer while they still have ice crystals in the center.
9. Patients should have a portable Emergency Kit they can take with them to a disaster relief center. Sample foods are listed in the following diet plan.

**Emergency Diet Plan**

If a food is not on this list, patients should not eat it.

**Meat and Protein Foods (three to four 1-oz choices/day)**

- 1 egg
- 1 ounce meat, fish, tofu or poultry
- $\frac{1}{4}$  cup unsalted or rinsed canned fish or poultry
- 2 tablespoons unsalted peanut butter
- $\frac{1}{4}$  cup cottage cheese
- $\frac{1}{2}$  can Ensure Plus, Boost Plus or Nepro

**Starch (six to ten choices/day)**

- 1 slice white bread
- $\frac{1}{2}$  English muffin or bagel
- 5 unsalted crackers
- 2 graham crackers
- 6 shortbread cookies, vanilla wafers
- 1 cup unsalted rice, noodles, pasta
- 1 cup puffed wheat, rice, shredded wheat
- 1 cup of rice or pasta

**Vegetables (one choice/day)**

- $\frac{1}{2}$ -cup serving of green beans, summer squash, corn, beets, carrots, or peas

Should be fresh or frozen, not canned

dialysis for days, or because they must be evacuated to a site that cannot meet their urgent nutritional needs.

**Medical Management (Conservative Treatment) or Palliative Care**

The decision to forego or discontinue dialysis and opt for end-of-life care is a difficult and emotional one. Factors such

**Fruits (three to four choices/day)**

- 1 small apple
- 15 grapes
- $\frac{1}{2}$  cup serving of berries, cherries, applesauce, canned pears or canned pineapple

**Fats and Oil (six or more choices/day)**

- 1 tsp butter, margarine, oil or mayonnaise

**Fluids (one to two choices/day)**

- 1 cup water, coffee, tea, soda pop
- $\frac{1}{2}$  cup Ensure Plus, Boost Plus or Nepro
- $\frac{1}{2}$  cup serving of milk, half and half, soy, or rice milk
- Cranberry, apple, or grape juice; or Kool-Aid

**Emergency Kit**

Have the following things stored in a box or bag easily accessible:

Foods listed in the Emergency Diet Plan

Can opener

Two gallon jugs of distilled water

Bleach, 1 Tbsp/gallon of water to sterilize

Flashlight and extra batteries

Sharp knife

Aluminum foil

Plastic mixing containers and lids

Measuring cup

Fork, knife, spoon

Battery-operated transistor radio

One-week supply of personal medicines kept in a handy place, including blood pressure medications and phosphate binders (insulin and some other medications must be kept refrigerated or cold)

**Storage Tips**

1. Store things in a clean, dry place such as a new garbage can or rubber tub.
2. Label and date when food is put in storage.
3. Change all food and water once a year. Eat unused food or donate to a food bank.

Dialysis Emergency Diet information from Katy Wilkens, MS, RD. Copyright Northwest Kidney Centers, 2011. For more emergency diet info see [www.nwkidney.org](http://www.nwkidney.org) or your local Network Coordinating Council website.

as religious practices, age, quality of life, and comorbid disease all play a role. Patients who are poor candidates for dialysis or transplantation may benefit from a low-protein, low-sodium diet to minimize physical symptoms, such as shortness of breath and uremia. Palliative care can be offered with the goal of balancing patient wishes for food choice with these complex side effects.

## CLINICAL SCENARIO

A 67-year-old white man is seen by his primary care physician. The patient lives with a significant other; has an active lifestyle (golfing, biking, swimming); and a history of hemicolectomy, diverticulitis, and hypertension. His weight is 240 lb. His laboratory values show serum creatinine of 3.3 mg/dL, blood urea nitrogen of 72, albumin of 4.1, potassium of 5.5, phosphate of 6.7, calcium of 8.3, and his parathyroid hormone is 365. Blood pressure is 160/92.

### Nutrition Diagnostic Statement

Altered laboratory values related to hypertension as evidenced by estimated glomerular filtration rate (eGFR) calculation.

### Nutrition Care Questions

1. What is the patient's calculated eGFR?
2. What is the patient's stage of chronic kidney disease (CKD)?
3. What is the first goal for teaching?
4. What referral would you make to the patient's primary care provider?
5. What dietary factors would you address based on laboratory values?
6. What is the goal for protein intake for this patient?
7. How would you assess for improvement or stability of his CKD?
8. What would you expect for this patient during the next few years if no diet intervention is followed?

tumor necrosis factor- $\alpha$  (cachectin)  
tumor suppressor genes

Cancer involves the abnormal division and reproduction of cells that can spread throughout the body. Usually thought of as a single disease, cancer actually consists of more than 100 distinct types. The American Cancer Society (ACS) predicts the lifetime risk for developing cancer in the United States is slightly less than half of men and a little more than one third of women (American Cancer Society [ACS], 2009a). Annually in the United States, cancer is responsible for almost one out of every four deaths (ACS, 2009a). Evidence suggests that one third of the more than 560,000 cancer deaths may be attributed to nutrition and lifestyle behaviors such as poor diet, physical inactivity, alcohol use, and overweight and obesity. Almost an additional 171,000 cancer deaths are caused by tobacco use (ACS, 2010). It is estimated that 50% to 70% of cancer deaths are potentially preventable by decreasing high-risk behaviors; with approximately 30% of cancer deaths attributed to tobacco use and at least an additional 30% to poor nutrition (Brawer et al., 2009).

The cost of cancer care in the United States has doubled in the past 20 years to more than \$48 billion annually (NCI, 2010a). Private insurance pays for 50% of the cost, Medicare coverage accounts for 34%, and Medicaid payment and other public programs cover the difference. Most medical care spending for cancer has shifted away from an inpatient care setting to outpatient care and treatment.

For dietetic professionals with interest in practicing in the area of oncology, the Standards of Practice and Standards of Professional Performance for Oncology Nutrition Practice provide guidance (Robien et al., 2010).

## ETIOLOGY

The most prevalent types of cancer diagnosed in the United States are prostate, lung and bronchus, colorectal, and urinary bladder cancers for men; and breast, lung and bronchus, colorectal, and uterine cancers for women. The ACS established *2015 Challenge Goals* to improve cancer prevention and early detection efforts for lowering cancer incidence and mortality rates. These national recommendations outline specific measures to expand the use of established screening guidelines for the early detection of cancer, and ways to influence individual health behaviors such as protection from the sun, reducing tobacco use, maintaining a healthy body weight, improving diet, and increasing regular physical activity (ACS, 2010).

Overall, fewer Americans are dying from cancer, a trend that began more than 15 years ago. For many, cancer is now a chronic disease, like heart disease and diabetes. According to the National Cancer Institute (NCI), there are 11.7 million Americans living with a history of cancer; this means they are cancer free, are living with evidence of disease, or are undergoing cancer treatment (National Cancer Institute [NCI], 2010g). As a result of improvements in early detection of cancer and the development of new anticancer therapies, the relative survival rate for all cancers is now 66%, up from 50% in the 1970s (ACS, 2009a; NCI, 2010g). *The Annual Report to the Nation on the Status of*

*Cancer, 1975-2006*, released in December 2009, found that rates of new diagnoses and rates of death from common cancers have declined significantly for men and women overall, as well as for most racial and ethnic populations. Although cancer rates continue to be higher for men than for women, men have experienced greater declines in cancer mortality. For colorectal cancer, the third most frequently diagnosed cancer in both men and women, overall rates have declined. Unfortunately, the incidence in men and women younger than 50 years old remains a concern.

## PATHOPHYSIOLOGY

Carcinogenesis is the origin or development of cancer. **Oncology** is the study of all forms of cancer, and an oncologist is the medical doctor who specializes in cancer. Researchers believe changes in gene function cause normal cells to transform into cancerous cells. Thus the study of genetic material and its function (*genomics*) is of great scientific interest in cancer and its treatment. See *Pathophysiology and Care Management Algorithm: Cancer*.

**Oncogenes** are altered genes that promote tumor growth and change programmed cell death (*apoptosis*). **Tumor suppressor genes** are the opposite of oncogenes; these genes become deactivated in cancer cells. This loss in function can lead to unregulated cell growth and, ultimately, cancer. Examples of tumor suppressor genes include adenomatosis polyposis coli (APC), breast cancer types BRCA1 and BRCA2; and tumor suppressor p53, a protein that is involved in preventing cancer. Only approximately 5% of all cancers have been shown to occur as result of inherited genetic alterations. Factors observed in families with hereditary cancers include:

- A cancer diagnosis at an earlier age than normal for certain kinds of cancer
- Individuals with one type of cancer being diagnosed with a second type of cancer
- Certain types of cancers observed in specific ethnic populations (e.g., individuals of Ashkenazi Jewish ancestry with breast and ovarian cancer)
- Recognized cancer syndromes such as hereditary nonpolyposis colorectal cancer or Lynch syndrome, which cause individuals to be at greater risk for developing gastrointestinal (GI), ovarian, uterine, brain, or skin cancer (NCI, 2010b)

Genetic counselors assist individuals and their families to evaluate their risk of hereditary predisposition, that is, testing positive for gene mutations.

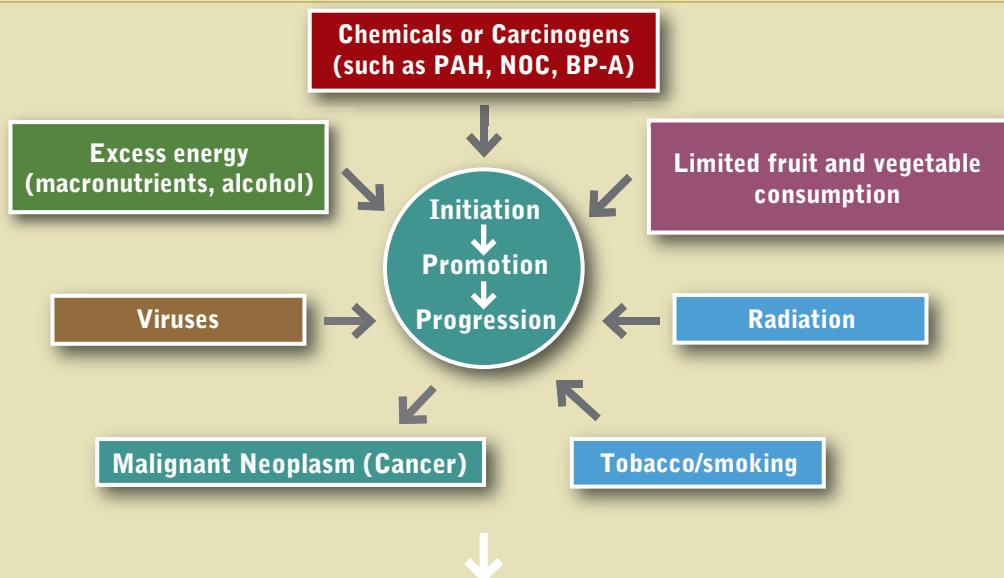

## Phases of Carcinogenesis

A **carcinogen** is a physical, chemical, or viral agent that induces cancer. **Carcinogenesis** is a biologic, multistage process that proceeds on a continuum in three distinct phases: initiation, promotion, and progression. **Initiation** involves transformation of cells produced by the interaction

## PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

### Cancer

#### Proliferation of Abnormal Cells (cells do not differentiate normally)

- Increased mass of cells
- Interference with normal tissue function
- Possible metastases

#### Medical Management

- Surgery
- Radiation therapy
- Chemotherapy
- Biotherapy
- Hematopoietic cell transplantation

#### Nutrition Management

- Prevent or correct nutritional deficiencies
- Minimize weight loss
- Maximize oral intake
- Enteral nutrition
- Parenteral nutrition

of chemicals, radiation, or viruses with cellular deoxyribonucleic acid (DNA). Transformation occurs rapidly, but cells can remain dormant for a variable period until they are activated by a promoting agent. After the initial cellular damage has occurred, transformation from normal cells to a detectable cancer can take many years or even decades.

During **promotion**, initiated cells multiply and escape the mechanisms set in place to protect the body from the growth and spread of such cells. A **neoplasm**, new and abnormal tissue with no useful function, is established. In the third phase (**progression**), tumor cells aggregate and grow into a fully **malignant neoplasm** or a **tumor**.

In the process known as **metastasis**, the neoplasm has the capacity for tissue invasion that can spread to distant tissues and organs. For a cancer to metastasize, it must develop its own blood supply to sustain its growth of rapidly dividing abnormal cells. In normal cells, **angiogenesis** promotes the formation of new blood vessels that are essential to supply the body's tissues with oxygen and nutrients. In cancer cells, tumor angiogenesis occurs when tumors release substances that aid in the development of new blood vessels needed for their growth and metastasis.

## NUTRITION AND CARCINOGENESIS

Nutrition may modify the carcinogenic process at any stage, including carcinogen metabolism, cellular and host defense, cell differentiation, and tumor growth. Gene expression can be promoted or altered by nutrients during pregnancy, childhood, and throughout a lifetime. Thus nutrition and diet contribute approximately 35% to causal factors for cancer (Greenwald et al., 2006). The strong influence of diet and nutrients is readily seen in studies of migration between cultures. Patterns of cancer occurrence often change over time to resemble that of the new country. For example, in Japan mortality from breast and colon cancer is low, and mortality from stomach cancer is high; the reverse is true among Japanese individuals living in the United States. After two or three generations, the cancer patterns become similar.

Studies looking at the role of nutrition and diet as causal factors of cancer seek to identify relationships between the diets of population groups and categories of individuals and the incidence of specific cancers. Sets of individuals are compared in case control, cohort, or cross-sectional studies. The strongest evidence comes from consistent findings of these different types of **epidemiologic studies** in diverse populations. In cancer research, epidemiologists look at human populations and evaluate how many people are diagnosed with cancer, what types of cancer occur in different populations and cultures, and what factors such as diet and lifestyle play a role in the development of the cancers.

The sheer complexity of diet presents a difficult challenge. There are literally thousands of chemicals in a normal

diet; some are well known, and others are little known and unmeasured. Some naturally occurring dietary carcinogens are natural pesticides produced by plants for protection against fungi, insects, or animal predators, or mycotoxins that are secondary metabolites produced by molds in foods (e.g., aflatoxins, fumonisins, or ochratoxin). Food preparation and preservation methods may also provide dietary carcinogens. Thus diets contain both inhibitors and enhancers of carcinogenesis. Dietary carcinogen inhibitors include **antioxidants** (e.g., vitamin C, vitamin A and the carotenoids, vitamin E, selenium, zinc) and **phytochemicals**. See Table 37-1 and Table 12-5. Dietary enhancers of carcinogenesis may be the fat in red meat or the polycyclic aromatic hydrocarbons (PAHs) that form with the grilling of meat at high heat. Complicating the study of nutrition, diet, and cancer is the fact that when one major component of the diet is altered, other changes take place simultaneously. For example, decreasing animal protein also decreases animal fat. This makes the interpretation of research findings difficult because the effects cannot be clearly associated with a single factor.

Cancer cells can have a long latency or dormant period. This makes the diet at the time of cancer cell initiation or promotion—not at the time of diagnosis—most important. Some prospective epidemiologic studies attempt to deal with this challenge by measuring diet at one point in time and following the same subjects for several years. Studies done with laboratory animals test this effect, and since the early part of the last century, laboratory scientists have shown that various nutritional manipulations influence the occurrence of cancerous tumors in animals. Epidemiologic research, together with animal studies, provide a viable method for discovering the links between nutrition and cancer in humans.

### Alcohol

Alcohol consumption is associated with increased cancer risk for cancers of the mouth, pharynx, larynx, esophagus, lung, colon, rectum, liver, and breast (both pre- and postmenopausal women) (World Cancer Research Fund [WCRF] and American Institute for Cancer Research [AICR], 2007). For cancers of the mouth, pharynx, larynx, and esophagus, daily consumption of two to three drinks

**TABLE 37-1**

#### Cancer-Protective Phytochemicals in Vegetables and Fruits

Color	Phytochemical	Vegetables and Fruits
Red	Lycopene	Tomatoes and tomato products, pink grapefruit, watermelon
Red and purple	Anthocyanins, polyphenols	Berries, grapes, red wine, plums
Orange	$\alpha$ - and $\beta$ -carotene	Carrots, mangos, pumpkin
Orange and yellow	$\beta$ -cryptoxanthin, flavonoids	Cantaloupe, peaches, oranges, papaya, nectarines
Yellow and green	Lutein, zeaxanthin	Spinach, avocado, honeydew, collard and turnip greens
Green	Sulforaphanes, indoles	Cabbage, broccoli, Brussels sprouts, cauliflower
White and green	Allyl sulphides	Leeks, onion, garlic, chives

increases risk two to three times compared with nondrinkers. When combined with tobacco use, the sum total risk is higher than the risk for just alcohol or tobacco alone, again compared with nondrinkers (Baan et al., 2007; WCRF and AICR, 2007). In addition, malnutrition associated with alcoholism is also likely to be important in the increased risk for certain cancers. In the United States, if people choose to drink, men are recommended to limit alcohol intake to two drinks per day and women to one drink per day. Serving sizes of popular alcoholic drinks include beer (12 oz), wine (5 oz), spirits/liquors (1.5 oz of 80-proof spirits). Three to four alcoholic drinks or more per week after breast cancer diagnosis may increase recurrence risk, especially among postmenopausal and overweight or obese women (Kwan, 2010).

## Energy Intake and Body Weight

In animal studies chronic restriction of food inhibited the growth of most experimentally induced cancers and the occurrence of many spontaneous cancers. This effect was observed even when underfed animals ingested more dietary fat than control animals ingested. Caloric restriction, without malnutrition, appears to have a positive effect on cancer prevention in animals; it is unclear whether that effect translates to humans (Longo et al., 2010).

Obesity is a risk factor for cancer and may account for 6% of all cancers (Polednak, 2008). Currently 68% of all American adults are overweight or obese (Flegal et al., 2010). See Chapter 22. Obesity increases the risk for developing and dying from cancer (Schelbert, 2009). The relationship between body weight, body mass index (BMI), or relative body weight and site-specific cancer has been widely investigated; a positive association has been seen with cancers of the esophagus, pancreas, gallbladder, liver, breast (postmenopausal), endometrium, kidney, colon, and rectum (Toles et al., 2008; WCRF and AICR, 2007). For men, increased BMI correlates with esophageal, thyroid, colon, and kidney cancers; a weaker association exists between BMI and malignant melanoma, multiple myeloma, rectal cancer, leukemia, and non-Hodgkin's lymphoma (NHL) (Brawer et al., 2009). In women, stronger correlations are found between increased BMI and endometrium, gallbladder, kidney, and esophageal cancers; and a weaker association between increased BMI and leukemia, thyroid, postmenopausal breast, pancreas, and colon cancers and NHL. Bariatric surgery using gastric bypass may reduce cancer mortality by as much as 60% (Brawer et al., 2009).

The median adult BMI should be between 21 and 23 depending on the normal range with different populations (WCRF and AICR, 2007). Body weight throughout childhood should be at the lower end of normal BMI, because excessive weight in adolescence has been correlated with twofold increased risk of death for colon cancer in adulthood (Anderson et al., 2009). Being overweight or obese also appears to increase risk of cancer recurrence and decrease cancer survival (Anderson et al., 2009).

Obesity, age, hyperglycemia, and the incidence of metabolic syndrome play a role in the circulating levels of

insulin-like growth factor-1 (IGF-1), a potentially cancer-causing compound. IGF-1 is a polypeptide secreted primarily by the liver and plays a key role in normal growth and development. It can promote the development and progression of prostate, breast, lung, and colon cancer. It has been hypothesized to stimulate the growth of cancer cells and inhibit their death (Blackburn, 2007; Pollack, 2008). IGF-1 secretion is increased when insulin levels are elevated. Obesity and high simple carbohydrate intakes potentially increase insulin resistance and raise circulating insulin levels. This area of research connects several known risk factors between nutrition, diet, and cancer (Parekh et al., 2010).

Overweight and obese cancer survivors are at risk for recurrence and for developing additional problems after surgery, including impaired wound healing, lymphedema following lymph node dissections, second cancers, heart disease, and diabetes mellitus (Anderson et al., 2009). Regular physical activity reduces mortality, especially in women and older individuals (Teucher, 2010). All types of physical activity help to protect against colon cancer, postmenopausal breast cancer, and endometrial cancer (Teucher, 2010). Therefore the ACS encourages all Americans to strive for 45–60 minutes of moderate to vigorous physical activity most days of the week (Doyle et al., 2006). Achieving and maintaining a reasonable weight should be a primary health goal for all cancer survivors (Doyle et al., 2006).

## Fat

Research shows a link between some types of cancers and the amount of fat in the diet. Diets high in fat often contain significant amounts of meat. The link between meat and colorectal cancer risk results from a number of possible mechanisms: production of carcinogens from a high-fat diet, from heterocyclic amines (HCAs) and/or polycyclic aromatic hydrocarbons (PAHs) from cooking; formation of carcinogenic **N-nitroso compounds (NOCs)** from processing and the influence of heme-iron are also suspected (WCRF and AICR, 2007).

Diets high in fat also tend to be high in calories, and contribute to overweight and obesity conditions. Because dietary fat intake is correlated with intake of other nutrients and dietary components, it is difficult to distinguish between the effects of dietary fats and protein, total calories, and fiber. Saturated fat in red meats may be associated with an increased risk of colorectal, endometrial, and possibly lymphoid and hematologic cancers (Ferguson, 2010; WCRF and AICR, 2007). Two large prospective randomized studies in the area of diet and breast cancer survival showed mixed results. The Women's Intervention Nutrition Study (WINS) found that an intervention that reduced dietary fat to 20% of total calories and caused a modest reduction in body weight may favorably influence breast cancer prognosis. However, the Women's Healthy Eating and Living (WHEL) study, which was very high in vegetables, fruit, and fiber and low in fat, demonstrated no significant survival benefit (Pierce et al., 2007).

Eating more  $\omega$ -3 fatty acids (foods such as fatty fish, flaxseed oil, walnuts, certain algae) in relation to  $\omega$ -6 fatty

acids (polyunsaturated fats like corn oil, safflower oil, and sunflower oil) may potentially reduce risk of colon and prostate cancers (Berquin et al., 2008). Fish is a healthier protein selection than red meat, is lower in fat, and is a potentially rich source of  $\omega$ -3 fatty acids. If choosing red meat, it is recommended to select leaner cuts and smaller portions. Poultry or legumes are also desirable alternatives to beef, veal, pork, and lamb.

### Fiber, Carbohydrates, and Glycemic Index

Higher-fiber foods such as complex carbohydrates and whole grains are an important part of a healthy diet. The intake of dietary fiber can influence the intake of meat, dietary fat, and simple carbohydrates. Unfortunately, the studies on dietary fiber and cancer have been inconsistent, so dietary fiber was not included in the oncology section of the Evidence Analysis Library of the American Dietetic Association (American Dietetic Association [ADA], 2010a). Epidemiologic studies looking at the possible relationship between dietary fiber and large-bowel cancer showed no effect of a low-fat, high-fiber, high-fruits, and high-vegetables diet on adenoma recurrence years after randomization (ADA, 2008.) Dietary fiber may play a role in preventing breast cancer through nonestrogen pathways among postmenopausal women, but more research needs to be done (Park et al., 2009). However, fiber-rich fruits and vegetables are excellent sources of vitamins, minerals, and phytochemicals. Legumes and lentils have both fiber and additional nutrients worth consuming.

### Nonnutritive and Nutritive Sweeteners

The Food and Drug Administration (FDA) has approved five nonnutritive sweeteners (acesulfame-K, aspartame, neotame, saccharin, and sucralose) for use in the food supply, and regulates them as food additives. They appear to be safe when used in moderation. Described as “high-intensity” sweeteners, nonnutritive sweeteners provide little or no energy because they sweeten in minute amounts. Nonnutritive sweeteners have been investigated primarily in relation to potential adverse health concerns, including long-term safety and carcinogenicity, but multiple studies during the past 20 years have indicated that when consumed in reasonable amounts, they are safe. Newer sugar substitutes on the market include Stevia, sugar alcohols (e.g., mannitol, sorbitol, xylitol), and blue agave. Stevia, a nonnutritive sweetener, is considered a dietary supplement but has approval from the FDA. Sugar alcohols are not considered nonnutritive sweeteners even though they are used in a similar way. Blue agave is the juice from the *Agave tequiliana* plant; the jury is still out on this sweetening option.

### Protein

Most diets that contain significant amounts of protein also contain significant amounts of meat and fat, and insignificant amounts of fiber. The effect of protein on carcinogenesis depends on the tissue of origin and the type of tumor, as well as on the type of protein and the calorie content of the diet. In general, tumor development is suppressed by diets that contain levels of protein below that required for

optimal growth and development; whereas it is enhanced by protein levels two to three times the amount that is required. The effects may be attributable to specific amino acids, a general effect of protein, or, in the case of low-protein diets, depressed food intake. Epidemiologic studies have found limited and conflicting results. Recommendations for lowering cancer risk and improving overall health encourage intake of plant foods and limiting foods from animal sources, including red meat and processed meats and poultry (WCRF and AICR, 2007).

### Smoked, Grilled, and Preserved Foods

Nitrates are added as preservatives to processed meats. Nitrates can be readily reduced to form nitrites, which in turn can interact with dietary substrates such as amines and amides to produce N-nitroso compounds (NOCs): nitrosamines and nitrosamides, which are known mutagens and carcinogens. Nitrates or nitrites are used in smoked, salted, and pickled foods. Sodium and potassium nitrates are present in a variety of foods, and give hot dogs and processed deli meats their pink color, but the main dietary sources are vegetables and drinking water.

NOCs are also produced endogenously in the stomach and colon of people who eat large amounts of red meat. Studies looking at the detrimental effects of smoked foods have not demonstrated a clear, consistent connection between these foods and stomach cancer (WCRF and AICR, 2007). Diets with high amounts of fruits and vegetables that contain vitamin C and phytochemicals that can retard the conversion of nitrites to NOCs should be encouraged (Kushi et al., 2006).

Charring or cooking meat at high temperatures over an open flame (400° F or more) can cause the formation of polycyclic aromatic hydrocarbons (PAHs) and heterocyclic amines. PAHs have shown clear indications of mutagenicity and carcinogenicity. Normal roasting or frying food does not produce large amounts of PAHs compared with the amount produced when cooking over open flames. Animal proteins that produce the greatest dripping of fat on to the flames register the highest PAH formation. For example, grilled beef produces larger amounts of PAHs than grilled chicken, which produces higher amounts than oven-grilled chicken. The source of the flame can also influence PAH production; charcoal grilling promotes the most, followed by flame gas, and finally oven grilling (Farhadian et al., 2010).

### Toxic Environments

The Environmental Protection Agency (EPA) was established in 1970, for the purpose of overseeing the acute and long-term health threats caused by substances in the environment. As part of this protection, the Toxic Substances Control Act passed in 1976 required manufacturers to submit health and safety information on all new chemicals. However, many were grandfathered in with the passage of this law and are still untested.

Everyday activities expose people to a myriad of chemicals through the air, and water, food, and beverages. In fact, 740 cancers per million people are estimated to be caused

by these very common exposures (Chey, 2008). Health care practitioners grapple with assessing exposure to so many different agents. A good environmental history can be performed at clinical visits and then quickly reviewed for outdoor air pollutants such as nitrogen dioxide, ozone, and carbon monoxide which pose health risks. Exposure to heavy metals, pesticides, herbicides, and occupational exposures may also be noted. In addition to determining the patient's environmental exposure, practitioners must also determine exposure of family members or others living in the same household. Oxidative stress caused by these environmental exposures can be alleviated by changes in lifestyle, including smoking and diet. High intakes of antioxidant-rich foods and a nutrient-rich diet (not supplementation) is suggested (Kushi et al., 2006).

### Toxicity from Bisphenol A

Bisphenol A (BPA) is an industrial chemical used since the 1960s in the manufacturing of many hard plastic bottles and the epoxy linings of metal-based food and beverage cans. It is also an ingredient in the production of epoxy resin used in paints and adhesives. Studies done when the product was developed indicated it was safe to use in food and beverage containers. However, recent studies employing novel approaches to test for subtle effects raised health concerns especially in developing fetuses, infants, and children (Layton, 2010). The National Toxicology Program at the National Institutes of Health (NIH) and the FDA are responding to growing evidence that BPA might increase the risk for cancer (FDA, 2010).

The shift in opinion likely resulted from a change in organizations evaluating the safety and the evaluative tools used (Beroni, 2010). The current goal is to reduce the use and exposure to BPA through several actions: encouraging the production of BPA-free baby bottles, using alternatives to the glue used in food containers, and increasing the oversight on the use of BPA in manufacturing and testing. The U.S. Department of Health and Human Services (USDHHS) supports eliminating it from infant and all food-related product production. Originally it was thought to leach from the plastic only when exposed to heat; now it is believed to leach even with cold temperatures. Exposure to BPA is so widespread in the food and beverage supply that it is estimated that 90% of Americans have traces of it in their urine (Layton, 2010).

## NUTRIENTS FOR CANCER PREVENTION

Eating behaviors play a very important role in health promotion and disease prevention. **Chemoprevention** involves specific compounds or drugs used to prevent, delay, or retard the development of cancer (Kashfi, 2009). Nonsteroidal antiinflammatory drugs may protect against colon cancer. Other natural products currently being investigated include the hundreds of polyphenols in fruits and vegetables, green tea, curcumin from curry, and resveratrol from

grapes and berries. Phenolic acid, flavonoids, stilbenes, and lignans are the most abundant polyphenols; the chemopreventive potential of these compounds comes from their ability to modulate epigenetic alterations in cancer cells. The epigenetic modification step occurs early in the development of a cancer cell, at a time when it is potentially reversible. Scientists are not completely clear how this process works. Yet it is reasonable to recommend a health-promoting diet rich in fruits, vegetables, soy, therapeutic culinary herbs such as turmeric and cinnamon, green tea, and coffee (Link et al., 2010). For this reason, health organizations have diet and lifestyle recommendations to reduce cancer risk. See Box 37-1.

### BOX 37-1

#### Cancer Prevention Recommendations

##### American Cancer Society

1. Adopt a physically active lifestyle. Adults should engage in at least 30 minutes of moderate to vigorous physical activity, above usual activities, on 5 or more days of the week and 45 to 60 minutes of intentional activity at least 5 days per week.
2. Achieve and maintain a healthy body weight throughout life.
3. Eat a variety of healthful, colorful foods, with an emphasis on plant sources.
4. Limit consumption of alcohol.

##### American Institute for Cancer Research

**Body Fatness:** Be as lean as possible within the normal range of body weight.

**Physical Activity:** Be physically active as part of everyday life.

**Foods and Drinks that Promote Weight Gain:** Limit consumption of energy-dense foods. Avoid sugary drinks.

**Plant Foods:** Eat mostly foods of plant origin.

**Animal Foods:** Limit intake of red meat and avoid processed meat.

**Alcoholic Beverages:** Limit alcoholic beverages.

**Preservation, Processing, Preparation:** Limit consumption of salt. Avoid moldy cereals (grains) or pulses (legumes).

**Dietary Supplements:** Aim to meet nutritional needs through diet alone.

**Breastfeeding:** Mothers to breastfeed; children to be breastfed.

**Cancer Survivors:** Follow the same recommendations.

Data from Kushi LH et al: American Cancer Society guidelines on nutrition and physical activity for cancer prevention: reducing the risk of cancer with healthy food choices and physical activity, CA Cancer J Clin 56:310, 2006; World Cancer Research Fund (WCRF), American Institute for Cancer Research (AIRC): Food, nutrition, physical activity, and the prevention of cancer: a global perspective, Washington, DC, 2007, WCRF and AIRC.

## Calcium and Vitamin D

Calcium supplementation and dairy, especially milk, may be associated with lower colorectal cancer risk. However, other studies suggest an increased risk for aggressive forms of prostate cancer with significant dairy intake or calcium supplementation (Chung et al., 2009; Huncharek et al., 2009). The relationships need to be explored further before clear recommendations can be made.

Vitamin D deficiencies are being detected in all age groups prompting exploration of the role of vitamin D in cancer prevention. For years, public health messages have encouraged use of sun screens and less direct exposure to the sun. Because of this there is reduced conversion of vitamin D on the skin surface and this may be responsible for the increase in deficiencies. Studies have reported that higher serum 25-hydroxyvitamin D (25(OH)D) levels are associated with lower incidence rates of colon, breast, ovarian, renal, pancreatic, aggressive prostate, and others cancers. Until more is learned about the interaction between vitamin D<sub>3</sub> and cancer prevention, taking 2000 IU of vitamin D per day to achieve serum 25(OH)D levels of 40–60 ng/mL is considered safe (Garland, 2009; Garland et al., 2011).

## Coffee and Tea

Coffee contains various antioxidant and phenolic compounds, some of which have been shown to have anticancer properties. Coffee also contains caffeine, a compound in the alkaloid phytochemical family. Coffee as a major source of antioxidants in the American diet may have a protective effect against cancer.

Tea is also a good source of phenols and antioxidants. Green tea is made from leaves that have been cooked, pressed, dried and not roasted, and because of this green tea, more so than black tea contains catechins that possess biologic activity with antioxidant, antiangiogenesis, and antiproliferative properties that are relevant to cancer prevention (Kuzuhara, 2008).

## Folate and Folic Acid

Folate, from foods, affects DNA methylation, synthesis, and repair. Folate-associated one-carbon metabolism may play an important role in colorectal carcinogenesis because of gene variations (Levine et al., 2010). Several epidemiologic studies suggest that higher folate intake is also associated with decreased pancreatic cancer risk (Oakset al., 2010). However, excessive folate may also contribute to deleterious effects in certain cancers (Bailey et al., 2010). More research is needed to evaluate variables such as genetic polymorphisms, and folate from food versus folic acid from supplements.

## Fruits and Vegetables

Fruit intake is protective against cancers of the mouth, pharynx, larynx, esophagus, cervix, lung and stomach (WCRF and AICR, 2007). Health benefits from vegetables are more difficult to quantify. Nonstarchy vegetables such as spinach, tomatoes, and peppers probably provide protection against mouth, pharynx, larynx, and esophageal cancers; all vegetables, but particularly green and yellow ones,

probably protect against stomach cancer (WCRF and AICR, 2007). Most countries have recommendations for the consumption of vegetables and fruits that vary, but generally are for three or more servings of vegetables and two or more servings of fruit daily with a serving being approximately 80 g or ½ cup (WCRF and AICR, 2007).

Anticarcinogenic agents found in fruits and vegetables include antioxidants such as vitamins C and E, selenium, and phytochemicals. Phytochemicals include carotenoids, flavonoids, isoflavones, lignans, organosulfides, phenolic compounds, and monoterpenes. It is still unclear which specific substances of fruits and vegetables are the most protective against cancer (Russo, 2007). These substances have both complementary and overlapping mechanisms, including the induction of detoxification enzymes, inhibition of nitrosamine formation, provision of substrate for formation of chemotherapy agents, dilution and binding of carcinogens in the digestive tract, alteration of hormone metabolism, and antioxidant effects. It appears extremely unlikely that any one substance is responsible for all of the observed associations. See Table 12-5 and Table 37-1 for discussion of chemoprotective agents in fruits and vegetables.

## Soy and Phytoestrogens

Soy is a plant-based protein, and it contains phytoestrogens (very weak plant-based estrogens) and isoflavones such as genistein and daidzein. Diets containing modest amounts of soy protect against breast cancer (Lee et al., 2010,) especially if the soy foods have been consumed before reaching adulthood apparently due to exposure to the weak estrogenic effects of isoflavones early in life (Lee et al., 2010). However, the use of soy remains controversial for women already diagnosed with hormone-sensitive cancers (e.g., breast, endometrium) and for postmenopausal women.

Commercially prepared soy supplement powders and foods made from soy products can, but may not always contain isoflavones at much higher concentrations than traditional whole soy foods such as edamame beans, tofu, or soy milk (Gardner et al., 2008; U.S. Department of Agriculture (USDA), 2010). The ACS advises breast cancer survivors to limit the consumption of soy foods to no more than three servings daily, and to avoid using prepared soy supplement powders and products (Doyle et al., 2006). Unlike the advice for women, men with hormone-sensitive cancer such as prostate cancer may benefit from regular consumption of soy foods. Prostate cancer is a testosterone driven cancer and estrogens (or phytoestrogens) are agonists.

## MEDICAL DIAGNOSIS AND STAGING OF CANCER

Assessing symptoms of cancer at the earliest stage is critical for treatment effectiveness and survival. Table 37-2 summarizes constitutional or systemic symptoms of cancer and metastatic disease. Many symptoms of early or metastatic cancer affect an individual's ability to eat, digest, or absorb. According to the ACS, the following early warning signs

and symptoms of cancer are described using the acronym “CAUTION”

- Change in bowel or bladder habits
- A sore that does not heal
- Unusual bleeding or discharge
- Thickening or lump in breast or elsewhere
- Indigestion or difficulty in swallowing or chewing
- Obvious change in a wart or mole
- Nagging cough or hoarseness

**TABLE 37-2****Signs and Symptoms of Cancer**

<b>Constitutional Symptoms of Cancer</b>	<b>Signs and Symptoms of Metastatic Cancer</b>
Anorexia	Pain
Fatigue	Enlarged lymph nodes or body organs
Weight loss	Cough with or without hemoptysis
Fever	Bone pain with or without fracture
Sweating	Neurological symptoms
Anemia	

Data from National Cancer Institute (NCI): Dictionary of terms, 2010d. Accessed 23 October 2010 from <http://www.cancer.gov/dictionary/>.

When symptoms or screening tests suggest cancer, physicians use the following to establish a definitive diagnosis: evaluation of an individual’s medical, social and family histories, physical examination, laboratory tests, imaging procedures, and tissue biopsy. Laboratory evaluation is composed of analysis of blood, urine, and other body fluids. In particular, oncologists evaluate **tumor markers** (e.g., α-fetoprotein [AFP], cancer antigen [CA] 125, CA 19-9, carcinoembryonic antigen [CEA], prostate-specific antigen [PSA]) and other substances in blood or body fluids that can be elevated in cancer. Imaging procedures and studies help determine a diagnosis (Table 37-3). Pathologists perform cytologic examinations by analyzing body fluids, sputum, urine, or tissue under a microscope. To detect malignant cells, they use a histopathologic examination to review specially stained tissue, flow cytometry to count and examine cells and chromosomes, immunohistochemistry to review antibodies for specific cell proteins, and cytogenetics to visualize genetic defects.

Oxidative damage to lipids in cellular membranes, proteins, and DNA is often permanent. Thus biomarkers may be used to estimate the DNA damage after exposure to cancer-causing agents such as tobacco smoke, asbestos fibers, heavy metals, and PAHs. 8-hydroxy-2'-deoxyguanosine (8-OHdG) is a new biomarker for the measurement of endogenous oxidative DNA damage and risk for cancer (Valavanidis et al., 2009). See Table 8-5 in Chapter 8.

**Staging** is used to identify how much a cancer has spread throughout the body. The stage of the cancer at the time of diagnosis is a strong predictor of survival and it directs

**TABLE 37-3****Imaging Studies for Cancer Diagnosis and Disease Monitoring**

<b>Type of Imaging</b>	<b>Description and Use in Cancer Diagnosis and Treatment</b>
CT Scan	<b>Description:</b> A CT scan is a radiographic procedure in which a series of detailed pictures of areas inside the body are taken from different angles. Images are created by a computer and are linked to an x-ray machine. <b>Use:</b> A CT scan is used to evaluate for abnormalities of possible cancer in a general anatomic area such as the head, chest, abdomen, or pelvis. Radiologists use CT scans to visualize suspicious lesions, internal organs, and lymph nodes.
MRI Scan	<b>Description:</b> An MRI scan is an imaging procedure that uses radio waves and a powerful magnet linked to a computer to create detailed pictures of areas inside the body. This type of scanning often creates better images of body organs and soft tissue than other type of scanning methods. <b>Use:</b> Images produced show differences between normal and cancerous tissue. In particular, an MRI scan is used to evaluate suspicious areas of the brain, spinal cord, and liver.
PET Scan	<b>Description:</b> A PET scan is a procedure in which a small amount of radioactive glucose is injected into a vein and a scanner is used to make detailed, computerized pictures of areas where glucose is used in the body. <b>Use:</b> Cancerous cells have an enhanced rate of glycolysis (they use more glucose than normal cells). Areas of glucose metabolism with high activity or “hot spots” appearing on the PET scan generally correlate to findings of cancer.

Data from American Cancer Society: Cancer glossary, 2010a. Accessed 10 June 2010 from <http://www.cancer.org/CancerGlossary/index>; National Cancer Institute (NCI): *Dictionary of terms*, 2010d. Accessed 23 October 2010 from <http://www.cancer.gov/dictionary/>.

CT, Computed tomography; MRI, magnetic resonance imaging; PET, positron emission tomography.

oncologists to the most effective treatment plan. Cancer staging is most frequently described as stage I, II, III, or IV—stage I being the least amount of disease and stage IV being the most advanced. The **tumor-node-metastasis (TNM) staging system** is also commonly used by oncologists. *T* stands for the size of the tumor, *N* stands for nodes or whether it has spread into lymph nodes, and *M* stands for metastasis, or whether the cancer has spread to distant organs.

For **classification**, tumors are often referred to as *solid* cancers, and hematologic-related cancers of the blood are frequently called *liquid* cancers. The classification of tumors is based on their tissue of origin, their growth properties, and their invasion of other tissues. Tumors that are not malignant are typically described as *benign*.

Because cancer occurs in cells that are replicating, the patterns of cancer are quite different in children and adults. In early life the brain, nervous system, bones, muscles, and connective tissues are still growing; therefore cancers involving these tissues are more prevalent in children than in adults. Common childhood cancers include neuroblastoma; medulloblastoma; osteosarcoma; and soft tissue sarcomas such as rhabdomyosarcoma, schwannoma, and germ cell tumors. Conversely, adult cancers frequently involve epithelial tissues that cover and line the body's internal and external surfaces. Cancers of the epithelial tissues include cancers of the skin, and circulatory, digestive, endocrine, reproductive, respiratory, and urinary systems. Cancers arising from these tissues are referred to as *carcinomas* and common types are classified as *adenocarcinomas*, *basal cell carcinomas*, *papillomas*, and *squamous cell carcinomas*.

Leukemias, lymphomas, and myelomas are cancers of the immune system and can occur in either children or adults. Leukemias arise most frequently from white blood cells of the bone marrow. Lymphomas are cancers that develop in the lymphatic system—its nodes, glands, and organs. Myeloma is cancer that originates in the plasma cells of the bone marrow and most frequently occurs in older adults.

Other types of cancer are related to infectious causes and cancer experts recommend antibiotics, vaccines, and changes in behavior for their prevention (ACS, 2009a). Examples include hepatocellular carcinoma linked to hepatitis B virus (HBV) exposure and alcoholic-related cirrhosis, oropharyngeal and cervical cancer incidence linked to human papillomavirus infection (HPV), and stomach cancer caused by chronic inflammation by *Helicobacter pylori*. See Chapter 28.

## MEDICAL TREATMENT

Cancer treatment in the United States and in more than 115 countries is guided by evidence-based standards known as the *National Comprehensive Cancer Network (NCCN) Clinical Practice Guidelines in Oncology* (2010). The NCCN Guidelines encompass evidenced-based care for 97% of all cancers treated in oncology practice. Also listed with these guidelines are evidence-based recommendations for providing supportive care (e.g., management for cancer and cancer treatment-related pain, fatigue, and nausea).

Conventional modalities include antineoplastic therapy (e.g., chemotherapy, biotherapy, antiangiogenic agents, or hormonal agents), radiation therapy, and surgery used alone or in combination with other cancer therapies. Solid tumors and hematologic malignant diseases such as leukemias, lymphomas, and multiple myelomas may be treated with **hematopoietic cell transplantation (HCT)**.

**Chemotherapy** is the use of chemical agents or medications to systematically treat cancer. Biotherapy is the use of biologic agents to produce anticancer effects indirectly by inducing, enhancing, or suppressing an individual's own immune response. Antiangiogenic agents are used to inhibit the development of new blood vessels needed by cancers (tumor vasculature) and thus prevent their growth, invasion, and spread. Hormonal therapy is systemic therapy used for the treatment of hormone-sensitive cancers (e.g., breast, ovarian, prostate) by blocking or reducing the source of a hormone or its receptor site.

Radiation oncologists work in the area of therapeutic **radiation therapy**, which uses high-energy (ionizing radiation) in multiple fractionated doses, or radioactive chemicals to treat cancer. Surgery involves the surgical removal of cancerous tissue.

Response to cancer treatment is defined as *complete* or *partial response* (improvement), *stable disease* (same), or *disease progression* (worsening). Factors that affect an individual's response to treatment include **tumor burden** (the larger the tumor, the greater risk of metastatic disease), **rate of tumor growth** (rapidly growing tumors are usually more responsive to therapy), and **drug resistance** (tumors mutate as they grow, and with successive mutations new cancer cells become more likely to be resistant to therapy). Other factors contributing to an individual's response to cancer treatment include comorbid diseases (e.g., diabetes, renal disease, cardiopulmonary disease), age, performance status, support system, bone marrow reserve, and overall general health (NCI, 2010d; Polovich et al., 2009).

## Goals of Treatment

The goal of cancer treatment may be to cure, control, or palliate. **Cure** is a complete response to treatment. Even if a treatment cannot cure a cancer, often there can be cancer **control** that extends life when a cure is not possible. Control measures may obscure microscopic metastases after tumors are surgically removed, reduce the size of tumors before surgery or radiation therapy, or alleviate symptoms and side effects of cancer. If a cancer cannot be cured or controlled, **palliative care** is offered. Palliative care helps individuals be as comfortable as possible. Palliation is designed to relieve pain and manage symptoms of illness; lessen isolation, anxiety and fear; and help maintain independence as long as possible (National Hospice and Palliative Care Organization [NHPCO], 2010). **Hospice** is care for individuals with a life expectancy of months and focuses on relieving symptoms, controlling pain, and providing support to patients and their families. Patients are made as comfortable as possible through the end of their lives.

## MEDICAL NUTRITION THERAPY

Dietetic professionals should use the nutrition care process steps when providing medical nutrition therapy (MNT) (ADA, 2011). To further assist clinicians working in the cancer care setting the American Dietetic Association has developed the *Oncology Toolkit* with MNT protocols for breast, colorectal, esophageal, gastric, head and neck, hematologic, lung, and pancreatic cancers (ADA, 2010b). It also includes instructional and documentation forms using the nutrition care process (NCP) and standardized language to help individualize nutrition care with recommendations based on the current state of science.

### Nutrition Screening and Assessment

With the recent shift of cancer care from the hospital setting to outpatient settings, nutrition screening and assessment should continue throughout the continuum of care. Ideally, nutrition screening and assessment for risk of nutrition problems should be interdisciplinary, instituted at the time of diagnosis, and reevaluated and monitored throughout treatment and recovery. The patient-generated Subjective Global Assessment has been adapted for use with cancer patients and incorporates sections completed by the patient or caregiver on weight history, food intake, symptoms, and functioning. Sections completed by a health care member (e.g., physician, nurse, registered dietitian, social worker) evaluate weight loss, disease, metabolic stress, and include a nutrition-focused physical examination. Nutritional risk and intervention are then determined by a scoring system (Charney and Cranganu, 2010).

Other tools are the Activities of Daily Living (ADL) tool, the Common Toxicity Criteria (CTC), and the Karnofsky Performance Scale (KPS) Index. The ADL tool assesses routine activities that people do each day without assistance such as bathing, dressing, and walking. CTC is an outcome measure used in cancer centers that compares acute toxicities of cancer treatment, and KPS is a scoring index that associates an individual's functional status with disease status and survival (McCallum, 2006).

In-depth assessment is undertaken to obtain more information and to identify nutrition problems. Careful review of the individual's appetite and oral intake is required, with an assessment of symptoms (e.g., nausea, vomiting, and diarrhea), weight status, comorbidities, and laboratory studies. A nutrition-focused physical examination is recommended to fully evaluate nutrition status and degree of risk (Fuhrman, 2009). Components of this type of assessment include a general survey of the body, review of vital signs and anthropometrics, and an evaluation of subcutaneous fat stores, muscle mass, and fluid status.

### Energy

Determining individualized energy needs is vital to helping people maintain their weight and prevent weight loss associated with cancer. Methods used to estimate energy requirements for adults include using standardized equations or measuring resting metabolic rate using indirect calorimetry

**TABLE 37-4**

### Estimating Energy Needs of People with Cancer

Condition	Energy Needs
Cancer, nutritional repletion, weight gain	30-40 kcal/kg/day
Cancer, normometabolic	25-30 kcal/kg/day
Cancer, hypermetabolic, stressed	35 kcal/kg/day
Hematopoietic cell transplant	30-35 kcal/kg/day
Sepsis	25-30 kcal/kg/day
Obese	21-25 kcal/kg/day

Data from Gottschlich MM, editor: The A.S.P.E.N. nutrition support core curriculum: a case-based approach—the adult patient. Silver Spring, MD, 2007, American Society for Parenteral and Enteral Nutrition; Hurst JD, Gallagher AL: Energy, protein, micronutrient, and fluid requirement. In Elliott L et al., editors: The clinical guide to oncology nutrition, ed 2, Chicago, 2006, American Dietetic Association.

(Russell and Malone, 2009). See Chapter 2 for methods for determining energy requirements such as the Mifflin-St. Jeor and Ireton-Jones equations. To ensure that adequate energy is being provided, the individual's diagnosis, presence of other diseases, intent of treatment (e.g., curative, control, or palliation), anticancer therapies (e.g., surgery, chemotherapy, biotherapy, or radiation therapy), presence of fever or infection, and other metabolic complications need consideration. Established guidelines for quickly estimating energy needs of people with cancer based on body weight are shown in Table 37-4.

### Protein

An individual's need for protein is increased during times of illness and stress. Additional protein is required by the body to repair and rebuild tissues affected by cancer therapy, and to maintain a healthy immune system (Hurst and Gallagher, 2006). Adequate energy should be provided, or the body will use its lean body mass as a fuel source. When determining protein requirements, dietetic professionals need to consider the degree of malnutrition, extent of disease, degree of stress, and ability to metabolize and use protein (Russell and Malone, 2009). For example, a cancer patient with a hematopoietic cell transplant may require 1.5-2 g/kg/day. A patient with severe stress may need 1.5-2.5 g/kg/day. Daily protein requirements are generally calculated using actual body weight.

### Fluid

Fluid management in cancer care must ensure adequate hydration and electrolyte balance, and prevent dehydration and hypovolemia. Altered fluid balance may occur with fever, ascites, edema, fistulas, profuse vomiting or diarrhea, multiple concurrent intravenous (IV) therapies, impaired renal function, or medications such as diuretics. Individuals need close monitoring for dehydration (e.g., intracellular fluid losses caused by inadequate intake of fluid because of mucositis or anorexia) and hypovolemia (e.g., extracellular fluid losses from fever or GI fluids such as vomiting, diarrhea or

malabsorption). Signs and symptoms of dehydration include fatigue, acute weight loss, hypernatremia, poor skin turgor, dry oral mucosa, dark or strong smelling urine, and decreased urine output. To carefully assess for hypovolemia, levels of serum electrolytes, blood urea nitrogen and creatinine should also be evaluated. A general guideline for estimating fluid needs for all adults without renal concerns is 30–35 mL/kg/day (Hurst and Gallagher, 2006). Another guideline is 1 mL fluid per 1 kcal of estimated calorie needs (Russell and Malone, 2009). In some instances, individuals undergoing cancer therapy may require IV fluid hydration to meet their treatment-related fluid needs.

## Vitamins and Minerals

Individuals diagnosed with cancer often take large amounts of vitamin and mineral supplements because they believe that these products can enhance their immune system or even reverse the course of their disease. Others may see dietary supplementation as a way to make up for existing nutritional deficiencies at the time of diagnosis caused by poor diet and lifestyle choices. If individuals are experiencing difficulty with eating and treatment-related side effects, a multivitamin and mineral supplement that provides no more than 100% of the dietary reference intakes (DRIs) is considered safe (Doyle et al., 2006). In contrast, the American Institute for Cancer Research (AICR) encourages all people (including cancer survivors) not to use dietary supplements for cancer prevention, citing evidence that high-dose dietary supplementation can have cancer-promoting effects (WCRF and AICR, 2007). Whether for primary or secondary prevention, all individuals should consume vitamin and minerals from the foods they eat rather than use dietary supplements. In some instances during and after a cancer diagnosis, supplementation or restriction of specific micronutrients may be required above or below DRI levels, depending on medical diagnosis and laboratory analysis (e.g., iron supplementation for iron-deficiency anemia).

## Supplement Use

The majority of cancer survivors use dietary supplements during all phases of anticancer treatment (Hardy, 2008). Despite increased use, oncology practitioners ask that patients avoid use of dietary supplements during treatment. Specifically, controversy continues over whether the use of antioxidant dietary supplements such as vitamins A, C, E, β-carotene, zinc, and selenium actually inhibits or enhances the antitumor effects of radiation therapy and chemotherapy (ACS, 2009b). Several randomized trials showed some potential for reducing treatment dose-limiting toxicities (Block et al., 2008). However, well-designed studies evaluating larger numbers of individuals are needed.

Cancer survivors should carefully evaluate the need and wisdom of taking dietary supplements both during and after treatment (Miller, 2008) and should avoid using antioxidant supplements while undergoing treatment until further research supports their use (ACS, 2009b; Hardy, 2008; WCRF and AICR, 2007). Individuals diagnosed with cancer should be encouraged to consume antioxidants from a

variety of colorful food sources such as fruits, vegetables, and whole grains as a way to safely consume these naturally occurring, health-promoting phytonutrients, vitamins, and minerals (Grant et al., 2010).

## Nutrition Diagnosis

Nutrition diagnosis identifies the specific nutrition problems that can be resolved or improved through nutrition intervention. (ADA, 2011). See Chapter 11. The following are examples of nutrition diagnoses using the “problem, etiology, and signs and symptoms” system developed for the cancer care setting:

### Intake Domain

- Inadequate oral intake *related to* pelvic radiation therapy *as evidenced by* diarrhea and 2.5-pound weight loss in the preceding week
- Inadequate enteral nutrition (EN) infusion *related to* intolerance of EN *as evidenced by* nausea, abdominal distention, and weight loss of 3 pounds in the preceding 5 days
- Malnutrition *related to* cancer cachexia *as evidenced by* wasting of temporalis and interosseous muscles, and weight loss of more than 7.5% in 3 months

### Clinical Domain

- Altered GI function *related to* recent ileostomy surgery *as evidenced by* 2 L/day ostomy diarrhea output, and the need for daily IV hydration during the preceding week
- Altered GI function *related to* biweekly chemotherapy *as evidenced by* nausea, vomiting, and anorexia in the preceding 4 days
- Swallowing difficulty *related to* an obstructing esophageal tumor *as evidenced by* dysphagia, odynophagia, and 10-pound weight loss in the preceding month

### Behavioral-Environmental Domain

- Limited access to nutrition-related supplies *related to* lack of insurance and financial resources *as evidenced by* not using the prescribed amount of tube feeding formula and continued weight loss to 80% of usual weight during the preceding month
- Intake of unsafe food *related to* exposure to contaminated food while neutropenic *as evidenced by* hospitalization, diarrhea, and positive stool culture for salmonella
- Undesirable food choices *related to* an unwillingness to apply nutrition information *as evidenced by* ongoing diarrhea and diet history of continued high fiber food intake while undergoing pelvic radiation therapy

## Nutrition Intervention

Nutrition intervention outlines specific actions to manage a nutrition diagnosis. It includes two distinct, interrelated components—planning and implementing nutrition interventions (ADA, 2011). The *Oncology Toolkit* recommends careful appraisal if the planned nutrition intervention will negatively affect patient safety or possibly interfere with the

cancer treatment (ADA, 2010b). The *Toolkit* also advises evaluation of the nutrition intervention's likely effectiveness for improving nutrition status, possible financial burden, and patient acceptance.

Intervention goals should be specific, achievable, and individualized to encourage cooperation. Goals need to be directed toward an objective measure such as body weight or some other meaningful index. Another goal is to minimize the effects of "nutrition impact symptoms" and to maximize the individual's nutritional parameters. **Nutrition impact symptoms** can be defined as symptoms and side effects of cancer and cancer treatment that directly affect the nutrition status. Consultation with the individual, caregivers, or family members regarding expected problems and their possible solutions should be initiated early in the course of cancer therapy and should continue in conjunction with follow-up nutrition assessment and care.

The adverse nutritional effects of cancer can be severe and may be compounded by the effects of the treatment regimens and the psychological effects of cancer. The result is often a profound depletion of nutrient stores and deterioration in nutrition status. Malnutrition, anorexia (loss of appetite), and weight loss are all significant issues in cancer care and are often present in many individuals at the time of diagnosis, even in children (Goldman et al., 2006). More than 50% of people with cancer lose body weight and more than one third lose more than 5% of their usual body weight (Skipworth, 2007). Studies consistently show that even small amounts of weight loss (less than 5% of body weight) before treatment is associated with a poorer prognosis and decreased quality of life, thus reinforcing the importance of early MNT (Fearon, 2008).

### Oral Nutrition Management Strategies

Ideally the route of feeding is oral, although individuals may experience symptoms that affect this. Strategies for modifying dietary intake may be necessary, and depend on the specific eating problem and the individual's nutritional status. Food and its presentation may need modification. Liquid medical food supplements may be recommended for those unable to consume enough energy and protein to maintain weight and nutrition status (see Chapter 14). Education materials with suggestions for improving oral intake and managing treatment-related side effects include *Eating Hints* (NCI, 2010e), *Chemotherapy and You* (NCI, 2010c), and *Radiation Therapy and You* (NCI, 2010f). Table 37-5 outlines examples of nutrition intervention strategies.

### Managing Anorexia and Alterations in Taste and Smell

Sometimes even before diagnosis, and then throughout cancer treatment, individuals may report anorexia, early satiety, and decreased food intake. Alterations in taste and smell are commonly experienced as well. Taste alterations can be associated with the disease itself, certain chemotherapy agents, radiation therapy, or surgery to the head and neck. Chemotherapy-induced, learned taste aversions have been reported in both adults and children. Individuals may

also develop a heightened sense of smell that results in sensitivity to food preparation odors and aversions to nonfood items such as soaps or perfumes. These sensation abnormalities do not consistently correlate with the tumor site, extent of tumor involvement, tumor response to therapy, or food preferences and intake. Nutrition interventions that decrease the aroma of foods, such as serving foods cold instead of hot, may be helpful (NCI, 2010e).

### Managing Alterations in Energy Metabolism

Energy metabolism is intimately related to carbohydrate, protein, and lipid metabolism, all of which are altered by tumor growth. Tumors exert a consistent demand for glucose, exhibit a characteristically high rate of anaerobic metabolism, and yield lactate as the end product. This expanded lactic acid pool requires an increased rate of host gluconeogenesis via Cori cycle activity, which is increased in some people with cancer but not in others. Both protein breakdown and lipolysis take place at increasing rates to maintain high rates of glucose synthesis. There is glucose intolerance and insulin resistance, characterized by excess fatty acid oxidation and decreased uptake and use of glucose by muscle.

Alterations in protein metabolism appear to be directed toward providing adequate amino acids for tumor growth. Most notable is the loss of skeletal muscle protein caused by increased protein breakdown, as well as decreased protein synthesis.

### Managing Cancer Cachexia

A common secondary diagnosis in people with advanced cancer is a variant of protein-energy malnutrition. This syndrome is termed **cancer cachexia** and is characterized by progressive weight loss, anorexia, generalized wasting and weakness, immunosuppression, altered basal metabolic rate, and abnormalities in fluid and energy metabolism. There is also increased loss of adipose tissue, which is related to an increased rate of lipolysis, rather than a decrease in lipogenesis. Increased levels of lipid-mobilizing factor and proteolysis-inducing factor secreted by tumor cells will lead to increased loss of both fat and muscle mass. Individuals at the time of diagnosis with breast or hematologic cancers rarely present with significant weight loss, whereas individuals with lung, esophageal, or head and neck cancers often exhibit substantial weight loss. Cancer cachexia is caused in part by **cytokines** (immune-modulating agents), produced by the cancer itself or by the immune system in response to the cancer. Cytokines can cause metabolic changes and wasting that is similar to changes seen in inflammation. Proinflammatory cytokines include **tumor necrosis factor (TNF)- $\alpha$  (cachectin)** and TNF- $\beta$ , interleukin (IL)-1, IL-6, and interferon- $\alpha$ . These cytokines have overlapping physiologic activities, which makes it likely that no single substance is the sole cause. Resting energy expenditure (REE) is elevated, which is in contrast to the REE in chronic starvation wherein the body adapts to conserve energy and preserve body tissue. Cancer cachexia often increases closer to the time of death.

**TABLE 37-5****Nutrition Intervention Strategies for Patients with Cancer**

<b>Side Effect or Symptom</b>	<b>Strategies</b>
Weight loss	<ul style="list-style-type: none"> <li>• Eat small, more frequent, nutrient dense meals and snacks.</li> <li>• Add protein and calories to favorite foods.</li> <li>• Use protein and calorie-containing supplements (e.g., whey or soy powder, nutritional supplements).</li> <li>• Keep nutrient dense foods close at hand and snack frequently.</li> </ul>
Poor appetite or anorexia	<ul style="list-style-type: none"> <li>• Capitalize on times when feeling best.</li> <li>• Eat meals and snacks in a pleasant atmosphere.</li> <li>• Keep nutrient dense foods close at hand and snack frequently.</li> <li>• Be as physically active as able.</li> </ul>
Nausea and vomiting	<ul style="list-style-type: none"> <li>• Sip on cool or room temperature clear liquids in small amounts.</li> <li>• Avoid high fat, greasy, spicy, or overly sweet foods.</li> <li>• Avoid foods with strong odors.</li> <li>• Eat bland, soft, easy-to-digest foods on scheduled treatment days.</li> </ul>
Diarrhea	<ul style="list-style-type: none"> <li>• Consume plenty of clear liquids such as water, clear juices, broth, gelatin, popsicles, sports drinks.</li> <li>• Decrease intake of high fiber foods such as nuts, raw fruits and vegetables, and whole-grain breads and cereals.</li> <li>• Avoid sugar alcohol-containing foods such as sugar-free candies and gums (e.g., mannitol, xylitol, sorbitol).</li> <li>• Eat applesauce, bananas, canned peaches, white rice or pasta, which are easy to digest and can firm up the stool.</li> </ul>
Constipation	<ul style="list-style-type: none"> <li>• Increase intake of high fiber foods such as whole grains, fresh or cooked fruits and vegetables, especially those with skins and seeds, dried fruits, beans, and nuts.</li> <li>• Drink plenty of healthy fluids to keep the digestive system moving.</li> <li>• Try to eat and snack at the same time each day.</li> <li>• Try to increase physical activity as able.</li> </ul>
Sore throat	<ul style="list-style-type: none"> <li>• Eat soft, moist foods with extra sauces, dressings, or gravies.</li> <li>• Avoid dry, coarse, or rough foods.</li> <li>• Avoid alcohol, citrus, caffeine, tomatoes, vinegar, and hot peppers.</li> <li>• Experiment with food temperatures (e.g. warm, cool, or icy) to find which temperature is the most soothing.</li> </ul>
Sore mouth, mucositis, or thrush	<ul style="list-style-type: none"> <li>• Maintain good oral hygiene (e.g., rinse mouth frequently, keep mouth clean).</li> <li>• Eat soft, moist foods with extra sauces, dressings, and gravies.</li> <li>• Avoid alcohol, citrus, caffeine, tomatoes, vinegar and hot peppers; and dry, coarse, or rough foods.</li> <li>• Try foods at room temperature or chilled.</li> </ul>
Fatigue	<ul style="list-style-type: none"> <li>• Consume easy-to-prepare, easy-to-eat foods.</li> <li>• Keep nutrient dense snacks close at hand and snack frequently.</li> <li>• Drink plenty of healthy fluids to keep the digestive system moving.</li> <li>• Be as physically active as possible.</li> </ul>
Neutropenia	<ul style="list-style-type: none"> <li>• Wash hands frequently and keep kitchen surfaces and utensils clean.</li> <li>• Do not eat raw or undercooked animal products, including meat, pork, game, poultry, eggs, and fish.</li> <li>• Wash all fresh fruits and vegetables.</li> <li>• “When in doubt, throw out” and “No oldy or moldy.”</li> </ul>
Altered taste or smell	<ul style="list-style-type: none"> <li>• Maintain good oral hygiene (e.g., rinse mouth frequently, keep mouth clean).</li> <li>• Try marinades and spices to mask strange tastes.</li> <li>• Use plastic utensils if metallic tastes are a problem.</li> <li>• Try cooler foods, rather than warmer foods.</li> </ul>
Thickened saliva	<ul style="list-style-type: none"> <li>• Sip on liquids throughout the day to keep the oral cavity moist.</li> <li>• Thin oral secretions with club soda, seltzer water, or papaya nectar.</li> <li>• Try guaifenesin to help thin oral secretions.</li> <li>• Try using a cool mist humidifier while sleeping.</li> </ul>
Xerostomia	<ul style="list-style-type: none"> <li>• Sip on liquids throughout the day to keep the oral cavity moist.</li> <li>• Try tart foods to stimulate saliva, if open sores are not present.</li> <li>• Eat soft, moist foods with extra sauces, dressings, or gravies.</li> <li>• Maintain good oral hygiene (e.g., rinse mouth frequently, keep mouth clean).</li> </ul>

Accessed 20 October 2010 from <http://www.cancer.gov/publications/>.

## Pharmacotherapy

The pharmacologic management of cachexia and anorexia requires careful evaluation based on the patient's treatment goals and prognosis, and on close monitoring of symptoms. Prescribed medications sometimes prevent adequate intake. Ideally these agents are prescribed in combination with nutrition counseling and physical activity. A number of pharmacologic agents are under investigation, including appetite stimulants, metabolic agents, cytokine blockers, prokinetic agents, and anabolic agents. Several trials have shown improved appetite and increased energy intake and body weight in cancer patients treated with megestrol acetate, a progestational agent. Prolonged use of corticosteroids is associated with negative side effects such as osteoporosis, fluid retention, adrenal suppression, glucose intolerance, electrolyte imbalance, or even arm- and leg-muscle wasting. Oxandrolone, a synthetic anabolic steroid, combined with a resistance exercise program, may increase total body weight and lean tissue weight. Growth hormones have been studied in patients with wasting associated with human immunodeficiency virus, but few data are available regarding their use with cancer.

## Managing Other Cancer-Related Metabolic Abnormalities

Metabolic alterations vary by tumor type. An individual's immunologic function can be impaired, apparently as the result of the disease, cancer treatment, or progressive malnutrition. In addition to the cancer-induced metabolic effects, the mass of the tumor may anatomically alter the physiology of specific organ systems. The activities of several enzyme systems involved with digestion and absorption can be affected, as can certain endocrine functions.

Critical imbalances in fluid and electrolyte status can occur in people who have cancers or are undergoing cancer treatments that promote excessive diarrhea, vomiting, or malabsorption. Profuse and often severe diarrhea can result from partial bowel obstructions and endocrine-secreting tumors such as those secreting serotonin (carcinoid tumors), calcitonin, or gastrin (Zollinger-Ellison syndrome). The use of antimetabolites, alkylating agents, and antibiotics may also lead to the development of severe diarrhea. In some instances, people who are immunocompromised or have undergone GI surgery may experience profuse diarrhea that is caused by intestinal pathogens such as *Clostridium difficile*.

Persistent vomiting is associated with intestinal obstruction, radiation therapy to the stomach and abdomen or brain, highly **emetogenic** (nausea-causing) chemotherapy agents, intracranial tumors, and advanced cancer (Grant, 2006). Careful assessment and evaluation of the cause of the diarrhea or vomiting is critical for effective management. Malabsorption may be caused by treatment-related pancreatic dysfunction, postsurgical short gut syndrome, acute or chronic **radiation enteritis** (inflammation of the GI tract tissues secondary to radiation), excess serotonin, steatorrhea, or chronic diarrhea.

Hypercalcemia may occur in individuals with bone metastases, caused by the osteolytic activity of tumor cells

releasing calcium into the extracellular fluid. Hypercalcemia is potentially fatal, and is associated most commonly with multiple myeloma, lung cancer, and advanced breast and prostate cancer. Nausea, weakness, fatigue, lethargy, and confusion occur. Medical management of hypercalcemia includes rehydration and use of antihypercalcemic agents. Calcium supplementation from dietary supplements and antacids should be avoided. Restricting the intake of foods containing calcium is not indicated because the consumption of these foods has little effect in the overall management of hypercalcemia.

## NUTRITIONAL IMPACT OF CANCER TREATMENTS

### Chemotherapy

Chemotherapy uses chemical agents or medications to treat cancer. Classifications of chemotherapy cytotoxic agents include alkylating agents, antimetabolites, antitumor antibiotics, miscellaneous agents, nitrosoureas, and plant alkaloids (Wilkes and Barton-Burke, 2010). Once in the bloodstream, these agents are carried through the body to reach as many cancer cells as possible. Routes of administration for chemotherapy include:

- Oral: capsule, pill, or liquid
- Intravenous (IV): delivery of medication via an injection or an indwelling catheter into a vein
- Intraperitoneal: delivery of medication via a catheter directly into the abdominal cavity
- Intravesicular: delivery of medication via a Foley catheter directly into the bladder
- Intrathecal: delivery of medication via an injection into the central nervous system using an Ommaya reservoir or a lumbar puncture (Polovich et al., 2009)

Whereas surgery and radiation therapy are used to treat localized tumors, chemotherapy is a systemic therapy that affects the malignant tissue and normal cells as well. Cells of the body with a rapid turnover such as bone marrow, hair follicles, and the mucosa of the alimentary tract are the most affected. As a result, nutrition intake and nutrition status can be adversely affected. Nutrition-related symptoms include **myelosuppression** (suppression of bone marrow production of neutrophils, platelets, and red blood cells), anemia, fatigue, nausea and vomiting, loss of appetite, mucositis, changes in taste and smell, xerostomia (mouth dryness), dysphagia, and altered bowel function such as diarrhea or constipation (Table 37-6).

The severity of the side effects depends on the specific agents used, dosage, duration of treatment, number of treatment cycles, accompanying drugs, individual response, and current health status. The timely and appropriate use of supportive therapies such as antiemetics, antidiarrheals, hematopoietic agents, and antibiotics, as well as dietary changes, is important. Many people experience significant side effects, especially in “dose-intensive” multiple-agent

**TABLE 37-6****Nutrition-Related Effects of Antineoplastic Agents: Chemotherapy, Biotherapy, Hormone Therapy, and Anti-angiogenic Agents**

<b>Agent Classification</b>	<b>Common Nutrition Impact Symptom</b>
<b>Chemotherapy</b>	
<b>Alkylating Agents</b>	
• Cisplatin (Platinol), cyclophosphamide (Cytoxin), oxaliplatin (Eloxatin), temozolomide (Temodar)	• Myelosuppression, anorexia, nausea, vomiting, fatigue, renal toxicity
<b>Antitumor Antibiotics</b>	
• Bleomycin (Blenoxane), mitomycin (Mutamycin)	• Myelosuppression, anorexia, nausea, vomiting, fatigue, diarrhea, mucositis
<b>Antimetabolites</b>	
• Capecitabine (Xeloda), 5-fluorouracil (5-FU), gemcitabine (Gemzar), methotrexate	• Myelosuppression, anorexia, nausea, vomiting, fatigue, diarrhea, mucositis
<b>Plant Alkaloids</b>	
• Camptosar (Irinotecan), etoposide (VP-16), docetaxel (Taxotere), paclitaxel (Taxol), vinorelbine (Navelbine)	• Myelosuppression, anorexia, nausea, vomiting, fatigue, peripheral neuropathy
<b>Miscellaneous</b>	
• Procarbazine (Mutalane)	• Myelosuppression, nausea, vomiting, diarrhea, MAO inhibitor/avoid foods high in tyramine
<b>Biotherapy</b>	
<b>Cytokines</b>	
• Interferon-alfa (Intron A), interleukin (IL-2)	• Myelosuppression, anorexia, fatigue, nausea, flu-like symptoms, chills
<b>Monoclonal Antibodies</b>	
• Cetuximab (Erbitux), rituximab (Rituxan), trastuzumab (Herceptin)	• Infusion reaction of chills, fever, headache, hypotension; myelosuppression; nausea; vomiting; rash
<b>Small Molecule Inhibitors</b>	
• Erlotinib (Tarseva), Imatinib mesylate (Gleevec)	• Fever, chills, rash, diarrhea, fatigue, anorexia
<b>Hematopoietic Growth Factors</b>	
• Epoetin alfa (Procrit), pegfilgrastim (Neulasta)	• Fever, bone pain, flu-like symptoms, nausea
<b>Hormone Therapy</b>	
<b>Antiandrogens</b>	
• Bicalutamide (Casodex)	• Hot flashes, nausea, alterations in elimination (diarrhea or constipation)
<b>Antihormones</b>	
• Leuprolide (Lupron)	• Hot flashes, edema, nausea, anorexia
<b>Antiestrogens</b>	
• Anastrozole (Arimidex), tamoxifen (Novadex)	• Thrombophlebitis/embolism, fluid retention, hot flashes, nausea, joint discomfort, diarrhea
<b>Progrestins</b>	
• Megestrol acetate (Megace)	• Increased appetite, weight gain, fluid retention
<b>Antiangiogenic Agents</b>	
• Bevacizumab (Avastin)	• Hemorrhage, hypertension, diarrhea, abdominal pain, myelosuppression, wound healing complications

Data from Polovich M et al: Chemotherapy and biotherapy guidelines and recommendations for practice, Pittsburgh, 2009, Oncology Nursing Society; Wilkes GM, Barton-Burke M: 2010 oncology nursing drug handbook, Boston, 2010, Jones and Bartlett.

chemotherapy regimens; **neutropenia** (reduced white blood cells or neutrophils) and myelosuppression are the primary factors limiting chemotherapy administration. Commonly experienced chemotherapy induced toxicities affecting the GI system include mucositis, nausea, vomiting, diarrhea, and constipation. Chemotherapy related taste abnormalities can lead to anorexia and decreased oral intake. Symptoms of GI toxicity are usually temporary; however, some multiagent chemotherapy regimens may lead to lasting GI side effects.

## Diarrhea

Diarrhea is a common side effect of certain chemotherapy agents. Left unmanaged, it can lead to depletion of fluids, electrolytes, malnutrition, and even hospitalization (Muehlbauer et al., 2009). The intestinal mucosa and digestive processes can be affected, thus altering digestion and absorption to some degree. Protein, energy, and vitamin metabolism may be impaired. Total lymphocyte count is often depressed and does not accurately reflect nutrition status after chemotherapy administration.

## Nausea and Vomiting

Chemotherapy induced nausea and vomiting are commonly classified as anticipatory (occurs before receiving treatment), acute (occurs within the first 24 hours after receiving treatment), or delayed (occurs 1 to 4 days after treatment), each of which is characterized by distinct pathophysiologic events and requires different therapeutic interventions (NCCN, 2010). Effective agents for treatment-related nausea and vomiting are the serotonin antagonists (e.g., ondansetron, granisetron, and dolasetron), neurokinin-1 (NK-1) receptor antagonists (e.g., aprepitant), dopamine antagonists (e.g., metoclopramide, prochlorperazine), and corticosteroids such as dexamethasone (Polovich et al., 2009; Tipton et al., 2007). Other antiemetic agents include cannabinoids (e.g., dronabinol, nabilone) and anxiolytics (e.g., lorazepam).

## Food-Drug Interactions

Dietetic professionals can gain valuable insights regarding possible drug-nutrient interactions and contraindications by reviewing product medication inserts, pharmacy resource books, and medication databases or by consulting with pharmacy personnel (see Chapter 9 and Appendix 31). Some chemotherapy agents can cause potentially severe adverse events (Grant and Byron, 2006); for example:

- Individuals with certain types of lung cancer who are being treated with pemetrexed (Alimta) require vitamin B<sub>12</sub> and folic acid supplementation throughout the duration of their therapy to avoid significant anemia associated with this chemotherapy agent.
- A severe hypertensive event is possible when tyramine-rich foods and beverages are consumed while taking procarbazine (Mutalane), a chemotherapy agent commonly used to treat brain cancer (see Chapter 9).

- Individuals with colon cancer receiving oxaliplatin (Eloxatin) should not drink, eat, or handle cold drinks or foods for up to 5 days because of treatment-related dysesthesias or transient paresthesias of the hands, feet, and throat.
- In order to prevent unnecessary gastric upset, individuals taking the medication, capecitabine (Xeloda), must take the medication within 30 minutes of eating food or a meal. Conversely, medications such as erlotinib (Tarceva) should not be taken with food and it can cause a rash and profound diarrhea unless taken on an empty stomach.

## Oral Changes

People with altered taste acuity (dysgeusia, hypogeusia, ageusia) may benefit from increased use of flavorings and seasonings during food preparation. Meat aversions may require the elimination of red meats, which tend to be strong in flavor, or the substitution of alternative protein sources. Herpes simplex virus and *Candida albicans* (thrush) account for most oral infections. In addition to causing oral infections, some agents, especially corticosteroids, can cause hyperglycemia and can lead to excessive losses of urinary protein, potassium, and calcium.

## Mucositis

Oral **mucositis**, an inflammation of the mucous membranes lining the oropharynx and esophagus, is a common side effect of some types of chemotherapy (Figure 37-1). Although many interventions exist, most strategies lack scientific evidence (Harris et al., 2008). General care guidelines include recommending daily oral care (e.g., keeping the mouth clean, avoidance of tobacco, alcohol, and irritating foods) and the use of bland rinses (e.g., baking soda or saline rinses). Bland liquids and soft solids are usually better tolerated in individuals with oral or esophageal mucositis and strong-flavored, acidic, or spicy foods should also be avoided. Commercially prepared liquid medical food supplements can be useful.

## Biotherapy

**Biotherapy** is immunotherapy, a group of cancer treatment drugs prescribed to stimulate the body's own immune system and natural defenses to treat cancer. Biotherapy is sometimes used by itself, but it is most often given in combination with chemotherapy drugs. Different kinds of biotherapy drugs used to help the immune system recognize cancer cells and strengthen its ability to destroy them include:

- **Cytokines** such as interferon and IL-2 for treatment of malignant melanoma and metastatic melanoma
- **Monoclonal antibodies** such as trastuzumab (Herceptin) for treatment of specific types of breast cancer, and rituximab (Rituxan) for treatment of NHL
- **Cancer vaccines** made from an individual's own cancer or substances from tumor cells are currently under

**FIGURE 37-1** Oral mucositis. (From Kanski JL: *Clinical diagnosis in ophthalmology*, ed 1, 2006, Elsevier.)

investigation in clinical cancer trials (Wilkes and Barton-Burke, 2010).

Other types of biotherapy drugs are groups of proteins that cause blood cells to grow and mature (NCI, 2010d). These drugs are called **hematopoietic growth factors** and they include supportive care medications such as darbepoetin (Aranesp) or epoetin alfa (Procrit) to stimulate red blood cell production, and filgrastim (Neupogen) or pegfilgrastim (Neulasta) to stimulate the production of neutrophils in the bone marrow (Polovich et al., 2009). Individuals receiving these agents may experience fatigue, chills, fever, and flulike symptoms.

### Hormone Therapy

Hormone therapy adds, blocks, or removes hormones to slow or stop the growth of hormone-sensitive breast or prostate cancer (NCI, 2010d). Examples of these agents include tamoxifen (Nolvadex) and anastrozole (Arimidex) for breast cancer and leuprolide (Lupron) or bicalutamide (Casodex) for prostate cancer (Wilkes and Barton-Burke, 2010). Side effects commonly include hot flashes, decreased libido, and bone pain.

### Antiangiogenic Therapy

**Antiangiogenic therapy** prevents or reduces the growth of new blood vessels, and prevents tumor invasion. These agents are most frequently used in combination with other chemotherapy agents to maximize their effectiveness. An example of an antiangiogenic agent used to treat colon or breast cancer is bevacizumab (Avastin).

### Radiation Therapy

Radiation therapy, ionizing radiation used in multiple fractionated doses, is used to cure, control, or palliate cancer. Radiation therapy can be delivered externally into the body from a megavoltage machine or with brachytherapy

by placing a radioactive source (implant) in or near the tumor to deliver a highly localized dose. Advances in technology to deliver radiation therapy with precise accuracy include radiation surgery (e.g., stereotactic radiosurgery) and intensity-modulated radiation therapy (IMRT). Whereas chemotherapy is a systemic therapy, radiation therapy affects only the tumor and the surrounding area. The side effects of radiation therapy are usually limited to the specific site being irradiated. Chemotherapy agents may also be given in combination with radiation therapy to produce a radiation-enhancing effect. People receiving multimodality therapy often experience side effects sooner and with greater intensity.

The acute side effects of radiation therapy when used alone generally occur around the second or third week of treatment, and usually resolve within 2 to 4 weeks after the radiation therapy has been completed. Late effects of radiation therapy may happen several weeks, months, or even years after treatment. Commonly experienced nutrition-related symptoms include fatigue, loss of appetite, skin changes, and hair loss in the area being treated (Table 37-7).

### Radiation to the Head and Neck

Treatment for head and neck cancer usually includes a multimodality approach with aggressive chemotherapy, radiation therapy, and often surgery. Radiation therapy to the head and neck can cause acute nutrition-related symptoms: sore mouth, altered taste and smell, dysphagia and odynophagia, mucositis, xerostomia, anorexia, fatigue, and weight loss (Havrila et al., 2010). Prophylactic placement of percutaneous endoscopic gastrostomy (PEG) feeding tubes can help to reduce treatment-associated weight loss and malnutrition (Cady, 2007).

Salivary stimulants and substitutes or oral lubricants are beneficial for temporary relief of xerostomia (diminished salivation or loss of salivation) caused by head and neck radiation therapy or certain types of medications (e.g., pain medications). In addition, liquids and foods with sauces and gravies are usually well tolerated. Late effects of radiation therapy may include dental caries, permanent xerostomia, **trismus** (an inability to fully open the mouth), and **osteoradionecrosis** of the jaw (necrosis of the bone caused by exposure to radiation therapy).

Before beginning therapy, individuals should undergo a dental evaluation and thorough teeth cleaning and receive instruction in good oral hygiene and care, including daily brushing and rinsing (National Institute of Dental and Craniofacial Research, 2010). After therapy has been completed, individuals should continue to have close dental monitoring and follow-up. Individuals may also benefit from a referral to a speech therapist for assessment and evaluation of swallowing function.

### Radiation to the Thorax

Nutrition-related symptoms of radiation therapy to the thorax (chest) can include heartburn and acute esophagitis,

**TABLE 37-7****Nutrition-Related Effects of Radiation Therapy**

<b>Site of Radiation Therapy</b>	<b>Common Nutrition-Related Symptom</b>
Central nervous system (brain and spinal cord)	<p><b>Acute Effects</b></p> <p>Nausea, vomiting Fatigue Loss of appetite Hyperglycemia associated with corticosteroids</p> <p><b>Late Effects (&gt;90 days after treatment)</b></p> <p>Headache, lethargy</p>
Head and neck (tongue, larynx, pharynx, oropharynx, nasopharynx, tonsils, salivary glands)	<p><b>Acute Effects</b></p> <p>Xerostomia Mucositis Sore mouth and throat Dysphagia, odynophagia Alterations in taste and smell Fatigue Loss of appetite</p> <p><b>Late Effects (&gt;90 days after treatment)</b></p> <p>Mucosal atrophy and dryness Salivary glands—xerostomia, fibrosis Trismus Osteoradionecrosis Alterations in taste and smell</p>
Thorax (esophagus, lung, breast)	<p><b>Acute Effects</b></p> <p>Esophagitis Dysphagia, odynophagia Heartburn Fatigue Loss of appetite</p> <p><b>Late Effects (&gt;90 days after treatment)</b></p> <p>Esophageal—fibrosis, stenosis, stricture, ulceration Cardiac—angina on effort, pericarditis, cardiac enlargement Pulmonary—dry cough, fibrosis, pneumonitis</p>
Abdomen and pelvis (stomach, ovaries, uterus, colon, rectum)	<p><b>Acute Effects</b></p> <p>Nausea, vomiting Changes in bowel function—diarrhea, cramping, bloating, gas Changes in urinary function—increased frequency, burning sensation with urination Acute colitis or enteritis Lactose intolerance Fatigue Loss of appetite</p> <p><b>Late Effects (&gt;90 days after treatment)</b></p> <p>Diarrhea, malabsorption, maldigestion Chronic colitis or enteritis Intestinal—stricture, ulceration, obstruction, perforation, fistula Urinary—hematuria, cystitis</p>

Data from: Bruner DW et al: Manual for radiation oncology and nursing practice and education, ed 3, Pittsburgh, 2005, Oncology Nursing Society; Havrila C et al: Medical and radiation oncology. In Marian M, Roberts S, editors: Clinical nutrition for oncology patients, Sudbury, MA, 2010, Jones and Bartlett.

accompanied by dysphagia and odynophagia. Late effects include possible esophageal fibrosis and stenosis. When this occurs, individuals are generally only able to swallow liquids, and the use of medical food supplements and nutrition support enteral nutrition (EN) may be necessary to meet nutritional needs. Often, individuals undergo esophageal dilations or swallowing therapy and rehabilitation to improve swallowing function.

### Radiation to the Abdomen or Pelvis

Radiation therapy to the abdomen or pelvis may cause gastritis or enteritis that can be accompanied by nausea, vomiting, diarrhea, and anorexia (Muehlbauer et al., 2009). Late effects can include lasting GI damage such as malabsorption of disaccharides (e.g., lactose), fats, vitamins, minerals, and electrolytes. Proactive management includes encouraging affected individuals to consume soluble fiber, to increase intake of hydrating liquids, and to avoid eating high non-soluble fiber or lactose containing foods. To alleviate symptoms, medications such as antidiarrheals like loperamide and antimotility agents (e.g., metoclopramide) may be given to reduce intestinal motility.

Chronic radiation enteritis can develop with diarrhea, ulceration, or obstruction, intensifying the risk of malnutrition. Chronic radiation enteritis combined with or without significant bowel resection can result in bowel dysfunction (see Chapter 29 regarding short bowel syndrome [SBS]). The severity of this condition depends on the length and location of the nonfunctional or resected bowel, and generally is diagnosed when the individual has less than 150 cm of small intestine remaining. The sequelae of SBS include malabsorption, malnutrition, dehydration, weight loss, fatigue, and lactose intolerance (Havrila et al., 2010).

Initially parenteral nutrition (PN) may be required, and frequent monitoring of fluids and electrolytes may be necessary for weeks or months. Individuals with SBS may require an oral diet restricted to defined formula tube feedings or to frequent small meals high in protein, low in fat and fiber, and lactose-free. Dietary supplements that contain vitamin B<sub>12</sub>; folic acid; thiamin; calcium; and vitamins A, E, and K are often indicated to prevent deficiencies. Serum concentrations of various minerals should also be monitored and adjusted as needed.

### Total-Body Irradiation

Total-body irradiation (TBI) is a technique of radiation therapy that is used in hematopoietic cell transplantation (HCT) to eliminate malignant cells, to ablate the bone marrow and make room for the engraftment of the infused hematopoietic cells, and to suppress the immune system to decrease the risk of rejection. Commonly encountered side effects are fever, nausea, vomiting, headache, mucositis, parotitis (inflammation of the parotid glands), xerostomia, diarrhea, anorexia, fatigue, and associated weight loss.

### Surgery

The surgical resection or removal of any part of the alimentary tract (mouth to anus), as well as the malignant disease process, can potentially impair normal digestion and absorption (Huhmann and August, 2010). Surgery may be used as a single mode of cancer treatment, or it may be combined with preoperative or postoperative adjuvant chemotherapy or radiation therapy. After surgery, individuals commonly experience fatigue, temporary changes in appetite and bowel function caused by anesthesia, and pain. They often require additional energy and protein for wound healing and recovery. Most side effects are temporary and dissipate after a few days following surgery. However, some surgical interventions have long-lasting nutritional implications (Table 37-8). When performing a nutrition assessment, it is very important to understand which part of the alimentary tract has been affected or surgically removed so the appropriate nutrition intervention can be recommended. Refer to Chapter 1 for a review gastrointestinal physiology.

### Head and Neck Cancer

Individuals with head and neck cancer often have difficulty with chewing and swallowing caused by the cancer itself or the specific surgical intervention required to remove cancerous tissues. There can be additional problems because of history of smoking and alcohol abuse, illicit drug use, and subsequent poor nutrition intake, which place them at high risk for malnutrition and postoperative complications. Surgery often necessitates temporary or long-term reliance on EN support (e.g., PEG tube feedings). See Chapter 14. Individuals who resume oral intake often have prolonged dysphagia and require modifications of food consistency and extensive training in chewing and swallowing. Referrals to a speech therapist can yield dramatic positive results through evaluation and individualized instruction in swallowing and positioning techniques, as well as evaluation for aspiration risk.

### Esophageal Cancer

Surgical intervention for treatment of esophageal cancer often requires partial or total removal of the esophagus. The stomach is commonly used for esophageal reconstruction. A feeding jejunostomy tube, which allows for early postoperative tube feedings, can be placed before an individual undergoes surgery or at the time of surgery. Usually the individual is able to progress to oral intake with specific dietary recommendations to minimize nutrition-related symptoms, which include reflux, dumping syndrome (discussed later in this chapter), dysmotility, gastroparesis, early satiety, vomiting, and fluid and electrolyte imbalances (Huhmann and August, 2010). Postsurgical recommendations include a low-fat diet with small, frequent feedings of energy-dense foods and avoidance of large amounts of fluids at any one time (see Chapter 28).

**TABLE 37-8****Nutrition-Related Effects of Surgery in Cancer Treatment**

Anatomic Site	Nutrition Impact Symptoms
Oral cavity	Difficulty with chewing and swallowing Aspiration potential Sore mouth and throat Xerostomia Alteration in taste and smell
Larynx	Alterations in normal swallowing, dysphagia Aspiration potential
Esophagus	Gastroparesis Indigestion, acid reflux Alterations in normal swallowing, dysphagia Decreased motility Anastomotic leak
Lung	Shortness of breath Early satiety
Stomach	Dumping syndrome Dehydration Early satiety Gastroparesis Fat malabsorption Vitamin and mineral malabsorption (vitamin B <sub>12</sub> and D; calcium, iron)
Gallbladder and bile duct	Gastroparesis Hyperglycemia Fluid and electrolyte imbalance Fat malabsorption
Liver	Vitamin and mineral malabsorption (vitamin A, D, E, and K; magnesium, calcium, zinc, iron) Hyperglycemia Hypertriglyceridemia Fluid and electrolyte malabsorption
Pancreas	Vitamin and mineral malabsorption (vitamin A, D, E, K, B <sub>12</sub> and folic acid, magnesium, zinc) Gastroparesis Fluid and electrolyte imbalance Hyperglycemia Fat malabsorption (vitamin A, D, E, K and B <sub>12</sub> ; calcium, zinc, iron)
Small bowel	Chyle leak Lactose intolerance Bile acid depletion Diarrhea Fluid and electrolyte imbalance
Colon and rectum	Vitamin and mineral malabsorption (vitamin A, D, E, K, and B <sub>12</sub> ; calcium, zinc, iron) Increased transit time Diarrhea Dehydration Bloating, cramping, gas Fluid and electrolyte imbalance
Ovaries and uterus	Vitamin and mineral malabsorption (vitamin B <sub>12</sub> , sodium, potassium, magnesium, calcium) Early satiety Bloating, cramping, and gas
Brain	Nausea, vomiting Hyperglycemia associated with corticosteroids

Data from Elliott L et al., editors: The clinical guide to oncology nutrition, ed 2, Chicago, 2006, American Dietetic Association; Huhmann MB, August D: Surgical oncology. In Marian M, Roberts S, editors: Clinical nutrition for oncology patients, Sudbury, MA, 2010, Jones and Bartlett.

## Gastric Cancer

Surgery is the most common treatment for cancer of the stomach, although chemotherapy and radiation therapy can be used before or after surgery to improve survival. Surgical interventions include partial, subtotal, or total gastrectomy. Placement of a jejunostomy feeding tube at surgery is advisable, and enteral nutrition (EN) support using a jejunal feeding tube is generally feasible within a few days after surgery.

Postgastrectomy syndrome encompasses a myriad of symptoms, including dumping syndrome, fat malabsorption, gastric stasis, lactose intolerance, anemias, and metabolic bone disease (osteoporosis, osteopenia, osteomalacia). **Dumping syndrome** is a common complication of gastric surgery, manifested by the rapid transit of foods or liquids, and the dilutional response of the small remaining stomach to highly osmotic bolus feedings. Individuals may experience GI and vasomotor symptoms such as abdominal cramps, diarrhea, nausea, vomiting, flushing, faintness, diaphoresis, and tachycardia (Huhmann and August, 2010). Individuals experiencing dumping syndrome should limit simple carbohydrates and liquids at meal times. See Chapter 28 for further recommendations for managing dumping syndrome.

Malabsorption is another complication of gastric surgery; deficiency of iron, folic acid, and less commonly vitamin B<sub>12</sub> can lead to anemia. Micronutrient deficiencies of calcium and fat-soluble vitamins are also common (Huhmann and August, 2010). Individuals benefit from consumption of six to eight small meals per day, with fluids taken between meals. There may be fat intolerance, especially if the vagal nerve is severed. Administration of pancreatic enzymes with meals may help when the duodenal mixing of food and pancreatic juices is inadequate.

## Pancreatic Cancer

Cancer of the pancreas, with or without surgical resection, can have significant nutritional consequences. The Whipple procedure and the pylorus-sparing pancreatic duodenectomy are the most common pancreatic cancer surgeries. Postsurgical complications include delayed gastric emptying, early satiety, glucose intolerance, bile acid insufficiency, diarrhea, and fat malabsorption. Pancreatic enzyme replacement, the use of small, more frequent low-fat meals and snacks, and avoidance of simple carbohydrates aid digestion and absorption.

## Cancers of the Intestinal Tract

Partial or total resections of the intestinal tract because of colorectal cancer or carcinoid syndrome may induce profound losses of fluid and electrolytes secondary to decreased transit time and diarrhea, the severity of which is related to the length and site of the resection. Resections of as little as 15 cm of the terminal ileum can result in bile salt losses that exceed the liver's capacity for resynthesis, and vitamin B<sub>12</sub> absorption is affected. With depletion of the bile salt

pool, steatorrhea develops. Nutrition intervention strategies consist of a diet low in fat, osmolality, lactose, and oxalates (see Chapters 29).

## Hematopoietic Cell Transplantation (HCT)

HCT is performed for the treatment of certain hematologic cancers such as leukemia, lymphoma, and multiple myeloma. The stem cells used for HCT arise from bone marrow, peripheral blood, or umbilical cord blood. The preparative regimen includes cytotoxic chemotherapy, with or without total-body irradiation (TBI). This treatment regimen is followed by intravenous (IV) infusion of hematopoietic cells from the individual (autologous) or from a histocompatible related or unrelated donor (allogeneic) or from an identical twin (syngeneic) (National Marrow Donor Program, 2010).

HCT procedures can significantly affect nutrition status. Dietetic professionals should conduct a thorough nutrition assessment of the individual before the initiation of therapy and reassessments and monitoring throughout the entire transplant course. The acute toxicities of immunosuppression that can last for 2 to 4 weeks after the transplant include nausea, vomiting, anorexia, dysgeusia, stomatitis, oral and esophageal mucositis, fatigue, and diarrhea. In addition, immunosuppressive medications can also adversely affect nutrition status.

Individuals typically have little or no oral intake and the GI tract is compromised during the first few weeks following transplant. Parenteral nutrition (PN) has become a standard component of care (Robien, 2010). Gastrostomy tubes are useful for long-term nutrition support; the PN should be reserved for individuals who are unable to tolerate oral or enteral feeding (ADA, 2010a). In addition, administration of optimal levels of PN is often complicated by the frequent need to interrupt it for the infusion of antibiotics, blood products, and IV medications. Careful monitoring and the use of more concentrated nutrient solutions, increased flow rates and volumes, and double- or triple-lumen catheters are needed.

Autologous HCT involves the use of the individual's own stem cells to reestablish hematopoietic stem cell function after the administration of high-dose chemotherapy. In some cases the use of mobilized stem cell progenitors has replaced autologous bone marrow as the source of hematopoietic progenitors for transplantation. Their use has shortened the period of **pancytopenia** (reduction in the cellular components of the blood), when individuals are at risk for bleeding, serious infections, or sepsis. These advances, along with improved prophylactic antibiotic regimens that are relatively easy to administer, have allowed individuals to receive autologous marrow transplantation in the outpatient setting. The reduced cost of transplantation has made it available to an increased number of people.

Because a majority of people receive much of their care outside the hospital, regular nutrition assessment and monitoring are important (Robien, 2010). The HCT procedure is associated with severe nutritional consequences that require prompt, proactive intervention. Nausea, vomiting,

and diarrhea are caused by the cytotoxic conditioning regimen and may later accompany antibiotic administration. Complications of delayed-onset nutrition-related symptoms include varying degrees of mucositis, xerostomia, and dysgeusia. Mucositis, which is often severe and extremely painful, develops in more than 75% of transplant patients (see Figure 37-1).

### Nutritional Precautions with Neutropenia

Individuals receiving HCT become immunocompromised and require supportive therapy, including medications and dietary changes to prevent infection. Of note, some cancer centers continue to prescribe a low-microbial or low-bacteria diet for people with low white blood cell counts (neutropenia). However, there is no clear evidence to support a strict “neutropenic” diet (only cooked foods) to reduce overall rates of infection or death (Gardner et al., 2008). Thus individuals should be instructed on food safety practices (Grant et al., 2010; Seattle Cancer Care Alliance [SCCA], 2010) that include:

- Avoidance of foods that contain unsafe levels of bacteria (raw meats, spoiled or moldy foods, and unpasteurized beverages)
- Thorough hand washing
- Special handling of raw meats, game, poultry, and eggs, utensils, cutting boards, and countertops
- Avoidance of untested well water
- Storage of foods at appropriate temperatures (below 40° F and above 140° F).

### Graft-versus-Host Disease (GVHD)

**Graft-versus-host disease (GVHD)** is a major complication seen primarily after allogeneic transplants, in which the donated “donor” stem cells react against the tissues of the transplant recipient “host.” The functions of several target organs (skin, liver, gut, lymphoid cells) are disrupted and are susceptible to infection. Acute GVHD can occur within the first 100 days after the transplant and may be seen as early as 7 to 10 days posttransplant. It may resolve, or it may develop into a chronic form that requires long-term treatment and dietary management. Skin GVHD is characterized by a maculopapular rash. GVHD of the liver, evidenced by jaundice and abnormal liver function tests, often accompanies GI GVHD and further complicates nutrition management.

The symptoms of acute GI GVHD can be severe; individuals may experience gastroenteritis, abdominal pain, nausea, vomiting, and large volumes of secretory diarrhea. Immunosuppressive medications and a phased dietary regimen should be instituted (Charuhas, 2006; SCCA, 2010). The first phase consists of total bowel rest and the use of PN until diarrhea subsides. Nitrogen losses associated with diarrhea can be severe and are compounded by the high-dose corticosteroids used to treat GVHD. The second

phase reintroduces oral feedings of beverages that are isosmotic, low-residue, and lactose-free so as to compensate for the loss of intestinal enzymes secondary to alterations in the intestinal villi and mucosa. If these beverages are tolerated, phase three includes the reintroduction of solids that contain low levels of lactose, fiber, fat, and total acidity and no gastric irritants. In phase four dietary restrictions are progressively reduced as foods are gradually introduced and tolerance is established. Phase five includes the resumption of the individual’s regular diet.

Chronic GVHD can develop up to 3 months after transplant and is observed with increased frequency in nonidentical related donors and unrelated donors. Chronic GVHD can affect the skin, oral mucosa (ulcerations, stomatitis, xerostomia), and the GI tract (anorexia, reflux symptoms, diarrhea) and can cause changes in body weight.

Another transplant-related complication is **sinusoidal obstructive syndrome (SOS)** (also known as venoocclusive disease), characterized by chemotherapy- or radiation therapy-induced damage to the hepatic venules. It can develop 1 to 3 weeks after transplant. Symptoms of right upper quadrant discomfort, hepatomegaly, fluid retention, and jaundice can occur; in severe cases individuals may experience progressive hepatic failure leading to encephalopathy and multiple-organ system failure. Nutrition support requires concentrated parenteral nutrients, careful fluid and electrolyte management, close monitoring, and adjustment of macronutrients and micronutrients based on the tolerance and response of each individual. The use of branched-chain amino acid formula is controversial. Serum ammonia level may not be a reliable indicator of protein tolerance, or of the development of encephalopathy (see Chapter 30).

Other acute or chronic complications of HCT include osteoporosis, pulmonary disease, impaired renal function, rejection of the graft, growth abnormalities in children, sepsis, and infection. Nutrition-related symptoms associated with HCT may persist; individuals receiving outpatient marrow transplantation require frequent monitoring and intervention.

## NUTRITION MONITORING AND EVALUATION

Dietetic professionals must determine and quantify their patients’ nutrition care goals by monitoring progress, measuring and evaluating outcomes and changes, and documenting this information throughout the process. See Chapter 11.

### Physical Activity

Physical activity is an important part of cancer care. The effect of cancer and cancer treatment on the individual’s quality of life should be addressed throughout cancer treatment and continue until the individual is able to

successfully resume activities of daily living. Recovery from cancer treatment also requires physical activity to rebuild muscle; regain strength, energy and flexibility; and help relieve symptoms of stress, anxiety, and even depression. Physical activity and exercise may be helpful in strengthening the immune system. However, before participating in any type of physical activity and exercise program, individuals should be advised to undergo evaluation by qualified professionals, who can then design an individualized physical assessment and activity plan. The American College of Sports Medicine (ACSM) now offers a certification program for trainers working with people diagnosed with cancer (a Certified Cancer Exercise Trainer) (ACSM, 2010). In addition, community-based programs such as the YMCA's LiveStrong are available across the United States and offer physical activity and exercise opportunities to support cancer survivors; see [www.livestrong.org/ymca](http://www.livestrong.org/ymca).

## PEDIATRIC CANCER

Like adults, children with cancer can experience malnutrition and nutrition-related symptoms as a result of their cancer and its treatment. The incidence of malnutrition ranges from 6% to 50% in the pediatric population, depending on the type, stage, and location of the cancer. It usually has greater severity in the presence of more aggressive cancers in later stages of the disease.

Psychogenic food refusal in children requires interventions that address underlying psychological issues. Families and caregivers often express their fears of dying through an extreme preoccupation with eating and maintaining weight. Creative efforts are required to minimize the psychological effects of fear, unpleasant hospital routines, unfamiliar foods, learned food aversions, and pain. Nutrition intervention strategies that use oral intake should stress the maximum use of favorite, nutrient-dense foods during times when intake is likely to be best and food aversions are least likely to occur. Oral medical foods can be useful, but their acceptance is often a problem; thus children should be offered a selection from which to choose.

EN support by nasogastric tube is indicated for selected children who are able to cooperate and who have functional GI tracts. Some children have even been taught to pass their own nasogastric tube for intermittent or nighttime feedings. It should be remembered, however, that aspiration is always a potential risk. PN is indicated for children who are receiving intense treatment associated with severe GI toxicity, and for children with favorable prognoses who are malnourished or have a high risk of developing malnutrition. PN is seldom indicated for children with advanced cancer associated with significant deterioration or with diseases that are unresponsive to therapy.

Universally accepted, evidenced-based guidelines for children diagnosed with cancer do not exist. However, the American Society for Parenteral and Enteral Nutrition (ASPEN) has established standards for the nutrition screening and

specialized nutrition support for all hospitalized pediatric patients (Wessel et al., 2005). The nutritional requirements of pediatric patients with cancer are similar, with an adjustment for activity, to those of normal growing children. Often pediatric patients with cancer are not bedridden, but are as active as their healthy peers. Factors that may alter nutrient requirements in cancer include the effect of the disease on host metabolism; the catabolic effects of cancer therapy; and physiologic stress from surgery, fever, malabsorption, and infection. Fluid requirements are increased during anticancer therapy or in the presence of fever, diarrhea, or renal failure. Micronutrients may require supplementation during periods of poor intake, stress, or malabsorption.

The best long-term indicator of adequate nutrient intake is growth. Children have increased nutritional requirements for growth and development that must be met despite extended periods of cancer treatment (see Chapters 17 through 19). A special vulnerability exists during the adolescent growth spurt. Ewing sarcoma is frequently associated with malnutrition.

Another reason why children with advanced cancer are at greater risk of severe nutritional depletion than adults is the frequent use of more aggressive, multimodality treatment. The long-term nutritional effects of cancer and its treatment in children are not well documented. Deficiencies in energy and protein can be expected to affect growth adversely, although the effects may be temporary, and catch-up growth depends on how much energy children are able to consistently consume (Corrales and Utter, 2005; Ringwald-Smith et al., 2006). However, some cancer treatment regimens may have an effect on growth and development that is independent of nutritional deprivation. HCT is now an accepted and increasingly successful intensive therapy for a wide range of disorders in children. Many supportive therapies may be safely managed in the outpatient arena, thus reducing the period of hospitalization.

## NUTRITION RECOMMENDATIONS FOR CANCER SURVIVORS

From the time of diagnosis through the balance of life, the ACS defines anyone living with a cancer diagnosis as a *cancer survivor* (Doyle et al., 2006). The ACS guidelines as well as the WCRF and AICR recommendations provide sound diet, nutrition, and physical activity advice for primary cancer prevention and health for all individuals, including cancer survivors. In addition, the ACS has published a Guide for Informed Choices for Nutrition and Physical Activity for cancer survivors. The ACS specifically declined to call these a set of "guidelines" or "recommendations" because the evidence in this area of study is not as plentiful as in the primary prevention realm.

Cancer survivors represent one of the largest groups of people living with a chronic disease. It is estimated that there were 11 million survivors in the United States in 2009,

and a projected number of 20 million in 2020 (Cancer Facts and Figures, 2009). The majority of individuals with cancer are able to return to full function and regain quality of life. This trend is expected to continue because of recent awareness in cancer prevention, advances in cancer detection, development of more effective cancer treatments, and advancements in determining the genetic causes of cancer. Nutrition can be a very important component in the long-term survival plan.

## COMPLEMENTARY AND INTEGRATIVE ONCOLOGY

*Integrative, complementary, and alternative medicine* describe therapies used by persons interested in the promotion of health or symptom management. **Complementary therapies** are typically noninvasive, inexpensive, and useful in controlling symptoms and improving quality of life during and after cancer treatment; they are used in addition to conventional medicine. Conversely, **alternative medicine** is used instead of conventional anticancer treatment; it can be expensive, possibly harmful, and may interfere with treatments or medications. **Integrative medicine** or integrative oncology is emerging as the preferred term to differentiate between alternative therapies that are unproven and potentially unsafe, and therapies that are more evidenced-based (Belk, 2006; Wesa et al., 2008). Integrative medicine works to integrate evidence-based complementary therapies into conventional cancer treatment. Integrative medicine uses strategies to promote self-empowerment, individual responsibility, and lifestyle changes that can potentially reduce risk for both cancer recurrence and second primary tumors (Sagar, 2009). Most experts agree that a large proportion of cancer survivors participate in these modalities; several studies report more than 90% participate in some form of CAM during and after treatment (Hardy, 2008).

The health care team working in oncology needs to be informed on the different therapies and knowledgeable regarding resources used to evaluate and educate the individuals in their care. Some cancer centers are fortunate; increasing consumer demand has encouraged health care institutions to create “Integrative Medicine” departments with onsite complementary services. Cancer survivors look for open, honest discussions or recommendations from their health care team. Medical, nursing, and nutrition assessments should include open-ended questions on dietary supplement use, such as, “What vitamins, minerals, herbs, or other dietary supplements are you currently taking?” and questions regarding the additional integrative or complementary therapies they are following at this time. The core components to discuss CAM therapies involve understanding and respecting the need people have to do something for themselves; having a willingness to listen to, explore, and respond frankly to questions; taking the time to discuss the options and offer advice; summarizing the discussion; documenting the dialog; and monitoring the progress of the therapy.

The NIH established a National Center for Complementary and Alternative Medicine (NCCAM) in 1999 and works to create a framework in which to evaluate and research CAM. See Box 37-2.

### Dietary Supplements

The most common form of CAM practiced in the United States is the use of dietary supplements. Consumers spend in excess of \$23 billion every year on natural products marketed to maintain or enhance health (Ashar, 2008). The largest percentage (18%) use nonvitamin, nonmineral natural products such as fish oil supplements and ginseng (Barnes, 2008). That number jumps significantly when surveying cancer survivors, in whom significant use occurs (Hardy, 2008). A primary motivation is symptom management but most also hope for tumor suppression (Wesa et al., 2008).

Nondisclosure of use is a common occurrence, with a reported 53% of individuals receiving chemotherapy not

### BOX 37-2

#### The National Center for Complementary and Alternative Medicine (NCCAM) Categories of Medical Systems

**Whole Medical Systems:** Western and non-Western practices of medicine built on complete systems of theory and practice. Examples include homeopathic medicine, naturopathic medicine, traditional Chinese medicine, and ayurvedic medicine.

**Mind-Body Therapies:** Mind-body therapies “utilize a variety of methods to enhance the mind’s capacity to affect bodily function and symptoms.” Examples include meditation, guided imagery, prayer, yoga, and music therapy.

**Biologically Based Practices:** These practices use substances found in nature and includes therapeutic diets, herbs and botanicals, and other dietary supplements.

**Manipulative and Body-based Practices:** Treatments of this type involve manipulation of one or more parts of the body. Examples are chiropractic medicine, massage therapy, and reflexology.

**Energy Medicine:** The two types of therapy in this domain: biofield and bioelectric magnetic-based, work to affect the purported energy field that surrounds and penetrates the body. The existence of such fields has not been scientifically proven. Biofield therapies include qi gong, Reiki, and therapeutic touch. Bioelectric magnetism includes the unconventional use of pulsed fields and magnetic fields.

Data from National Center for Complementary and Alternative Medicine (NCCAM): Main page, 2010. Accessed 23 October 2010 from <http://nccam.nih.gov/>.

discussing use of dietary supplements with their health care team (Hardy, 2008). Unfortunately, many people view dietary supplements as natural, inexpensive alternatives for prescription medications or a quick, easy remedy to an underlying medical problem. Distrust of the medical system, fear of being “fired” or dismissed by their doctor, or anticipated ignorance from the health care team may prevent cancer survivors from discussing use of dietary supplements. Ashar and Lee outline five steps: 1) inquire about use, 2) evaluate the supplement, 3) discuss any relevant regulatory issues, 4) discuss available safety and efficacy data, and 5) compare risks and benefits of use to available conventional therapies (Ashar et al., 2008). Although time consuming, conversations that include most or all of these steps will not only help open lines of communication between health care provider and survivor, but also help prevent an adverse event

or poor treatment decisions. Table 37-9 lists some of the commonly used supplements.

## Diet Therapies

**Metabolic therapy** is a term used for a variety of cancer management methods, including unproven and disproved diagnostic methods and treatments (ACS, 2009b). Metabolic practitioners generally claim that diseases, including cancer, are caused by an accumulation of toxic substances in the body. They allege that, if these toxins are removed, the body can heal itself naturally. Three basic steps are common to metabolic therapy: detoxification, strengthening of the immune system, and the use of special modalities to attack cancer. These therapy regimens generally include colonic cleansing with coffee, wheat grass, or other substances;

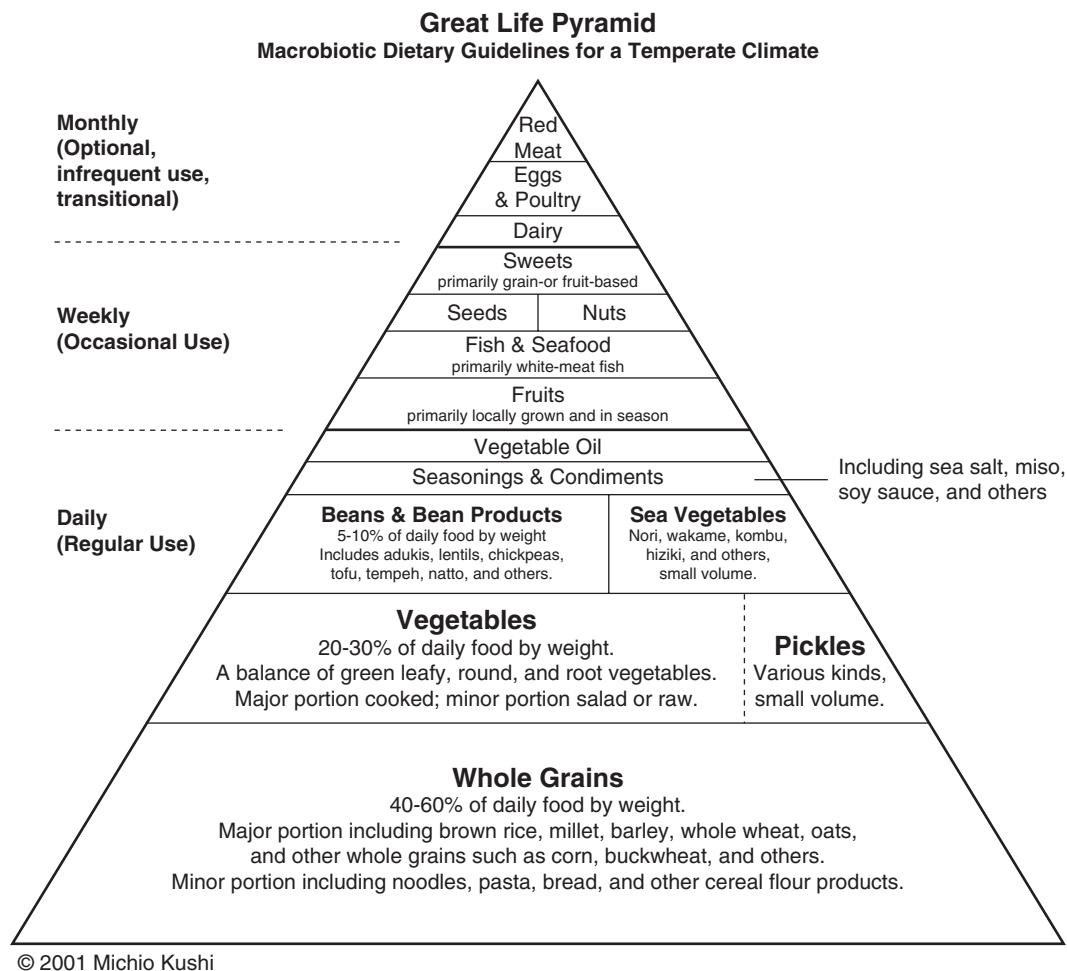

**TABLE 37-9**

**Potential Adverse Events with Integrative Therapies Commonly Used by Cancer Survivors**

Dietary Supplement	Claim and Common Uses	Potential Adverse Event
Echinacea	Boosts the immune system.	May cause inflammation of the liver if used in conjunction with other medications such as anabolic steroids, methotrexate (chemotherapy), or others.
Garlic	Helps lower cholesterol.	May increase risk for excessive bleeding, especially when used with certain anticoagulants.
Ginger	Helps with nausea.	May increase risk for excessive bleeding, especially when used with certain anticoagulants.
Ginkgo	Helps increase blood circulation and oxygenation. Enhances memory and mental concentration.	May increase risk for excessive bleeding especially when used with certain anticoagulants.
Ginseng	Increases physical stamina and mental concentration.	May increase risk for excessive bleeding, especially when used with certain anticoagulants; may increase heart rate and high blood pressure; may increase bleeding in women after menopause.
Goldenseal	Helps reduce inflammation and promote good bowel function.	May worsen swelling or high blood pressure.
Licorice	Helps soothe the stomach.	Certain licorice mixtures may cause high blood pressure, increase swelling, and cause electrolyte imbalances. May interact with other hormone therapies.
Saw palmetto	Helps with enlarged prostate and urinary inflammation.	
St. John's wort	Helps with mild to moderate depression, anxiety, or sleep disorders.	May decrease effectiveness of all currently marketed medication using cytochrome P450 pathway in the liver: HIV and AIDS medications (NNRTIs and PIs), carbamazepine, cyclosporine, irinotecan (Camptosar) for chemotherapy, midazolam (Versed), nifedipine (Procardia), simvastatin (Zocor), theophylline, warfarin (Coumadin).
Valerian	Helps as mild sedative or sleep aid, or muscle relaxant.	May increase effects of certain antiseizure medications or prolong effects of anesthetic agents.

Data from Natural Standards, 2010.

AIDS, Acquired immune deficiency syndrome; HIV, human immunodeficiency virus; NNRTI, nonnucleoside reverse transcriptase inhibitor; PI, protease inhibitor.

**FIGURE 37-2** The Great Life Pyramid proposed for a macrobiotic diet. <http://www.holistic-cooking.co.uk/WhatIsMacrobiotics.htm> (© Michio Kushi and permission given by Kushi Institute.)

special diets; and vitamin and mineral supplementation. Complications of colonic irrigation include electrolyte imbalance, toxic colitis, bowel perforation, and sepsis. Most regimens promote “natural” and “organic” foods and recommend restriction of animal products, refined flours and sugars, and foods that are processed or contain artificial ingredients. Examples of metabolic therapies include the Gerson therapy, the Gonzalez regimen, the Livingston-Wheeler therapy and the Issels treatment. The special diets associated with cancer care promote the idea that food is medicine. Diet plans are individualized and food specifically chosen and prepared.

The **macrobiotic diet** and lifestyle is a program promoting natural healing, popularized in the United States by Michio Kushi in the late 1970s. This macrobiotic diet derives 40% to 60% of its calories from whole grains; 20% to 30% from vegetables; and the remainder from beans, bean products, sea vegetables, fruit, seeds, nuts, white-meat fish, and very occasionally seafood, poultry, red meat, eggs, and dairy (Kushi et al., 2006) (Figure 37-2). Research has

determined that the diet is naturally deficient in calcium and vitamin B<sub>12</sub>. The macrobiotic diet has not been scientifically proven to treat or cure cancer.

### Orthomolecular Medicine

Orthomolecular medicine (OM) is the practice of restoring an optimal environment in the body by correcting imbalances and deficiencies, another alternative medicine practice in cancer care. The treatment is based on the theory that by correcting imbalances and deficiencies, the body will regain health. This has not been proven in clinical trials, and instead is extrapolated from basic science. Infusions or supplementation may involve large doses of vitamins, minerals, essential fatty acids, fiber, amino acids, or enzymes. Orthomolecular practitioners (often medical doctors) consider a number of CAM practices to be consistent with OM philosophy and may incorporate parts of naturopathic medicine, nutrition, acupuncture, mind-body therapies, and manipulative and body-based practices such as massage into their treatments.

## Advanced Cancer and Palliative Care

Palliative care is the active total care of an individual when curative measures are no longer considered an option by either the medical team or the individual. Hospice care focuses on relieving symptoms and supporting individuals with a life expectancy of months, not years (NAPCO, 2010). The objectives are to provide for optimal quality of life; relieve physical symptoms; alleviate isolation, anxiety, and fear associated with advanced disease; and to help patients maintain independence as long as possible (McCallum and Fornari, 2006). The goals of nutrition intervention should focus on managing nutrition-related symptoms such as pain, weakness, loss of appetite, early satiety, constipation, weakness, dry mouth, and dyspnea (McCallum and Fornari, 2006). Another important goal is maintaining strength and

energy to enhance quality of life, independence, and ability to perform activities of daily living. Nutrition should be provided “as tolerated or as desired” along with emotional support and awareness of and respect for individual needs and wishes. Thus the pleasurable aspects of eating should be emphasized, without concern for quantity or nutrient and energy content.

The use of nutrition support and hydration in individuals with advanced, incurable cancer is a difficult and often controversial issue and should be determined on a case-by-case basis. Advance directives are legal documents that guide health care providers regarding the specific wishes of individuals, outlining the extent of their desired medical care, including the provision of artificial nutrition and hydration. Whenever providing nutrition care, consideration should be given to advanced directives that may be in place.

## CLINICAL SCENARIO 1

**J**anice is a 55-year-old mother of four children. Recently she was diagnosed with breast cancer (estrogen-receptor positive). Surgery, radiation therapy to her breast and five years of tamoxifen are planned for treatment of her disease. In the next 3 weeks she will undergo a lumpectomy, followed by 5 to 6 weeks of external-beam radiation therapy. She is 5'8" tall, weighs 185 lb, and has a history of mild hypertension that has been controlled with dietary measures. She currently does not engage in regular physical activity but is motivated to make changes in her lifestyle to improve her fitness and overall health. She also is attracted to the use of multiple vitamins/minerals and dietary supplements, and complementary and alternative therapies for reducing her cancer recurrence risk and managing treatment-related side effects and postmenopausal symptoms.

### Nutrition Diagnostic Statement 1

Physical inactivity related to lack of regular exercise plan as evidenced by patient reports of no exercise

### Nutrition Diagnostic Statement 2

Food- and nutrition-related knowledge deficit related to medical nutrition therapy related to cancer treatment and

secondary prevention as evidenced by patient requesting more information

### Nutrition Care Questions

- What recommendations would you give Janice to prepare her for surgery?
- After radiation therapy and surgery, what side effects might Janice experience? List some dietary strategies Janice may follow if she experiences the following: fatigue, intermittent nausea, a slight difficulty in swallowing (esophagus is in the radiation field), and an increased caloric intake (mostly caused by her need to “take care of” herself, which results in weight gain).
- Is Janice at her ideal body weight? If not, what suggestions would you recommend? Consider her hypertension, planned surgery, and radiation therapy.
- What dietary recommendations, if any, are appropriate for patients receiving tamoxifen?
- What guidance should be provided with regard to the appropriate use of vitamin and mineral supplements and ways to evaluate alternative therapies? How does soy affect estrogen-receptor-positive forms of breast cancer? How should she manage hot flashes now that she is advised not to take estrogen replacement therapy?

## CLINICAL SCENARIO 2

**M**ichael is a 58-year-old man with a recent diagnosis of esophageal cancer. He has experienced gastroesophageal reflux (GERD) for the past 5 years and had been advised to undergo an endoscopic examination to rule out Barrett's esophagus, but he never followed up on his doctor's referral. He lost 40 pounds in the four months prior to his diagnosis because of lack of appetite and progressive difficulty

swallowing solid foods. Prediagnosis, his diet consisted of drinking “muscle drinks” his son purchased at the local gym. He has been very pleased with his weight loss, but knew something was wrong.

Michael underwent an esophagogastrectomy 1 month ago and received some nutrition information from the inpatient registered dietitian right before he was discharged, but he

## CLINICAL SCENARIO 2—cont'd

reports that he never read it. He has lost an additional 20 pounds in the past month, and has been admitted once for dehydration caused by lack of fluid intake and because of continued symptoms related to postsurgical dumping syndrome.

His current food and nutrition history includes small meals with a usual intake of approximately 1500 calories daily. He eats three times a day. He reports he does not have the energy to prepare food so while his wife is at work, he relies on frozen meals warmed in the microwave and canned soup. He has a sweet tooth and, because eating is difficult, he rewards himself with ice cream or a cookie after each meal. His beverages include whole milk, apple juice, and a “finger” of scotch each night. He finally has agreed to see the outpatient registered dietitian because he feels dehydrated again, has no energy, and needs to get back to work.

### Biochemical Data

Albumin: 3.0 mg/dL

Blood urea nitrogen: 18 mg/dL

Creatinine: 0.6 mg/dL

Blood pressure: 110/60

Pulse rate of 90

### Anthropometric Data

Height: 72"

Weight history: Usual body weight: 200 lb, preoperative weight: 160 lb, 1 month postoperative weight: 140lb

Body mass index: 19

### Medications

Metoclopramide (Reglan) 30 minutes before each meal

Atorvastatin (Lipitor)

Metoprolol (Toprol)

Hydrochlorothiazide

### Dietary Supplements

One-A-Day for Men

### Nutrition Diagnostic Statements

- Food- and nutrition-related knowledge deficit related to lack of education and counseling for appropriate medical nutrition therapy as evidenced by food history with inappropriate food choices.

- Altered gastrointestinal function related to esophagogastrectomy as evidenced by weight loss, dehydration, and dumping syndrome.
- Inadequate protein and energy intake related to postsurgery recovery as evidenced by decreased food and beverage intake, weight loss, and muscle wasting causing decreased creatinine.

### Nutrition Interventions

**Nutrition prescription:** Small frequent meals consisting of energy-dense, lower-fat foods and limited simple carbohydrates; majority of fluid consumption between meals (sips during meals okay to aid in chewing and swallowing).

**Nutrition education:** Update Michael's knowledge of appropriate nutrition therapy following an esophagogastrectomy. Discuss tolerance of different food groups; sources of protein; energy-dense, easy-to-prepare menu options; and healthy beverage selections, including advising him to discontinue consumption of daily alcoholic beverage; and goal caloric intake needed for slow, steady weight gain. Suggest he consider eating every 2 hours, on the even hour, to create an external reminder to eat. Recommend he review his hypertension medication types and doses with his physicians because his need for medication may have changed with his significant weight loss.

At follow-up visits address weight-gain progress, bowel function, food and beverage intake and tolerance; encourage physical activity (physician approved) starting with short walks to regain muscle strength. JE needs to be accompanied by a friend or family member on these walks.

**Nutrition counseling:** Coordinate with patient and wife to ensure appropriate foods and beverages are available for consumption. Discuss expected acute and long-term side effects from surgery. Establish slow, steady weight gain and physical activity goals for next 3 months.

### Nutrition Monitoring and Evaluation

- Body weight trends
- Hydration status
- Serum albumin levels and creatinine levels (over 3 months)
- Physical activity
- Schedule follow-up session in 2 weeks, with optional phone call between visits

## CHAPTER 38

Kimberly R. Dong, MS, RD  
Cindy Mari Imai, MS, RD

# Medical Nutrition Therapy for HIV and AIDS

### KEY TERMS

acquired immune deficiency syndrome (AIDS)  
acute HIV infection  
antiretroviral therapy (ART)  
asymptomatic HIV infection  
CD4+ cells  
CD4 count  
clinical latency  
drug resistance

HIV-associated lipodystrophy syndrome (HALS)  
human immunodeficiency virus (HIV)  
long-term nonprogression  
opportunistic infections (OIs)  
seroconversion  
symptomatic HIV infection  
T-helper lymphocyte cells  
viral load

**Acquired immune deficiency syndrome (AIDS)** is caused by the human immunodeficiency virus (HIV). HIV affects the body's ability to fight off infection and disease, which can ultimately lead to death. Medications used to treat HIV have enhanced the quality of life and increased life expectancy of HIV-infected individuals. These antiretroviral therapy (ART) medications slow the replication of the virus but do not eliminate HIV infection. With increased access to ART, people are living longer with HIV. Unfortunately, health issues such as cardiovascular disease and insulin resistance are increasingly prevalent in this population.

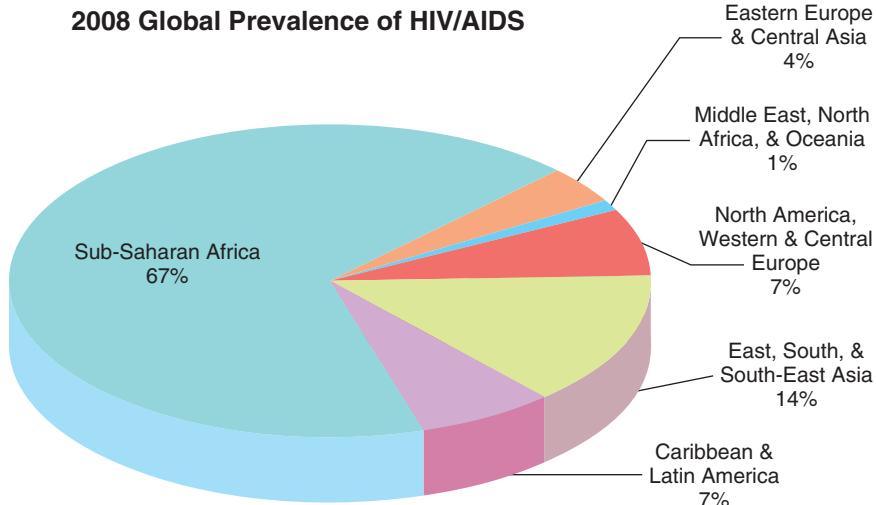

Nutritional status plays an important role in maintaining a healthy immune system and delaying the progression of HIV to AIDS. To develop appropriate nutrition recommendations, the nutrition professional should be familiar with the pathophysiology of HIV infection, the medication and nutrient interactions, and the barriers to adequate nutrition. Mental health status and illicit drug use should be considered since it may affect nutrition intake.

### EPIDEMIOLOGY AND TRENDS

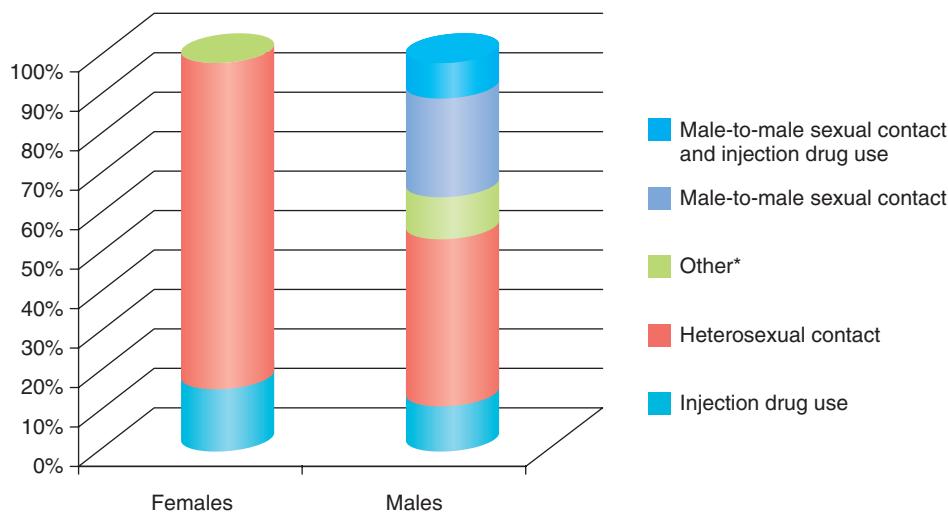

#### Global Status of HIV and AIDS

The first cases of AIDS were described in 1981. Soon after, HIV was isolated and identified as the core agent leading to AIDS. Since then, the number of people with HIV has gradually increased, leading to a global pandemic affecting socioeconomic development worldwide. The continuing rise in the population of people living with HIV is reflective of new HIV infections and the widespread use of ART, which has delayed the progression of HIV infection to death. At the end of 2008 an estimated 33.4 million people were living with HIV or AIDS. There were 2.7 million new infections reported, an average of 7400 infections daily, and 2 million HIV-related deaths (Joint United Nations Programme on HIV/AIDS [UNAIDS] and the World Health Organization [WHO], 2009).

Despite increased prevention efforts and availability of ART, geographic variations in HIV infection is evident. The

**FIGURE 38-1** Global prevalence of HIV and AIDS. (*UNAIDS and WHO: 2009 AIDS epidemic update. Accessed 12 July 2010 from [http://data.unaids.org/pub/Report/2009/JC1700\\_Epi\\_Update\\_2009\\_en.pdf](http://data.unaids.org/pub/Report/2009/JC1700_Epi_Update_2009_en.pdf). From UNAIDS/ONUSIDA 2009.*)

\* Includes hemophilia, blood transfusion, perinatal exposure, and risk factors not report or not identified

majority of infections continue to occur in the developing world (Figure 38-1) where more than 97% occur in low- and middle-income countries (UNAIDS and WHO, 2009). Sub-Saharan Africa remains the region most heavily affected by HIV, accounting for two thirds of current HIV infections and 72% of HIV-related deaths (UNAIDS and WHO, 2009). However, increases in new infections are being seen in higher-income countries in eastern Europe such as Ukraine and the Russian Federation. Within sub-Saharan Africa, heterosexual transmission is the most prevalent mode of HIV transmission (UNAIDS and WHO, 2009). In other regions, populations affected by HIV include injection drug users, men who have sex with men, sex workers, and clients of sex workers.

### The United States

Within the United States, more than 1.2 million people are living with HIV or AIDS and 21% may be unaware of their HIV status (Centers for Disease Control and Prevention [CDC], 2006, UNAIDS, 2008). Although more people are living with a diagnosis of HIV or AIDS, incidence

has remained relatively stable since the 1990s. In 2008 men accounted for 75% of all diagnoses of HIV infection. The rate of new infections in men has been trending up since 2005, whereas the rate among women has remained stable (CDC, 2010). The largest percentage of persons living with HIV infection is among those aged 40-44; this same group accounts for the highest rate of new HIV infections. Ethnic populations disproportionately affected by HIV include blacks and Latinos, who accounted for 52% and 25% of HIV diagnoses, respectively, in 2008 (CDC, 2010). The most common route of transmission among men is male-to-male sexual contact and among women is heterosexual contact (Figure 38-2).

### PATHOPHYSIOLOGY AND CLASSIFICATION

Primary infection with **human immunodeficiency virus (HIV)** is the underlying cause of AIDS. HIV invades the genetic core of the **CD4+ cells**, **T-helper lymphocyte cells**, which are the principal agents involved in protection against infection.

HIV infection causes a progressive depletion of CD4+ cells, which eventually leads to immunodeficiency.

HIV infection progresses through four clinical stages: acute HIV infection, clinical latency, symptomatic HIV infection, and progression of HIV to AIDS. The two main biomarkers used to assess disease progression are HIV ribonucleic acid (RNA) (**viral load**) and CD4+ T-cell count (CD4 count).

**Acute HIV infection** is the time from transmission of HIV to the host until the production of detectable antibodies against the virus (**seroconversion**) occurs. Half of individuals experience physical symptoms such as fever, malaise, myalgia, pharyngitis, or swollen lymph glands at 2–4 weeks following infection, but these generally subside after 1–2 weeks. Because of the nonspecific clinical features and short diagnostic window, acute HIV infection is rarely diagnosed. HIV seroconversion occurs within 3 weeks to 3 months after exposure. If HIV testing is done before seroconversion occurs, a “false negative” may result despite HIV being present. During the acute stage, the virus replicates rapidly and causes a significant decline in CD4+ cell counts. Eventually, the immune response reaches a viral setpoint where viral load stabilizes and CD4+ cell counts return closer to normal.

A period of **clinical latency** or **asymptomatic HIV infection**, then follows. Further evidence of illness may not be exhibited for as long as 10 years postinfection. The virus is still active and replicating, although at a decreased rate compared with the acute stage, and CD4+ cell counts continue to steadily decline. In 3% to 5% of HIV-infected individuals, **long-term nonprogression** occurs, in which CD4+ cell counts remain normal and viral loads can be undetectable for years without medical intervention (Department of Health and Human Services [DHHS], 2010). It has been suggested that this unique population has different and fewer receptor sites for the virus to penetrate cell membranes (Wanke et al., 2009).

In the majority of cases, HIV slowly breaks down the immune system, making it incapable of fighting the virus. When CD4+ cell counts fall below 500 cells/mm<sup>3</sup> individuals are more susceptible to developing signs and symptoms such as persistent fevers, chronic diarrhea, unexplained weight loss, and recurrent fungal or bacterial infections, all of which are indicative of **symptomatic HIV infection**.

As immunodeficiency worsens and CD4 counts fall to even lower levels, the infection becomes symptomatic and progresses to AIDS. The progression of HIV to AIDS increases risk of **opportunistic infections (OIs)**, which generally do not occur in individuals with healthy immune systems. The CDC classifies AIDS cases as positive laboratory confirmation of HIV infection in persons with a CD4+ cell count less than 200 cells/mm<sup>3</sup> (or less than 14%) or documentation of an AIDS-defining condition (Box 38-1).

HIV is transmitted via direct contact with infected body fluids like blood, semen, preseminal fluid, vaginal fluid, and breast milk. Cerebrospinal fluid surrounding the brain and spinal cord, synovial fluid surrounding joints, and amniotic

## BOX 38-1

### 2008 CDC Case Definition AIDS-Defining Clinical Conditions

- Bacterial infections, multiple or recurrent (among children <13 years)
- Candidiasis (bronchi, trachea, or lungs)
- Candidiasis (esophagus)
- Cervical cancer (invasive)
- Coccidioidomycosis (disseminated or extrapulmonary)
- Cryptococcosis (extrapulmonary)
- Cryptosporidiosis (intestinal, >1 month duration)
- Cytomegalovirus disease (other than liver, spleen, or nodes)
- Cytomegalovirus retinitis (with loss of vision)
- Encephalopathy (HIV related)
- Herpes simplex: chronic ulcers (>1 month duration)
- Herpes simplex: bronchitis, pneumonitis, or esophagitis
- Histoplasmosis (disseminated or extrapulmonary)
- Isosporiasis (intestinal, >1 month duration)
- Kaposi's sarcoma
- Lymphoid interstitial pneumonia or pulmonary lymphoid hyperplasia complex
- Lymphoma, Burkitt (or equivalent term)
- Lymphoma, immunoblastic (or equivalent term)
- Lymphoma, primary (brain)
- Mycobacterium avium* complex (disseminated or extrapulmonary)
- Mycobacterium kansasii* (disseminated or extrapulmonary)
- Mycobacterium tuberculosis* (any site, pulmonary, disseminated, or extrapulmonary)
- Pneumocystis jiroveci* pneumonia
- Pneumonia (recurrent)
- Progressive multifocal leukoencephalopathy
- Salmonella* septicemia (recurrent)
- Toxoplasmosis (brain)
- Wasting syndrome attributed to HIV: >10% involuntary weight loss of baseline body weight plus (1) diarrhea (two loose stools per day for ≥30 days) or (2) chronic weakness and documented fever (≥30 days, intermittent or constant) in the absence of concurrent illness or condition other than HIV infection that could explain the findings (e.g., cancer, tuberculosis).

Source: Schneider E et al: Revised surveillance case definitions for HIV infection among adults, adolescents, and children aged <18 months and for HIV infection and AIDS among children aged 18 months to <13 years—United States, 2008. MMWR Recomm Rep 57(RR-10):1, 2008.

AIDS, Acquired immune deficiency syndrome; CDC, Centers for Disease Control and Prevention; HIV, human immunodeficiency virus.

fluid surrounding a fetus are other fluids that can transmit HIV. Saliva, tears, and urine do not contain enough HIV for transmission. Sexual transmission is the most common way HIV is transmitted and injection drug use is the second most prevalent method of transmission (see Figure 38-2).

Most people have HIV-1 infection, which, unless specified, is the type discussed in this chapter. HIV-1 mutates readily and has become distributed unevenly throughout the world in different strains, subtypes, and groups. HIV-2, first isolated in western Africa, is less easily transmitted and the time between infection and illness takes longer.

## MEDICAL MANAGEMENT

HIV-related morbidity and mortality stem from the HIV virus weakening the immune system as well as the virus's effects on organs (such as the brain and kidney). If untreated, the HIV virion (virus particle) can replicate at millions of particles per day and rapidly progress through the stages of HIV disease. The introduction of three-drug combination ART in 1996 transformed the treatment of patients infected with HIV and has significantly decreased AIDS-defining conditions and mortality. Most drugs are formulated as individual medications, but increasingly many are available as fixed-dose combinations to simplify treatment regimens, decrease pill burden, and potentially improve patient medication adherence.

**CD4 count** is used as the major indicator of immune function in people with HIV infection. It is used to determine when to initiate ART and is the strongest predictor of disease progression. CD4 counts are generally monitored every 3 to 4 months. In addition, HIV RNA (viral load) is monitored on a regular basis because it is the primary indicator to gauge the efficacy of ART. Table 38-1 provides the current guidelines on when to initiate ART.

The fundamental goals of ART are to achieve and maintain viral suppression, reduce HIV-related morbidity and mortality, improve the quality of life, and restore and preserve immune function. This can generally be achieved within 12-24 weeks if there are no complications with adherence, or resistance to medications (DHHS, 2010). Because the guidelines for HIV management evolve rapidly, it is beneficial to frequently check for updated recommendations.

## Classes of Antiretroviral Therapy Drugs

Currently **antiretroviral therapy (ART)** includes more than 20 antiretroviral agents from six mechanistic classes of drugs:

- Nucleoside and nucleotide reverse transcriptase inhibitors (NRTIs)
- Nonnucleoside reverse transcriptase inhibitors (NNRTIs)
- Protease inhibitors (PIs)
- Fusion inhibitors
- CCR5 (chemokine receptor 5) antagonists
- Integrase strand transfer inhibitors (INSTIs)

The most widely studied combination regimen for treatment of naïve patients consists of two NRTIs plus either one NNRTI or a PI (with or without ritonavir boosting). Recently, a regimen consisting of raltegravir was approved for treatment-naïve patients, making the combination of an INSTI with two NRTIs another option (DHHS, 2010).

Although a reasonable number of different antiretroviral medications are currently available for the treatment of HIV infections, there is a growing need for new drugs that have fewer long-term toxicities and greater potency. However, because eradication of HIV is not yet possible, and the need for treatment is lifelong, adverse effects of medications, including metabolic complications and other toxicities, become increasingly important because they may lead to nonadherence to the prescribed regimen. Nonadherence to ART can lead to **drug resistance**.

## Predictors of Adherence

When initiating ART, patients must be willing and able to commit to lifelong treatment and should understand the benefits and risks of therapy and the importance of adherence. The patient's understanding about HIV disease and the specific regimen prescribed is critical. A number of factors have been associated with poor adherence, including low levels of literacy, certain age-related challenges (e.g., vision loss, cognitive impairment), psychosocial issues (e.g.,

**TABLE 38-1**

### Indications for the Initiation of ART in HIV-infected Individuals

Clinical Category	CD4 Count	Recommendation
Asymptomatic, AIDS	<350 cells/mm <sup>3</sup>	Treat
Asymptomatic	350-500 cells/mm <sup>3</sup>	Treatment recommended
Asymptomatic	>500 cells/mm <sup>3</sup>	Some clinicians recommend initiating therapy and some view treatment as optional
Symptomatic (AIDS, severe symptoms)	Any value	Treat
Pregnancy, HIV-associated nephropathy, HBV coinfection when treatment of HBV is indicated	Any value	Treat

From National Institutes of Health: Guidelines for the use of antiretroviral agents in HIV-1-infected adults and adolescents, 2009. Accessed 23 October 2010 from <http://www.aidsinfo.nih.gov/contentfiles/AdultandAdolescentGL.pdf>.

AIDS, Acquired immune deficiency syndrome; ART, antiretroviral therapy; HBV, hepatitis B virus; HIV, human immunodeficiency virus.

depression, homelessness, low social support, stressful life events, dementia, or psychosis), active substance use, stigma, difficulty with taking medication (e.g., trouble swallowing pills, daily schedule issues), complex regimens (e.g., pill burden, dosing frequency, food requirements), adverse drug effects, and treatment fatigue (DHHS, 2010).

When using boosted PIs and efavirenz, their longer half-lives may permit more lapses in adherence since drug levels stay high in the body for many days (Bangsberg, 2006; Raffa, 2008). However, these drugs are more likely to contribute to drug resistance if discontinued due to rapid viral mutation. Continued encouragement is needed to help patients adhere as closely as possible to the prescribed doses for all ART regimens.

### Illicit Drug Use

In the United States, injection drug use is the second most common mode of HIV transmission. The most commonly used illicit drugs associated with HIV infection are heroin, cocaine, methamphetamine, and amyl nitrate (poppers). The chaotic lifestyle associated with drug use is associated with poor or inadequate nutrition, food insecurity, and depression. This complicates treatment of HIV if the individual is using drugs, and can potentially lead to poor adherence with ART medications. Special considerations should be taken into account if the liver is damaged from drug use or coinfection with hepatitis, and increased nutrient excretion from diuresis and diarrhea (Hendricks, 2009; Tang, 2010).

Injection drug use is strongly linked with transmission of bloodborne infections such as HIV, hepatitis B virus, and hepatitis C virus (HCV), especially if needles are reused or shared (see *Focus On: HIV and Hepatitis C Virus Coinfection*). Coinfection of HIV and HCV increases the risk of cirrhosis. Chronic HCV infection also complicates HIV treatment because of ART-associated hepatotoxicity.

### Food-Drug Interactions

Some ART medications require attention to dietary intake. It is important to ask individuals with HIV to report all medications, including vitamins, supplements, and recreational substances that they consume to fully assess their needs and prevent drug interactions and nutrient deficiencies. Some nutrients can affect how drugs are absorbed or metabolized. Interactions between food and drugs can influence the efficacy of the drug or may cause additional or worsening adverse effects. For example, grapefruit juice and PIs both compete for the cytochrome P450 enzymes; thus individuals taking PIs who also drink grapefruit juice may have either increased or decreased blood levels of the drug. Tables 38-2, 38-3, 38-4, and 38-5 provide potential nutrient interactions with ART medications.

Some ART medications can cause diarrhea, fatigue, gasteroesophageal reflux, nausea, vomiting, dyslipidemia, and insulin resistance. Timing is also important for ART efficacy, so patients with HIV must take medications on a schedule. Some medications indicate that they must be taken with food or on an empty stomach. Sometimes food

## HIV and Hepatitis C Virus Coinfection

**A**n estimated 200,000 to 300,000 people in the United States have human immunodeficiency virus (HIV) and hepatitis C virus (HCV). According to the CDC, 50% to 90% of HIV-infected injection drug users are also infected with HCV (CDC, 2007). Although it is unknown if HCV accelerates HIV disease progression, it has been shown to damage the liver more quickly in HIV-infected persons. In the presence of hepatic impairment, the metabolism and excretion of antiretroviral medications may be impaired, affecting the efficacy of HIV treatment. In addition, three classes of anti-HIV medications (nucleoside and nucleotide reverse transcriptase inhibitors, nonnucleoside reverse transcriptase inhibitors, and protease inhibitors) are associated with hepatotoxicity. Therefore it is important for HIV-infected patients to be tested for HCV to appropriately manage treatment and prolong healthy liver function.

HCV is viewed as an opportunistic infection (not an acquired immune deficiency syndrome-defining illness) in HIV-infected persons because it is associated with higher titers of HCV, more rapid progression to liver disease, and increased risk of cirrhosis (CDC, 2007). Nutrition recommendations (see Chapter 30) and dosing and choice of HIV medications must be adjusted for those with liver failure.

needs to be taken within a specific time frame of administering a medication.

## MEDICAL NUTRITION THERAPY

For people living with HIV, adequate and balanced nutrition intake is essential to maintain a healthy immune system and prolong lifespan. It has been documented that both children and adults who are living with HIV have lower fat-free and total fat mass (American Dietetic Association, 2010). Proper nutrition may help maintain lean body mass, reduce the severity of HIV-related symptoms, improve quality of life, and enhance adherence and effectiveness of ART. Therefore medical nutrition therapy (MNT) is integral to successfully manage HIV. See *Pathophysiology and Care Management Algorithm: Human Immunodeficiency Virus Disease*.

A registered dietitian (RD) can help the patient manage many of the necessary requirements for medications, minimize adverse effects, and address nutritional concerns. Some common nutrition diagnoses in this population include:

- Inadequate oral food and beverage intake
- Increased nutrient needs
- Swallowing difficulty

**TABLE 38-2****Medication Interactions and Common Adverse Effects with NRTI Medications**

<b>Medication Name</b>	<b>Timing Considerations</b>	<b>Common Adverse Effects with Nutrition Implications</b>
<b>emtricitabine (Emtriva, FTC)*</b>	Timing of food intake is not a consideration. Snacks may limit GI upset.	NRTIs in general can potentially lead to anemia, loss of appetite, low vitamin B <sub>12</sub> , low copper, low zinc, and low carnitine.
<b>lamivudine (Epivir, 3TC)<sup>†</sup></b>	Timing of food intake is not a consideration. Snacks may limit GI upset.	NRTIs in general can potentially lead to anemia, loss of appetite, low vitamin B <sub>12</sub> , low copper, low zinc, and low carnitine.
<b>zidovudine (Retrovir, ZDV, AZT)<sup>†</sup></b>	Timing of food intake is not a consideration.	Constipation Taste alterations Macrocytic anemia or neutropenia NRTIs in general can potentially lead to anemia, loss of appetite, low vitamin B <sub>12</sub> , low copper, low zinc, and low carnitine.
<b>abacavir, lamivudine, and zidovudine (Trizivir)<sup>†</sup></b>	Timing of food intake is not a consideration.	Nausea Vomiting Diarrhea Abdominal pain Fat maldistribution NRTIs in general can potentially lead to anemia, loss of appetite, low vitamin B-12, low copper, low zinc, and low carnitine.
<b>didanosine (Videx, Videx EC, DDL)<sup>‡</sup></b>	Take 30 minutes before or 2 hours after a meal. Do not mix with acids such as grapefruit juice, oranges, or other citrus; tomatoes or tomato juice. Do not take antacids with magnesium or aluminum within 2 hours.	Pancreatitis Nausea NRTIs in general can potentially lead to anemia, loss of appetite, low vitamin B <sub>12</sub> , low copper, low zinc, and low carnitine.
<b>tenofovir (Viread, TDF)*</b>	Timing of food intake is not a consideration.	Diarrhea Nausea Vomiting Flatus Renal issues NRTIs in general can potentially lead to anemia, loss of appetite, low vitamin B <sub>12</sub> , low copper, low zinc, and low carnitine.
<b>stavudine (Zerit, Zerit XR, d4T)<sup>‡</sup></b>	Timing of food intake is not a consideration. Snacks may limit GI upset.	Hyperlipidemia Lipodystrophy: significantly associated with lipoatrophy Pancreatitis Mouth and esophageal ulcers NRTIs in general can potentially lead to anemia, loss of appetite, low vitamin B <sub>12</sub> , low copper, low zinc, and low carnitine.
<b>abacavir (Ziagen, ABC)<sup>†</sup></b>	Timing of food intake is not a consideration. Snacks may limit GI upset.	Alcohol can increase drug levels Nausea Vomiting Diarrhea Loss of appetite NRTIs in general can potentially lead to anemia, loss of appetite, low vitamin B <sub>12</sub> , low copper, low zinc, and low carnitine.

## PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

### Human Immunodeficiency Virus Disease

**Etiology**

**Pathophysiology**

#### Clinical Findings

**Acute HIV infection (Acute retroviral syndrome)** Fever, fatigue, rash, headache, generalized lymphadenopathy, pharyngitis, myalgia, nausea/vomiting, diarrhea, night sweats, adenopathy, oral ulcers, genital ulcers, neurological symptoms, malaise, anorexia, weight loss, wasting syndrome

#### Seroconversion

**HIV Positive Test** HIV rapid tests; ELISA test, Western blot; PCR test

**Asymptomatic HIV infection** Abnormal metabolism, change of body composition (body cell mass loss with/without weight loss, lipoatrophy, lipohypertrophy), vitamin B<sub>12</sub> deficiency, susceptibility to pathogens

**Symptomatic HIV infection** Weight loss, thrush, fever, loss of LBM with/without weight loss, diarrhea, oral hairy leukoplakia, herpes zoster, peripheral neuropathy, idiopathic thrombocytopenic purpura, pelvic inflammatory disease

#### Asymptomatic AIDS

**Symptomatic AIDS (AIDS defined conditions)** CD4 cell count <200/mm<sup>3</sup>, opportunistic infectious diseases (pneumocystis jirovecii, pneumonia, others), Kaposi's sarcoma, lymphoma, HIV associated dementia, HIV associated wasting, vitamins/minerals deficiencies

**Management**

#### Medical Management

##### Treat possible co-morbidities

Hyperglycemia, hyperlipidemia, hypertension, body composition changes, pancreatitis, kidney and liver diseases, hypothyroidism, hypogonadism, osteopenia, hepatitis-C

##### Monitoring

Fasting blood lipid, fasting glucose/insulin level, protein status, blood pressure, TSH/testosterone level, CD4 cell count, and viral load

##### Medication

Antiretroviral therapy, lipid lowering agents, antidiabetic agents, antihypertensive agents, appetite stimulants, hormone replacement therapy, treatment for coinfectious diseases (i.e. hepatitis), prophylaxis and treatment for opportunistic infectious diseases

#### Nutrition Management

- Complete nutrition assessment 2-6 times/year. See Fig. 38-3
- Emphasize importance of early/ongoing nutritional intervention
- Promote adequate intake of nutrients and fluids
- Emphasize importance of food and water safety and sanitation
- Emphasize regular exercise and physical activity
- If psycho-social economic barriers to food, give resources
- Dietary multiple vitamin and mineral supplements
- Inform patient of possible side effects, symptoms and/or complications
- Monitor/manage metabolic abnormalities
- Small, frequent, nutrient-dense meals
- If mouth ulcers present, foods made need to be mashed or ground
- Appetite stimulants if necessary
- Parenteral nutrition if necessary
- Anabolic therapies

**TABLE 38-5****Medication Interactions and Common Adverse Effects with Entry Inhibitor, INSTIs, and Combination Medications**

<b>Class of Medication</b>	<b>Medication Name</b>	<b>Timing Considerations</b>	<b>Common Adverse Effects with Nutrition Implications</b>
Fusion inhibitors	enfuvirtide (Fuzeon, T20)*	Take without regard to food.	Nausea Vomiting
CCR5 antagonists	selzentry (Maraviroc, MVC) <sup>†</sup>	Take without regard to food.	Abdominal pain Hepatotoxicity
Integrase inhibitors	isentress (Raltegravir, RAL) <sup>‡</sup>	Take without regard to food.	Nausea Diarrhea
Combinations	efavirenz, tenofovir, and emtricitabine (Atripla) <sup>§</sup>	Take on empty stomach. Take at bedtime to decrease adverse effects.	Nausea Vomiting Gas

Hammer SH et al: 2006 recommendations of the International AIDS Society—USA Panel, *JAMA* 296:827, 2006.

 §Made by Gilead ([www.gilead.com](http://www.gilead.com)).

- Altered gastrointestinal (GI) function
- Food-medication interaction
- Involuntary weight loss
- Overweight and obesity
- Food- and nutrition-related knowledge deficit
- Oversupplementation
- Impaired ability to prepare foods or meals
- Inadequate access to food
- Intake of unsafe foods

All individuals with HIV infection should have access to a RD or other qualified nutrition professional. Patients should undergo a baseline nutrition assessment once they are diagnosed with HIV. Follow-up should be ongoing and take into consideration the multifactorial complications that may affect patient care. The American Dietetic Association recommends that a RD should provide at least one to two MNT encounters per year for individuals with asymptomatic HIV infection and at least two to six MNT encounters per year for symptomatic but stable HIV infection. Individuals diagnosed with AIDS usually need to be seen more often as they may require nutrition support (see Chapter 14).

Ultimately, MNT should be individualized and frequency of nutrition counseling should be determined by the patient's needs. The major goals of MNT for persons living with HIV infection are to optimize nutritional status, immunity, and well-being; to maintain a healthy weight and lean body mass; to prevent nutrient deficiencies and reduce the risk of comorbidities; and to maximize the effectiveness of medical and pharmacologic treatments. Thus screening should be performed on all patients medically diagnosed with HIV to

identify those at risk for nutritional deficiencies or in need of MNT.

Patients who exhibit the various HIV-related symptoms or conditions listed in Figure 38-3 should be referred to a dietitian with expertise in managing this disease. A comprehensive nutrition assessment should be performed at the initial visit. In addition, regular monitoring and evaluation are essential to detect and manage any undesirable nutritional consequences of medical treatments or the disease process. Adverse nutrition implications are summarized in Table 38-6. Key factors for assessment are listed in Table 38-7.

### Medical Factors

HIV infection should be confirmed by laboratory testing and not based on patient report (CDC, 2008b). The presence of comorbidities such as heart disease, diabetes, hepatitis, and OIs may complicate the patient's treatment profile. The assessment should include the patient's past medical history and pertinent immediate family history for heart disease, diabetes, cancers, or other disorders. Metabolic issues such as dyslipidemia and insulin resistance are common in people with HIV, and should be monitored. Biochemical measurements should be documented to determine course of HIV treatment, need for ART, efficacy of ART, and underlying malnutrition and nutrient deficiencies. Some common biochemical measurements include CD4 count, viral load, albumin, hemoglobin, iron status, lipid profile, liver function, renal function, glucose, insulin, and vitamin levels. See Table 38-8 for a list of common conditions associated with HIV and their nutritional implications.

I. Nutrition Screen and Referral Criteria for Adults with HIV/AIDS					
Today's Date _____					
Name _____	Phone _____	Messages: <input type="checkbox"/> Yes <input type="checkbox"/> No <input type="checkbox"/> Discreet			
Gender _____	Language _____	DOB ____ / ____ / ____	Age _____	File # _____	
Medicaid Waiver Client? <input type="checkbox"/> Yes <input type="checkbox"/> No	Insurance _____	Case Managed By _____			
Referred By _____	Date _____	Phone _____			
<b>Screen every six months and/or per status change. Automatically refer to a registered dietitian for any of the following:</b> (Check and circle all that apply)					
<b>A. Medical Diagnosis and Nutrition Assessment</b>					
1. <input type="checkbox"/> Newly diagnosed HIV infection 2. <input type="checkbox"/> Newly diagnosed with AIDS 3. <input type="checkbox"/> Any change in disease, diet or nutritional status 4. <input type="checkbox"/> No nutrition assessment by a registered dietitian or not seen by a registered dietitian in six months					
<b>B. Physical Changes and Weight Concerns</b>					
1. <input type="checkbox"/> $\geq 3\%$ unintentional weight loss from usual body weight in the last 6 months or since last visit (% wt. loss formula: usual body weight – current body wt/usual body wt $\times 100$ ) 2. <input type="checkbox"/> Visible wasting, $<90\%$ ideal body weight, BMI $<20 \text{ kg/m}^2$ , or decrease in body cell mass (BCM) 3. <input type="checkbox"/> Uses anabolic steroids or growth hormone for weight, muscle gain or metabolic complications 4. <input type="checkbox"/> Lipodystrophy: lipoatrophy, central fat adiposity and/or fat accumulation on the neck, upper back, breasts or other areas 5. <input type="checkbox"/> Abdominal obesity: Waist circumference $>102 \text{ cm}$ or 40 inches (men) and $>88 \text{ cm}$ or 35 inches (women) 6. <input type="checkbox"/> Client or MD initiated weight management, or obesity: BMI $>30 \text{ kg/m}^2$					
<b>C. Oral/GI Symptoms</b>					
1. <input type="checkbox"/> Uses an appetite stimulant or suppressant 2. <input type="checkbox"/> Loss of appetite, desire to eat or poor oral intake of food or fluid for $>3$ days 3. <input type="checkbox"/> Missing teeth, severe dental caries, difficulty chewing and/or swallowing 4. <input type="checkbox"/> Mouth sores, thrush, or mouth, tooth or gum pain 5. <input type="checkbox"/> Persistent diarrhea, constipation or change in stools (color, consistency, frequency, smell) 6. <input type="checkbox"/> Persistent nausea or vomiting 7. <input type="checkbox"/> Persistent gas, bloating or heartburn 8. <input type="checkbox"/> Changes in perception of taste or smell 9. <input type="checkbox"/> Food allergies or food intolerances (fat, lactose, wheat, etc.) 10. <input type="checkbox"/> Medication involving food or meal modification 11. <input type="checkbox"/> Receives or needs evaluation for oral supplement or enteral or parenteral nutrition					
<b>D. Metabolic Complications and Other Medical Conditions</b>					
1. <input type="checkbox"/> Diabetes mellitus, impaired glucose tolerance, impaired fasting glucose, insulin resistance, or history of hypoglycemia or hyperglycemia 2. <input type="checkbox"/> Hyperlipidemia: cholesterol $>200 \text{ mg/dL}$ , triglycerides $\geq 150 \text{ mg/dL}$ , LDL $>100 \text{ g/dL}$ , and/or HDL $<40 \text{ mg/dL}$ (men), $<50 \text{ mg/dL}$ (women) 3. <input type="checkbox"/> Hypertension: two BP readings 120-139/80-90 mm Hg or diagnosed with HTN 4. <input type="checkbox"/> Hepatic disease: Hepatitis C, Hepatitis B, cirrhosis, steatotasis, or other: _____ 5. <input type="checkbox"/> Osteopenia/osteoporosis risk, e.g., elevated alkaline phosphatase, DEXA of the hip and spine low T-scores 6. <input type="checkbox"/> Other conditions: renal disease, anemia, heart disease, pregnancy, cancer or other: _____ 7. <input type="checkbox"/> Albumin $<3.5 \text{ mg/dL}$ , prealbumin $<19 \text{ mg/dL}$ , or cholesterol $<120 \text{ mg/dL}$ 8. <input type="checkbox"/> Scheduled chemotherapy or radiation therapy					
<b>E. Barriers to Nutrition, Living Environment, Functional Status</b>					
Usually or always needs assistance with: Patient is: 1. <input type="checkbox"/> Eating                          4. <input type="checkbox"/> Homebound                          7. <input type="checkbox"/> Has limited or no cooking skills 2. <input type="checkbox"/> Preparing food                    5. <input type="checkbox"/> Homeless                                  8. <input type="checkbox"/> Income at or below Federal Poverty Guidelines 3. <input type="checkbox"/> Shopping for food and necessities        6. <input type="checkbox"/> Unable to secure food                    9. <input type="checkbox"/> Has no stove or refrigerator					
<b>F. Behavioral Concerns or Unusual Eating Behaviors</b>					
1. <input type="checkbox"/> Disordered eating, e.g., binges, purges, purposely skips meals, avoids eating when hungry, pica 2. <input type="checkbox"/> Alcoholic consumption: $>2/\text{day}$ (men), $>1/\text{day}$ (women), or with contraindicated condition 3. <input type="checkbox"/> Substance abuse, e.g., alcohol, tobacco, drugs 4. <input type="checkbox"/> Vegetarianism 5. <input type="checkbox"/> Client initiated vitamin and/or mineral supplementation, or complimentary or alternative diet or related therapies					

**FIGURE 38-3** Nutrition screen and referral criteria for adults with HIV and AIDS. (From ADA MNT Evidence Based Guides for Practice © 2005, American Dietetic Association, March 2005. For interim revisions see [www.bivaidsdpg.org/](http://www.bivaidsdpg.org/).)

**TABLE 38-6****Nutrition Recommendations for General Adverse Effects**

<b>Adverse Effect</b>	<b>Nutrition Recommendations</b>
Nausea, vomiting	Eat small, frequent meals. Avoid drinking liquids with meals. Drink cool, clear liquids. Try dry crackers or toast. Try bland foods such as potatoes, rice, or canned fruits. Limit high-fat, greasy foods or foods that have strong odors such as ripe cheese or fish. Eat foods at room temperature or cooler. Wear loose-fitting clothes. Rest sitting up after meals. Keep a log of when nausea and vomiting occur and which foods seem to trigger it.
Diarrhea	Try plain carbohydrates such as white rice, rice congee, noodles, crackers, or white toast. Try low-fiber fruits like bananas and applesauce. Drink fluids that will replace electrolytes such as broths and oral hydration drinks. Try small, frequent meals. Avoid fatty, greasy foods. Avoid highly spiced foods. Avoid sugary items such as soda and fruit juice. Avoid milk and milk products. Limit caffeine.
Loss of appetite	Eat small, frequent meals. Focus on nutrient-dense foods such as milkshakes, lean protein, eggs, nut butters, vegetables, fruits, and whole grains.
Taste alterations	Try to eat in a pleasant environment Add spices and herbs to foods. Avoid canned foods or canned oral supplements.
Hyperlipidemia	NCEP diet (refer to Chapter 34).
Hyperglycemia	Diet for patients with diabetes (refer to Chapter 31)
Mouth and esophageal ulcers and sore throat	Try soft foods such as oatmeal, rice, applesauce, scrambled eggs, milkshakes, or yogurt. Avoid acidic foods such as citrus, vinegar, spicy, salty, or hot foods. Moisten foods with gravy or sauces. Drink liquids with meals. Avoid acidic beverages. Try foods and beverages at room temperature.
Pancreatitis	Focus on low-fat foods and limit fat at each meal. See Chapter 30. May need pancreatic enzymes to aid in digestion.
Weight loss	Eat small, frequent meals. See Chapter 22. Focus on nutrient-dense foods such as milkshakes, lean protein, eggs, nut butters, vegetables, fruits, whole grains, trail mixes, and tofu. Add rice, barley, and legumes to soups. Add dry milk powder or protein powder to casseroles, hot cereals, and milkshakes Try oral supplements

NCEP, National Cholesterol Education Program.

**TABLE 38-7****Factors to Consider in Nutrition Assessment**

Medical	Stage of HIV disease Comorbidities Opportunistic infections Metabolic complications Biochemical measurements
---------	--

**TABLE 38-7****Factors to Consider in Nutrition Assessment—cont'd**

Physical	Changes in body shape Weight or growth concerns Oral or gastrointestinal symptoms Functional status (i.e., cognitive function, mobility) Anthropometrics
Social	Living environment (support from family and friends) Behavioral concerns or unusual eating behaviors Mental health (i.e., depression)
Economical	Barriers to nutrition (i.e., access to food, financial resources)
Nutritional	Typical intake Food shopping and preparation Food allergies and intolerances Vitamin, mineral, and other supplements Alcohol and drug use

HIV, Human immunodeficiency virus.

**TABLE 38-8****HIV-related Conditions with Specific Nutrition Implications**

Condition	Brief Description	Nutrition Implications
PCP	Potentially fatal fungal infection	Difficulty chewing and swallowing caused by shortness of breath
TB	Bacterial infection that attacks the lungs	Prolonged fatigue, anorexia, nutrient malabsorption, altered metabolism, weight loss
Cryptosporidiosis	Infection of small intestine caused by parasite	Watery diarrhea, abdominal cramping, malnutrition and weight loss, electrolyte imbalance
Kaposi's Sarcoma	Type of cancer causing abnormal tissue growth under the skin	Difficulty chewing and swallowing caused by lesions in oral cavity or esophagus
Lymphomas	Abnormal, malignant growth of lymph tissue	Diarrhea or intestinal obstruction caused by lesions in intestine
Brain	Changes in motor and cognitive abilities	Inability to prepare food and coordinate movement
Small bowel	Malabsorption	Weight loss, diarrhea, loss of appetite
Cytomegalovirus (disseminated)	Infection caused by herpes virus	Loss of appetite, weight loss, fatigue, enteritis, colitis
Candidiasis	Infection caused by fungi or yeast	Oral sores in mouth, difficulty chewing and swallowing, change in taste
HIV-induced enteropathy	Idiopathic, direct or indirect effect of HIV on enteric mucosa	Chronic diarrhea, weight loss, malabsorption, changes in cognition and behavior
HIV encephalopathy (AIDS dementia)	Degenerative disease of brain cause by HIV infection	Loss of coordination and cognitive function, inability to prepare food
<i>Pneumocystis jirovecii</i> pneumonia	Infection caused by fungi	Fever, chills, shortness of breath, weight loss, fatigue
<i>Mycobacterium avium</i> complex (disseminated)	Bacterial infection in lungs or intestine, spreads quickly through bloodstream	Fever, cachexia, abdominal pain, diarrhea, malabsorption

## Physical Changes

The physical presentation of the patient should be considered during initial and follow-up assessments. Patients with HIV are aware of changes in their body shape and are instrumental in identifying these changes. Health care professionals should remember to ask patients about body shape changes every 3 to 6 months. Changes in body shape and fat redistribution can be monitored by anthropometric measurements. Commonly these are taken as circumferences around the waist, hip, mid-upper arm, and thigh, and as skinfold measurements of the tricep, subscapular, suprailiac, thigh, and abdomen. See [Chapter 6](#). If a dorsocervical fat pad (fat behind the neck) is present, measurement of the neck diameter can help track changes in this area. These physical changes are referred to as **HIV-associated lipodystrophy syndrome (HALS)**. Unintentional weight changes should be monitored closely because they can indicate progression of HIV disease. Peripheral neuropathy is a potential side effect, most frequently associated with NRTIs. The resulting nerve damage causes stiffness, numbness, or tingling generally in the lower extremities. Patients experiencing neuropathy may be unable to work or be physically active.

## Social and Economic Factors

Depending on a patient's mental status, psychosocial issues may take precedence over nutrition counseling. Depression is common, so the need to treat and provide services for mental health issues should be monitored. When individuals are unable to care for themselves, discussion with caretakers may be necessary to understand the patient's nutrition history. Particular habits, food aversions, timing of meals with medications, and related concerns should be documented.

Access to safe, affordable, and nutritious food should be evaluated. Common barriers include cost, location of supermarkets, lack of transportation, and lack of knowledge of healthier choices. In addition, because medications are costly, they often compete with food for available resources.

## Nutrient Recommendations

When collecting the diet history, a review of current intake, changes in intake, limitations with food access or preparation, food intolerances or allergies, supplement use, current medications, and alcohol and recreational drug use will help determine the potential for any nutrient deficiencies and assist in making individualized recommendations.

Adequate nutrition intake can help patients with HIV with symptom management and improve the efficacy of medications, disease complications, and overall quality of life. Refer to [Figure 38-3](#) for a sample nutrition screening form. Note that a one-size-fits-all approach does not address the complexity of HIV. RDs must provide recommendations to improve nutritional status, immunity, and quality of life, address drug-nutrient interactions or side effects, and identify barriers to desirable food intake ([Box 38-2](#)).

## BOX 38-2

### Education Needed by HIV Patients

#### Pregnancy, Lactation, Infancy, and Childhood

- Nutrition and food choices for healthy pregnancy and lactation
- Transmission risk in breastfeeding and replacement feeding alternatives
- Growth failure and developmental delay in children
- Support for normal growth trends in children

#### General Lifestyle Tips for Adults

- Basic nutrition concepts and healthy habits
- Physical activity recommendations
- Body image and altered body weight and shape
- Nutrition and food-related knowledge related to cultural or ethnic practices

#### Nutrition Interactions

- Prevention, restoration, and maintenance of optimal body composition with an emphasis on lean tissues
- Medication-nutrition interactions
- Management of barriers to nutritional wellness, nutrition-related side effects of treatments, and symptoms requiring attention
- Review of oral beverage or nutrient supplements
- Review of potential interactions with nonprescription medications and herbal supplements
- Evaluation of interactions with alcohol and recreational drugs

#### Life Skills and Socioeconomic Issues

- Safe food handling and water sources
- Access to adequate food choices
- Food preparation skills and abilities.

Adapted from American Dietetic Association: Position paper on nutrition intervention and Human Immunodeficiency Virus infection, *J Am Diet Assoc* 110:1105, 2010.

*HIV*, Human immunodeficiency virus.

In the early stages of nutrition therapy for HIV, the focus was on treatment and prevention of unintentional weight loss and wasting. Now with access to ART, new nutrition issues have arisen caused by HALS. HIV-related death from OIs has shifted to other chronic disease conditions such as heart disease and diabetes in healthier individuals who are living with HIV ([Leyes, 2008](#)).

## Energy and Fluid

When determining energy needs, it is important to establish if the individual needs to gain, lose, or maintain weight. Other factors such as altered metabolism, nutrient deficiencies, severity of disease, comorbidities, and OIs should be taken into account when evaluating energy needs. Calculating energy and protein needs for this population is difficult

because of other issues with wasting, obesity, HALS, and lack of accurate prediction equations. Some research suggests that resting energy expenditure is increased by approximately 10% in adults with asymptomatic HIV (Polo, 2007). After an OI, nutritional requirements increase by 20% to 50% in both adults and children (WHO, 2005a). Continuous medical and nutrition assessment is necessary to make adjustments as needed. Individuals with well-controlled HIV are encouraged to follow the same principles of healthy eating and fluid intake recommended for everyone.

## Protein

The current recommended dietary reference intake (DRI) is 0.8 g of protein per kilogram of body weight per day for healthy individuals. Deficiency of protein stores and abnormal protein metabolism occur in HIV and AIDS, but no evidence exists for increased protein intake over and above that necessary to accompany the required increase in energy (WHO, 2005b). For people with HIV who have adequate weight and are not malnourished, protein supplementation may not be sufficient to improve lean body mass (Sattler, 2008). However, with an OI, an additional 10% increase in protein intake is recommended because of increased protein turnover (WHO, 2005b). If other comorbidities such as renal insufficiency, cirrhosis, or pancreatitis are present, protein recommendations should be adjusted accordingly.

## Fat

There is evidence that dietary fat requirements are different with HIV infection (WHO, 2005b). General heart-healthy guidelines should be the focus for dietary fat intake. Recent research has focused on immune function and ω-3 fatty acids. There is some research to suggest increasing the intake of ω-3 fatty acids in individuals with HIV who have elevated serum triglycerides. See below.

## Micronutrients

Vitamins and minerals are important for optimal immune function. Nutrient deficiencies can affect immune function and lead to disease progression. Micronutrient deficiencies are common in people with HIV infection as a result of malabsorption, drug-nutrient interactions, altered metabolism, gut infection, and altered gut barrier function. Vitamin A, zinc, and selenium serum levels are often low during times of response to infection, so it is important to assess dietary intake to determine whether correction of serum micronutrients is warranted (Coyne-Meyers and Trombley, 2004).

There are benefits to correcting some depleted serum levels of micronutrients. Low levels of vitamins A, B<sub>12</sub>, and zinc are associated with faster disease progression (Coyne-Meyers and Trombley, 2004). Higher intakes of vitamins C and B have been associated with increased CD4 counts and slower disease progression to AIDS (Coyne-Meyers and Trombley, 2004). The Nutrition for Healthy Living study found that minorities and women tend to have lower micronutrient intakes and may benefit from nutrition counseling and dietary assessment (Jones, 2006).

Studies on micronutrients are difficult to interpret because there are a variety of study designs and outcomes. Serum micronutrient levels reflect conditions such as acute infection, liver disease, technical parameters, and recent intake. Adequate micronutrient intake through consumption of a balanced, healthy diet should be encouraged. However, diet alone may not be sufficient in people with HIV. A multivitamin and mineral supplement that provides 100% of the DRI may also be recommended. Megadosing on some micronutrients such as vitamins A, B<sub>6</sub>, D, E, and copper, iron, niacin, selenium, and zinc may be detrimental to health outcomes and may not warrant protection against prevention of chronic diseases. At this time, there is no evidence to support micronutrient supplementation in adults with HIV-infection above the recommended levels of the DRI (Kawai, 2010, WHO, 2005c). See Table 38-9 for a summary.

## SPECIAL CONSIDERATIONS

### Wasting

Wasting implies unintentional weight loss and loss of lean body mass, which have been strongly associated with an increased risk of disease progression and mortality. Despite the efficacy of ART, wasting continues to be a common problem in the HIV population. Wasting may be caused by a combination of factors including inadequate dietary intake, malabsorption, and increased metabolic rates from viral replication or complications from the disease (WHO, 2005b). Until the underlying cause of weight loss is discovered, it will remain difficult to target effective nutrition therapy.

### Obesity

Obesity in people with HIV has also been noted (Hendricks, 2006). Unintentional weight loss in HIV infection has been associated with mortality, but there needs to be more careful review in overweight or obese HIV-infected individuals. In the era of ART, it is no longer believed that continuously gaining body weight is a protective cushion against HIV-related wasting and progression to AIDS.

Some of the ART medications increase the risk of hyperlipidemia, insulin resistance, and diabetes. It is important to monitor these risk factors and provide nutrition recommendations to maintain a healthy weight. Physical activity, aerobic exercise, and resistance training are recommended to work synergistically with optimal nutrition intake to achieve a healthy weight and maintain lean body mass.

### HIV-Associated Lipodystrophy Syndrome (HALS)

HALS refers to the metabolic abnormalities and body shape changes seen in patients with HIV, similar to the metabolic syndrome found in the general population. The typical body shape changes include fat deposition (generally visceral adipose tissue in the abdominal region or as a dorsocervical fat pad and breast hypertrophy) or fat atrophy seen as loss of subcutaneous fat in the extremities, face, and buttocks. The metabolic abnormalities include hyperlipidemia

**TABLE 38-9****Common Micronutrient Deficiencies and Indications for Supplementation**

Vitamin or Mineral	Potential Cause for Deficiency	Results of Vitamin Deficiency	Supplementation Indications
B <sub>12</sub>	Malabsorption Inadequate intake	Increased risk of progression to AIDS Dementia Peripheral neuropathy Myelopathy Diminished performance (information processing and problem-solving skills)	Little evidence of benefits to supplementation beyond correcting low serum levels
A	Inadequate intake	Increased risk of progression to AIDS	Necessary to correct low levels Should not exceed DRI when serum levels are normal High intakes beyond correcting low levels can be detrimental to health and potentially increase risk of mortality from AIDS (Coyne-Meyers and Trombley, 2004) Needs more research
β-carotene	Inadequate intake Fat malabsorption	Potential relationship with oxidative stress	Recommend only amounts found in multivitamin supplement
E	Inadequate intake	Potentially weakens Immune function Potential increased progression to AIDS Oxidative stress Impaired immune response High intake: may be associated with increased surrogate markers of atherosclerosis	Needs more research Needs more research
D	Inadequate intake Inadequate exposure to sunshine	Immune suppression	Correct low levels Needs more research
Selenium	Inadequate intake	Potential increased progression to AIDS Weakened immune function Oxidative stress	Multivitamin providing DRI recommended Higher doses not recommended at this time until further research
Zinc	Inadequate intake	Increased risk for HIV-related mortality Weakened immune system Impaired healing processes Lower CD4 counts	Recommend supplementing to intakes of DRI High levels above DRI may lead to faster disease progression Needs more research
Iron	Low levels during initial asymptomatic HIV infection caused by inadequate absorption Inadequate intake	Anemia Progression and mortality in HIV infection High levels of iron potentially increase viral load Increase susceptibility to and severity from other infections such as TB	Correct low levels as needed Recommend intakes at DRI Needs more research

AIDS, Acquired immune deficiency syndrome; DRI, dietary reference intake; TB, tuberculosis.

(particularly high triglycerides and low-density lipoprotein [LDL] cholesterol and low high-density lipoprotein [HDL] cholesterol) and insulin resistance. There is no consensus on the clinical definition of HALS and the manifestations vary greatly from patient to patient. Each part of the syndrome may occur independently or simultaneously.

The cause of HALS is multifactorial and includes duration of HIV infection, duration of ART medications, age, gender, race and ethnicity, increased viral load, and increased body mass index. Physical changes should be discussed with the health care team. It is important to monitor these changes by taking anthropometric measurements. Monitoring trends with body weight is important; however, doing so will not likely identify body shape changes. Generally, there is a shift in body composition even though weight remains stable. Taking waist, hip, arm, mid-upper arm, and thigh circumference measurements and tricep, subscapular, suprailiac, abdominal, and thigh skinfold measurements are useful in monitoring exact locations of either fat hypertrophy or atrophy.

Nutrition interventions associated with HALS are limited. For nutrition recommendations, the guidelines set by the National Cholesterol Education Program and American Diabetes Association are followed (see Chapters 31 and 34). Recommendations for physical activity, including aerobic exercise and resistance training, should complement dietary intake. In addition, special focus should be on achieving adequate dietary fiber intake. This can potentially decrease the risk of fat deposition (Dong et al., 2006; Hendricks, 2003) and improve glycemic control.

For patients who have high triglycerides, ω-3 fatty acids may be useful. Omega-3 fatty acids decrease serum triglycerides and may reduce inflammation and improve depression. In some studies, 2–4 g of fish oil supplements per day have been shown to lower serum triglyceride levels in patients with HIV (Wohl, 2005; Woods, 2009). Potential side effects from supplementation include GI distress, hyperglycemia, and increased LDL cholesterol levels. Use of supplements should be monitored and discussed with the health care team.

## HIV IN WOMEN

Around the world, 15.7 million women are living with HIV or AIDS. In the United States, women accounted for more than 10,000 (25%) of the estimated number of new HIV infections in 2008 (CDC, 2010). The highest rate of new HIV infection is seen in African American women, which is 15 times as high as that of white women and nearly 4 times that of Hispanic women (CDC, 2010).

Although HIV-infected women are a minority in the United States, there are several factors that put them at higher risk of contracting HIV. Biologically, women are more likely to get HIV during unprotected vaginal sex because the lining of the vagina provides a larger area that can be exposed to HIV-infected semen. Barriers to receiving appropriate medical care also exist. Social and cultural stigma, lack of financial resources, responsibility to care for

others, and fear of disclosure may prevent women from seeking proper care.

## Preconception and Prenatal Considerations

HIV-infected women of child-bearing age should receive counseling prior to conception to learn how to decrease the risk of mother-to-child transmission. Current recommendations include prenatal screening for HIV, initiation of ART during pregnancy, and ART for the child once it is born. In the United States, these interventions have reduced the risk of mother-to-child transmission to less than 2% (DHHS, 2010a). Similar to HIV-negative women, adequate nutritional status and nutrient deficiencies should be monitored during pregnancy. Supplementation of vitamins B, C, and E have been shown to reduce the incidence of adverse pregnancy outcomes (e.g., low birth weight, fetal death) and decrease rates of mother-to-child transmission in women with compromised immune and nutrition status (Kawai, 2010). It is important to note if women have deficient serum vitamin A levels prior to supplementation, since different serum levels may affect risk of HIV transmission. Benefits may only be noted in those needing repletion of low levels.

## Postpartum and Other Considerations

In the United States breastfeeding is not recommended for HIV-infected women, including those on ART, where safe, affordable, and feasible alternatives are available and culturally appropriate (DHHS, 2009). In developing countries, recommendations may differ depending on safety and availability of formula and access to clean drinking water.

## HIV IN CHILDREN

An estimated 430,000 new HIV infections occurred globally among children younger than the age of 15 in 2008 (UNAIDS and WHO, 2009). In the United States an estimated 200 HIV-infected children are born each year. The majority of these infections stem from mother-to-child transmission in utero, during delivery, or through consumption of HIV-infected breastmilk. Recently, premasturbation (chewing foods or medicine before administering to a child) was reported as a route of transmission through blood in saliva (CDC, 2011).

Growth is the most valuable indicator of nutritional status in childhood. Poor growth may be an early indicator for progression of HIV disease. Growth failure can result from HIV infection itself and HIV-associated OIs (Guillen, 2007). Weight and height of HIV-infected children generally lags behind uninfected children of the same age. Loss of lean body mass with no changes in total body weight can also occur. To appropriately measure body changes, serial anthropometric measurements should be recorded, along with tracking of height and weight on growth charts (Sabery et al., 2009).

HIV treatment has improved the clinical outcomes for children, with ART initiation resulting in significant catch-up in weight and height but not to the level of uninfected children. The presence of HALS seen in adults is also common in children. With the increasing number of years on ART,

more morphologic and metabolic abnormalities, as described in the section on HALS, are being documented in children (Sabery and Duggan, 2009). Multivitamin and micronutrient supplementation may be beneficial at the DRI levels for children who are malnourished. Research does not currently support any supplementation at higher doses.

## COMPLEMENTARY AND ALTERNATIVE THERAPIES

In general, any treatment method that is not practiced in conventional medicine is considered complementary and alternative medicine (CAM). Dietary supplements, herbal treatments, megavitamins, acupuncture, yoga, and meditation are just a few of the therapies that are categorized as CAM. See Chapter 13.

The use of CAM is prevalent in patients with HIV infection. On average 60% of people living with HIV use CAM to treat HIV-related health concerns (Littlewood, 2008). People experiencing greater HIV symptom severity and longer disease duration are more likely to use CAM in an attempt to delay disease progression and alleviate side effects of HIV infection and treatment (Bormann, 2009). In addition, CAM use is more common in men who have sex with men, nonminorities, the better educated, and less impoverished individuals (Littlewood, 2008).

Despite the high percentage of CAM use, only one third of patients disclose CAM use to their health care providers (Liu, 2009). Some patients with HIV have noted benefits with taking dietary supplements; however, potential interactions with ART medications should be addressed (Hendricks, 2007). Therefore it is important that each patient be questioned carefully about use of alternative therapies, particularly those taken orally or subcutaneously. Information should be collected on the brands, dosage, frequency, timing, duration, and cost of the supplements. This should be compared with additional clinical information such as current medications, biochemical parameters, and nutrition intake. Each item should be researched for potential drug-drug and drug-nutrient interactions because they may interfere with ART use. For example, garlic and St. John's wort (*Hypericum perforatum*) decrease blood levels of ART medications, decreasing the efficacy of ART and potentially leading to drug resistance.

A key point in counseling patients who are using alternative therapies is to understand why they choose to use them. Most studies have found that there may not be any additional benefit to supplementing beyond correcting deficiencies. Food should be recommended first and patients should keep in mind that more is not always better. Caution should be used because dietary supplement labels can make a statement of nutrition support and health benefit, but it must be accompanied by the disclaimer, "This statement has not been evaluated by the Food and Drug Administration (FDA). This product is not intended to diagnose, treat, cure, or prevent any disease." Adverse event reporting for dietary supplements is voluntary, leading to a underreporting or underestimation of events.

## CLINICAL SCENARIO

**W** is a 42-year-old male who has been HIV positive for 20 years. His viral load is undetectable and his CD4+ count is 643. His current HIV antiretroviral regimen is raltegravir (Isentress), atazanavir (Reyataz), ritonavir (Norvir), and emtricitabine (Emtriva); he also takes atorvastatin (Lipitor) and ranitidine (Zantac). His height is 5'9" and his weight is 188 lb. His fasting lipid profile is total cholesterol 184 mg/dL, triglycerides 304 mg/dL, high-density lipoprotein 25 mg/dL, and low-density lipoprotein 96 mg/dL. Since his last visit 6 months ago, he has noticed changes in his body composition including loss of buccal fat and increasing abdominal girth. He lives by himself and doesn't like to cook; he also receives one meal per day from a community program. He walks 30 minutes daily. Upon taking a 24-hour recall, you find his caloric intake to be 2700 kcal/day.

### Nutrition Diagnostic Statement

Excessive dietary intake caused by frequent intake of pre-packaged meals as evidenced by diet history.

### Nutrition Care Questions

- What factors might be contributing to the body shape changes that the patient is experiencing?
- What nutrition and lifestyle interventions would you recommend to address his nutrition diagnosis?
- What are some biochemical and nutritional parameters you would monitor to determine if the nutrition intervention was successful?
- How would you evaluate your desired nutrition outcomes to determine if the goals have been met?
- The patient has also been complaining of nausea and diarrhea. What recommendations do you suggest for these symptoms? Are there any drug-nutrient interactions to be aware of?

# Medical Nutrition Therapy for Metabolic Stress: Sepsis, Trauma, Burns, and Surgery

### KEY TERMS

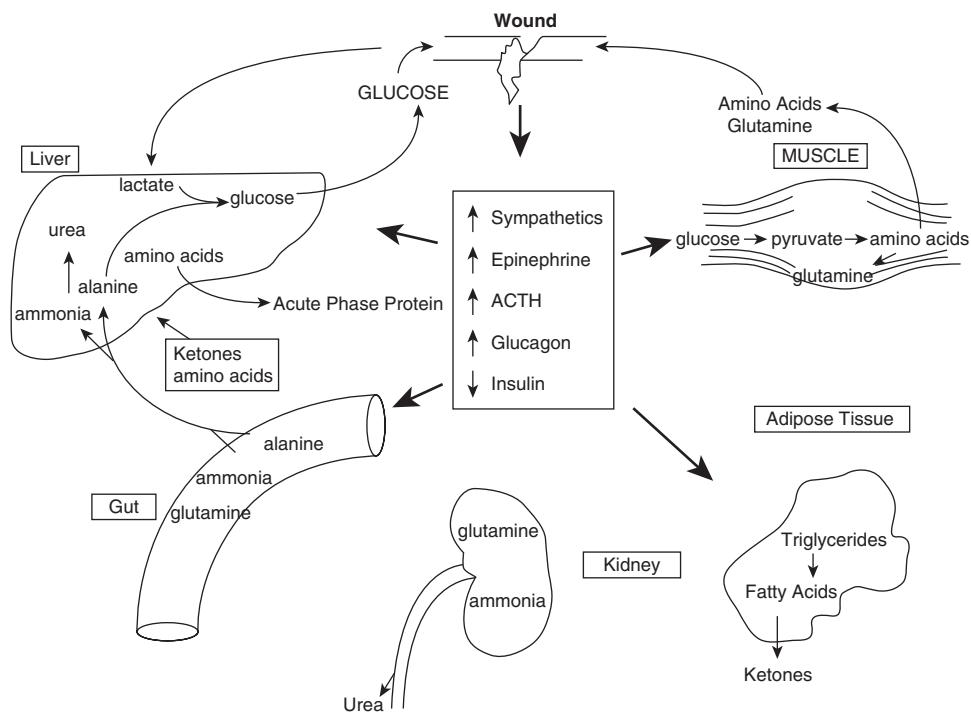

abdominal compartment syndrome  
acute-phase proteins  
adrenocorticotrophic hormone  
catecholamines  
cortisol  
counter-regulatory hormones  
cytokines  
ebb phase  
epithelial barrier function (EBF)  
flow phase

hemodynamic  
ileus  
interleukin-1 (IL-1)  
interleukin-6 (IL-6)  
multiple organ dysfunction syndrome (MODS)  
nutrition support therapy  
sepsis  
shock  
systemic inflammatory response syndrome (SIRS)  
tight junctions  
tumor necrosis factor (TNF)

Trauma from motor vehicle accidents, gunshots, stab wounds, falls, and burns are major causes of disability and death. Unintentional injuries and motor vehicle accidents are ranked as the fifth leading cause of death after heart disease, cancer, stroke, and chronic lower respiratory diseases. Injury results in profound metabolic alterations, beginning at the time of injury and persisting until wound healing and recovery are complete. Whether the event involves **sepsis** (infection), trauma, burns, or surgery, the systemic response is activated. The physiologic and metabolic changes that follow may lead to shock and other negative outcomes (Figure 39-1). Variable responses relate in part to the patient's age, previous state of health, preexisting disease, type of infection, and presence of multiple organ dysfunction syndrome (MODS).

### METABOLIC RESPONSE TO STRESS

The metabolic response to critical illness, traumatic injury, sepsis, burns, or major surgery is complex and involves most metabolic pathways. Accelerated catabolism of lean body or skeletal mass occurs, which clinically results in net negative nitrogen balance and muscle wasting. The response to critical illness, injury, and sepsis characteristically involves both ebb and flow phases. The **ebb phase**, occurring immediately following injury, is associated with hypovolemia, shock, and tissue hypoxia. Typically decreased cardiac output, oxygen consumption, and body temperature occur in this phase. Insulin levels fall in direct response to the increase in glucagon, most likely as a signal to increase hepatic glucose production (Table 39-1).

**FIGURE 39-1** Neuroendocrine and metabolic consequences of injury, ACTH, adrenocorticotrophic hormone. (Reprinted from Lowry SF and Perez JM in *Modern Nutrition in Health and Disease*, Lippincott Williams & Wilkins, Philadelphia, PA, 2006, 1381-1400.)

**TABLE 39-1**

**Characteristics of Metabolic Phases Occurring After Severe Injury**

EBB-Phase Response	Flow Phase	
	Acute Response	Adaptive Response
<b>Hypovolemic Shock</b>	<b>Catabolism Predominates</b>	<b>Anabolism Predominates</b>
↓ Tissue perfusion ↓ Metabolic rate ↓ Oxygen consumption ↓ Blood pressure ↓ Body temperature	↑ Glucocorticoids ↑ Glucagon ↑ Catecholamines Release of cytokines, lipid mediators Production of acute-phase proteins ↑ Excretion of nitrogen ↑ Metabolic rate ↑ Oxygen consumption Impaired use of fuels	Hormonal response gradually diminishes ↓ Hypermetabolic rate Associated with recovery Potential for restoration of body protein Wound healing depends in part on nutrient intake

From Enteral nutrition support in critical care, Columbus, OH, 1994, Ross Products Division, Abbott Labs.

Increased cardiac output, oxygen consumption, body temperature, energy expenditure, and total body protein catabolism characterize the **flow phase** that follows fluid resuscitation and restoration of oxygen transport. Physiologically, a marked increase occurs in glucose production, free fatty acid release, circulating levels of insulin, **catecholamines** (epinephrine and norepinephrine released by the adrenal medulla), glucagon, and cortisol. The magnitude of hormonal response appears to be associated with the severity of injury.

### Hormonal and Cell-Mediated Response

Metabolic stress is associated with an altered hormonal state that results in an increased flow of substrate but poor use of carbohydrate, protein, fat, and oxygen. **Counter-regulatory hormones**, which are elevated after injury and sepsis, play a role in accelerated proteolysis. Glucagon promotes gluconeogenesis, amino acid uptake, ureagenesis, and protein catabolism. **Cortisol**, which is released from the adrenal cortex in response to stimulation by **adrenocorticotrophic**

**TABLE 39-2****Metabolic Responses During Stress**

Organ	Response
Liver	↑ Glucose production ↑ Amino acid uptake ↑ Acute-phase protein synthesis ↑ Trace metal sequestration
Central nervous system	Anorexia Fever
Circulation	↑ Glucose ↑ Triglycerides ↑ Amino acids ↑ Urea ↓ Iron ↓ Zinc
Skeletal muscle	↑ Amino acid efflux (especially glutamine), leading to loss of muscle mass
Intestine	↓ Amino acid uptake from both luminal and circulating sources, leading to gut mucosal atrophy
Endocrine	↑ Adrenocorticotropic hormone ↑ Cortisol ↑ Growth hormone ↑ Epinephrine ↑ Norepinephrine ↑ Glucagon ↑ Insulin (usually)

From Michie HR: Metabolism of sepsis and multiple organ failure, World J Surg 20:461, 1996.

**hormone** secreted by the anterior pituitary gland, enhances skeletal muscle catabolism and promotes hepatic use of amino acids for gluconeogenesis, glycogenolysis, and acute-phase protein synthesis (Table 39-2).

After injury or sepsis, energy production increasingly depends on protein. Branched-chain amino acids (BCAAs leucine, isoleucine, and valine) are oxidized from skeletal muscle as a source of energy for the muscle; carbon skeletons are made available for the glucose-alanine cycle and muscle glutamine synthesis. The mobilization of **acute-phase proteins**, those secretory proteins in the liver that are altered in response to injury or infection, results in rapid loss of lean body mass and an increased net negative nitrogen balance, which continues until the inflammatory response resolves. Breakdown of protein tissue also causes increased urinary losses of potassium, phosphorus, and magnesium. Lipid metabolism is also altered in stress and sepsis. Increased circulation of free fatty acids is thought to result from increased lipolysis caused by elevated catecholamines and cortisol, as well as a marked elevation in the ratio of glucagon to insulin.

Most notable is the hyperglycemia observed during stress. This initially results from a marked increase in glucose production and uptake secondary to gluconeogenesis and

elevated levels of hormones, including epinephrine, that diminish insulin release. Stress also initiates the release of aldosterone, a corticosteroid that causes renal sodium retention, and vasopressin (antidiuretic hormone), which stimulates renal tubular water resorption. The action of these hormones results in conservation of water and salt to support the circulating blood volume, noted in Table 39-2.

The response to injury is also regulated by metabolically active **cytokines** (proinflammatory proteins) such as **interleukin (IL)-1, IL-6**, and **tumor necrosis factor (TNF)**, which are released by phagocytic cells in response to tissue damage, infection, inflammation, and some medications. IL-6 is secreted by T cells and macrophages to stimulate the immune response to trauma or other tissue damage leading to inflammation; it has both proinflammatory and anti-inflammatory actions. Cytokines are thought to stimulate hepatic amino acid uptake and protein synthesis, accelerate muscle breakdown, and induce gluconeogenesis. IL-1 appears to have a major role in stimulating the acute-phase response. The vagus nerve helps to regulate cytokine production through a “cholinergic anti-inflammatory pathway,” releasing nicotinic acetylcholine receptor alpha 7 to reduce excessive cytokine activity (Galloswitsch-Puerta and Tracey, 2005).

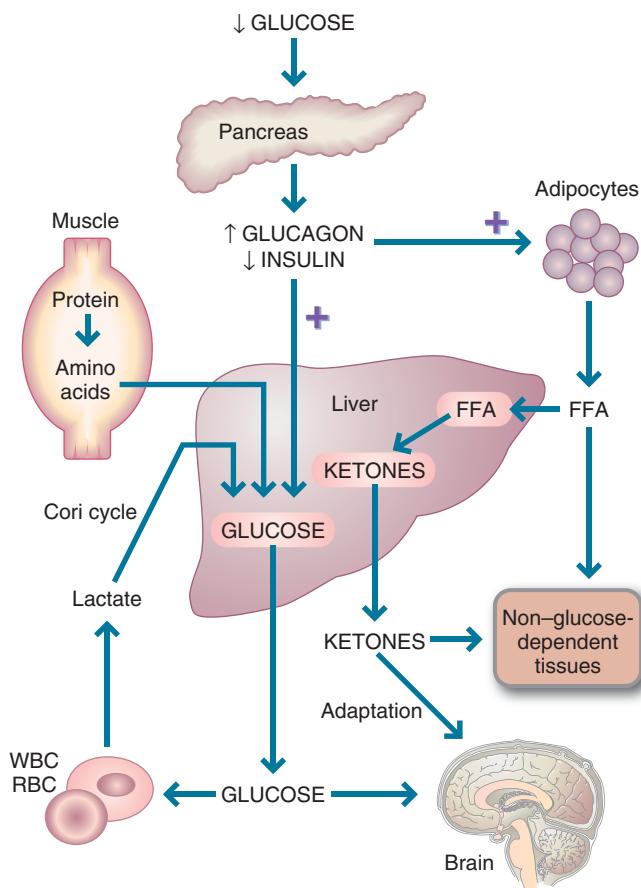

As part of the acute-phase response, serum iron and zinc levels decrease, and levels of ceruloplasmin increase, primarily because of sequestration and, in the case of zinc, increased urinary zinc excretion. The net effect of the hormonally and cell-mediated response is an increase in oxygen supply and a greater availability of substrates for metabolically active tissues.

## STARVATION VERSUS STRESS

The metabolic response to critical illness is very different from simple or uncomplicated starvation, in which loss of muscle is much slower in an adaptive response to preserve lean body mass. Stored glycogen, the primary fuel source in early starvation, is depleted in approximately 24 hours. After the depletion of glycogen, glucose is available from the breakdown of protein to amino acids, depicted in Figure 39-2. The depressed glucose levels lead to decreased insulin secretion and increased glucagon. During the adaptive state of starvation, protein catabolism is reduced, and hepatic gluconeogenesis decreases.

Lipolytic activity is also different in starvation and in stress. After 1 week of fasting or food deprivation, a state of ketosis—in which ketone bodies supply the bulk of energy needs, thus reducing the need for gluconeogenesis and conserving body protein to the greatest possible extent—develops. In late starvation, as in stress, ketone body production is increased, and fatty acids serve as a major energy source for all tissues except the glucose-obligated brain, nervous system, and red blood cells.

Starvation is characterized by decreased energy expenditure, diminished gluconeogenesis, increased ketone body production, and decreased ureagenesis. Conversely, energy

**FIGURE 39-2** Metabolic changes in starvation. *FFAs*, Free fatty acids; *RBCs*, red blood cells; *WBCs*, white blood cells. (From Simmons RL, Steed DL: *Basic science review for surgeons*, Philadelphia, 1992, Saunders.)

expenditure in stress is markedly increased, as are gluconeogenesis, proteolysis, and ureagenesis. As discussed, the stress response is activated by hormonal and cell mediators—counter-regulatory hormones such as catecholamines, cortisol, and growth hormone. This mediator activation does not occur in starvation.

## SYSTEMIC INFLAMMATORY RESPONSE SYNDROME AND MULTIPLE ORGAN DYSFUNCTION SYNDROME

### Pathophysiology

Sepsis and the systemic inflammatory response syndrome (SIRS) often complicate the course of a critically ill patient. The term *sepsis* is used when a patient has a documented infection and an identifiable organism. Bacteria and their toxins lead to a stronger inflammatory response. Other microorganisms that lead to an inflammatory response include viruses, fungi, and parasites.

**Systemic inflammatory response syndrome (SIRS)** describes the widespread inflammation that can occur in infection, pancreatitis, ischemia, burns, multiple trauma,

### BOX 39-1

#### Diagnosis for Systemic Inflammatory Response Syndrome (SIRS)

Site of infection established and at least two of the following are present:

- Body temperature above 38° C or less than 36° C
- Heart rate more than 90 beats/min
- Respiratory rate greater than 20 breaths/min (tachypnea)
- $\text{Paco}_2$  of less than 32 mm Hg (hyperventilation)
- White blood cell count above 12,000/mm<sup>3</sup> or less than 4000/mm<sup>3</sup>
- Bandemia—the presence of more than 10% bands (immature neutrophils) in the absence of chemotherapy-induced neutropenia and leukopenia

Data from Bone et al: ACCP/SCCM Consensus Conference: Definitions for sepsis and organ failure and guidelines for the use of innovative therapies in sepsis, *Chest* 101:1664, 1992.

hemorrhagic shock, or immunologically mediated organ injury. The inflammation is usually present in areas remote from the primary site of injury, affecting otherwise healthy tissue. Each condition leads to release of cytokines, proteolytic enzymes, or toxic oxygen species (free radicals) and activation of the complement cascade. The American College of Chest Physicians (ACCP)–Society of Critical Care Medicine (SCCM) consensus conference definitions of sepsis are shown in Box 39-1.

A common complication of SIRS is the development of **multiple organ dysfunction syndrome (MODS)**. The syndrome generally begins with lung failure and is followed by failure of the liver, intestines, and kidney in no particular order. Hematologic and myocardial failures usually manifest later; however, central nervous system changes can occur at any time. MODS can be primary as the direct result of injury to an organ from trauma. Examples of primary MODS include pulmonary contusion, renal failure caused by rhabdomyolysis, or coagulopathy from multiple blood transfusions. Secondary MODS occurs in the presence of inflammation or infection in organs remote from the initial injury.

Patients with SIRS and MODS are clinically hypermetabolic and exhibit high cardiac output, low oxygen consumption, high venous oxygen saturation, and lactic acidemia. Patients generally have a strong positive fluid balance associated with massive edema and a decrease in plasma protein concentrations.

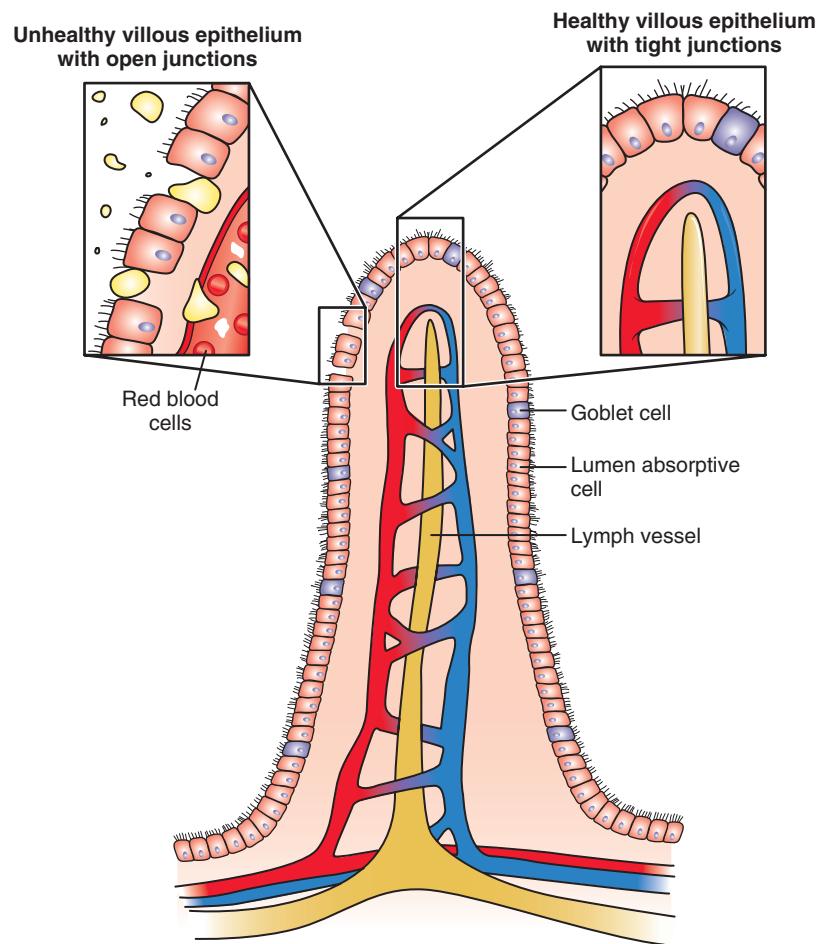

Multiple hypotheses have been proposed to explain the development of SIRS or MODS. In some studies, SIRS leading to MODS appears to be mediated by excessive production of proinflammatory cytokines and other mediators of inflammation. The gut hypothesis suggests that the trigger is injury or disruption of the gut barrier function, with corresponding translocation of enteric bacteria into the mesentery lymph nodes, liver, and other organs. Unique

gut-derived factors carried in the intestinal lymph but not the portal vein usually lead to acute injury- and shock-induced SIRS and MODS (Deitch et al., 2006).

**Shock** results in gut hypoperfusion; the hypoperfused gut is a source of proinflammatory mediators. Early gut hypoperfusion causes an **ileus** or lack of peristalsis in both the stomach and small bowel, and late infections cause further worsening of this gut dysfunction. Early enteral feeding is thought to restore gut function and influence the clinical course. The mechanism for this effect is due to the enhanced functional and structural integrity of the gut (Society of Critical Care Medicine [SCCM] and American Society for Parenteral and Enteral Nutrition [A.S.P.E.N.], 2009).

Enteral nutrition (EN) may have a role in maintaining **tight junctions** between the intraepithelial cells, stimulating blood flow and inducing the release of trophic factors (Figure 39-3). Maintenance of villous height supports the secretory immunocytes that make up the gut-associated lymphoid tissue (Kang & Kudsk, 2007). With central parenteral nutrition (PN), mucosal atrophy and a loss of **epithelial barrier function (EBF)** may occur. A rise in interferon gamma and decline in IL-10 contribute to the loss of EBF in animal models along with a dramatic decline in the expression of tight junction and adherens junction proteins (Yang et al., 2009). Studies in animals suggest that glutamine added to the parenteral solution may protect the EBF (Nose et al., 2010).

**FIGURE 39-3** Tight junction in the intestinal villus, supporting gut membrane integrity.

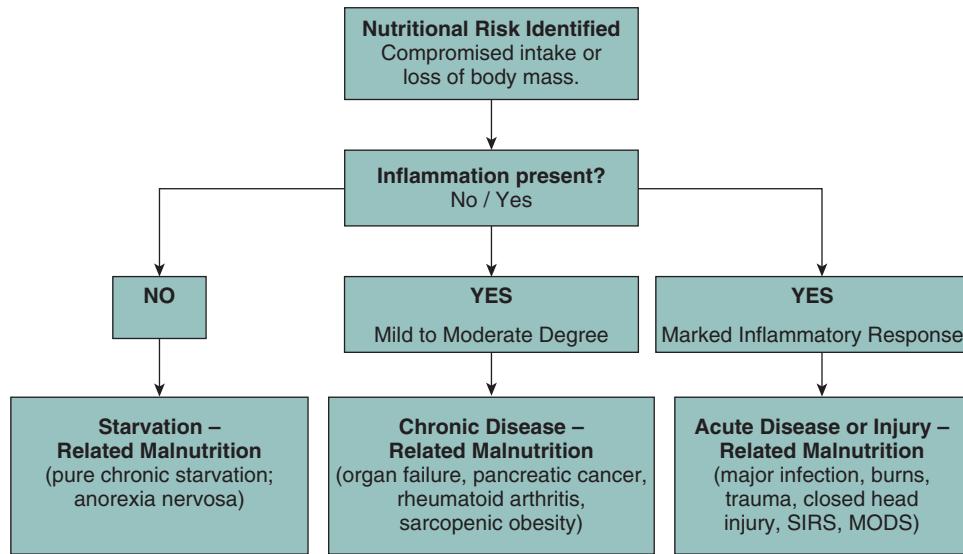

## MALNUTRITION: THE ETIOLOGY-BASED DEFINITION

The historical approach to defining malnutrition in the patient undergoing the stress response has recently been reevaluated. In an effort to provide consistency in its definition, an international group of nutrition support leaders developed an etiology basis for the definition of malnutrition for hospitalized adult patients. This approach focuses on the following three etiologies: starvation-related malnutrition, chronic disease-related malnutrition, or acute disease-related malnutrition (Figure 39-4). The latter category includes those patients experiencing SIRS and MODS and is characterized by a heightened cytokine response which in turn leads to profound losses in fat-free mass. Of note, in this setting, despite adequate provision of nutrition support therapy, repletion of lean body mass cannot occur (Jensen et al., 2009; Jensen et al., 2010).

### Medical Nutrition Therapy

The critically ill patient typically enters an intensive care unit (ICU) because of a cardiopulmonary diagnosis, intraoperative or postoperative complication, multiple trauma, burn injury, or sepsis. Traditional methods of assessing nutritional status are often of limited value in the ICU setting. The severely injured patient is usually unable to

**FIGURE 39-4** Diagram of Malnutrition Definitions. (*Adapted from Jensen GL et al: Malnutrition syndromes: a conundrum versus continuum, JPEN J Parenter Enteral Nutr 33:710, 2009; and Jensen G et al: Adult starvation and disease-related malnutrition: a proposal for etiology-based diagnosis in the clinical practice setting from the International Consensus Guideline Committee, JPEN J Parenter Enteral Nutr 34:156, 2010.*)

provide a dietary history. Values for weight may be erroneous after fluid resuscitation, and anthropometric measurements are not easily attainable, nor are they sensitive to acute changes. Hypoalbuminemia reflects severe illness, injury, and inflammation; thus serum albumin should not be used as a marker of nutritional status. Other plasma proteins such as prealbumin and transferrin often drop precipitously, related not to nutrition status but to an inflammation-induced decrease in hepatic synthesis and changes caused by compartmental shifts in body fluid. This is part of the acute-phase response in which secretory and circulating proteins are altered in response to inflammation or injury.

The critical role of physical assessment cannot be overlooked. Loss of lean body mass and accumulation of fluid are common to the ICU patient, and the ability to recognize these, as well as other important physical parameters is essential. In general, assessment focuses on the preadmission, preoperative, or preinjury nutrition status; presence of any organ system dysfunction; the need for early nutrition support therapy; and options that exist for enteral or parenteral access. Care planning should consider these factors. When monitoring critically ill patients, one must focus on laboratory data, not to define or determine nutrition status but to design the nutrition prescription (see Chapter 14).

Because the patient is so ill, oral intake of food or fluid may be severely limited. Therefore some common nutrition diagnoses include:

- Inadequate oral food and beverage intake (requiring other mode of nutrient or fluid administration)
- Inadequate or excessive intake from EN or PN infusion (for body requirements in nonambulatory patient)
- Inappropriate infusion of EN or PN (for example, using PN when EN is possible)

- Inadequate or excessive fluid intake (from intravenous [IV] infusions, nutrient solutions, tube flushes)
- Increased nutrient needs (such as protein for wound healing)
- Excessive carbohydrate intake (as when giving a parenteral solution to a chronically malnourished patient, with potential for refeeding syndrome)
- Abnormal nutrition-related laboratory values
- Altered gastrointestinal (GI) function (such as vomiting, diarrhea, constipation).

### Nutrition Support Therapy

**Nutrition support therapy** incorporates early EN when feasible, appropriate macro- and micronutrient delivery, and glycemic control. Favorable expected outcomes from these practices include reduced disease severity, decreased length of time in the ICU, and decreased infectious morbidity and overall mortality.

The traditional goals of nutrition support therapy during sepsis and after injury include minimization of starvation, prevention or correction of specific nutrient deficiencies, provision of adequate calories to meet energy needs while minimizing associated metabolic complications, and fluid and electrolyte management to maintain adequate urine output and normal homeostasis (see *Pathophysiology and Care Management Algorithm: Hypermetabolic Response*).

Today, goals focus more on attempting to attenuate the metabolic response to stress, preventing oxidative cellular injury, and modulating the immune response (SCCM and A.S.P.E.N., 2009). The first emphasis of care in the ICU is establishing **hemodynamic** stability (maintenance of airway and breathing, adequate circulating fluid volume and tissue oxygenation, and acid-base neutrality). It is important to follow the patient's heart rate, blood pressure, cardiac

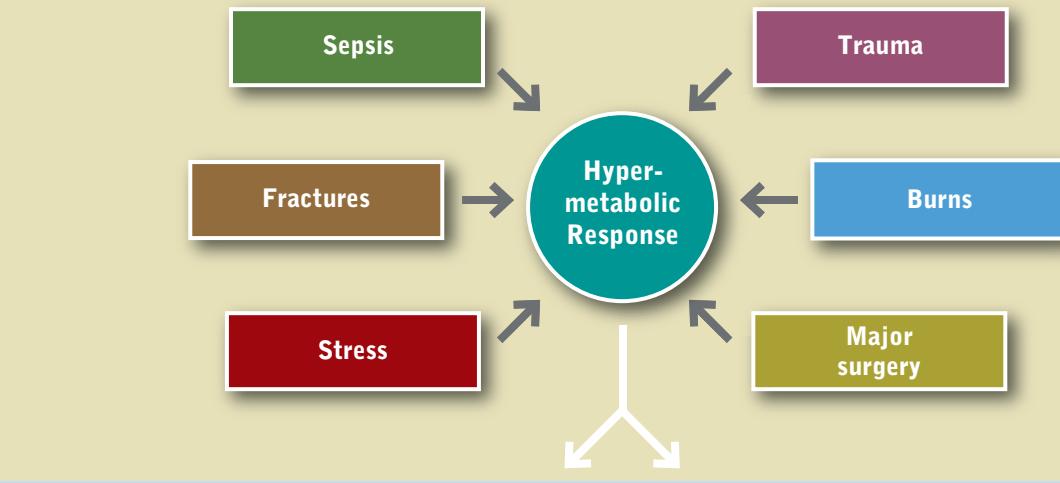

## PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

### Hypermetabolic Response

ETIOLOGY

PATHOPHYSIOLOGY

MANAGEMENT

#### EBB Phase

- Hypovolemia
- Shock
- Tissue hypoxia
- Decreased:**
  - Cardiac output
  - O<sub>2</sub> consumption
  - Body temperature

#### Flow Phase

- Acute-phase proteins**
- Hormonal responses**
- Immune responses (cell-mediated and antibody)**
- Increased:**
  - Cardiac output
  - O<sub>2</sub> consumption
  - Body temperature
  - Energy expenditure
  - Protein catabolism

#### Medical Management

- Treat cause of hypermetabolism
- Hemodynamic stability

#### Nutrition Management

- Minimize catabolism
- Meet energy requirements, but do not overfeed
  - Use indirect calorimetry if possible
  - Non-obese: 25-30 kcal/kg/day
  - Obese: 14-18 kcal/kg/day of actual body weight
- Meet protein, vitamin, and mineral needs
- Establish and maintain fluid and electrolyte balance
- Plan nutrition therapy (oral, enteral, and/or parenteral nutrition)
- Need for pharmaconutrients
- Physical therapy
- Exercise

output, mean arterial pressure, and oxygen saturation to assess hemodynamic stability and whether nutrition support therapy can commence.

Glycemic control and its relationship to improved outcomes has been the focus of extensive study. It is now recognized that more moderate (150–180 mg/dL), rather than tight (80–110 mg/dL), control is associated with positive outcomes in critically ill patients (American Dietetic Association, 2010). Dietitians must recognize the significant contribution of dextrose in PN formulas and its influence on glycemic control.

## Nutritional Requirements

**Energy.** Ideally, indirect calorimetry (IC) should be used to determine energy requirements for critically ill patients. Oxygen consumption is an essential component in the determination of energy expenditure. Septic and trauma patients have substantial increases in energy expenditure associated with the magnitude of injury. IC can be performed serially as a patient's clinical status changes (Compher et al., 2006); this allows a more accurate assessment of energy requirements during a patient's stay in the ICU (see Chapter 2). IC is not appropriate for all patients, however, and should be performed and interpreted by experienced clinicians (Compher et al., 2006). High oxygen requirements, the presence of a chest tube, acidosis, and the use of supplemental oxygen are factors that may produce invalid results. In these situations measurement of energy expenditure by IC is not recommended (Malone, 2002).

In the absence of a metabolic cart for IC, energy requirements may be calculated as 25–30 kcal/kg/day (SCCM and A.S.P.E.N., 2009) or by using one of the many published predictive equations (see Chapter 2). Avoidance of overfeeding in the critically ill patient is important. Although adequate energy is essential for metabolically stressed patients, excess calories can result in complications such as hyperglycemia, hepatic steatosis, and excess carbon dioxide production, which can exacerbate respiratory insufficiency or prolong weaning from mechanical ventilation.

The amount of energy to provide critically ill obese patients is of current interest. Improved glycemic control and positive clinical outcomes occur in obese patients provided with 22 kcal/kg/day of ideal weight in conjunction with increased protein (Choban and Dickerson, 2005). There is some debate in practice as to what value should be used for weight in predictive equations. Actual body weight is a better predictor of energy expenditure than ideal body weight in obese individuals (Breen and Ireton-Jones, 2004). A recent evidence analysis review found the Penn State Equation, using actual body weight, to be 70% accurate in predicting energy expenditure if IC is unavailable (Frankenfield et al., 2007).

Research suggests that hypocaloric, high-protein nutrition support therapy or “permissive underfeeding” in critically ill obese patients results in achievement of net protein anabolism and minimizes complications resulting from overfeeding. Dickerson (2005) summarized a review of studies using hypocaloric specialized nutrition support

in obese patients in the ICU. Although there is no agreement as to what constitutes hypocaloric feeding, studies suggest that this approximates 14–18 kcal/kg/day of actual body weight or 22 kcal/kg/day of ideal body weight (SCCM and A.S.P.E.N., 2009). More research is needed to validate hypocaloric feeding as the standard approach to nutrition support in obese patients, especially because of the wide variability in body composition (Port and Apovian, 2010).

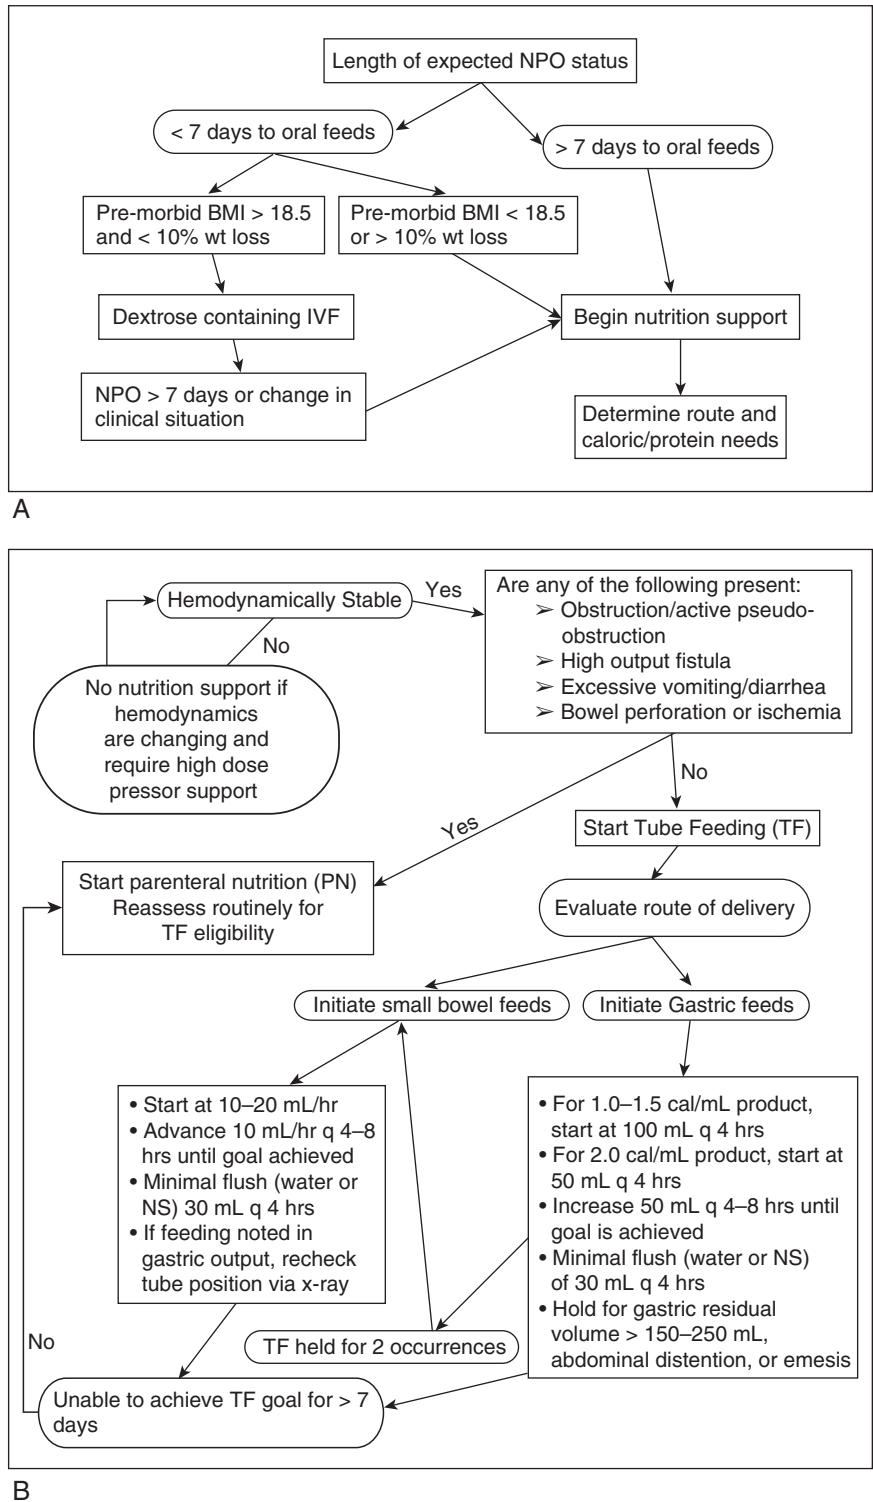

**Protein.** Determination of protein requirements is difficult for critically ill patients. Patients typically require 1.2–2 g/kg/day depending on their baseline nutritional status, degree of injury and metabolic demand, and abnormal losses (e.g., through open abdominal wounds or burned skin) (SCCM and A.S.P.E.N., 2009). Administration of excessive amounts of protein will not decrease the characteristic net negative nitrogen balance seen among hypermetabolic patients.

**Vitamins, Minerals, and Trace Elements.** No specific guidelines exist for the provision of vitamins, minerals, and trace elements in metabolically stressed individuals. Micronutrient needs are elevated during acute illness because of increased urinary and cutaneous losses and diminished GI absorption, altered distribution, and altered carrier protein concentrations. With increased caloric intake there may be an increased need for B vitamins, particularly thiamin and niacin. Catabolism and loss of lean body tissue increase the loss of potassium, magnesium, phosphorus, and zinc. GI and urinary losses, organ dysfunction, and acid-base imbalance necessitate that mineral and electrolyte requirements be determined and adjusted individually. Fluid and electrolytes should be provided to maintain adequate urine output and normal serum electrolytes.

**Feeding Strategies.** The preferred route for nutrient delivery is an oral diet. However, critically ill patients are often unable to eat because of endotracheal intubation and ventilator dependence. Furthermore, oral feeding may be delayed by impairment of chewing, swallowing, by anorexia induced by pain-relieving medications, or by posttraumatic shock and depression. Patients who are able to eat may not be able to meet the increased energy and nutrient requirements associated with metabolic stress and recovery. They often require combinations of oral nutritional supplements, enteral tube nutrition, and PN. When EN fails to meet nutritional requirements or when GI feeding is contraindicated, PN support should be initiated (Figure 39-5).

**Timing and Route of Feeding.** EN is the preferred route of feeding for the critically ill patient who cannot eat food and who has good intestinal function. Feedings should be initiated early within the first 24–48 hours of ICU admission and advanced toward goal during the next 48–72 hours (SCCM and A.S.P.E.N., 2009). Intake of 50% to 65% of goal calories during the first week of hospitalization is thought to be sufficient to achieve the clinical benefit of EN. This practice is intended for patients who are hemodynamically stable. In the setting of hemodynamic instability (large volume requirements or use of high-dose catecholamine agents), tube feeding should be withheld until the patient is

**FIGURE 39-5** Timing and determining the route of nutrition support in the critically ill patient. **A**, Timing of nutrition support initiation. **B**, Determining optimal route of nutrition support. (Reprinted with permission from Beth Taylor.)

fully resuscitated or stable to minimize risk of ischemic or reperfusion injury (see Figure 39-5).

Either gastric or small-bowel feedings can be used. Small-bowel feedings are indicated when gastric residuals exceed 250 mL. Nasoenteric or surgically placed feedings tubes can be placed intraoperatively for patients with severe head, major thoracic, or spinal injury; facial injury requiring jaw wiring; proximal gastric or esophageal injuries, and major

pancreatic or duodenal injury; and severe trauma with plans for repeated surgeries.

Enteral tolerance should be monitored by assessing level of pain, presence of abdominal distention, passage of flatus and stool, physical examination and, if appropriate, abdominal x-ray examination. Steps to reduce aspiration risk should be implemented, including elevating the head of the bed and use of promotility agents. The cause of diarrhea, when

present, should be determined. Patients should be evaluated for intake of hyperosmolar medications and broad-spectrum antibiotics, and should be assessed for infectious diarrhea.

PN is indicated for patients in whom EN is unsuccessful or contraindicated. Supplemental PN is appropriate after 7–10 days of enteral feeding in situations in which goal requirements cannot be met (SCCM and A.S.P.E.N., 2009). For patients with preexisting malnutrition, PN should be used within 5–7 days of surgery and continue into the postoperative period.

**Formula Selection.** Choosing an enteral product should be based on fluid, energy, and nutrient requirements, as well as GI function. Most standard polymeric enteral formulas can be used to feed the critically ill patient. Some critically ill patients demonstrate intolerance to standard diets because of the fat content of the formula and temporarily require a lower-fat diet or a product containing a higher ratio of medium-chain triglycerides. Several commercially available products are marketed specifically for patients with trauma and metabolic stress. These products typically have higher protein content and a higher ratio of BCAs or additional glutamine or arginine.

Immune modulating enteral formulations that contain arginine, glutamine, nucleic acids, antioxidants, and  $\omega$ -3 fatty acids have potential beneficial effects and favorable outcomes for critically ill patients who have undergone GI surgery, as well as for trauma and burn patients. These formulations should not be routinely used for ICU patients with sepsis because they may worsen the inflammatory response (SCCM and A.S.P.E.N., 2009). Insoluble fiber should be avoided in critically ill patients; however, soluble fiber may be beneficial for the hemodynamically stable, critically ill patient who develops diarrhea (SCCM and A.S.P.E.N., 2009). Patients at high risk for bowel ischemia should not receive fiber-containing formulas or diets.

## TRAUMA AND THE OPEN ABDOMEN

Following major abdominal trauma, bowel distention, and states of shock, some patients experience increased intraabdominal pressure leading to hypoperfusion and ischemia of the intestines and other peritoneal and retroperitoneal structures. **Abdominal compartment syndrome** occurs when there is increased intraabdominal pressure, often following major abdominal trauma or sepsis. This condition has profound consequences, including hemodynamic instability and respiratory, renal, and neurologic abnormalities. Because the abdominal cavity has become too small, management consists of emergent decompressive laparotomy to relieve the intraabdominal pressure (Walker and Cridle, 2003). Closure of the abdomen is not performed and instead a temporary sterile dressing may be applied.

Patients with an open abdomen have severe metabolic alterations, increased loss of fluids, and elevated nutritional requirements. The open abdomen may also be a significant source of protein loss depending on the amount of drainage (Cheatham et al., 2007). There has been some controversy

as to whether patients with an open abdomen can be enterally fed. As long as the patient is hemodynamically stable and does not require large-volume fluid resuscitation or increasing doses of pressor agents, enteral feeding should be possible (Byrnes et al., 2010; Collier et al., 2007; Dissanaike et al., 2008). Ideally, a nasojejunal feeding tube should be positioned at the time of surgery to facilitate early EN support therapy.

Management of intestinal fistulas and large draining wounds are also challenging both surgically and nutritionally. These patients have metabolic abnormalities associated with losses of fluid, electrolytes, and nutrients. The priorities for management of intestinal fistulas are to restore blood volume, replace fluid and electrolyte losses, treat sepsis, control fistula drainage, protect the surrounding skin, and provide optimal nutrition support therapy. The use of PN has decreased mortality associated with fistulas and is associated with spontaneous fistula closure; however, these same outcomes are possible with EN if a feeding tube can be placed through or distal to the fistula site. See Chapter 14.

## MAJOR BURNS

### Pathophysiology

Major burns result in severe trauma. Energy requirements can increase as much as 100% above resting energy expenditure (REE), depending on the extent and depth of the injury (Figure 39-6). Exaggerated protein catabolism and increased urinary nitrogen excretion accompany this hypermetabolism. Protein is also lost through the burn wound exudate. Burn patients are particularly susceptible to infection, and this markedly increases requirements for both energy and protein. Because patients with major burns may develop an ileus and are anorexic, nutrition support therapy can be a real challenge. In children, healing after burn and trauma requires not only restoration of oxygen delivery and adequate calories to support metabolism and repair, but awareness of how children differ from adults in metabolic rate, growth requirements, and physiological response (Cook and Blinman, 2010).

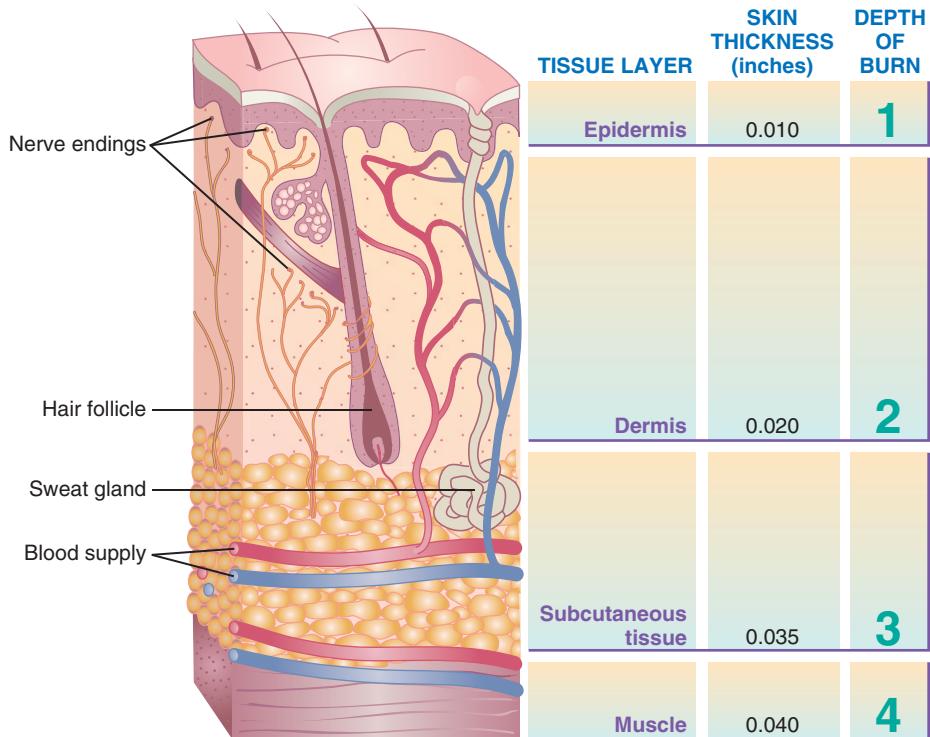

### Medical Management

#### Fluid and Electrolyte Repletion

The first 24 to 48 hours of treatment for thermally injured patients are devoted to fluid resuscitation. Several formulas have been developed to calculate the volume of resuscitation fluid needed. These formulas are based on the physiologic response of the body to thermal injury and are a good starting point for resuscitation. Generally half of the calculated volume for the first 24 hours is given during the first 8 hours following burn injury and the remaining half in the next 16 hours. Urine output is used to titrate the rate of IV fluid replacement.

The volume of fluid needed is based on the age and weight of the patient and the extent of the injury designated by percentage of total body surface area (TBSA) burned.

**FIGURE 39-6** Interpretation of burn classification based on damage to the integument.

Once resuscitation is complete, ample fluids must be given to cover both maintenance requirements and evaporative losses that continue through open wounds. Evaporative water loss can be estimated at 2 to 3.1 mL/kg of body weight per 24 hours per percent of TBSA burn. Serum sodium, osmolar concentrations, and body weight are used to monitor fluid status. Providing adequate fluids and electrolytes as soon as possible after injury is paramount for maintaining circulatory volume and preventing ischemia.

### Wound Management

Wound management depends on the depth and extent of the burn. Current surgical management promotes use of topical antimicrobial agents and biologic and synthetic dressings, early debridement, excision, and grafting. Energy expenditure may be reduced slightly by the practice of covering wounds as early as possible to reduce evaporative heat and nitrogen losses and prevent infection.

### Ancillary Measures

Passive and active range of motion exercises should be started early in the hospital to prevent contracture formation. Physical and occupational therapy helps maintain function and prevents muscle wasting and atrophy. A warm environment minimizes heat loss and the expenditure of energy to maintain body temperature. Thermal blankets, heat lamps, and individual heat shields are often used to maintain environmental temperature near 30° C (86° F). Minimizing fear and pain with reassurance from the staff and adequate pain medication can also reduce catecholamine stimulation and help avoid increases in energy expenditure. Treatments such as biofeedback, guided imagery,

and good sleep hygiene are helpful. Finally, antacids are given to patients with major burns to prevent formation of stress-related Curling ulcers in the gastric or duodenal mucosa.

### Medical Nutrition Therapy

A burn patient has greatly accelerated metabolism and needs increased energy, carbohydrates, proteins, fats, vitamins, minerals, and antioxidants to heal and prevent detrimental sequelae (Chan and Chan, 2009). A healthy liver is also essential. Hepatic acute phase proteins are strong predictors for postburn survival through their roles in gluconeogenesis, glycogenolysis, lipolysis, and proteolysis (Jeschke, 2009).

The goals of nutrition support therapy following major burn injury include provision of adequate calories to meet energy needs while minimizing associated metabolic complications, prevention or correction of specific nutrient deficiencies, and fluid and electrolyte management for adequate urine output and normal homeostasis. Adequate surgical care, infection control, and nutrition should be available as soon as possible after the burn (Dylewski et al., 2010). Delays in admission to an organized burn unit can be detrimental, especially for children, because malnutrition is a common concern.

Achievement of enteral access and provision of a sufficient volume of enteral nutrients early in the hospital course of a critically ill burned patient affords an opportunity to improve the outcome of that patient. Enteral feeding provides a conduit for the delivery of immune stimulants and serves as effective prophylaxis against stress-induced gastropathy and GI hemorrhage. Tube placement beyond the

stomach into the small bowel in hypermetabolic, severely ill patients prone to ileus and disordered gut motility may aid delivery of enteral nutrients while reducing risk of aspiration. Placement of enteral tubes during surgery has been practiced at some burn centers in an effort to minimize the length of time a burn patient is without nutrition support therapy. See Box 39-2 for the nutritional care goals for the burned person.

### Energy

Increased energy needs of the burned patient vary according to the size of the burn with severe injuries often approaching two times predicted energy expenditure. Once a burn exceeds 50% to 60% TBSA, minimum increases in energy expenditure do not usually occur. Measuring energy expenditure via indirect calorimetry is the most reliable method for assessing energy expenditure in burned patients. Increasing energy requirements by 20% to 30% is necessary to account for energy expenditure associated with wound care and physical therapy. The Ireton-Jones equation is frequently used for assessing energy expenditure in the burned patient because it accounts for burn injury and ventilatory status (Ireton-Jones and Jones, 2002) (Box 39-3).

Additional calories may be required to meet the needs because of fever, sepsis, multiple traumas, or the stress of surgery. Although weight gain may be desirable for the severely underweight patient, this is generally not feasible until acute illness has resolved. Generally, caloric goals should not exceed more than 2 times the REE.

Weight maintenance should be the goal for overweight patients until the healing process is complete. Obese individuals may be at higher risk of wound infection and graft disruption. The energy requirement for the obese burned person is probably more than that calculated when ideal body weight is used but less than that calculated when actual

body weight is used. IC is the most accurate method of determining the energy needs of the obese person who is burned.

### Protein

The protein needs of burned patients are elevated because of losses through urine and wounds, increased use in gluconeogenesis, and wound healing. Recent evidence promotes the feeding of high amounts of protein. Providing 20% to 25% of total calories as protein of high biologic value is also recommended.

The adequacy of energy and protein intake is best evaluated by monitoring wound healing, graft take, and basic nutrition assessment parameters. Wound healing or graft take may be delayed if weight loss exceeds 10% of the usual weight. An exact evaluation of weight loss may be difficult to obtain because of fluid shifts or edema or because of differences in the weights of dressings or splints. The coordination of weight measurement with dressing changes or hydrotherapy may allow recording of a weight without dressings and splints (Mayes and Gottschlich, 2003). Generally the fluid gained during the resuscitation period is lost within 2 weeks. Trends in weight change can then be identified.

Nitrogen balance often is used to evaluate the efficacy of a nutritional regimen, but it cannot be considered accurate without accounting for wound losses, which is difficult to accomplish in a clinical setting. Nitrogen excretion should begin to decrease as wounds heal or are grafted or covered. However, serum albumin levels usually remain depressed until major burns are healed. Proteins with shorter half-lives such as prealbumin, retinol-binding protein, and transferrin help to assess the resolution of the inflammatory response and the adequacy of nutrition support therapy of burn patients (see Chapter 8).

### BOX 39-2

#### Medical Nutrition Therapy Goals for Burned Patients

1. Minimize metabolic stress response by:
  - Controlling environmental temperature
  - Maintaining fluid and electrolyte balance
  - Controlling pain and anxiety
  - Covering wounds early
2. Meet nutritional needs by:
  - Providing adequate calories to prevent weight loss of greater than 10% of usual body weight
  - Providing adequate protein for positive nitrogen balance and maintenance or repletion of circulating proteins
  - Providing vitamin and mineral supplementation as indicated
3. Prevent Curling stress ulcer by:
  - Providing antacids or continuous enteral feedings

### BOX 39-3

#### Ireton-Jones Equations

Ireton-Jones equation for obese patients:

$$\text{EE} = 606 \text{ S} + 9 \text{ W} - 12 \text{ A} + 400 \text{ V} + 1444$$

Ireton-Jones equation for ventilator patients:

$$\text{EE} = 1925 - 10 \text{ A} + 5 \text{ W} + 281 \text{ S} + 292 \text{ T} + 851 \text{ B}$$

#### Key

EE: energy expenditure in kcal/day (no stress correction required).

A: age in years

S: sex (1 = male, 0 = female)

T: trauma (0 = absent, 1 = present)

B: burn (0 = absent, 1 = present)

W: weight in kg (actual)

V: ventilator (0 = absent, 1 = present)

## Micronutrients and Antioxidants

Vitamin needs generally increase for burn patients, but exact requirements have not been established. Supplements may be needed for patients who are eating food; however, most patients who receive tube feeding or PN receive amounts of vitamins in excess of the dietary reference intakes because of the high calorie intake. Vitamin C is involved in collagen synthesis and immune function and may be required in increased amounts for wound healing. Doses of 500 mg twice daily are the routine protocol at some burn centers (Mayes and Gottschlich, 2003). Vitamin A is also an important nutrient for immune function and epithelialization. Provision of 5000 units of vitamin A per 1000 calories of EN is often recommended (Mayes and Gottschlich, 2003).

Electrolyte imbalances that involve serum sodium or potassium are usually corrected by adjusting fluid therapy. Hyponatremia may be seen in patients whose evaporative losses are reduced drastically by the application of dressings or grafts; who have had changes in maintenance fluids; or who have been treated with silver nitrate soaks, which tend to draw sodium from the wound. Restricting the oral consumption of free water and sodium-free fluids may help correct hyponatremia. Hypokalemia often occurs after the initial fluid resuscitation and during protein synthesis. Slightly elevated serum potassium may indicate inadequate hydration.

Depression of serum calcium levels may be seen in patients with burns that involve more than 30% TBSA. Hypocalcemia often accompanies hypoalbuminemia. Calcium losses may be exaggerated if the patient is immobile or being treated with silver nitrate soaks. Early ambulation and exercise should help minimize these losses. Administration of calcium supplements may be necessary to treat symptomatic hypocalcemia.

Hypophosphatemia has also been identified in patients with major burns. This occurs most commonly in patients who receive large volumes of resuscitation fluid along with parenteral infusion of glucose solutions and large amounts of antacids for stress ulcer prophylaxis. Serum levels need to be monitored, and appropriate phosphate supplementation provided. Magnesium levels may also require attention because a significant amount of magnesium can be lost from the burn wound. Supplemental phosphorus and magnesium are often given parenterally to prevent GI irritation.

A depressed serum zinc level has been reported in burn patients, but whether this represents total body zinc nutriture or is an artifact of hypoalbuminemia is unclear, because zinc is bound to serum albumin. Zinc is a cofactor in energy metabolism and protein synthesis. Supplementation with 220 mg of zinc sulfate is appropriate (Mayes and Gottschlich, 2003). The anemia initially seen following a burn is usually unrelated to iron deficiency and is treated with packed red blood cells.

## Methods of Nutrition Support Therapy

Methods of nutrition support therapy need to be implemented on an individual basis. Most patients with burns of

less than 20% TBSA are able to meet their needs with a regular high-calorie, high-protein oral diet. Often the use of concealed nutrients such as protein added to puddings, milks, and gelatins is helpful because consuming large volumes of foods can be overwhelming to the patient. Patients should have immediate access to food and fluids at the bedside. They should be encouraged to consume calorically dense, high-protein drinks. Involving family and caregivers during mealtimes helps to promote good oral intake. Research is needed to identify ideal timing and forms of nutrition for critically ill infants and children, as this is currently not available (Joffe et al., 2009).

Patients with major burns, elevated energy expenditure, or poor appetites may require tube feeding or PN. Enteral feeding is the preferred method of nutrition support therapy for burn patients, but PN may be necessary with early excision and grafting to avoid the frequent interruptions of tube feeding required for anesthesia. Because ileus is often present only in the stomach, severely burned patients can be successfully fed by tube into the small bowel. PN may be needed for patients with persistent ileus who do not tolerate tube feedings or who have a high risk of aspiration. With careful monitoring, central lines for PN can be maintained through burn wounds. See Chapter 14.

## SURGERY

The delivery of correctly formulated and safely administered nutritional and metabolic support is a matter of life or death in surgical and critical care units; obese patients have a higher surgical risk (Blackburn et al., 2010). Although surgical morbidity correlates best with the extent of the primary disease and the nature of the operation performed, malnutrition may also compound the severity of complications. A well-nourished patient usually tolerates major surgery better than a severely malnourished patient. Malnutrition is associated with a high incidence of operative complications, morbidity, and death. If a malnourished patient is expected to undergo major upper GI surgery and EN is not feasible, PN should be initiated 5–7 days preoperatively and continued into the postoperative period if the duration of therapy is anticipated to be longer than 7 days (SCCM and A.S.P.E.N., 2009). See Chapter 14.

## Medical Nutrition Therapy

### Preoperative Nutrition Care

The routine practice of ordering that a patient take nothing by mouth (NPO) at midnight prior to surgery has been discontinued in many settings. The American Society of Anesthesiologists historically recommended withholding solids for 6 hours preoperatively and clear liquids for 2 hours prior to induction of anesthesia. This practice was intended to minimize aspiration and regurgitation, but two Cochrane reviews suggest that patients may be allowed to take fluids up until a few hours before surgery without causing increased morbidity (Brady et al., 2003; Brady et al., 2009). The use of a carbohydrate-rich beverage in the preoperative period

has been shown to enhance glycemic control; and decrease losses of nitrogen, lean body mass, and muscle strength following abdominal and colorectal surgery (Svanfeldt et al., 2007).

In emergency patients, preoperative fasting is not possible and surgery should be timed according to urgency; patients are treated as if the stomach is full (Søreide and Ljundqvist, 2006).

### Postoperative Nutrition Care

Postoperative patients who are critically ill and in the ICU should receive early EN unless there is an absolute contraindication (SCCM and A.S.P.E.N., 2009). This practice following major GI surgery is associated with reduced infection and decreased hospitalization (Lewis et al., 2009). The use of immune-enhanced formulas is associated with a decrease in wound complications in patients who have undergone GI surgery (Mizock, 2010). If oral feeding is not possible or an extended NPO period is anticipated, an access device for

enteral feeding should be inserted at the time of surgery. Combined gastrostomy-jejunostomy tubes offer significant advantages over standard gastrostomies because they allow for simultaneous gastric drainage from the gastrostomy tube and enteral feeding via the jejunal tube. Studies are underway to evaluate the effect of the use of fish oil with nutrition therapy to improve surgical outcomes in older adults after major surgery; early results show promise for reducing systemic inflammation, loss of lean muscle, and weight loss (Miller et al., 2010).

The timing of introduction of solid food after surgery depends on the patient's degree of alertness and condition of the GI tract. A general practice has been to progress over a period of several meals from clear liquids to full liquids and finally to solid foods. However, no physiologic reason exists for solid foods not to be introduced as soon as the GI tract is functioning and a few liquids are tolerated (Lewis et al., 2009). Surgical patients can be fed a regular solid-food diet rather than a clear liquid diet.

### CLINICAL SCENARIO

## Chronological Clinical Scenario with Suggested Answers

### First Assessment

A 57-year-old man with pancreatitis of unknown cause was admitted to a hospital where he was managed conservatively, ingesting nothing by mouth (NPO) for 9 days without enteral or parenteral nutrition therapy. On hospital day 9 he was found to have pseudocysts and was transferred to a tertiary care center for further management.

### Screening and Assessment Data:

Height = 71" (180 cm)

Weight = 150 lb (68 kg)

Body mass index = 21 kg/m<sup>2</sup>

Weight change in the 6 months prior to admission: yes

Amount of weight lost: 25 lb

Decreased intake in the previous 2 weeks: yes

Gastrointestinal symptoms persisting for more than 2 weeks: yes

Physical examination: temporal wasting

Radiologic examination: moderately dilated small bowel loops consistent with adynamic ileus

Maximum body temperature previous 24 hr ( $T_{max}$ ) 37° C

Currently receiving 0.45% normal saline + 30 mEq KCl/L @ 125 mL/hr

Intake/Output = 4000/3800 mL

### Laboratory Values

Sodium: 130 mmol/dL

Potassium: 3.4 mmol/dL

Chloride: 100 mmol/dL

Carbon dioxide: 20 mmol/dL

Blood urea nitrogen: 23 mg/dL

Creatinine: 0.8 mg/dL

Calcium: 8 mg/dL

Magnesium: 1.9 mg/dL

Phosphorus: 2.2 mg/dL

Albumin: 3 gm/dL

1. Write pertinent nutrition diagnosis statements (problem, etiology, and signs and symptoms [PES] format) in order of priority for this patient.

Malnutrition related to inadequate oral food and beverage intake during a prolonged period as evidenced by 14% weight loss during 6 months and intake remains nil.  
Altered nutrition-related laboratory values related to the metabolic response to stress and a lack of electrolyte intake in diet and intravenous fluids as evidenced by low serum sodium, potassium, and phosphorus.

2. Should he be started on parenteral nutrition (PN)? Explain.

By the information presented in the case, he should be started on PN because he is malnourished, has been NPO for 9 days, and does not appear to be ready to begin enteral feeding (secondary to ileus). It will be important to discuss enteral feeding via jejunal access with the physicians once ileus has resolved.

**CLINICAL SCENARIO—cont'd**

## Chronological Clinical Scenario with Suggested Answers

**3. Calculate his nutritional needs.**

His caloric requirement should be estimated using the Mifflin-St. Jeor equation, although the equation will not account for whatever level of hypermetabolism exists, and there are no studies to guide the choice of the “stress factor.” The Mifflin-St. Jeor equation should be used because it is the most accurate of all the equations used for obese or nonobese, healthy people. The patient is not in a state that would justify the use of the available critical care equations. Actual body weight should be used.

Mifflin-St. Jeor equation result for this patient is 1525 kcals/day.

Protein requirement may be set at 1.5 g/kg body weight or 102 g/day.

### First Change of Status with Reassessment

On hospital day 4 (day 13 of total hospitalization), the patient's body temperature spikes to 39° C and he is found to have infected pseudocysts. He goes to the operating room for drainage of pseudocysts and irrigation and debridement of the pancreas. Afterwards he is admitted to the intensive care unit sedated and mechanically ventilated. Current status is noted:

$T_{\max}$  39.3 degrees centigrade

VE = 15.6 L/min (minute ventilation)

PN continues

Intravenous fluids: 0.45% normal saline solution 50 mL/hr

Intake/output = 6200/3000 mL

### Laboratory Values

Sodium: 135 mmol/dL

Potassium: 3.8 mmol/dL

Chloride: 100 mmol/dL

Carbon dioxide: 29 mmol/dL

Blood urea nitrogen: 33 mg/dL

Creatinine: 1.0 mg/dL

Glucose: 210 mg/dL

Calcium: 8.4 mg/dL

Magnesium: 1.5 mg/dL

Phosphorus: 2.3 mg/dL

Albumin: 2.3 gm/dL

Arterial blood gas: 7.31/50/115/30

**4. Upon monitoring, what is his metabolic state?**

He has become hypermetabolic and probably hypercatabolic.

Hyperglycemia has worsened.

Electrolyte depletion (phosphorus, magnesium).

**5. What is his acid-base status?**

He has a respiratory acidosis (elevated arterial carbon dioxide pressure and decreased pH) with rising bicarbonate (attempted compensation for the respiratory acidosis, which has not been sufficient to return the pH to the normal range).

**6. Write updated PES statements:**

Increased nutrient needs (energy and protein) related to a systemic inflammatory response as evidenced by fever and elevated minute ventilation.

Altered nutrition-related laboratory values

(hyperglycemia) related to stress metabolism and glucose intake as evidenced by blood glucose of 210 mg/dL.

Altered nutrition-related laboratory values related to the metabolic response to stress and sepsis as evidenced by low serum sodium, phosphorus, and magnesium. Note: his hyponatremia could be a result of fluid overload rather than inadequate sodium intake.

**7. Is the patient's blood glucose control adequate? If not, why and what should be done?**

His blood glucose is not adequately controlled.

There is evidence that when glucose levels are controlled between 180–215 mg/dL, survival is better.

The dextrose load in his PN should be reduced or a standardized insulin protocol should be instituted, or both. In addition, energy intake should be assessed to confirm absence of overfeeding because this could result in hyperglycemia. Medication administration should also be monitored because some can significantly contribute to elevated glucose levels (i.e., intravenous steroids).

**8. Why is his serum albumin level falling?**

Decreased acute-phase proteins are a response to the inflammatory process his body has mounted to try to reestablish homeostasis.

**9. Recalculate his nutritional needs.**

Protein requirement has probably increased (2 g/kg body weight or 136 g/day). Metabolic rate calculated by the Penn State equation is 2330 kcal:

Penn State Equation:

$$HBE(1.1) + Ve(32) + T_{\max}(140) - 5340$$

$$1500(1.1) + 15.6(32) + 39.3(140) - 5340$$

$$1667 + 499 + 5502 - 5340 = 2330$$

## Chronological Clinical Scenario with Suggested Answers

*HBE* is Harris Benedict using actual weight, *V<sub>e</sub>* is minute ventilation in L/min, *T<sub>max</sub>* is maximum body temperature in the past 24 hours in degrees centigrade.

### Second Change of Status with Reassessment

On hospital day 6, the patient returned to the operating room for further debridement. During the surgery, a nasojejunal tube was placed. Postoperatively he remains febrile with elevated minute ventilation, and requires fluid administration to maintain adequate blood pressure. On rounds, the dietitian asks whether the patient is stable enough to start tube feeding through the nasojejunal tube. The critical care team believes that despite his early postoperative state, the patient is sufficiently stable hemodynamically to initiate a trophic tube feeding.

10. What feeding formula should be used? Is an immune-enhancing tube feeding formula indicated?

Commercial immune-enhancing formulas that combine several nutrients thought to enhance immune

function are not indicated for routine use, and may be contraindicated in the severely critically ill, such as this patient.

Most of the studies of enteral feeding in pancreatitis use peptide-based feeding formulas; it is reasonable to do the same in this case. However, it is possible that a polymeric formula would work as well. If a 1.0 kcal/mL formula is chosen, the infusion volume will be approximately 3 L/day; if a 1.5 kcal/mL formula is chosen, the volume will be approximately 2 L/day.

An enteral feeding with a peptide formula was initiated via nasojejunal access and gradually advanced to goal rate during the next 3–4 days. Tolerance was demonstrated via no change in abdominal distention, pain, or nausea and vomiting. As the feeding advanced, the PN was gradually weaned, then discontinued when goal enteral feeding was achieved.

## CHAPTER 40

F. Enrique Gómez, PhD  
Martha Kaufer-Horwitz, DSc, NC

# Medical Nutrition Therapy for Rheumatic Disease

### KEY TERMS

activities of daily living (ADLs)  
anti-inflammatory diet  
anti-nuclear antibodies (ANA)  
arachidonic acid (ARA)  
biologic response modifiers  
capsaicinoids  
chronic fatigue syndrome (CFS)  
c-reactive protein (CRP)  
cytokines  
disease-modifying anti-rheumatic drugs (DMARDs)  
eicosanoids  
fibromyalgia  
gout  
juvenile rheumatoid arthritis

osteoarthritis (OA)  
prostaglandins (PGs)  
prostanoids  
purines  
Raynaud's syndrome  
rheumatic disease  
rheumatoid arthritis (RA)  
rheumatoid cachexia  
rheumatoid factor (RF)  
scleroderma  
Sjögren's syndrome (SS)  
synovial fluid  
systemic lupus erythematosus (SLE)  
temporomandibular disorders (TMDs)

**Rheumatic disease** and related conditions include more than 100 different manifestations of inflammation and loss of function of connective tissue and supporting body structures, including joints, tendons, ligaments, bones, muscles, and sometimes internal organs. Rheumatic disease is thought to have an autoimmune component. Because no identifiable cause or cure is known, pharmacotherapy, physical and occupational treatment, and medical nutrition therapy (MNT) play important roles in managing the symptoms. Table 40-1 provides an overview of the disorders and their management.

Rheumatic disease affects all population groups. According to the National Arthritis Data Workgroup, osteoarthritis (OA) affects 27 million Americans; gout, 3 million;

fibromyalgia, 5 million; rheumatoid arthritis (RA), 1.5 million; Sjögren's syndrome (SS), 1 to 4 million; and systemic lupus erythematosus (SLE), 161,000 to 322,000 (Helmick et al., 2008; Lawrence et al., 2008). Estimates for the number of people in the United States with systemic sclerosis is 49,000. Arthritis and the related disorders are among the most prevalent chronic disease conditions in the United States and are associated with total direct and indirect costs to the U.S. economy of \$128 billion per year in medical care and lost wages (Centers for Disease Control and Prevention [CDC], 2007).

*Arthritis* is a generic term that comes from the Greek word *Arthro*, which means “joint,” and the suffix *-itis*, which means “inflammation.” There are two distinct categories of disease: systemic, autoimmune rheumatic disease and non-systemic OA. The more debilitating and autoimmune arthritis group includes RA, **juvenile rheumatoid arthritis**,

Sections of this chapter were written by Kristine Duncan, RD for the previous edition of this text.

TABLE 40-1

## Summary of Medical Nutrition Therapy for Rheumatic Diseases

Disease	Medical Nutrition Therapy	Alternative Therapy	Supplements or Herbs That Can Be Safely Considered	Therapies without Adequate Evidence
Rheumatoid arthritis	Vegetarian, vegan, Mediterranean diet; anti-inflammatory diet; appropriate calories for maintenance of normal body weight; RDA for protein unless malnutrition present; moderate-fat diet with emphasis on ω-3 PUFAs and fish 1–2 times per week; modifications as needed for jaw pain, anorexia	Exercise, meditation, tai chi, spiritual practice, relaxation techniques	Supplement diet as needed to meet DRI for antioxidant nutrients and, calcium, folate, vitamins B <sub>6</sub> , B <sub>12</sub> , D; GLA; fish oils; rosemary, turmeric, curcumin, curry, ginger and other culinary herbs	China root, willow bark, valerian, feverfew, boswellia, copper or copper salts, devil's claw, thunder god vine, fasting, DHEA
Osteoarthritis	Weight management; diet adequate in calcium, folate, vitamins B <sub>6</sub> , D, K; magnesium; anti-inflammatory diet (Box 40-2)	Exercise, acupuncture; SAM-e	Supplement diet as needed to meet DRI for antioxidant nutrients and, calcium, folate, vitamins B <sub>6</sub> , B <sub>12</sub> , and D; glucosamine, chondroitin; oils; diacercin; avocado soybean unsaponifiables, hyaluronic acid	Shark cartilage
Gout	Weight management; purine-controlled diet; adequate fluid consumption; alcohol, particularly beer, restricted or eliminated; fructose from sweetened beverages and juices restricted.	Exercise; alkaline-ash foods; see Clinical Insight box on Urinary pH in Chapter 36		
Lupus	Tailor diet to individual needs; calories to maintain IBW; restriction of protein, fluid, and sodium if renal involvement; check for gluten intolerance		Supplement diet as needed to meet DRI for antioxidant nutrients	
Scleroderma	Adequate fluid; high-energy, high-protein supplements as needed to prevent/correct weight loss; moist foods; modifications for GERD if needed			
Fibromyalgia and chronic fatigue syndrome	Vegetarian diets, vegan diet, weight control, ω-3 fatty acids	Moderate intensity graded exercise, cognitive behavioral therapy, stress management, massage	Riboflavin (B <sub>2</sub> ), CoQ <sub>10</sub> , carnitine	Biofeedback, relaxation, chlorella, homeopathy, acupuncture, guaifenesin, magnesium, SAM-e
Sjögren's syndrome	Balanced diet with adequate B <sub>6</sub> or vitamin supplementation; restrict sugary foods and beverages; modify food consistency and size to improve chewing and swallowing processes			
TMD	Balanced diet with soft foods in small pieces, to improve chewing and reduce pain			

DHEA, Dehydroepiandrosterone; DRI, Dietary reference intake; GERD, gastroesophageal reflux disease; GLA, Gamma-linolenic acid; IBW, ideal body weight; PUFA, polyunsaturated fatty acid; RDA, recommended dietary allowance; SAM-e, S-adenosyl-L-methionine; TMD, temporomandibular disorder.

gout, SS, fibromyalgia, SLE, and scleroderma. The OA group includes OA, bursitis, and tendonitis. Other rheumatic diseases include spondyloarthropathies, polymyalgia rheumatica, and polymyositis.

Body changes associated with aging—including decreased somatic protein, body fluids, and bone density, and an increase in total body fat—may contribute to the onset and progression of arthritis. The aging body mass causes changes in neuroendocrine regulators, immune regulators, and metabolism, which affect the inflammatory process. Therefore recent increases in the frequency of these conditions may be the result of aging of the U.S. population. By 2030 approximately 20% of Americans (approximately 72 million people) will be older than 65 years and subsequently will be at high risk for rheumatic disease (National Institute of Arthritis and Musculoskeletal and Skin Diseases [NIAMS], 2006).

Unfortunately, the cause of most rheumatic conditions remains unknown. In addition, some forms of rheumatic conditions can affect other organs such as the skin or blood vessels. Rheumatic conditions have no known cure and are usually chronic, but may present as acute episodes with short or intermittent duration. Chronic arthritic conditions are associated with alternating periods of remission without symptoms, and flares with worsening symptoms that occur without any identifiable cause. Risk factors include repetitive joint injury, inherited cartilage weakness, genetic susceptibility, family history, gender, and environmental factors.

## PATHOPHYSIOLOGY AND INFLAMMATION

Inflammation plays an important role in health and disease. The inflammatory process normally occurs to protect and repair tissue damaged by infections, injuries, toxicity, or wounds via accumulation of fluid and cells. Once the cause is resolved, the inflammation usually subsides. Whether inflammation is due to stress on the joints (OA) or to an autoimmune response (RA), an uncontrolled inflammatory reaction causes more damage than repair.

Polyunsaturated fatty acids (PUFAs) play an important role in inflammation as precursors of a potent group of modulators of inflammation termed **eicosanoids** (*eicos* means “20” in Greek). Eicosanoids include the **prostaglandins (PGs)**, thromboxanes (Tx<sub>s</sub>) and leukotrienes (LTs) among others. PG and Tx are the product of the enzyme cyclooxygenase (COX) and are termed **prostanoids**, whereas LTs are the product of the enzyme lipoxygenase. For the synthesis of prostanoids, the COX reaction consumes two double bonds from the original PUFA, whereas lipoxygenase reaction consumes none (Box 40-1; see Chapter 6).

Depending on the PUFA used as substrate, different eicosanoids are produced: **arachidonic acid (ARA)** (20:4, ω-6) is the precursor of the series 2 of PG and Tx, and the series 4 of LT. If eicosapentaenoic acid (20:5, ω-3) is the substrate, series 3 of PG and Tx and series 5 of LT are

## BOX 40-1

### Production of Eicosanoids from Omega-3 and Omega-6 PUFAs

#### Eicosapentaenoic Acid (20:5, ω-3)

Thromboxane A<sub>3</sub>: Weak vasoconstrictor and weak platelet aggregator  
Prostacyclin PGI<sub>3</sub>: Vasodilator and platelet antiaggregator  
Leukotriene B<sub>3</sub>: Weak inflammation inducer and weak chemotactic agent

#### Arachidonic Acid (20:4, ω-6)

Thromboxane A<sub>2</sub>: Vasoconstrictor and potent platelet aggregator  
Prostaglandin E<sub>2</sub>: Vasodilator and platelet antiaggregator  
Leukotriene B<sub>4</sub>: Inflammation inducer and potent leukocyte chemotaxis and adherence inducer

#### Dihomo-γ-linolenic acid DGLA (20:3, ω-6)

Thromboxane A<sub>1</sub>: Anti-inflammatory, pain reducer  
Prostaglandin E<sub>1</sub>: Vasodilator, inhibits monocyte and neutrophil function, prevents platelet aggregation  
Leukotriene B<sub>3</sub>: Very weak pro-inflammatory effects  
From Galli C: Effects of fat and fatty acid intake on inflammatory and immune responses: A critical review, Ann Nutr Metab 55:123, 2009.  
PUFA, Polyunsaturated fatty acid.

produced. Finally, dihomo-γ-linoleic acid (DGLA) (20:3, ω-6) is the precursor of series 1 of PG and Tx, and of series 3 of LT.

The series 2 compounds (PG<sub>2</sub> and Tx<sub>2</sub>) are the most abundant because ARA is abundant in plasma membranes of cells involved in inflammation (macrophages, neutrophils, fibroblasts), and are the most potent inflammatory eicosanoids. On the other hand, PG<sub>1</sub> and Tx<sub>1</sub>, derived from DGLA, have antiinflammatory activities. Thus diets enriched with PUFAs that enhance the synthesis of antiinflammatory prostanoids are, at least theoretically, desirable for the long-term management of rheumatic disease, but usually do not replace the use of medications.

## MEDICAL DIAGNOSIS AND TREATMENT

A thorough history of symptoms and a detailed physical examination are the cornerstones for an accurate diagnosis. However, laboratory testing can help to further refine the diagnosis and identify appropriate treatment.

### Biochemical Assessment

Acute-phase proteins are plasma proteins whose concentration increases of more than 25% during inflammatory states.

Two acute-phase proteins traditionally used to screen for and monitor rheumatic disease are **rheumatoid factor (RF)** and **C-reactive protein (CRP)**, although they are nonspecific and may also indicate an infection or even a recent cardiac event. The term RF is used to refer to a group of self-reacting antibodies (an abnormal IgM against normal IgG), found in the sera of rheumatic patients. The American College of Rheumatology (ACR) recommends periodic measurements of RF and CRP in addition to a detailed assessment of symptoms and functional status, and radiographic examination to determine the current level of disease activity in these patients.

**Antinuclear antibodies (ANA)** appear to be present in many autoimmune diseases and can assist with proper diagnosis when used correctly; antineutrophil cytoplasmic antibodies and myositis-specific antibodies can provide information about the presence of rheumatic disease as well. Measurements of RF and anticyclic citrullinated peptide antibodies may provide unique data in the management of RA (Colgazier and Sutej, 2005). Routine blood testing can include complement, a complete blood count, creatinine, hematocrit, and a white blood cell count, in addition to analysis of urine or **synovial fluid** secreted by the synovial membrane in the joints.

## Pharmacotherapy
