Eisler, Ronald, 1932—

Handbook of chemical risk assessment: health hazards to humans, plants, and animals / by Ronald Eisler
p. cm.

Includes bibliographical references and index.

Contents: v. 1. Metals — v. 2. Organics — v. 3. Metalloids, radiation, cumulative index to chemicals and species.
ISBN 1-56670-503-7 (v. 1: alk. paper) — ISBN 1-56670-504-5 (v. 2: alk. paper) — ISBN 1-56670-505-3
(v. 3: alk. paper) — ISBN 1-56670-506-1 (set: alk. paper)

1. Pollutants — Handbooks, manuals, etc. 2. Hazardous substances — Risk assessment — Handbooks, manuals,
etc. 3. Environmental chemistry — Handbooks, manuals, etc. 4. Environmental risk assessment — Handbooks,
manuals, etc. I. Title.

About the Author

Ronald Eisler received his A.B. degree from New York University in biology and chemistry, and M.S. and Ph.D. degrees from the University of Washington in aquatic sciences and radio-ecology, respectively. He attended the University of Miami Marine Laboratory prior to military service. He is a member of the American Chemical Society, the American Fisheries Society, the Marine Biological Association of the United Kingdom, and the Society for Environmental Geochemistry and Health. Since 1955 he has authored more than 125 technical articles and books on contaminant hazards to living organisms.

From 1984 to the present, Dr. Eisler has been a senior research biologist at the U.S. Geological Survey, Patuxent Wildlife Research Center, located in Laurel, Maryland. Prior to 1984, he held the following positions, in order: bioscience advisor, U.S. Fish and Wildlife Service, Washington, D.C.; research aquatic toxicologist, U.S. Environmental Protection Agency, Narragansett, Rhode Island; fishery research biologist, U.S. Fish and Wildlife Service, Highlands, New Jersey; radiochemist, University of Washington Laboratory of Radiation Ecology, Seattle, Washington; aquatic biologist, New York State Department of Environmental Conservation, Raybrook, New York; biochemist, U.S. Army Medical Nutrition Laboratory, Medical Service Corps, Denver, Colorado.

He has held several adjunct professor appointments and was especially active at the Graduate School of Oceanography, University of Rhode Island; the Department of Oceanography and Marine Biology, Hebrew University of Jerusalem; and the Department of Biology, American University, Washington, D.C.

Dr. Eisler is currently on the editorial board of *Marine Ecology Progress Series* and other technical journals.

Contents

Chapter 1

Cadmium

- 1.1 Introduction
- 1.2 Environmental Chemistry
- 1.3 Concentrations in Field Collections
- 1.4 Lethal Effects
- 1.5 Sublethal Effects
- 1.6 Bioaccumulation
- 1.7 Teratogenesis, Mutagenesis, and Carcinogenesis
- 1.8 Recommendations
- 1.9 Summary
- 1.10 Literature Cited

Chapter 2

Chromium

- 2.1 Introduction
- 2.2 Environmental Chemistry
- 2.3 Concentrations in Field Collections
- 2.4 Beneficial and Protective Properties
- 2.5 Lethal Effects
 - 2.5.1 General
 - 2.5.2 Aquatic Organisms
 - 2.5.3 Terrestrial Invertebrates
 - 2.5.4 Mammals and Birds
- 2.6 Sublethal Effects
 - 2.6.1 General
 - 2.6.2 Aquatic Organisms: Freshwater
 - 2.6.3 Aquatic Organisms: Marine
 - 2.6.4 Birds
 - 2.6.5 Mammals
- 2.7 Field Investigations
- 2.8 Recommendations
- 2.9 Summary
- 2.10 Literature Cited

Chapter 3

Copper

- 3.1 Introduction
- 3.2 Sources and Uses
 - 3.2.1 General
 - 3.2.2 Sources
 - 3.2.3 Uses
- 3.3 Chemical and Biochemical Properties
 - 3.3.1 General
 - 3.3.2 Chemical Properties
 - 3.3.3 Metabolism
 - 3.3.4 Interactions
- 3.4 Carcinogenicity, Mutagenicity, and Teratogenicity
 - 3.4.1 General
 - 3.4.2 Carcinogenicity

- 3.4.3 Mutagenicity
- 3.4.4 Teratogenicity
- 3.5 Concentrations in Field Collections
 - 3.5.1 General
 - 3.5.2 Abiotic Materials
 - 3.5.3 Terrestrial Plants and Invertebrates
 - 3.5.4 Aquatic Organisms
 - 3.5.5 Amphibians and Reptiles
 - 3.5.6 Birds
 - 3.5.7 Mammals
- 3.6 Copper Deficiency Effects
 - 3.6.1 General
 - 3.6.2 Terrestrial Plants and Invertebrates
 - 3.6.3 Aquatic Organisms
 - 3.6.4 Birds and Mammals
- 3.7 Lethal and Sublethal Effects
 - 3.7.1 General
 - 3.7.2 Terrestrial Plants and Invertebrates
 - 3.7.3 Aquatic Organisms
 - 3.7.4 Birds
 - 3.7.5 Mammals
- 3.8 Proposed Criteria and Recommendations
- 3.9 Summary
- 3.10 Literature Cited

Chapter 4

Lead

- 4.1 Introduction
- 4.2 Sources and Uses
- 4.3 Chemical Properties
- 4.4 Mode of Action
- 4.5 Concentrations in Field Collections
 - 4.5.1 General
 - 4.5.2 Nonbiological Samples
 - 4.5.3 Fungi, Mosses, Lichens
 - 4.5.4 Terrestrial Plants
 - 4.5.5 Terrestrial Invertebrates
 - 4.5.6 Aquatic Biota
 - 4.5.7 Amphibians and Reptiles
 - 4.5.8 Birds
 - 4.5.9 Mammals
- 4.6 Lethal and Sublethal Effects
 - 4.6.1 General
 - 4.6.2 Terrestrial Plants and Invertebrates
 - 4.6.3 Aquatic Biota
 - 4.6.4 Amphibians and Reptiles
 - 4.6.5 Birds
 - 4.6.6 Mammals
- 4.7 Recommendations
- 4.8 Summary
- 4.9 Literature Cited

Chapter 5

Mercury

- 5.1 Introduction
- 5.2 Sources of Environmental Mercury
- 5.3 Chemical and Biochemical Properties
- 5.4 Mercury in Minamata, Japan
- 5.5 Concentrations in Field Collections
 - 5.5.1 General
 - 5.5.2 Nonbiological
 - 5.5.3 Biological
- 5.6 Lethal Effects
 - 5.6.1 General
 - 5.6.2 Aquatic Organisms
 - 5.6.3 Birds
 - 5.6.4 Mammals
 - 5.6.5 Other Groups
- 5.7 Sublethal Effects
 - 5.7.1 General
 - 5.7.2 Carcinogenicity, Genotoxicity, and Teratogenicity
 - 5.7.3 Aquatic Organisms
 - 5.7.4 Birds
 - 5.7.5 Mammals
 - 5.7.6 Other Groups
- 5.8 Recommendations
- 5.9 Summary
- 5.10 Literature Cited

Chapter 6

Nickel

- 6.1 Introduction
- 6.2 Sources and Uses
 - 6.2.1 General
 - 6.2.2 Source
 - 6.2.3 Uses
- 6.3 Chemical and Biological Properties
 - 6.3.1 General
 - 6.3.2 Physical and Chemical Properties
 - 6.3.3 Metabolism
 - 6.3.4 Interactions
- 6.4 Carcinogenicity, Mutagenicity, and Teratogenicity
 - 6.4.1 General
 - 6.4.2 Carcinogenicity
 - 6.4.3 Mutagenicity
 - 6.4.4 Teratogenicity
- 6.5 Concentrations in Field Collections
 - 6.5.1 General
 - 6.5.2 Abiotic Materials
 - 6.5.3 Terrestrial Plants and Invertebrates
 - 6.5.4 Aquatic Organisms
 - 6.5.5 Amphibians
 - 6.5.6 Birds

- 6.5.7 Mammals
- 6.5.8 Integrated Studies
- 6.6 Nickel Deficiency Effects
 - 6.6.1 General
 - 6.6.2 Bacteria and Plants
 - 6.6.3 Birds
 - 6.6.4 Mammals
- 6.7 Lethal and Sublethal Effects
 - 6.7.1 General
 - 6.7.2 Terrestrial Plants and Invertebrates
 - 6.7.3 Aquatic Organisms
 - 6.7.4 Birds
 - 6.7.5 Mammals
- 6.8 Proposed Criteria and Recommendations
- 6.9 Summary
- 6.10 Literature Cited

Chapter 7

Silver

- 7.1 Introduction
- 7.2 Sources and Uses
 - 7.2.1 General
 - 7.2.2 Sources
 - 7.2.3 Uses
- 7.3 Chemistry and Metabolism
 - 7.3.1 General
 - 7.3.2 Physical and Chemical Properties
 - 7.3.3 Metabolism
- 7.4 Concentrations in Field Collections
 - 7.4.1 General
 - 7.4.2 Nonbiological Materials
 - 7.4.3 Plants and Animals
- 7.5 Lethal and Sublethal Effects
 - 7.5.1 General
 - 7.5.2 Terrestrial Plants
 - 7.5.3 Aquatic Organisms
 - 7.5.4 Birds and Mammals
- 7.6 Recommendations
- 7.7 Summary
- 7.8 Literature Cited

Chapter 8

Tin

- 8.1 Introduction
- 8.2 Chemical and Biochemical Properties
 - 8.2.1 General
 - 8.2.2 Inorganic Tin
 - 8.2.3 Organotins
- 8.3 Sources and Uses
- 8.4 Concentrations in Field Collections
 - 8.4.1 General

- 8.4.2 Nonbiological Samples
- 8.4.3 Biological Sample
- 8.5 Effects
 - 8.5.1 General
 - 8.5.2 Aquatic Organisms
 - 8.5.3 Birds
 - 8.5.4 Mammals
 - 8.5.5 Terrestrial Invertebrates
- 8.6 Recommendations
- 8.7 Summary
- 8.8 Literature Cited

Chapter 9

Zinc

- 9.1 Introduction
- 9.2 Sources and Uses
- 9.3 Chemical and Biochemical Properties
 - 9.3.1 General
 - 9.3.2 Chemical Properties
 - 9.3.3 Metabolism
 - 9.3.4 Interactions
- 9.4 Carcinogenicity, Mutagenicity, and Teratogenicity
 - 9.4.1 General
 - 9.4.2 Carcinogenicity
 - 9.4.3 Mutagenicity
 - 9.4.4 Teratogenicity
- 9.5 Concentrations in Field Collections
 - 9.5.1 General
 - 9.5.2 Nonbiological
 - 9.5.3 Terrestrial Plants and Invertebrates
 - 9.5.4 Aquatic Organisms
 - 9.5.5 Birds
 - 9.5.6 Mammals
- 9.6 Zinc Deficiency Effects
 - 9.6.1 General
 - 9.6.2 Terrestrial Plants
 - 9.6.3 Aquatic Organisms
 - 9.6.4 Birds
 - 9.6.5 Mammals
- 9.7 Lethal and Sublethal Effects
 - 9.7.1 General
 - 9.7.2 Terrestrial Plants and Invertebrates
 - 9.7.3 Aquatic Organisms
 - 9.7.4 Birds
 - 9.7.5 Mammals
- 9.8 Recommendations
- 9.9 Summary
- 9.10 Literature Cited

Contents

Chapter 10

Acrolein

- 10.1 Introduction
- 10.2 Sources and Uses
 - 10.2.1 General
 - 10.2.2 Sources
 - 10.2.3 Uses
- 10.3 Environmental Chemistry
 - 10.3.1 General
 - 10.3.2 Chemical Properties
 - 10.3.3 Persistence
 - 10.3.4 Metabolism
- 10.4 Lethal and Sublethal Effects
 - 10.4.1 General
 - 10.4.2 Terrestrial Plants and Invertebrates
 - 10.4.3 Aquatic Organisms
 - 10.4.4 Birds
 - 10.4.5 Mammals
- 10.5 Recommendations
- 10.6 Summary
- 10.7 Literature Cited

Chapter 11

Atrazine

- 11.1 Introduction
- 11.2 Environmental Chemistry
- 11.3 Concentrations in Field Collections
- 11.4 Effects
 - 11.4.1 General
 - 11.4.2 Terrestrial Plants and Invertebrates
 - 11.4.3 Aquatic Plants
 - 11.4.4 Aquatic Animals
 - 11.4.5 Birds
 - 11.4.6 Mammals
- 11.5 Recommendations
- 11.6 Summary
- 11.7 Literature Cited

Chapter 12

Carbofuran

- 12.1 Introduction
- 12.2 Chemical Properties and Persistence
- 12.3 Lethal Effects
 - 12.3.1 General
 - 12.3.2 Aquatic Organisms
 - 12.3.3 Birds and Mammals
 - 12.3.4 Terrestrial Invertebrates
 - 12.3.5 Plants
- 12.4 Sublethal Effects

- 12.4.1 General
 - 12.4.2 Aquatic Organisms
 - 12.4.3 Birds
 - 12.4.4 Mammals
 - 12.4.5 Terrestrial Invertebrates
- 12.5 Recommendations
 - 12.6 Summary
 - 12.7 Literature Cited

Chapter 13

Chlordane

- 13.1 Introduction
- 13.2 Chemical and Biochemical Properties
- 13.3 Uses
- 13.4 Concentrations in Field Collections
 - 13.4.1 General
 - 13.4.2 Nonbiological Samples
 - 13.4.3 Terrestrial Crops
 - 13.4.4 Aquatic Invertebrates
 - 13.4.5 Fishes
 - 13.4.6 Amphibians and Reptiles
 - 13.4.7 Birds
 - 13.4.8 Mammals
- 13.5 Lethal and Sublethal Effects
 - 13.5.1 General
 - 13.5.2 Terrestrial Invertebrates
 - 13.5.3 Aquatic Organisms
 - 13.5.4 Amphibians and Reptiles
 - 13.5.5 Birds
 - 13.5.6 Mammals
- 13.6 Recommendations
- 13.7 Summary
- 13.8 Literature Cited

Chapter 14

Chlorpyrifos

- 14.1 Introduction
- 14.2 Environmental Chemistry
- 14.3 Laboratory Investigations
 - 14.3.1 Aquatic Organisms
 - 14.3.2 Birds and Mammals
- 14.4 Field Investigations
- 14.5 Recommendations
- 14.6 Summary
- 14.7 Literature Cited

Chapter 15

Cyanide

- 15.1 Introduction
- 15.2 Chemical Properties
- 15.3 Mode of Action

- 15.4 Clinical Features
- 15.5 Antidotes
- 15.6 Sources and Uses
- 15.7 Concentrations in Field Collections
- 15.8 Persistence in Water, Soil, and Air
- 15.9 Lethal and Sublethal Effects
 - 15.9.1 Terrestrial Flora and Invertebrates
 - 15.9.2 Aquatic Organisms
 - 15.9.3 Birds
 - 15.9.4 Mammals
- 15.10 Recommendations
- 15.11 Summary
- 15.12 Literature Cited

Chapter 16

Diazinon

- 16.1 Introduction
- 16.2 Environmental Chemistry
- 16.3 Lethal Effects
 - 16.3.1 General
 - 16.3.2 Aquatic Organisms
 - 16.3.3 Birds
 - 16.3.4 Mammals
 - 16.3.5 Terrestrial Invertebrates
- 16.4 Sublethal Effects
 - 16.4.1 General
 - 16.4.2 Aquatic Organisms
 - 16.4.3 Birds
 - 16.4.4 Mammals
 - 16.4.5 Terrestrial Invertebrates
- 16.5 Recommendations
- 16.6 Summary
- 16.7 Literature Cited

Chapter 17

Diflubenzuron

- 17.1 Introduction
- 17.2 Environmental Chemistry
 - 17.2.1 General
 - 17.2.2 Chemical and Biochemical Properties
 - 17.2.3 Persistence in Soil and Water
- 17.3 Uses
- 17.4 Lethal and Sublethal Effects
 - 17.4.1 General
 - 17.4.2 Terrestrial Plants
 - 17.4.3 Terrestrial Invertebrates
 - 17.4.4 Aquatic Organisms: Laboratory Studies
 - 17.4.5 Aquatic Organisms: Field Studies
 - 17.4.6 Birds
 - 17.4.7 Mammals
- 17.5 Recommendations

- 17.6 Summary
- 17.7 Literature Cited

Chapter 18

Dioxins

- 18.1 Introduction
- 18.2 Environmental Chemistry
- 18.3 Concentrations in Field Collections
- 18.4 Lethal and Sublethal Effects
 - 18.4.1 General
 - 18.4.2 Terrestrial Plants and Invertebrates
 - 18.4.3 Aquatic Organisms
 - 18.4.4 Birds
 - 18.4.5 Mammals
- 18.5 Recommendations
- 18.6 Summary
- 18.7 Literature Cited

Chapter 19

Famphur

- 19.1 Introduction
- 19.2 Uses
- 19.3 Chemistry and Metabolism
- 19.4 Lethal and Sublethal Effects
 - 19.4.1 General
 - 19.4.2 Terrestrial Invertebrates
 - 19.4.3 Aquatic Organisms
 - 19.4.4 Birds
 - 19.4.5 Mammals
- 19.5 Recommendations
- 19.6 Summary
- 19.7 Literature Cited

Chapter 20

Fenvvalerate

- 20.1 Introduction
- 20.2 Environmental Chemistry
 - 20.2.1 General
 - 20.2.2 Chemical Properties
 - 20.2.3 Uses
 - 20.2.4 Persistence
- 20.3 Mode of Action
 - 20.3.1 General
 - 20.3.2 Types of Pyrethroids
 - 20.3.3 Sodium Gating Kinetics
 - 20.3.4 Metabolism
 - 20.3.5 Mutagenicity, Teratogenicity, and Carcinogenicity
- 20.4 Effects
 - 20.4.1 General
 - 20.4.2 Terrestrial Plants and Invertebrates
 - 20.4.3 Aquatic Organisms

- 20.4.4 Birds
- 20.4.5 Mammals
- 20.5 Recommendations
- 20.6 Summary
- 20.7 Literature Cited

Chapter 21

Mirex

- 21.1 Introduction
- 21.2 Chemical Properties
- 21.3 Lethal Effects
 - 21.3.1 Aquatic Organisms
 - 21.3.2 Birds and Mammals
- 21.4 Sublethal Effects
 - 21.4.1 Aquatic Organisms
 - 21.4.2 Birds
 - 21.4.3 Mammals
- 21.5 Bioaccumulation
 - 21.5.1 Aquatic Organisms
 - 21.5.2 Birds and Mammals
- 21.6 Mirex in the Southeastern United States
- 21.7 Mirex in the Great Lakes
- 21.8 Mirex in Other Geographic Areas
- 21.9 Recommendations
- 21.10 Summary
- 21.11 Literature Cited

Chapter 22

Paraquat

- 22.1 Introduction
- 22.2 Uses
- 22.3 Concentrations in Field Collections
- 22.4 Environmental Chemistry
 - 22.4.1 General
 - 22.4.2 Chemical Properties
 - 22.4.3 Mode of Action
 - 22.4.4 Fate in Soils and Water
- 22.5 Lethal and Sublethal Effects
 - 22.5.1 General
 - 22.5.2 Terrestrial Plants and Invertebrates
 - 22.5.3 Aquatic Organisms
 - 22.5.4 Birds
 - 22.5.5 Mammals
- 22.6 Recommendations
- 22.7 Summary
- 22.8 Literature Cited

Chapter 23

Pentachlorophenol

- 23.1 Introduction
- 23.2 Environmental Chemistry

- 23.2.1 General
- 23.2.2 Sources and Uses
- 23.2.3 Properties
- 23.2.4 Fate
- 23.3 Concentrations in Field Collections
 - 23.3.1 General
 - 23.3.2 Biological and Nonbiological Samples
- 23.4 Effects
 - 23.4.1 General
 - 23.4.2 Terrestrial Plants and Invertebrates
 - 23.4.3 Aquatic Biota
 - 23.4.4 Birds
 - 23.4.5 Mammals
- 23.5 Recommendations
- 23.6 Summary
- 23.7 Literature Cited

Chapter 24

Polychlorinated Biphenyls

- 24.1 Introduction
- 24.2 Sources and Uses
- 24.3 Chemical and Biochemical Properties
 - 24.3.1 General
 - 24.3.2 Physical Properties
 - 24.3.3 Toxic Equivalency Factors
 - 24.3.4 Structure–Function Relations
 - 24.3.5 Quantitation
- 24.4 Concentrations in Field Collections
 - 24.4.1 General
 - 24.4.2 Nonbiological Materials
 - 24.4.3 Marine Mammals
 - 24.4.4 Other Aquatic Organisms
 - 24.4.5 Reptiles
 - 24.4.6 Birds
 - 24.4.7 Terrestrial Mammals
- 24.5 Lethal and Sublethal Effects
 - 24.5.1 General
 - 24.5.2 Aquatic Organisms
 - 24.5.3 Birds
 - 24.5.4 Mammals
- 24.6 Recommendations
- 24.7 Summary
- 24.8 Literature Cited

Chapter 25

Polyyclic Aromatic Hydrocarbons

- 25.1 Introduction
- 25.2 Environmental Chemistry, Sources, and Fate
 - 25.2.1 Properties
 - 25.2.2 Sources
 - 25.2.3 Fate

- 25.3 Concentrations in Field Collections
 - 25.3.1 General
 - 25.3.2 Nonbiological Samples
 - 25.3.3 Biological Samples
- 25.4 Lethal and Sublethal Effects
 - 25.4.1 General
 - 25.4.2 Fungi
 - 25.4.3 Terrestrial Plants
 - 25.4.4 Aquatic Biota
 - 25.4.5 Amphibians and Reptiles
 - 25.4.6 Birds
 - 25.4.7 Mammals
- 25.5 Recommendations
- 25.6 Summary
- 25.7 Literature Cited

Chapter 26

- Sodium Monofluoroacetate
- 26.1 Introduction
 - 26.2 Uses
 - 26.2.1 Domestic Use
 - 26.2.2 Nondomestic Use
 - 26.3 Environmental Chemistry
 - 26.3.1 General
 - 26.3.2 Chemical Properties
 - 26.3.3 Persistence
 - 26.3.4 Metabolism
 - 26.3.5 Antidotes
 - 26.4 Lethal and Sublethal Effects
 - 26.4.1 General
 - 26.4.2 Terrestrial Plants and Invertebrates
 - 26.4.3 Aquatic Organisms
 - 26.4.4 Amphibians and Reptiles
 - 26.4.5 Birds
 - 26.4.6 Mammals
 - 26.5 Recommendations
 - 26.6 Summary
 - 26.7 Literature Cited

Chapter 27

- Toxaphene
- 27.1 Introduction
 - 27.2 Environmental Chemistry
 - 27.3 Concentrations in Field Populations
 - 27.4 Lethal Effects
 - 27.5 Sublethal Effects
 - 27.6 Recommendations
 - 27.7 Summary
 - 27.8 Literature Cited

Contents

Chapter 28

Arsenic

- 28.1 Introduction
- 28.2 Sources, Fate, and Uses
- 28.3 Chemical and Biochemical Properties
- 28.4 Essentiality, Synergism, and Antagonism
- 28.5 Concentrations in Field Collections
 - 28.5.1 General
 - 28.5.2 Nonbiological Samples
 - 28.5.3 Biological Samples
- 28.6 Lethal and Sublethal Effects
 - 28.6.1 General
 - 28.6.2 Carcinogenesis, Mutagenesis, and Teratogenesis
 - 28.6.3 Terrestrial Plants and Invertebrates
 - 28.6.4 Aquatic Biota
 - 28.6.5 Birds
 - 28.6.6 Mammals
- 28.7 Recommendations
- 28.8 Summary
- 28.9 Literature Cited

Chapter 29

Boron

- 29.1 Introduction
- 29.2 Environmental Chemistry
 - 29.2.1 General
 - 29.2.2 Sources and Uses
 - 29.2.3 Chemical Properties
 - 29.2.4 Mode of Action
- 29.3 Concentrations in Field Collections
 - 29.3.1 General
 - 29.3.2 Nonbiological Materials
 - 29.3.3 Plants and Animals
- 29.4 Effects
 - 29.4.1 General
 - 29.4.2 Terrestrial Plants
 - 29.4.3 Terrestrial Invertebrates
 - 29.4.4 Aquatic Organisms
 - 29.4.5 Birds
 - 29.4.6 Mammals
- 29.5 Recommendations
- 29.6 Summary
- 29.7 Literature Cited

Chapter 30

Molybdenum

- 30.1 Introduction
- 30.2 Environmental Chemistry

- 30.2.1 General
- 30.2.2 Sources and Uses
- 30.2.3 Chemical Properties
- 30.2.4 Mode of Action
- 30.3 Concentrations in Field Collections
 - 30.3.1 General
 - 30.3.2 Nonbiological Samples
 - 30.3.3 Biological Samples
- 30.4 Effects
 - 30.4.1 General
 - 30.4.2 Terrestrial Plants
 - 30.4.3 Terrestrial Invertebrates
 - 30.4.4 Aquatic Organisms
 - 30.4.5 Birds
 - 30.4.6 Mammals
- 30.5 Recommendations
- 30.6 Summary
- 30.7 Literature Cited

Chapter 31

Selenium

- 31.1 Introduction
- 31.2 Environmental Chemistry
- 31.3 Concentrations in Field Collections
- 31.4 Deficiency and Protective Effects
- 31.5 Lethal Effects
 - 31.5.1 Aquatic Organisms
 - 31.5.2 Mammals and Birds
- 31.6 Sublethal and Latent Effects
 - 31.6.1 Aquatic Organisms
 - 31.6.2 Terrestrial Invertebrates
 - 31.6.3 Birds
 - 31.6.4 Mammals
- 31.7 Recommendations
- 31.8 Summary
- 31.9 Literature Cited

Chapter 32

Radiation

- 32.1 Introduction
- 32.2 Physical Properties of Radiation
 - 32.2.1 General

Chapter 33

Cumulative Index to Chemicals and Species

- 33.1 Introduction
- 33.2 Index to Chemicals
- 33.3 Index to Species
- 33.4 Summary
- 33.5 Literature Cited

LIST OF TABLES

- 1.1 Cadmium burdens and residence times in the principal global reservoirs
- 1.2 Cadmium concentrations in field collections of selected species of plants and animals
- 1.3 Lethal concentrations (LC) of cadmium to freshwater biota during various exposure intervals
- 1.4 Maximum allowable toxicant concentrations (MATC) of cadmium to sensitive species of freshwater teleosts
- 1.5 Sublethal effects of cadmium to selected species of aquatic biota
- 1.6 Cadmium residues, in mg/kg dry weight (ppm) in soil, flora, and fauna collected near two zinc smelters in Palmerton, Pennsylvania
- 1.7 Bioconcentration of cadmium from ambient medium by selected species of aquatic biota
- 1.8 Proposed cadmium criteria for the protection of living resources and human health

- 2.1 Chromium concentrations in abiotic materials
- 2.2 Concentrations of total chromium and Cr⁺⁶ in air, water, soil, and sludge near industrial sites and sewage outfalls in the United States
- 2.3 Chromium concentrations in field collections of selected species of marine, freshwater, and terrestrial plants and animals
- 2.4 Acute toxicities of hexavalent and trivalent chromium to aquatic life
- 2.5 Maximum acceptable toxicant concentration (MATC) values for hexavalent and trivalent chromium to aquatic life based on life cycle or partial life cycle exposures
- 2.6 Proposed chromium criteria for the protection of human health and natural resources

- 3.1 Some properties of copper and copper sulfate
- 3.2 Copper concentrations in selected abiotic materials
- 3.3 Copper concentrations (milligrams of copper per kilogram fresh weight [FW], dry weight [DW], or ash weight [AW]) in field collections of representative plants and animals
- 3.4 Effects of copper on representative terrestrial plants and invertebrates
- 3.5 Effects of copper on representative aquatic plants and animals
- 3.6 Effects of copper on selected birds.
- 3.7 Effects of copper on selected mammals
- 3.8 Proposed copper criteria for the protection of natural resources and human health

- 4.1 World lead production, consumption, and principal end uses
- 4.2 Use patterns for lead in selected countries
- 4.3 Amounts of lead in global reservoirs
- 4.4 Lead concentrations in selected nonbiological materials
- 4.5 Lead concentrations in field collections of representative species of plants and animals
- 4.6 Lethal and sublethal effects of lead to selected species of aquatic organisms
- 4.7 Lethal and sublethal effects of lead to selected species of birds
- 4.8 Lethal and sublethal effects of lead to selected species of mammals
- 4.9 Proposed lead criteria for the protection of natural resources and human health

- 5.1 Industrial and other uses of mercury in the United States in 1959 and in 1969
- 5.2 Amount of mercury in some global reservoirs and residence time
- 5.3 Some properties of mercury and its compounds

- 5.4 Mercury concentrations in selected biological and nonbiological materials collected from Minamata Bay, Japan, and environs
 - 5.5 Mercury concentrations in selected abiotic materials
 - 5.6 Mercury concentrations in field collections of selected species of plants and animals
 - 5.7 Lethality of inorganic and organic mercury compounds to selected species of aquatic organisms
 - 5.8 Lethality to birds of mercury administered by oral, dietary, or other routes
 - 5.9 Lethality of organomercury compounds to selected mammals
 - 5.10 Sublethal effects of organomercury compounds administered to selected species of mammals
 - 5.11 Proposed mercury criteria for protection of various resources and human health
-
- 6.1 Nickel chronology
 - 6.2 World mine production of nickel
 - 6.3 Nickel consumption in the United States by intermediate product and end-use industry in 1985
 - 6.4 Inventory of nickel in various global environmental compartments
 - 6.5 Nickel concentrations in selected abiotic materials
 - 6.6 Nickel concentrations (milligrams of nickel per kilogram fresh weight [FW] or dry weight [DW]) in field collections of representative plants and animals
 - 6.7 Nickel effects on selected aquatic plants and animals
 - 6.8 Nickel effects on birds
 - 6.9 Nickel effects on selected mammals
 - 6.10 Proposed nickel criteria for protection of natural resources and human health
-
- 7.1 Estimated release of silver to the environment in the United States in 1978
 - 7.2 Industrial domestic use of silver during 1966–72
 - 7.3 Some properties of silver and silver nitrate
 - 7.4 Silver concentrations in representative nonbiological materials
 - 7.5 Silver concentrations (milligrams of silver per kilogram fresh weight [FW], dry weight [DW], or ash weight [AW]) in field collections of selected plants and animals
 - 7.6 Effects of silver on representative aquatic plants and animals
 - 7.7 Effects of silver on selected mammals
 - 7.8 Proposed silver criteria for the protection of natural resources and human health
-
- 8.1 Biological and abiotic degradation times of selected organotins
 - 8.2 Annual tin production and consumption
 - 8.3 Major uses of inorganic and organic tin compounds
 - 8.4 Possible modes of entry of organotins into air, soil, and water
 - 8.5 Total tin flux to the atmosphere and hydrosphere
 - 8.6 Tin concentrations in nonbiological materials
 - 8.7 Tin concentrations in field collections of living flora and fauna
 - 8.8 Lethal and sublethal effects of inorganic and organic tin compounds in ambient medium to selected species of aquatic organisms
 - 8.9 Toxicity of selected diorganotin and triorganotin compounds to zoeae of the marine mud crab (*Rithropanopeus harrisii*) exposed from hatching to age 14 days
 - 8.10 Lethal and sublethal effects of selected organotin compounds to birds
 - 8.11 Effects of tin compounds on selected species of mammals
 - 8.12 Proposed organotin criteria for protection of natural resources and human health

- 9.1 Estimated annual zinc inputs to United States coastal marine ecosystems; study area comprised 116,000 km².
- 9.2 Some properties of zinc, zinc chloride, and zinc sulfate
- 9.3 Zinc concentrations (milligrams of zinc per kilogram fresh weight [FW] or dry weight DW) in representative nonbiological materials
- 9.4 Zinc concentrations (milligrams of zinc per kilogram fresh weight [FW] or dry weight [DW]) in field collections of representative plants and animals
- 9.5 Effects of zinc on representative terrestrial plants and invertebrates
- 9.6 Effects of zinc on representative aquatic plants and animals
- 9.7 Effects of zinc on representative birds
- 9.8 Effects of zinc on representative mammals
- 9.9 Proposed zinc criteria for the protection of natural resources and human health
- 10.1 Chemical and other properties of acrolein
- 10.2 Acrolein effects on representative aquatic organism
- 10.3 Acrolein effects on birds
- 10.4 Acrolein effects on selected mammals
- 10.5 Proposed acrolein criteria for the protection of living resources and human health

- 11.1 Chemical and other properties of atrazine
- 11.2 Atrazine concentrations in selected watersheds
- 11.3 Atrazine effects on selected species of terrestrial plants
- 11.4 Atrazine effects on selected species of aquatic plants
- 11.5 Lethal and sublethal effects of atrazine on selected species of aquatic animals
- 11.6 Atrazine effects on selected species of birds
- 11.7 Lethal and sublethal effects of atrazine on selected species of mammals

- 12.1 Carbofuran and its degradation products (in mg/kg dry weight) in corn (*Zea mays*) at silage stage (117 days) and at harvest (149 days) following application of carbofuran (10%) granules at 5.41 kg/ha
- 12.2 Effect of pH, soil type, and application rate on carbofuran degradation in soils
- 12.3 Acute toxicities of carbofuran to aquatic organisms
- 12.4 Acute oral toxicities of carbofuran to birds and mammals
- 12.5 Toxicity of dietary carbofuran to birds and mammals
- 12.6 Acute aerosol inhalation toxicity of carbofuran to warm-blooded animals
- 12.7 Rates of carbofuran metabolism by various organisms

- 13.1 Chlordane concentrations in selected nonbiological samples
- 13.2 Chlordane concentrations in field collections of selected animals
- 13.3 Chlordane effects on selected aquatic organisms
- 13.4 Chlordane effects on selected birds
- 13.5 Chlordane effects on selected mammals
- 13.6 Proposed chlordane criteria for protection of natural resources and human health

- 14.1 Selected chlorpyrifos formulations and carriers
- 14.2 Chemical and other properties of chlorpyrifos
- 14.3 Acute toxicities of chlorpyrifos to selected species of aquatic invertebrates and fishes
- 14.4 Chlorpyrifos bioconcentration factor (BCF) of selected species of fishes
- 14.5 Chlorpyrifos lethality to selected birds and mammals via single oral dose route of administration

- 14.6 Dietary toxicity of chlorpyrifos to selected species of birds
- 14.7 Chlorpyrifos effects on selected ecosystems

- 15.1 Some properties of potassium cyanide, hydrogen cyanide, and sodium cyanide
- 15.2 Concentrations of cyanide in field collections of selected living resources and nonbiological materials
- 15.3 Cyanide effects on selected species of aquatic organisms
- 15.4 Cyanide effects on selected species of birds
- 15.5 Cyanide effects on selected species of mammals
- 15.6 Proposed free cyanide criteria for the protection of living resources and human health

- 16.1 Persistence of diazinon in plants, soil, and water
- 16.2 Acute toxicity of diazinon to aquatic organisms
- 16.3 Mortality of mallard embryos after immersion for 30 seconds in graded strength diazinon solutions
- 16.4 Acute oral toxicity of diazinon to birds and mammals
- 16.5 Toxicity of diazinon to laboratory animals via dermal, inhalation, dietary, and chronic oral routes of administration
- 16.6 Accumulation of diazinon by aquatic organisms
- 16.7 Lowest tested diazinon concentrations that in medium produced significant nonlethal biological effects to aquatic organisms
- 16.8 Sublethal effects of diazinon in selected mammals

- 17.1 Chemical and other properties of diflubenzuron
- 17.2 Diflubenzuron persistence in soil and water
- 17.3 Diflubenzuron effects on selected terrestrial invertebrates
- 17.4 Diflubenzuron effects on selected aquatic organisms: laboratory studies
- 17.5 Diflubenzuron effects on selected aquatic organisms: field studies
- 17.6 Diflubenzuron effects on selected birds
- 17.7 Diflubenzuron effects on selected mammals

- 18.1 Levels of PCDDs in commercial chlorinated phenols, and levels of 2,3,7,8-TCDD in 2,4,5-T acid and ester formulations
- 18.2 Chemical and physical properties of 2,3,7,8-TCDD, also known as CAS Registry No. 1746-01-6
- 18.3 Concentrations of PCDDs measured in selected organisms and nonbiological materials collected from various locales
- 18.4 Effects of 2,3,7,8-TCDD and other PCDDs on representative species of freshwater organisms
- 18.5 Acute toxicities of selected PCDD isomers to the guinea pig and the mouse
- 18.6 Acute oral toxicities of 2,3,7,8-TCDD to mammals
- 18.7 Proposed 2,3,7,8-TCDD criteria for the protection of natural resources and human health

- 19.1 Chemical and other properties of famphur
- 19.2 Famphur effects on selected terrestrial invertebrates
- 19.3 Famphur effects on birds
- 19.4 Famphur effects on mammals

- 20.1 Chemical and other properties of fenvalerate

- 20.2 Fenvalerate persistence in water, sediments, and soils
 - 20.3 Fenvalerate persistence in plants and animals under field conditions
 - 20.4 Lethal and sublethal effects of fenvalerate on terrestrial invertebrates
 - 20.5 Lethal and sublethal effects of fenvalerate on aquatic organisms
 - 20.6 Lethal and sublethal effects of fenvalerate on birds
 - 20.7 Lethal and sublethal effects of fenvalerate on mammals
 - 20.8 Proposed fenvalerate criteria for the protection of natural resources and human health
-
- 21.1 Acute oral toxicity of mirex to birds and mammals
 - 21.2 Dietary toxicity of mirex to vertebrate organisms
 - 21.3 Uptake of mirex from ambient medium or diet by selected species
 - 21.4 Mirex residues in water, sediments, and fauna in a South Carolina coastal marsh 18 months after application of 4.2 g/ha
 - 21.5 Temporal persistence of residues for 1 year after applications of mirex 4X formulation to bahia grass pastures
 - 21.6 Mirex residues in fauna near Jacksonville, Florida, at various intervals posttreatment following single application of 1.12 g mirex/ha
 - 21.7 Mirex and its degradation products in herring gull eggs collected from the Great Lakes in 1977
 - 21.8 Biomagnification of mirex in Great Lakes food chains
-
- 22.1 Paraquat concentrations in field collections of selected organisms and nonbiological materials
 - 22.2 Chemical and other properties of paraquat
 - 22.3 Effects of paraquat on selected species of aquatic plants and animals
 - 22.4 Effects of paraquat on selected species of birds
 - 22.5 Effects of paraquat on selected species of mammals
 - 22.6 Proposed paraquat criteria for the protection of natural resources and human health
-
- 23.1 Chemical and other properties of pentachlorophenol
 - 23.2 Partial list of contaminants detected in technical-grade and purified pentachlorophenol
 - 23.3 Pentachlorophenol (PCP) concentrations in nonbiological and living materials
 - 23.4 Lethal and sublethal effects of pentachlorophenol (PCP) on selected species of aquatic organisms
 - 23.5 Effects of pentachlorophenol (PCP) on selected species of birds
 - 23.6 Effects of pentachlorophenol on selected mammals
 - 23.7 Proposed pentachlorophenol criteria for the protection of natural resources and human health
-
- 24.1 Estimated PCB loads in the global environment
 - 24.2 Polychlorinated biphenyls: structure, retention times, response factors, and octanol/water partition coefficients ($\log K_{ow}$)
 - 24.3 Proposed toxicity equivalency value (TEF) relative to 2,3,7,8-TCDD of non-*ortho*, mono-*ortho*, and di-*ortho* planar PCBs
 - 24.4 Interactive effects of PCBs on the induction of rat (*Rattus* sp.) liver microsomal cytochrome P-450c
 - 24.5 Summary of PCB structure-function relations in rats (*Rattus* sp.)
 - 24.6 PCB congeners in Aroclor 1254 and 1260

- 24.7 Effect of oven drying of sediments on percent loss of selected PCB congeners present at >0.1 mg/kg fresh weight
 - 24.8 PCB concentrations in field collections of selected nonbiological materials
 - 24.9 PCB concentrations in field collections of selected aquatic organisms
 - 24.10 PCB concentrations in field collections of selected reptiles
 - 24.11 PCB concentrations in field collections of selected birds
 - 24.12 PCB concentrations in field collections of selected mammals
 - 24.13 Effects of PCBs on representative aquatic organisms
 - 24.14 Effects of PCBs on selected birds
 - 24.15 Effects of PCBs on selected mammals
 - 24.16 Proposed PCB criteria for the protection of natural resources and human health
-
- 25.1 Some physical and chemical properties of selected PAHs
 - 25.2 Major sources of PAHs in atmospheric and aquatic environments
 - 25.3 PAH concentrations in selected nonbiological materials
 - 25.4 PAH concentrations in field collections of selected biota
 - 25.5 Toxicity of selected PAHs to aquatic organisms
 - 25.6 PAH bioconcentration factor (BCF) for selected species of aquatic organisms
 - 25.7 Benzo[*a*]pyrene effects on selected aquatic vertebrates
 - 25.8 Some effects of PAHs on selected laboratory mammals
 - 25.9 Proposed PAH criteria for protection of human health and aquatic life
-
- 26.1 Some properties of sodium monofluoroacetate
 - 26.2 Effects of 1080 on representative amphibians and reptiles
 - 26.3 Effects of 1080 on representative birds
 - 26.4 Effects of 1080 on representative mammals
-
- 27.1 Toxaphene concentrations in field collections of selected living organisms and abiotic materials
 - 27.2 Acute toxicity of toxaphene to aquatic organisms
 - 27.3 Maximum acceptable toxicant concentration values (MATC) for toxaphene and aquatic organisms, based on exposure for the entire or most of the life cycle
 - 27.4 Acute oral toxicity of toxaphene to birds and mammals
 - 27.5 Sublethal effects of toxaphene to aquatic biota
 - 27.6 Bioconcentration factor (BCF) for toxaphene and selected species of aquatic biota
 - 27.7 Sublethal effects of toxaphene on selected mammals
 - 27.8 Proposed toxaphene criteria for protection of natural resources and human health
-
- 28.1 Total arsenic concentrations in selected nonbiological materials
 - 28.2 Arsenic concentrations in field collections of selected species of plants and animals
 - 28.3 Lethal and sublethal effects of various arsenic compounds on selected species of terrestrial plants and invertebrates
 - 28.4 Lethal and sublethal effects of various arsenic compounds on selected species of aquatic biota
 - 28.5 Lethal and sublethal effects of various arsenicals on selected species of birds
 - 28.6 Lethal and sublethal effects of various arsenicals on selected species of mammals
 - 28.7 Proposed arsenic criteria for the protection of selected natural resources and human health
-
- 29.1 Environmental sources of domestic boron

- 29.2 Boron concentrations in selected nonbiological materials
 - 29.3 Boron concentrations in field collections of selected species of plants and animals
 - 29.4 Boron toxicity to some terrestrial plants
 - 29.5 Boron concentrations in soil water associated with optimal growth and plant injury
 - 29.6 Lethal and sublethal effects of boron on terrestrial invertebrates
 - 29.7 Lethal and sublethal effects of boron on aquatic organisms
 - 29.8 Lethal and sublethal effects of boron on birds
 - 29.9 Lethal and sublethal effects of boron on mammals
 - 29.10 Proposed boron criteria for the protection of natural resources and human health
-
- 30.1 Molybdenum concentrations in selected nonbiological materials
 - 30.2 Molybdenum concentrations in field collections of selected species of animals and plants
 - 30.3 Molybdenum effects on selected species of aquatic organisms
 - 30.4 Molybdenum effects on selected species of mammals
 - 30.5 Proposed molybdenum criteria for the protection of living resources and human health
-
- 31.1 Selenium concentrations in nonbiological materials
 - 31.2 Selenium concentrations in field populations of selected species of flora and fauna
 - 31.3 Toxicity of selenium salts to aquatic biota
 - 31.4 Selenium effects on birds
 - 31.5 Proposed criteria for prevention of selenium deficiency and for protection against selenosis
-
- 32.1 Selected radionuclides: symbol, mass number, atomic number, half-life, and decay mode
 - 32.2 Radiation weighting factors for various types of ionizing radiations
 - 32.3 New units for use with radiation and radioactivity
 - 32.4 Annual effective dose equivalent to humans from natural sources of ionizing radiation
 - 32.5 Annual whole-body radiation doses to humans from various sources
 - 32.6 Sources and applications of atomic energy
 - 32.7 Annual effective dose equivalent from nuclear weapons testing to humans in the north temperate zone
 - 32.8 Estimated fallout of ^{90}Sr and ^{137}Cs over the Great Lakes, 1954–1983, in cumulative millions of Bq/km²
 - 32.9 Fission products per kg ^{235}U reactor charge at 100 days cooling
 - 32.10 Radioactive waste disposal at sea
 - 32.11 Theoretical peak dose, in microsieverts per year, received from plutonium and americium by three human populations
 - 32.12 Time required to transport selected radionuclides added into marine waters at surface from the upper mixed layer by biological transport
 - 32.13 Radionuclide concentrations in field collections of selected abiotic materials
 - 32.14 Radionuclide concentrations in field collections of selected living organisms
 - 32.15 Radionuclide concentrations in selected samples from the Pacific Proving Grounds

- 32.16 Selected fission products in the Chernobyl reactor core and their estimated escape into the environment
 - 32.17 Regional total effective human dose-equivalent commitment from the Chernobyl accident
 - 32.18 Radionuclide concentrations in biotic and abiotic materials from various geographic locales before or after the Chernobyl nuclear accident on April 26, 1986
 - 32.19 Radiation effects on selected terrestrial plants
 - 32.20 Radiation effects on selected terrestrial invertebrates
 - 32.21 Radiation effects on selected aquatic organisms
 - 32.22 Concentration factors for cesium-137 and strontium-90 in aquatic organisms
 - 32.23 Approximate maximum concentration factors for selected transuranics in marine sediments, macroalgae, and fish
 - 32.24 Maximum concentration factors reported for selected elements in marine organisms at various trophic levels
 - 32.25 Radiation effects on selected amphibians and reptiles
 - 32.26 Radiation effects on selected birds
 - 32.27 Radiation effects on selected mammals
 - 32.28 Recommended radiological criteria for the protection of human health
-
- 33.1 Chemical and trade names of substances listed in the *Handbook of Chemical Risk Assessment* series
 - 33.2 Common and scientific names of plants and animals listed in the *Handbook of Chemical Risk Assessment* series

LIST OF FIGURES

- 5.1 Major transformations of mercury in the environment
5.2 Mercury concentrations in livers of four species of pinniped mammals
8.1 Environmental degradation scheme for tributyltin and triphenyltin compounds
10.1 Proposed scheme for *in vitro* mammalian metabolism of acrolein and allyl alcohol, a precursor of acrolein
11.1 Structural formula of atrazine
12.1 Structural formula for carbofuran (2,3-dihydro-2,2-dimethyl-1,7-benzofuranyl methylcarbamate)
13.1 Chemical structure of chlordane-related compounds
14.1 Structures of chlorpyrifos and some of its metabolites
15.1 Summary of lethal and sublethal effects of free cyanide on freshwater fish
16.1 Structural formula of diazinon
17.1 Generalized degradation pattern for diflubenzuron
18.1 Upper: numbering system used for identification of individual PCDD isomers.
Lower: the isomer 2,3,7,8-tetrachlorodibenzo-*para*-dioxin (2,3,7,8-TCDD)
19.1 Metabolic scheme for famphur in mammals
20.1 Fenvalerate and its isomers
22.1 Structural formulas of paraquat cation (*upper*) and paraquat dichloride salt (*lower*)
22.2 Proposed pathway of paraquat degradation by a bacterial isolate (*upper*) and by ultraviolet irradiation (*lower*)
23.1 Structural formula of pentachlorophenol
23.2 Some impurities found in technical-grade pentachlorophenol
24.1 Structure of biphenyl
24.2 Planar polychlorinated biphenyls and their derivatives
25.1 Nomenclature of PAHs
25.2 Ring structures of representative noncarcinogenic PAHs
25.3 Ring structures of representative tumorigenic, cocarcinogenic, and carcinogenic PAHs
25.4 The bay region dihydrodiol epoxide route of benzo[*a*]pyrene
32.1 The spectrum of electromagnetic waves, showing the relationship between wavelength, frequency, and energy
32.2 The principal uranium-238 decay series, indicating major decay mode and physical half-time of persistence
32.3 The three still-existing natural decay series
32.4 Natural radiations in selected radiological domains
32.5 Plutonium-239+240 in environmental samples at Thule, Greenland, between 1970 and 1984, after a military accident in 1968
32.6 Chernobyl air plume behavior and reported initial arrival times of detectable radioactivity
32.7 Acute radiation dose range fatal to 50% (30 days postexposure) of various taxonomic groups
32.8 Relation between diet, metabolism, and body weight with half-time retention of longest-lived component of cesium-137
32.9 Survival time and associated mode of death of selected mammals after whole-body doses of gamma radiation
32.10 Relation between body weight and radiation-induced LD50 (30 days postexposure) for selected mammals

Preface

Risk assessment is an inexact science. Successful risk assessment practitioners rely heavily on extensive and well-documented databases. In the case of chemicals entering the environment as a result of human activities, these databases generally include the chemical's source and use; its physical, chemical, and metabolic properties; concentrations in field collections of abiotic materials and living organisms; deficiency effects, in the case of chemicals essential for life processes; lethal and sublethal effects, including effects on survival, growth, reproduction, metabolism, mutagenicity, teratogenicity, and carcinogenicity; proposed regulatory criteria for the protection of human health and sensitive natural resources; and recommendations for additional research when databases are incomplete. Of the hundreds of thousands of chemicals discharged into the environment yearly from agricultural, domestic, industrial, mining, manufacturing, municipal, and military operations, there is sufficient information on only a small number to attempt preliminary risk assessments.

The chemicals selected for inclusion in this handbook series were recommended by environmental specialists of the U.S. Fish and Wildlife Service and other resource managers responsible for protecting our fish, wildlife, and biological diversity. Their choices were based on real or potential impact of each contaminant on populations of free-living natural resources — including threatened and endangered species — and on insufficient knowledge on how best to mitigate damage effects. Each chapter selectively reviews and synthesizes the technical literature on a specific priority contaminant in the environment and its effects on notably terrestrial plants and invertebrates, aquatic plants and animals, avian and mammalian wildlife, and other natural resources. Early versions of individual chapters were published between 1985 and 1999 in the *Contaminant Hazard Reviews* series of the U.S. Department of the Interior. This series rapidly became an important reference tool for contaminant specialists, scientists, educational institutions, state and local governments, natural resources agencies, business and industry, and the general public. More than 105,000 copies of individual reports were distributed in response to specific requests before supplies became exhausted. The current offering is updated to reflect the burgeoning literature in this subject area. I authored the original versions and the updates while stationed at the Patuxent Wildlife Research Center; however, all interpretations are my own and do not necessarily reflect those of the U.S. government. Moreover, mention of trade names or commercial products is not an endorsement or recommendation for use by the U.S. government.

Ronald Eisler, Ph.D.
Senior Research Biologist
U.S. Geological Survey
Patuxent Wildlife Research Center
Laurel, Maryland

Acknowledgments

This project was completed under the aegis of James A. Kushlan, director of the U.S. Geological Survey Patuxent Wildlife Research Center (PWRC), and Richard L. Jachowski, chief scientist at PWRC. I am grateful for their support and encouragement. Other research managers and scientists at PWRC who contributed significantly to the project over the 17 years that it was operative — and to whom I am indebted — include Peter H. Albers, Andre A. Belisle, W. Nelson Beyer, Lawrence J. Blus, Donald R. Clark, Jr., Nancy C. Coon, Harry N. Coulombe, Thomas W. Custer, Lawrence R. DeWeese, W. James Fleming, John B. French, Jr., Martha L. Gay, Christopher E. Grue, Russell J. Hall, Gary H. Heinz, Charles J. Henny, Paula F. P. Henry, Elwood F. Hill, David J. Hoffman, Kirk A. King, Alex J. Kryniwsky, Jerry R. Longcore, T. Peter Lowe, Mark J. Melancon, John F. Moore, Harold J. O'Conner, Harry M. Ohlendorf, Oliver H. Pattee, H. Randolph Perry, Jr., Matthew C. Perry, Barnett Rattner, Gregory J. Smith, Donald W. Sparling, Charles J. Stafford, Kenneth L. Stromborg, Douglas M. Swineford, Michael W. Tome, David L. Trauger, Donald H. White, and Stanley N. Wiemeyer.

Computer and graphics assistance was kindly provided by PWRC specialists Kinard Boone, Henry C. Bourne, Lois M. Loges, and Robert E. Munro. Library services — a major component of this project — were expertly provided by Lynda J. Garrett, chief librarian at PWRC, and a number of assistant librarians, most notably P. Wanda Manning.

I also acknowledge the technical assistance provided in early phases of this project by numerous scientists and editors from other U.S. Department of the Interior installations, especially researchers from the U.S. Geological Survey Columbia Environmental Research Center, and by scientists from the U.S. Environmental Protection Agency, the U.S. Department of Agriculture, various universities, the International Atomic Energy Agency, the Canadian Wildlife Service, and the U.S. Department of Energy.

CHAPTER 1

Cadmium

1.1 INTRODUCTION

There is no evidence that cadmium (Cd) is biologically essential or beneficial; on the contrary, it has been implicated as the cause of numerous human deaths and various deleterious effects in fish and wildlife. In sufficient concentration, it is toxic to all forms of life, including microorganisms, higher plants, animals, and man. It is a relatively rare metal, usually present in small amounts in zinc ores, and is commercially obtained as an industrial by-product of the production of zinc, copper, and lead. Major uses of cadmium are in electroplating, in pigment production, and in the manufacture of plastic stabilizers and batteries. Anthropogenic sources of cadmium include smelter fumes and dusts, the products of incineration of cadmium-bearing materials and fossil fuels, fertilizers, and municipal wastewater and sludge discharges; concentrations are most likely highest in the localized regions of smelters or in urban industrialized areas (Hammons et al. 1978; U.S. Environmental Protection Agency [USEPA] 1980; Nriagu 1980, 1981; Hutton 1983b; Eisler 1985; Scheuhammer 1987; U.S. Public Health Service [USPHS] 1993; Cooke and Johnson 1996). Industrial consumption of cadmium in the United States, estimated at 6000 metric tons in 1968, is increasing; projected use in the year 2000 is about 14,000 tons, primarily for electroplating of motor parts and in the manufacture of batteries. The cadmium load in soils and terrestrial biota in other industrialized countries also appears to be increasing and is of great concern in Scandinavia (Tjell et al. 1983), Germany (Markard 1983), and the United Kingdom (Hutton 1983a).

1.2 ENVIRONMENTAL CHEMISTRY

Cadmium, as cadmium oxide, is obtained mainly as a by-product during the processing of zinc-bearing ores and also from the refining of lead and copper from sulfide ores (USPHS 1993). In 1989, the United States produced 1.4 million kg of cadmium (usually 0.6 to 1.8 million kg) and imported an additional 2.7 million kg (usually 1.8 to 3.2 million kg). Cadmium is used mainly for the production of nickel–cadmium batteries (35%), in metal plating (30%), and for the manufacture of pigments (15%), plastics and synthetics (10%), and alloys and miscellaneous uses (10%) (USPHS 1993).

Cadmium is a silver-white, blue-tinged, lustrous metal that melts at 321°C and boils at 767°C. This divalent element has an atomic weight of 112.4, an atomic number of 48, and a density of 8.642 g/cm³. It is insoluble in water, although its chloride and sulfate salts are freely soluble (Windholz et al. 1976; USPHS 1993). The availability of cadmium to living organisms from their immediate physical and chemical environs depends on numerous factors, including adsorption and desorption rates of cadmium from terrigenous materials, pH, Eh, chemical speciation, and many

other modifiers. The few selected examples that follow demonstrate the complex behavior of cadmium in aquatic systems.

Microbial extracellular polymeric substances (EPS) — ubiquitous features in aquatic environments — actively participate in binding dissolved overlying and pore-water metals in sediments. Organic sediment coatings in the form of bacterial EPS equivalent to about 0.5% organic matter can adsorb cadmium under estuarine conditions (Schlekat et al. 1998). EPS aggregates rapidly sorbed up to 90% of cadmium from solution. Changes in pH affected cadmium sorption, with the proportion of freed Cd to sorbed Cd changing from 90% at pH 5 to 5% at pH 9; desorption was enhanced with increasing salinity (Schlekat et al. 1998).

Adsorption and desorption processes are likely to be major factors in controlling the concentration of cadmium in natural waters and tend to counteract changes in the concentration of cadmium ions in solution (Gardiner 1974). Adsorption and desorption rates of cadmium are rapid on mud solids and particles of clay, silica, humic material, and other naturally occurring solids. Concentration factors for river muds varied between 5000 and 500,000 and depended mainly on the type of solid, the particle size, the concentration of cadmium present, the duration of contact, and the concentration of complexing ligands; humic material appeared to be the main component of river mud responsible for adsorption (Gardiner 1974). Changes in physicochemical conditions, especially pH and redox potential, that occur during dredging and disposal of cadmium-polluted sediments may increase chemical mobility and, hence, bioavailability of sediment-bound cadmium (Khalid et al. 1981). For example, cadmium in Mississippi River sediments spiked with radiocadmium was transformed from potentially available organic forms to more mobile and readily available dissolved and exchangeable forms (i.e., increased bioavailability) under regimens of comparatively acidic pH and high oxidation (Khalid et al. 1981). The role of dissolved oxygen and aquatic plants on cadmium cycling was studied in Palestine Lake, a 92-ha eutrophic lake in Kosciusko County, Indiana, a long-term recipient of cadmium and other waste metals from an electroplating plant. The maximum recorded concentration of dissolved cadmium in the water column was 17.3 µg/L; for suspended particulates, it was 30.3 µg/L (Shephard et al. 1980). During anaerobic conditions in the lake's hypolimnion, a marked decrease in the dissolved fraction and a corresponding increase in the suspended fraction were noted. The dominant form of cadmium was free, readily bioavailable, cadmium ion, Cd²⁺; however, organic complexes of cadmium, which are comparatively nonbioavailable, made up a significant portion of the total dissolved cadmium. Cadmium levels in sediments of Palestine Lake ranged from 1.5 mg/L in an uncontaminated area of the lake to 805 mg/L near the outlet of a metal-bearing ditch that entered the lake (McIntosh et al. 1978). The dominant form of cadmium in sediments was as a carbonate. Levels of cadmium in water varied over time and between sites, but usually ranged from 0.5 to 2.5 µg/L. It is possible that significant amounts of cadmium are transferred from the sediments into rooted aquatic macrophytes and later released into the water after macrophyte death (natural or herbicide-induced), particularly in heavily contaminated systems. In Palestine Lake, cadmium levels in pondweed (*Potamogeton crispus*), a rooted aquatic macrophyte, were about 90 mg/kg dry weight; a maximum burden of 1.5 kg was retained by the population of *P. crispus* in the lake (McIntosh et al. 1978). Release of the total amount could raise water concentrations by a maximum of 1 µg/L. This amount was considered negligible in terms of the overall lake cadmium budgets; however, it might have limited local effects.

1.3 CONCENTRATIONS IN FIELD COLLECTIONS

Small amounts of cadmium enter the environment from the natural weathering of minerals, but most is released as a result of human activities such as mining, smelting, fuel combustion, disposal of metal-containing products, and application of phosphate fertilizers or sewage sludges (USPHS 1993). In 1988, an estimated 306,000 kg of cadmium entered the domestic environment as a result

Table 1.1 Cadmium Burdens and Residence Times in the Principal Global Reservoirs

Reservoir	Concentration	Total Cd in Reservoir, in Metric Tons	Residence Time
Atmosphere	0.00003 µg/m ³	1500	7 days
Oceans			
Dissolved	0.06 µg/kg	84,000,000	21,000 years
Suspended particulates (total)	1.0 mg/kg	1,400,000	—
Particulate organic matter	4.5 mg/kg	320,000	1.3 years
Freshwaters			
Dissolved	0.05 µg/kg	16,000	—
Sediments	0.16 mg/kg	100,000	3.6 years
Groundwater	0.1 µg/kg	400	—
Glaciers	0.005 µg/kg	82,000	—
Sediment pore waters	0.2 µg/kg	64,000,000	—
Swamps and marshes, biomass	0.6 mg/kg	3600	—
Biosphere			
Marine plants	2.0 mg/kg	400	18 days
Marine animals	4.0 mg/kg	12,000	—
Land plants	0.3 mg/kg	720,000	20 days
Land animals	0.3 mg/kg	6000	—
Freshwater biota	3.5 mg/kg	7000	3.5 years
Human biomass	50 mg/person	200	1–40 years
Terrestrial litter	0.6 mg/kg	1,300,000	42 years
Lithosphere (down to 45 km)	0.5 mg/kg	2.8 × 10 ¹³	1 billion years

Adapted from Nriagu, J.O. (ed.) 1980. *Cadmium in the Environment. Part I: Ecological Cycling*. John Wiley, NY. 682 pp.

of human activities, mostly from industrial releases that were subsequently applied to soils (USPHS 1993). Where cadmium is comparatively bioavailable, these values are very near those that have been shown to produce harmful effects in sensitive biological species, as will be discussed later.

Loading of cadmium in uncontaminated, nonbiological compartments extended over several orders of magnitude, with most of the cadmium in lithosphere and ocean reservoirs (Table 1.1; Korte 1983). Concentrations (µg/L or µg/kg) of cadmium reported in uncontaminated compartments ranged from 0.05 to 0.2 in freshwater, up to 0.05 in coastal seawater, from 0.01 to 0.1 in open-ocean seawater, 0.1 to 14 in stormwater runoff, up to 5000 in riverine and lake sediments, 30 to 1000 in marine sediments, 10 to 1000 in soils of nonvolcanic origin, as much as 142 in human dietary items, up to 4500 in soils of volcanic origin, 1 to 600 in igneous rock, up to 100,000 in phosphatic rock, and 0.001 to 0.005 µg/m³ in air (Korte 1983; USPHS 1993). Higher values are reported in abiotic materials and living organisms from cadmium-contaminated environments, being highest near cadmium-emitting industries such as smelters, municipal incinerators, and fossil fuel combustion facilities (Eisler 1985; USPHS 1993).

Cadmium, unlike synthetic compounds, is a naturally occurring element, and its presence has been detected in more than 1000 species of aquatic and terrestrial flora and fauna. Concentrations of cadmium in selected species of biota are shown in Table 1.2; more extensive documentation was presented by Hammons et al. (1978), NRCC (1979), Jenkins (1980), and Eisler (1981). At least six trends are evident from Table 1.2. First, marine biota generally contained significantly higher cadmium residues than their freshwater or terrestrial counterparts, probably because total cadmium levels are higher in seawater. Second, cadmium tends to concentrate in the viscera of vertebrates, especially the liver and kidneys. Third, concentrations of cadmium are higher in older organisms than in younger stages; this relationship is especially pronounced in carnivores and marine vertebrates (Eisler 1984). Fourth, higher concentrations reported for individuals of a single species collected at several locations are almost always associated with proximity to industrial and urbanized

areas or to point source discharges of cadmium-containing wastes. Fifth, background levels of cadmium in crops and other plants are usually <1.0 mg/kg (ppm). Little is known about the cadmium concentrations required to reduce plant yields; however, plants growing in cadmium-contaminated soils contain abnormally high residues that may be detrimental to plant growth and to animal and human consumers. Finally, it is apparent from [Table 1.2](#) that species analyzed, season of collection, ambient cadmium levels, and sex of organism all modify concentrations of cadmium in organisms. In freshwater isopods, for example, cadmium was stored mainly in the hepatopancreas; cadmium concentrations were higher in juveniles than in adults; and seasonal fluctuations accounted for as much as 79% of the within-population variability (van Hattum et al. 1996).

Cadmium tends to accumulate in avian tissues in the order of kidney, liver, brain, bone, and muscle, with the highest concentrations in older birds and those found closest to a point source of cadmium (Pedersen and Myklebust 1993; Ferns and Anderson 1994; Garcia-Fernandez et al. 1996). In Norwegian birds, cadmium in tissues is generally higher in adults than in juveniles, higher in winter than in other seasons, positively correlated with tissue copper burdens, and positively correlated with selective consumption of seeds of the willow (*Salix* sp., known to have a high level of cadmium) and insects living on the willow (Hogstad 1996). However, cadmium concentrations in kidneys of canvasback ducks (*Aythya valisineria*) foraging on the submerged plant *Vallisneria americana* do not seem to reflect dietary cadmium intake (Lovvorn and Gillingham 1996). Cadmium and other metals also tend to concentrate in feathers, and molting frequency is important in the depuration process (Pilstro et al. 1993). Most birds molt their body feathers once a year, but some — such as Franklin's gulls (*Larus pipixcan*) — molt twice. Therefore, they have a greater opportunity than other birds to rid the body of contaminants (Burger and Gochfeld 1996).

The relationship between reported tissue cadmium concentrations of “unstressed” populations and hazard to the organism or its consumer is not well documented. For example, cadmium in eggs of successful nests of Cooper’s hawks (*Accipiter cooperii*) collected in Arizona and New Mexico ranged from 0.015 to 0.24 mg/kg fresh weight (FW); concentrations were higher in eggs from unsuccessful nests (Snyder et al. 1973). Cadmium concentrations in the livers of breeding birds were higher in two declining colonies of puffins in St. Kilda and Clo Mor (12.9 to 22.3 mg/kg DW) than in colonies of puffins from other areas, or in livers of other seabirds examined (Parslow et al. 1972). However, the link to cadmium requires elucidation. Among marine teleosts, whole-body levels exceeding 5 mg/kg FW or 86 mg/kg ash weight (AW) in laboratory-stressed fish suggested that death would follow within 4 weeks (Eisler 1971). Marine bivalve molluscs occasionally contain more than 13 mg Cd/kg soft parts FW ([Table 1.2](#)), a level considered acutely toxic to humans (Zaroogian and Cheer 1976). However, many species of marine and terrestrial mammals frequently contained more than 20 mg Cd/kg FW in various tissues without apparent adverse effects to the organism ([Table 1.2](#); Taylor et al. 1989; Gamberg and Scheuhammer 1994). The significance of cadmium residues to organism health is further developed later.

In terrestrial mammals, cadmium tends to accumulate with increasing age in kidneys and livers of hares (Venalainen et al. 1996), moles and shrews (Talmage and Walton 1991), deer (Musante et al. 1993), and caribou (*Rangifer tarandus*) and muskox (*Ovibos moschatus*; Gamberg and Scheuhammer 1994). Concentration of cadmium in the kidneys of deer increased from <0.002 mg/kg DW at age zero to 10.5 at age 7 in males; in females, these values were 6.5 mg/kg DW at age 3, 12.5 at age 7, and 20 to 40 at age 8 (Musante et al. 1993). Cadmium concentrations were positively correlated with age in kidneys of caribou and muskox collected from the Canadian Yukon and Northwest Territories between 1985 and 1990. The highest cadmium concentration measured, 166 mg/kg DW, was in renal tissue of a 15-year-old caribou. Caribou diets rely heavily on lichens which accumulate cadmium to a greater extent than do sedges (muskox diet; Gamberg and Scheuhammer 1994). The mean kidney concentration of 467 mg Cd/kg DW of beavers from a cadmium-contaminated estuary in Germany is the greatest reported in free-ranging herbivores (Nolet et al. 1994).

1.4 LETHAL EFFECTS

The lethal effects of cadmium are thought to be caused by free cadmium ions, that is, cadmium not bound to metallothioneins or other proteins. Free cadmium ions may inactivate various metal-dependent enzymes; however, cadmium not bound to metallothionein may have the capacity to directly damage renal tubular membranes during uptake (USPHS 1993).

A substantial toxicological database for cadmium and freshwater biota demonstrates that ambient cadmium water concentrations exceeding 10 µg/L are associated with high mortality, reduced growth, inhibited reproduction, and other adverse effects. Inasmuch as one recommended drinking water criterion for human health protection is 10 µg Cd/L (USEPA 1980), it is noteworthy that several species of freshwater aquatic insects, crustaceans, and teleosts exhibited significant mortality at cadmium concentrations of 0.8 to 9.9 µg/L during exposures of 4 to 33 days. Mortality generally increased as exposure time increased, water hardness decreased, and organism age decreased (Table 1.3). Daphnids (*Daphnia magna*), for example, were more resistant to the biocidal properties of cadmium under conditions of increasing concentrations of dissolved organic materials and water hardness, especially Ca²⁺ (Penttinen et al. 1998). Prior exposure to elevated sublethal concentrations of waterborne cadmium protects a minnow (*Phoxinus phoxinus*) against subsequent exposure to a lethal waterborne dose of cadmium; this phenomenon was associated with reduced uptake of ¹⁰⁹Cd into the gills of a minnow when this species was challenged with a lethal dose of waterborne cadmium (Glynn and Olsson 1991). In the case of larval toads (*Bufo arenarum*) and northwestern salamanders (*Ambystoma gracile*), adverse effects on survival were documented at 250 to 468 µg Cd/L, with mortality greatest at elevated temperatures and early developmental stages (Ferrari et al. 1993; Herkovits and Coll 1993; Nebeker et al. 1994, 1995; Perez-Coll and Herkovits 1996).

Resistance to cadmium is higher in marine than in freshwater organisms and survival usually is higher at the lower temperatures and higher salinities for any given level of cadmium in the medium (Eisler 1985). Cadmium was fatal to 50% of nauplii of copepods (*Eurytemora affinis*) at 51 µg/L and 5 ppt salinity, and 83 to 213 µg/L at higher salinities. A similar pattern was evident for larvae of the sheepshead minnow (*Cyprinodon variegatus*); the free ion (Cd²⁺) accounted for 20% of total cadmium at 5 ppt, 8% at 15 ppt, and 4.5% at 25 ppt salinity (Hall et al. 1995). Decapod crustaceans are also sensitive in short-term tests; LC50 (96 h) values ranged from 320 to 420 µg/L for the grass shrimp (*Palaemonetes vulgaris*), the hermit crab (*Pagurus longicarpus*), and the sand shrimp (*Crangon crangon*) (Eisler 1971). Studies of longer duration demonstrated that survival of shrimp groups was low at >250 µg/L during 6 weeks of exposure and that hermit crab deaths were recorded at 60 µg/L after 6 weeks, although some survivors remained at 10 weeks when the studies ended (Pesch and Stewart 1980). In another study, an LC50 range of 14.8 to 19.5 µg Cd/L was reported for two species of mysid shrimp subjected to “lifetime” (i.e., 23 to 27 days) exposure to cadmium salts (Gentile et al. 1982). Studies with *Leptocheirus plumulosus*, an estuarine amphipod, showed that gravid females were more resistant than males or mature females to the biocidal properties of aqueous Cd²⁺; juveniles were more sensitive than adults; sensitivity was greatest among starved animals and immediately after molting; and field-collected animals were more sensitive to dissolved cadmium than laboratory animals, regardless of season of collection (McGee et al. 1998).

Birds are comparatively resistant to the biocidal properties of cadmium. Adult drake mallards (*Anas platyrhynchos*) fed up to 200 mg cadmium per kg diet for 90 days all survived with no loss of body weight (White and Finley 1978). Laying hens fed 200 mg Cd/kg diet also survived; egg production was suppressed at that concentration but not at lower concentrations (White and Finley 1978). Marine and terrestrial animals, including ducks, have been shown to be particularly abundant in a wildlife community associated with a marine sewer outfall (Brown et al. 1977). These animals were contaminated with high levels of cadmium, as well as zinc and copper, but were apparently protected from the deleterious effects of high metal body burdens by metallothioneins. Amounts

Table 1.3 Lethal Concentrations (LC) of Cadmium to Freshwater Biota during Various Exposure Intervals
 (Concentrations shown are in µg Cd/L (ppb) of medium fatal to 10% or 50% of test organisms)

of these metal-binding proteinaceous metallothioneins and heavy metal loading appear to depend primarily on the degree of pollution and secondarily on the species of animal and its position in the food web. Ducks contained the highest levels of metallothioneins of all groups examined (Brown et al. 1977).

Mammals, like birds, are comparatively resistant to cadmium. The lowest oral dose, in mg/kg body weight of cadmium (as fluoroborate) producing death, was 250 in rats (*Rattus* sp.) and 150 (as cadmium fluoride) in guinea pigs (*Cavia* sp.; USEPA 1980). Exposure to high levels of cadmium by inhalation or orally are fatal in humans and other animals (USPHS 1993). Inhalation of a lethal dose of cadmium can occur without signs of acute distress during exposure, although high oral doses of cadmium sometimes induce vomiting in humans. Cause of death is pulmonary edema after inhalation exposure, and massive fluid imbalance and widespread gastrointestinal, liver, and other organ damage after oral exposure — due mainly to the destruction of lung cell membranes (inhalation) and gastrointestinal tract membranes (oral) at the point of entry (USPHS 1993). Suicidal doses in 2 humans are reported at 25 and at 1500 mg Cd/kg BW (USPHS 1993).

1.5 SUBLETHAL EFFECTS

Studies of 30 to 60 days' duration with three comparatively sensitive species of freshwater fishes demonstrated that concentrations of >1 and <3 μg Cd/L in water of low alkalinity caused reductions in growth, survival, and fecundity of brook trout (*Salvelinus fontinalis*), the most sensitive species tested (Table 1.3). Under conditions of increasing alkalinity, the maximum allowable cadmium concentration range for brook trout increased to >7 and <12 $\mu\text{g}/\text{L}$; a similar case was made for the walleye (*Stizostedion vitreum*; Table 1.3).

Among all species of freshwater biota examined, cadmium concentrations of 0.47 to 5.0 $\mu\text{g}/\text{L}$ were associated with decreases in standing crop, decreases in growth, inhibition of reproduction, immobilization, and population alterations (Table 1.4). Juvenile rainbow trout (*Oncorhynchus mykiss*) exposed to 1 or 5 μg Cd/L for 30 days showed reductions in liver size, glycogen content, growth rate, and plasma calcium with changes attributed in part to disrupted endocrine function (Ricard et al. 1998). Cadmium interactions with other metals and compounds are significant. For example, 4 μg Zn/L or 11 μg Se/L were effective in counteracting the decrease in oxygen uptake induced by ionic cadmium in *Channa punctatus*, freshwater teleost (Sastry and Shukla 1994). There is abundant technical literature documenting numerous sublethal effects at higher concentrations of cadmium salts. However, these were excluded if the effects were observed at >10.0 $\mu\text{g}/\text{L}$, a recommended criterion for drinking water. Delayed effects of cadmium intoxication, however, need to be considered. Studies with daphnids, amphipods, and fathead minnows indicate that exposure to cadmium concentrations as low as 370 $\mu\text{g}/\text{L}$ for as little as 30 minutes caused increasing immobility for up to 172 h after exposure (Brent and Herricks 1998).

For marine organisms, ambient cadmium concentrations between 0.5 and 10.0 $\mu\text{g}/\text{L}$ resulted in decreases in growth, respiratory disruption, molt inhibition, shortened life span of F1-generation crustaceans, altered enzyme levels, and abnormal muscular contractions. Effects, in general, were more pronounced at lower salinities and higher temperatures (Table 1.5). Marine algae accumulated more cadmium at lower salinities than at higher salinities; algae bound only free cadmium ions, and these are inversely related to the concentration of the suspended particulate matter (Favero et al. 1996). Adaptation to environmental cadmium stress is reported for mussels (*Mytilopsis sallei*) exposed to high (>50 μg Cd/L) sublethal concentrations for at least 96 h. The decrease in oxygen consumption and the increased metabolism of glycogen and carbohydrates during exposure to cadmium suggest that *M. sallei* might shift to anaerobic metabolism to counter the environmental cadmium stress (Devi 1996).

One of the more sensitive indicators of cadmium exposure is the inhibition of non-thionein hepatic metal binding proteins; inhibition was observed in juvenile bluegills (*Lepomis macrochirus*)

Table 1.4 Maximum Allowable Toxicant Concentrations (MATC) of Cadmium to Sensitive Species of Freshwater Teleosts

Organism and Exposure Period (days)	Water Alkalinity, (mg CaCO ₃ /L)	MATC, (µg Cd/L)
Brook trout, <i>Salvelinus fontinalis</i>		
60	30	>1-<3
60	177	>7-<12
Channel catfish, <i>Ictalurus punctatus</i>		
60	34	>11-<17
60	172	>12-<17
Walleye, <i>Stizostedion vitreum vitreum</i>		
30	33	>9-<25
30	172	>86.7

Adapted from Brungs, W.A., R.A. Carlson, W.B. Horning II, J.H. McCormick, R.L. Spehar, and J.D. Young. 1978. Effects of pollution on freshwater fish. *Jour. Water Pollut. Control Fed.* 50:1582-1637.

at concentrations as low as 0.8 µg Cd/L (Cope et al. 1994). Cadmium at elevated concentrations (100 µg/L) significantly inhibits the Na⁺/K⁺-ATPase activity in different tissues of rat, frog, rabbit, and trout, and also sometimes at concentrations as low as 16 µg/L in the case of gill basolateral membrane vesicle of European eels (*Anguilla anguilla*). Inhibition of ATPase activities may lead to severe perturbations of osmoregulation processes, causing disturbances in migration and perhaps the survival of feral eel populations (Lemaire-Gony and Mayer-Gostan 1994). In the scorpionfish (*Scorpaena guttata*), cadmium disrupts cytosol balance and inhibits copper–zinc–superoxide dismutase activity in the intestine (Bay et al. 1990; Brown et al. 1990), with important implications for detoxification. Dose-dependent induction of liver metallothionein proteins within 24 h were observed in juvenile winter flounders (*Pleuronectes americanus*) after subcutaneous injection of high doses of cadmium (5 to 20 mg Cd/kg BW), with RNA disruption reported at the highest dose (Jessen-Eller and Crivello 1998).

Sublethal effects in birds are similar to those in other species and include growth retardation, anemia, renal effects, and testicular damage (Hammons et al. 1978; Di Giulio et al. 1984; Blus et al. 1993). However, harmful damage effects were observed at higher concentrations when compared to aquatic biota. For example, Japanese quail (*Coturnix japonica*) fed 75 mg Cd/kg diet developed bone marrow hypoplasia, anemia, and hypertrophy of both heart ventricles at 6 weeks (Richardson et al. 1974). In zinc-deficient diets, effects were especially pronounced and included all of the signs mentioned plus testicular hypoplasia. A similar pattern was evident in cadmium-stressed quail on an iron-deficient diet. In all tests, 1% ascorbic acid in the diet prevented cadmium-induced effects in Japanese quail (Richardson et al. 1974). In studies with Japanese quail at environmentally relevant concentrations of 10 µg Cd/kg BW daily (for 4 days, administered per os), absorbed cadmium was transported in blood in a form that enhanced deposition in the kidney; less than 0.7% of the total administered dose was recovered from liver plus kidneys plus duodenum (Scheuhammer 1988).

In wood ducks (*Aix sponsa*) fed rations containing 10 mg Cd/kg, no renal effects were noted even though kidneys contained 62 mg Cd/kg FW. Renal damage was noted when wood ducks were fed diets containing 100 mg Cd/kg and their kidneys contained 132 mg Cd/kg FW (Blus et al. 1993). Adult male white leghorn chickens (*Gallus* sp.) given 2 mg CdSO₄ daily by intraperitoneal injection for 15 to 22 days, or a total dose of 60 mg of cadmium per chicken, developed anemia, an enlarged heart, myocardial infarction, and other abnormalities (Sturkie 1973). Testicular damage was observed in ring doves (*Streptopelia* sp.) 20 days after intramuscular injection of 6.6 mg Cd/kg body weight (BW) (Richardson et al. 1974); in domestic pigeons (*Columba livia*), however, testicular damage was observed after a single subcutaneous injection of only 0.5 mg/kg BW (Sarker and Mondal 1973), and cardiovascular disease developed after exposure to 600.0 µg/L in drinking water (Revis et al. 1981). In mallard ducklings fed 20 mg Cd/kg ration for 12 weeks, blood chemistry

Table 1.5 Sublethal Effects of Cadmium to Selected Species of Aquatic Biota

Medium, Taxonomic Group, Organism, and Other Variables	Cd, µg/L	Exposure Period	Effect	Reference ^a
FRESHWATER				
Algae				
<i>Asterionella formosa</i>	2.0	—	Decreased growth rate	1
Mollusca				
<i>Lymnaea stagnalis</i>	25.0	7 weeks	Inhibited reproduction	28
Arthropoda				
<i>Daphnia pulex</i>	1.0	20 weeks	Reduced reproduction	2
<i>Nephrops norvegicus</i>	1–25	18 days	Adult males had dose-dependent decrease in gill Na, K-ATPase activity; adult females had dose-dependent decrease in gill Mg-ATPase activity	26
<i>Daphnia galeata mendotae</i>	4.0	22 weeks	Reduced biomass	3
<i>Eucyclops agilis</i>	5.0	52 weeks	Population reduction	4
<i>Cambarus latimanus</i>	5.0	22 weeks	Increased mortality	5
<i>Daphnia magna</i>	2.6	21 days	Immobilization threshold	6
<i>Daphnia magna</i>	0.7	21 days	Decreased reproduction (50%)	6
<i>Daphnia magna</i>	0.17	21 days	No effect	6
<i>Daphnia magna</i>	0.37	20 days	No effect	7
<i>Daphnia magna</i>	4.7	20 days	Decreased reproduction (50%)	7
<i>Asellus aquaticus</i>	20–100	96 h	Reduced predation from the turbellarian <i>Dendrocoelum lacteum</i>	20
Annelida				
<i>Pristina</i> sp.	5.0	52 weeks	Population reduction	4
Miscellaneous mixed macro-invertebrates	5.0	52 weeks	Reduction in biomass and number of taxa	4
Fish				
Common carp, <i>Cyprinus carpio</i>	22.0	21 days	Skin histopathology beginning at 24 h and continuing through day 21; no deaths	21
<i>C. carpio</i>	560.0	8 days	Skin histopathology at 1 h; all dead by day 8	21
Tilapia, <i>Oreochromis mossambica</i>	22.0	96 h	LC 50 for 3-day-old larvae; survivors had cadmium accumulation rate of 4.9 ng/larva daily	22
<i>O. mossambica</i>	83.0	96 h	LC 50 for 1-day-old larvae; cadmium accumulation rate of 2.6 ng/larva daily	22
Rainbow trout, <i>Oncorhynchus mykiss</i>	1.8–3.4	—	Eggs taken from adults exposed for 90 weeks failed to develop to the fry stage	23
<i>O. mykiss</i>	5.5	90 weeks	No effect on adult growth or survival	23
Guppy, <i>Poecilia reticulata</i>	500	30 days	Growth reduction; RNA decrease	27
Brown trout, <i>Salmo trutta</i>	9.3–29.1	—	Oogenesis delayed in eggs taken from adults exposed for 90 weeks	23
<i>S. trutta</i>	29.1	54 weeks	LC 50 for adults	23
Brook trout, <i>Salvelinus fontinalis</i>	2.0	8 weeks	Disrupted lactic dehydrogenase activity and blood glucose levels	8
Atlantic salmon, <i>Salmo salar</i>	0.47	12 weeks	Alevin growth reduction	9
<i>Salmo salar</i>	2.0	60 days	Cranial pathology, reduced growth, death	10
<i>Salmo salar</i>	0.2	60 days	Normal growth and development	10

was altered and mild to severe kidney lesions developed (Cain et al. 1983). But mallard juveniles were unaffected when given diets containing 50 mg Cd/kg ration for 6 weeks (Di Giulio et al. 1984). Mallard juveniles fed diets containing 150 mg Cd/kg ration and higher for 6 weeks had elevated liver (>135 mg Cd/kg DW) and kidney (>335 mg Cd/kg DW) burdens, disrupted plasma fatty acid concentrations, and increased adrenal and kidney weights (Di Giulio et al. 1984). Altered avoidance behavior in the form of hyperresponsiveness was observed in young American black ducks (*Anas rubripes*) produced from parents fed 4 mg/kg dietary cadmium for about 4 months before egg laying; this behavioral effect was observed only at comparatively low dietary cadmium levels and is considered harmful to wild birds (Heinz and Haseltine 1983). Cadmium readily reacts with sulfhydryl groups and may compete, especially with zinc, for binding sites on proteins and, thus, may inhibit a variety of enzymatic reactions. The addition of zinc, iron, ascorbic acid, calcium, or selenium to diets ameliorated the effects of cadmium damage, whereas the addition of lead or mercury exacerbated them (Hammons et al. 1978).

In male rats (*Rattus* sp.) and mice (*Mus* sp.), acute oral exposure to near-fatal doses (7 to 14 mg Cd/kg BW daily for 90 to 120 days) can cause testicular atrophy and necrosis, and decreased fertility (USPHS 1993). Oral intake of cadmium disrupts calcium metabolism of laboratory and free-living rodents (Shore et al. 1995). Bank voles (*Clethrionomys glareolus*) on low-calcium diets given diets equivalent to 1.5 to 1.7 mg Cd/kg BW daily had significantly poorer calcium net gut absorption efficiency than animals fed cadmium-free diets and were in negative calcium balance. Cadmium-mediated impairment of calcium assimilation may be important in calcium-poor habitats (Shore et al. 1995), suggesting more research in this area. Among small laboratory mammals it appears that physiologically bound cadmium is more effective than CdCl₂ in producing metabolic iron irregularities. For example, in young mice fed oysters containing 1.8 mg Cd/kg ration for 28 days, hematocrit and hemoglobin values were depressed and other blood chemistry factors were altered (Siewicki et al. 1983). Diets containing intrinsic oyster cadmium at 1.8 mg/kg were more effective in producing hematopoietic alterations than were diets containing CdCl₂ at 3.6 mg/kg (Siewicki et al. 1983). Adequate dietary iron supplementation markedly reduced cadmium retention and cadmium-induced anemia in rats. Iron supply and the increased iron demand during growth of rats can be disturbed within one week by a daily cadmium intake as low as 0.7 to 1.3 mg Cd/kg BW (Schumann et al. 1996).

A study by Beyer et al. (1985) of metal contamination in wildlife from the vicinity of two zinc smelters in Palmerton, Pennsylvania, demonstrated the difficulties in interpretation of cadmium residues from biota in the presence of other potentially hazardous metal contaminants (Table 1.6). The soil litter horizon at Palmerton was heavily contaminated with lead (2700 mg/kg), zinc (24,000 mg/kg), copper (440 mg/kg), and cadmium (710 mg/kg). Invertebrates that fed on soil litter or soil organic matter, such as earthworms, slugs, and millipedes, were rare or absent in the vicinity of the smelters but not at more distant sampling sites (Table 1.6). Concentrations of all metals tended to be higher in these invertebrates than in other invertebrate groups collected. Amphibians and reptiles were also rare or absent at the Palmerton site, but not at more distant stations. Mean cadmium concentrations, in mg/kg dry weight, were highest in carrion insects (25), followed by fungi (9.8), leaves (8.1), shrews (7.3), moths (4.9), mice (2.6), songbirds (2.5), and berries (1.2). By contrast, average concentrations of lead, in mg/kg dry weight, were highest in shrews (110), followed by songbirds (56), leaves (21), mice (17), carrion insects (14), moths (4.3), berries (4), and fungi (3.7). Evidence for lead poisoning in shrews included high residues in kidney (280 mg/kg wet weight) and reduced blood enzyme levels. In addition, livers from two yellow-billed cuckoos (*Coccyzus americanus*) from Palmerton had lead concentrations of 18 and 25 mg/kg wet weight; however, they and other songbirds appeared to be healthy. Concentrations of zinc and copper tended to be highest in the same organisms that contained the highest concentrations of cadmium, emphasizing the importance of documenting organism body burdens of all suspected contaminants before significance is attributed to any single component. Beyer et al. (1985) demonstrated that only a small portion of all metals measured in the soil became incorporated into plant foliage and suggested that most of the metal contamination detected in biota came from aerial deposition.

Table 1.6 Cadmium Residues (mg/kg dry weight [ppm]) in Soil, Flora, and Fauna Collected near Two Zinc Smelters in Palmerton, Pennsylvania

Soil and Category of Plants and Animals	Direction and Distance of Areas from Smelter Emissions	
	Downwind (about 2.1 km)	Upwind (9.7 km)

Modified from Beyer, W.N., O.H. Pattee, L. Sileo, D.J. Hoffman, and B.M. Mulhern. 1985. Metal contamination in wildlife living near two zinc smelters. *Environ. Pollut.* 38 A:63–86.

The kidney is the critical organ in mammalian cadmium toxicity and is the first organ in which damage is observed or adverse functional changes start to occur. Cadmium concentrations in excess of 200 mg/kg FW kidney cortex results in renal dysfunction in about 10% of the exposed human population; a similar pattern is evident in mice, rats, and rabbits (Cooke and Johnson 1996). In male rats given a single intravenous injection of 0.15 mg metallothionein-bound Cd/kg BW, DNA fragmentation was seen in kidney 12 hours after injection; cycloheximide (3 mg/kg BW) inhibited Cd-induced DNA fragmentation, suggesting that protein synthesis is impaired (Ishido et al. 1998). In human tissues, there was a significant increase in cadmium burdens in 1980 when compared to the period 1897 to 1939. Cadmium content in the renal cortex portion of the kidney increased by a factor of 47 during this interval, and whole-body burden increased by a factor near 5 (Drasch 1983). The significance of this increase is not fully clear, but one study has suggested that cadmium and lead are associated with increased risk of heart-related death, even in light of known conventional causes of such fatalities (Voors et al. 1982). Similar data for wildlife are lacking, and this clearly indicates an area for additional research.

1.6 BIOACCUMULATION

Cadmium biomagnifies in terrestrial food chains and tends to accumulate in liver and kidneys of older apex organisms (Scheuhammer 1987). This process was documented in the chain of soil to vegetation to invertebrates to upper trophic level consumers, including roe deer (*Capreolus capreolus*), barn owls (*Tyto alba*), weasels (*Mystela nivalis*), and kestrels (*Falco tinnunculus*; Gorree

et al. 1995). Radishes (*Raphanus sativa*) accumulated cadmium from the soil in roots and shoots over a 75-day period; uptake was decreased markedly with liming or increased soil pH (Han and Lee 1996). However, centipedes (*Lithobius forficatus*) near a zinc smelter, with body burdens as high as 80 mg Cd/kg DW, on transfer to an uncontaminated site for 10 weeks lost all but 18 mg Cd/kg DW despite the very high cadmium diet provided (Descamps et al. 1996).

Biological half times of cadmium in humans is lengthy. Based on body burden and excretion data, cadmium may remain in the human body for 13 to 47 years. Although cadmium is excreted primarily in urine and feces, it tends to increase in concentration with the age of the organism and eventually acts as a cumulative poison (Hammons et al. 1978). These phenomena have not been documented adequately in wildlife species.

In marine mammals, cadmium was present in all liver and kidney samples analyzed (Taylor et al. 1989). Cadmium concentrations in livers of beluga whales (*Delphinapterus leucas*) were positively correlated with age, and in ringed seals (*Phoca hispida*) with length, increasing from <0.7 to 3.6 mg Cd/kg FW in belugas and <0.14 to 8.8 mg/kg FW in seals (Mackey et al. 1996). A similar case is made for kidney and liver tissues of the Baikal seal (*Phoca sibirica*; Watanabe et al. 1998). Pilot whales (*Globicephala melas*) contained higher concentrations of cadmium in the liver and kidney tissues than did other marine mammals, and this is attributed, in part, to the elevated cadmium (as much as 5.8 mg Cd/kg DW) content in squids (*Loligo forbesi*) — a major dietary item (Caurant and Amiard Triquet 1995). Similarly, elevated levels of cadmium in Pacific walruses (*Odobenus rosmarus divergens*) are considered related to elevated cadmium burdens in clams (*Mya* sp.), a major food item (Miles and Hills 1994). Also, uptake of cadmium from cadmium-contaminated prey by fish plays an important role in contaminated waters (Kraal et al. 1995).

Red-eared turtles (*Trachemys scripta*) given very high doses of cadmium (10 mg Cd/kg BW daily for 6 days) by intraperitoneal injection accumulated 42% of the cadmium body burden in liver, followed by kidney (20%), spleen (12%), heart (8%), gonads (8%), and shell (5%). Lesser amounts were measured in lung, muscle, brain, and blood (Thomas et al. 1994). Turtle metallothioneins, which are similar to those of other vertebrates, seemed to control the accumulation process. Frogs seem relatively resistant to cadmium. Adult female water frogs (*Rana ridibunda*) were held in solutions containing 200 mg Cd/L, as CdCl₂, for 30 days (Vogiatzis and Loumbourdis 1998). Cadmium accumulated in kidneys and livers in a time-dependent manner, and metallothionein and glutathione concentrations increased with increasing liver cadmium burdens. After 30 days, livers had 240 mg Cd/kg DW and kidneys 657 mg Cd/kg DW (Vogiatzis and Loumbourdis 1998).

Freshwater and marine aquatic organisms accumulate cadmium from water containing cadmium concentrations not previously considered hazardous to public health or to many species of aquatic life (USPHS 1993; Currie et al. 1998; Table 1.7). In American oysters (*Crassostrea virginica*), held for 40 weeks in flowing seawater containing 5.0 µg Cd/L, edible meats contained 13.6 mg Cd/kg fresh weight, a level considered to be an emetic threshold for human consumers (Zaroogian and Cheer 1976). These oysters retained virtually all accumulated cadmium (12.5 mg/kg) during a 16-week posttreatment immersion in clean seawater (Zaroogian 1979). Human emetic thresholds for cadmium in oysters were surpassed in 5 weeks at 25 µg/L and in only 2 weeks at 100 µg/L (Shuster and Pringle 1969). The emetic threshold for juvenile northwestern salamanders (*Ambystoma gracile*) is higher than that of humans; regurgitation occurred between 2458 and 5701 mg Cd/kg diet with no regurgitation at 982 mg Cd/kg diet and lower (Nebeker et al. 1995).

Two species of freshwater aquatic mosses (*Fontinalis dalecarlica*, *Platyhypnidium riparoides*) exposed to concentrations between 0.5 and 6.5 µg Cd/L for 28 days had accumulation factors as high as 137,000 and 158,000, respectively (Gagnon et al. 1998). Accumulations increased with increasing cadmium concentration and decreasing water hardness. Cadmium tended to persist in these mosses. During a depuration period of 28 days following the 28-day exposure, only 37 to 48% of the accumulated cadmium was eliminated (Gagnon et al. 1998).

Cadmium uptake from the medium by aquatic organisms usually increased with increasing water temperature in the range of 5 to 25°C; in the case of midge (*Chironomus riparius*) larvae,

^a 1, Giesy et al. 1979; 2, Kumada et al. 1980; 3, Williams and Giesy 1978; 4, Giesy et al. 1977; 5, Ferard et al. 1983; 6, Eisler et al. 1972; 7, Zaroogian and Cheer 1976; 8, Sundelin et al. 1983; 9, Gagnon et al. 1998.

about 60% of the increased uptake is due to increased respiration (Bervoets et al. 1996). However, mayfly (*Hexagenia rigida*) nymphs accumulated more cadmium at 15°C than at 25°C. In that study, more cadmium was bioavailable for uptake owing to the higher pH of 7.5 at 15°C vs. pH 5.0 at 25°C (Odin et al. 1996). In another study with *Hexagenia rigida* nymphs, cadmium accumulation from sediments containing 0 to 41 mg Cd/kg DW was higher with increasing exposure duration (0 to 60 days), increasing water temperature (12 to 24°C), and increasing sediment cadmium concentration (Andreou et al. 1998). Cadmium was accumulated by fish hepatoma cells to a greater degree than were other metals tested. Present in declining order of accumulation were: cadmium, nickel, copper, cobalt, zinc, and lead (Bruschweiler et al. 1996). There is considerable variation in the ability of teleost tissues to accumulate cadmium from the ambient medium. Cadmium accumulation

rates in larvae of tilapia (*Oreochromis mossambica*) increased with increasing larval development and were inversely related to LC50 (96 h) values (Hwang et al. 1995). Sequestering agents, such as EDTA, reduced by 34% the accumulation of cadmium from the medium (15 µg/L) by sac fry of the African tilapia (*Oreochromis niloticus*; Siriwardena et al. 1995). Among rainbow trout exposed for 2 weeks to 9 µg Cd/L, bioconcentration factors (BCF) were 260 for gill, 17 for liver, 26 for kidney, and zero for spleen and heart tissues (Roberts et al. 1979). At slightly higher ambient dissolved cadmium levels of 10 µg/L and exposure for 3 months, BCF values were substantially higher: 1740 for gill, 4900 for liver, 740 for kidney, 160 for spleen, and 100 for heart tissues (Roberts et al. 1979). The evidence for cadmium transfer through various trophic levels suggests that only the lower trophic levels exhibit biomagnification. In the freshwater food chain extending from the alga *Chlorella vulgaris*, to the cladoceran *Daphnia magna*, to the teleost *Leucospius delineatus*, it was demonstrated that algae held 10 days in water containing 10 µg Cd/L had 30 mg Cd/kg dry weight, up from 4.5 mg/kg at the start (Ferard et al. 1983). Cladocerans feeding on cadmium-loaded algae for 20 days contained 32 mg Cd/kg dry weight, up from 1.4 mg/kg at the start. However, fish fed cadmium-contaminated cladocerans for 4 days showed no change in body burdens.

Cadmium resistance has recently been documented in marine annelids (Wallace et al. 1998). Oligochaetes (*Limnodrilus hoffmeisteri*) from Foundry Cove, New York — a severely cadmium-contaminated site — were more tolerant of cadmium than conspecifics from a reference site, surviving twice as long in a 7-day acute toxicity bioassay (1.0 mg Cd/L) and with bioconcentration factors of 2020 vs. 577 for the controls (radiocadmium-109). The cadmium-resistant worms produced metal-rich granules and metallothioneins for cadmium storage and detoxification, whereas nonresistant worms only produced metallothioneins. Grass shrimp (*Palaemonetes pugio*) fed cadmium-resistant worms absorbed 21% of the ingested cadmium vs. 75% for shrimp fed nonresistant worms (Wallace et al. 1998).

In laboratory studies with chipping sparrows (*Spizella passerina*) fed radiocadmium-109 in their diets for 3 weeks, it was demonstrated that cadmium became localized in the liver and kidneys (Anderson and Van Hook 1973). During posttreatment on a radiocadmium-free diet, there was an initial rapid drop in radioactivity, and the remaining radiocadmium had an estimated biological half-life of 99 days (Anderson and Van Hook 1973). Marine killifish (*Fundulus heteroclitus*) containing radiocadmium-115m lost 90% of the accumulated radiocadmium during a 6-month posttreatment observation period; the liver usually contained 75 to 80% of the total body dose at any time (Eisler 1974). Mallards fed 200 mg Cd/kg diet for about 13 weeks all survived, but levels in liver and kidney were elevated at 110 and 134 mg/kg fresh weight, respectively (White and Finley 1978). Mallard ducklings fed only 20 mg Cd/kg in the diet for 12 weeks contained 42 mg Cd/kg liver (Cain et al. 1983).

The exact mechanism of acute cadmium poisoning is unknown, but, among teleosts, it depends in part on exposure period, concentration of dissolved and ionic cadmium in the medium, and water temperature and salinity. Under conditions of high cadmium concentration and short exposure, the gill seems to be the primary site of damage and accumulation; under conditions of prolonged exposure and low cadmium levels, the intestine, kidney, and possibly other tissues were measurably affected. Retention of cadmium by teleosts depends on tissue biomagnification potential, length of postexposure recovery period, and other factors. The significance of comparatively low concentrations of cadmium in tissues of fish, other aquatic organisms, and wildlife, and the implications for organism health, is not fully understood. Although numerous physical, chemical, and biological factors demonstrably modify uptake and retention of cadmium by fish and wildlife (Hammons et al. 1978; USEPA 1980; Eisler 1981, 1984, 1985; Scheuhammer 1987; USPHS 1993), the significance of relatively high cadmium residues to animal and plant health is difficult to interpret. There is some evidence, however, that life-threatening concentrations are 200 mg Cd/kg fresh weight in the renal cortex of the mammalian kidney (Hammons et al. 1978) and 5.0 mg/kg fresh weight whole body of estuarine teleosts (Eisler 1974).

1.7 TERATOGENESIS, MUTAGENESIS, AND CARCINOGENESIS

Teratogenic effects on animals appear to be greater for cadmium than for other metals, including lead, mercury, copper, indium, and arsenic (Ferm and Layton 1981). Among amphibians, frog embryos reared in 5000 to 7500 µg Cd/L showed nonclosure of the neural tube (Ferm and Layton 1981). In embryos of fathead minnows from adults reared in water containing 37 to 57 µg Cd/L, and from eggs transferred directly to such media, percent hatching was reduced, deformities were increased, and various blood clots developed (Pickering and Gast 1972). Embryos of the bluegill (*Lepomis macrochirus*) held in water at 80 µg Cd/L and higher showed edema, microcephalia, and malformed caudal fins (Eaton 1974). Eggs of a marine killifish (*Fundulus heteroclitus*) were little affected at up to 10,000 µg Cd/L (Weis and Weis 1977). Caudal and hindlimb abnormalities were observed in chickens following injection of eggs with 0.1 to 1.0 mg/kg egg of cadmium chloride; excess zinc appeared to have a protective effect (Ferm and Layton 1981). Rats subjected to >6 mg Cd per kg body weight daily during pregnancy produced fetuses with jaw defects, cleft palates, club feet, and pulmonary hyperplasia (Ferm and Layton 1981). Among hamsters (*Cricetus spp.*), cadmium administration was associated with embryonic tail defects; effects were synergized by salts of lead or mercury and antagonized by selenium (Ferm and Layton 1981). No conclusive evidence of cadmium teratogenesis in humans is available.

At high concentrations, cadmium is genotoxic to isolated cells (Shimada et al. 1998). From a variety of studies in which mice and bacteria were used as models, it appears likely that cadmium has mutagenic effects. Mice injected with 3 or 6 mg CdCl₂/kg body weight showed changes in chromosome number 12 h later. Similar changes were observed in hamsters at 1.5 to 3.0 mg/kg (Ferm and Layton 1981). Very high dosages (>100 mg/kg) produced chromosomal abnormalities in plant seeds. Also, CdCl₂ had a mutagenic effect on indicator strains of *Salmonella* bacteria. However, the evidence for these effects is still diffuse and often contradictory (Ferm and Layton 1981).

Laboratory studies with mice and rats have conclusively demonstrated that the injection of cadmium metal or salts causes malignancies (sarcoma) at the site of injection and testicular tumors. However, the simultaneous administration of zinc is protective against sarcoma and interstitial cell tumor development (USEPA 1980). In rats, no dose-related increases in tumors were found at maximum oral daily doses of 4.4 mg Cd/kg BW (USPHS 1993). Among humans, the available epidemiological evidence is not sufficient to conclude that cadmium is definitely implicated as a carcinogen (USEPA 1980; Nomiyama 1982), although cadmium exposure is associated with lung cancer in humans (Shimada et al. 1998).

1.8 RECOMMENDATIONS

Proposed limits for cadmium in water, diet, tissues, air, soils, and sewage sludge for the protection of human health, plants, and animals are shown in [Table 1.8](#). It is noteworthy that the current upper limit of 10.0 µg Cd/L in drinking water for human health protection is not sufficient to protect many species of freshwater biota against the biocidal properties of cadmium or against sublethal effects, such as reduced growth and inhibited reproduction. Ambient water-quality criteria formulated for protection of freshwater aquatic life state that, for total recoverable cadmium, the criterion, in µg/L, is the numerical value given by $e^{(1.05(\ln(\text{hardness})) - 8.53)}$ as a 24-h average, and the concentration, in µg/L, should never exceed the numerical value given by $e^{(1.05(\ln(\text{hardness})) - 3.73)}$. Thus, at water hardnesses of 50, 100, and 200 mg/L as CaCO₃, the criteria are 0.012, 0.025, and 0.051 µg Cd/L, respectively, and the concentration of total recoverable cadmium should never exceed 1.5, 3.0, and 6.3 µg/L, respectively. Unfortunately, data are accumulating that demonstrate that even these comparatively rigorous criteria are not sufficient to protect the most sensitive species of

^b Assumes consumption of 0.75 kg food per day by 70-kg adult

^c Includes uncertainty factor of 10.

^d Includes uncertainty factor of 3.

^e Assumes an absorption rate of 5% and a daily excretion rate of 0.005%.

^f Concentrations greater than 3.4 µg Cd/L are frequently encountered in the Chesapeake and Delaware Canal and infrequently greater than 1.4 µg Cd/L in other portions of the bay.

^g However, surface water levels in numerous Canadian lakes subjected only to atmospheric deposition within mining areas are often >1.0 µg Cd/L and may not be sufficiently low to prevent adverse physiological effects on early life stages of sensitive aquatic species.

freshwater insects, plants, crustaceans, and teleosts. It now appears that levels in excess of 3.0 µg Cd/L in freshwater are potentially hazardous to aquatic biota and that levels near 1.0 µg/L are cause for concern in waters of low alkalinity. Not listed in Table 1.8, but still recognized as proposed criteria (USEPA 1973), are the comparatively high levels of 10.0 µg Cd/L allowed for agricultural

use on all soils (except neutral and alkaline soils, which may be irrigated with water having levels as high as 50.0 µg Cd/L) and public water supplies for livestock purposes, which may not exceed 50.0 µg Cd/L.

The saltwater aquatic life protection criterion of 4.5 µg Cd/L seems adequate to prevent death, but will not prevent potentially deleterious physiological effects, including disrupted respiration in crustaceans and teleosts. Incidentally, at 5.0 µg Cd/L, the lowest concentration critically examined, oysters biomagnify ambient levels to concentrations hazardous to human consumers and possibly other animal consumers. The maximum allowable saltwater concentration (MAC) during a 24-h period was recommended as 59.0 µg/L ([Table 1.8](#)). However, death of various species of marine crustaceans was reported at 60.0 µg Cd/L after exposure for 6 weeks and at 14.8 to 19.5 µg/L after 23 to 27 days. Furthermore, a MAC of 59 µg Cd/L may be met with daily discharges of 59 µg/L for 2 h and no discharge of cadmium for the rest of the day. The effects of exposure of marine life to 59 µg/L of cadmium salts for 2 h daily for protracted periods have not yet been investigated. Accordingly, seawater concentrations in excess of 4.5 µg/L of total cadmium at any time should be considered potentially hazardous to marine life until additional data prove otherwise.

Food is recognized as the major source of cadmium in humans, except in comparatively rare cases of occupational air exposure. The recommended upper limit for cadmium in food is 75 µg/day ([Table 1.8](#)). On the basis of an absorption factor of 0.1 (USEPA 1980), a total of 7.5 µg Cd will be retained daily. A 70-kg adult ingests an estimated 0.75 kg of food daily, which suggests that human diets should not exceed 100 µg/kg. Regular weekly consumption by humans of kidney tissue (range 23 to 166 mg Cd/kg DW) from Arctic caribou (*Rangifer tarandus*) and from muskox (*Ovibos moschatus*) older than 1 year (2.4 to 12.4 mg Cd/kg DW kidney) will probably cause the World Health Organization provisional weekly tolerable intake of cadmium (400 µg) to be exceeded (Gamberg and Scheuhammer 1994). On cadmium-contaminated habitats, common shrews (*Sorex araneus*) may ingest more than 3.5 to 7.5 mg Cd/kg BW daily (associated with reproductive effects in laboratory animals) without apparent harm (Shore and Douben 1994). Large cadmium concentrations in body organs of shrews may reflect their ability to store cadmium in a nontoxic metallothionein-bound state. Adverse effects were, however, observed in feral rodents that consumed more than 3.5 mg Cd/kg BW daily, and this suggests a need to establish dose–residue–effect relationships for intakes and residues appropriate for feral organisms (Shore and Douben 1994).

Ducks, geese, and other species of wildlife, unlike adult humans, may consume 6 to 7% of their total body weight daily and may graze extensively on crops directly affected by sewage and other wastes containing high cadmium residues. Feeding studies with mallards indicated that diets containing 200 mg Cd/kg produced no obvious deleterious effects after 13 weeks. At the end of that study, however, kidney cadmium levels under those conditions were about 134 mg/kg fresh weight, a level near the 200 mg/kg fresh weight designated a “critical threshold” (and presumably life-threatening) for the renal cortex of the human kidney. Field observations on ducks and laboratory studies are not strictly comparable. Under field conditions, birds and other wildlife may consume food containing high cadmium levels, but it is almost certain that these diets also contain other potentially harmful contaminants, as well as metals or compounds that may ameliorate cadmium toxicity. The significance of foods containing complex mixtures of contaminants and their resultant toxicological interactions are imperfectly understood. Until other data become available, wildlife dietary levels exceeding 100 µg Cd/kg diet fresh weight on a sustained basis should be viewed with caution — as they are for humans.

Recommendations for cadmium in air and human health protection under the worst scenario ([Table 1.8](#)) assume that total daily air intake is 27.14 m³ for an adult human who spends about 6.3 h in occupational exposure to air containing 100 µg Cd/m³ (USEPA 1980). Under these conditions, a 70-kg adult would retain about 361 µg Cd/day, based on an absorption factor of 0.5 (USEPA 1980), and most of this cadmium would probably be translocated to the kidney; a critical threshold level of 200 mg Cd/kg in the kidney would be reached in about 1.52 years. It is not now known

whether respiration rates of wildlife, particularly birds, are comparable to those of humans, or whether cadmium absorption energetics are similar, or whether wildlife species that frequent point sources of air contaminated by high cadmium levels for protracted periods are at greater risk than humans. Evidence given by Beyer et al. (1985) demonstrated that flora and fauna in the vicinity of industrial smelters were affected by cadmium and its associated heavy metals. This strongly suggests that proposed recommendations for cadmium levels under occupational air exposure should be revised downward for wildlife protection.

Additional research on cadmium is recommended in three areas: (1) effects on cancer, genotoxicity, and reproductive toxicity under conditions of acute, intermediate, and chronic durations of exposure, and administered by way of diet, inhalation, and dermal routes of exposure; (2) emphasis on studies with pregnant animals; and (3) methods for reducing toxic effects (USPHS 1993). Finally, the issue of the significance of cadmium residues in various body parts requires resolution. At this time, it appears that cadmium residues in the vertebrate kidney or liver that exceed 10.0 mg/kg fresh weight or 2.0 mg/kg in whole-body fresh weight should be viewed as evidence of probable cadmium contamination. Elevated levels of 13.0 to 15.0 mg Cd/kg tissue fresh weight probably represent a significant hazard to animals of the higher trophic levels, and residues of 200.0 mg Cd/kg fresh weight kidney cortex or more than 5.0 mg Cd/kg whole animal fresh weight should be considered life-threatening.

1.9 SUMMARY

Cadmium contamination of the environment is especially severe in the vicinity of smelters and urban industrialized areas. There is no evidence that cadmium, a relatively rare heavy metal, is biologically essential or beneficial; on the contrary, cadmium is a known teratogen and carcinogen, a probable mutagen, and has been implicated as the cause of severe deleterious effects on fish and wildlife. The freshwater biota is the most sensitive group. Concentrations of 0.8 to 9.9 µg Cd/L (ppb) in water were lethal to several species of aquatic insects, crustaceans, and teleosts, and concentrations of 0.7 to 570 µg/L were associated with sublethal effects such as decreased growth, inhibited reproduction, and population alterations. These effects were most pronounced in waters of comparatively low alkalinity. Marine organisms were more resistant than freshwater biota. Decapod crustaceans, the most sensitive saltwater group, died at concentrations of cadmium in seawater ranging from 14.8 to 420 µg/L. Sublethal effects to marine animals recorded at concentrations of 0.5 to 10 µg Cd/L included decreased growth, respiratory disruption, altered enzyme levels, and abnormal muscular contractions; effects were usually most obvious at relatively low salinities and high temperatures. Freshwater and marine aquatic organisms accumulated measurable amounts of cadmium from water containing concentrations not previously considered hazardous to public health or to many species of aquatic life; i.e., 0.02 to 10 µg Cd/L.

Mammals and birds are comparatively resistant to the biocidal properties of cadmium. The lowest single oral doses producing death in rats and guinea pigs ranged from 150 to 250 mg Cd/kg body weight. Although mallards and chickens tolerated 200 mg Cd/kg diet for protracted periods, kidney cadmium exceeded 130 mg/kg fresh weight under this regimen, a concentration considered life-threatening to some organisms. Sublethal effects of cadmium in birds, which were similar to those in other animals, included growth retardation, anemia, and testicular damage. However, these effects were observed at higher concentrations than in aquatic biota. Although the evidence is incomplete, wildlife populations, especially migratory birds that feed on crops growing on fields fertilized with municipal sewage sludges, may be exposed to considerable risk of harmful effects from cadmium.

It is now conservatively estimated that adverse effects on fish or wildlife are either pronounced or probable when cadmium concentrations exceed 3 µg/L in freshwater, 4.5 µg/L in saltwater,

100 µg/kg in the diet, or 100 µg Cd/m³ in air. Cadmium residues in vertebrate kidney or liver that exceed 10 mg/kg fresh weight or 2 mg/kg whole-body fresh weight should be viewed as evidence of probable cadmium contamination; residues of 200 mg Cd/kg fresh weight kidney, or more than 5 mg/kg whole-animal fresh weight, are probably life-threatening to the organism.

CHAPTER 2

Chromium

2.1 INTRODUCTION

Environmental effects of chromium (Cr) have been extensively reviewed (National Academy of Sciences [NAS] 1974; Steven et al. 1976; Snyder et al. 1977; Towill et al. 1978; Taylor and Parr 1978; Langard and Norseth 1979; Post and Campbell 1980; Hatherill 1981; Ecological Analysts 1981; Eisler 1986; Nriagu and Nieboer 1988; Outridge and Scheuhammer 1993; U.S. Public Health Service [USPHS] 1993). These authorities agree that chromium is used widely in domestic and industrial products and that some chemical forms, notably hexavalent chromium (Cr^{+6}), are toxic, and others, notably trivalent chromium (Cr^{+3}), are essential nutrients. In North America, thousands of tons of chromium ore and concentrates are imported annually for the production of stainless steels, chrome-plated metals, pigments for inks and paints, and a wide variety of chemicals. Reports from Europe, Scandinavia, Asia, and North America all emphasize the high incidence of lung cancer and other respiratory diseases among workers involved in the manufacture of chromates. Others document that land dumping of wastes from chromate production and electroplating operations has been responsible for groundwater contamination; that discharge of chromium wastes into streams and lakes has caused damage to aquatic ecosystems and accidental poisoning of livestock; and that large amounts of Cr^{+3} and Cr^{+6} are reintroduced into the environment as sewage and solid wastes by the disposal of consumer products containing chromium.

2.2 ENVIRONMENTAL CHEMISTRY

Chromium is the seventh most abundant element on earth with more than 2108 million tons of chromium metal, most of it residing in the core and mantle (Nriagu 1988). The annual world production of chromium is estimated at 9 million metric tons. Most of the ore, in the form of chromite ($\text{FeO}\text{Cr}_2\text{O}_3$), is produced by the Former Soviet Union and the Republic of South Africa. In the United States, trivalent chromium compounds are used as pigments and in leather tanning, and hexavalent chromium compounds are used principally in the ferrochrome and chemical industries (Langard and Norseth 1979; Nriagu 1988; Walsh et al. 1994). The combined production of chromium ferroalloys and chromium metal in the United States in 1988 was 119,645 metric tons from producers in West Virginia, South Carolina, New Jersey, Ohio, Kentucky, New York, Indiana, Utah, Pennsylvania, California, Texas, and North Carolina (USPHS 1993). Exports of chromium materials from the United States in 1988 was 39,887 tons, mostly to Mexico, Canada, the Netherlands, Japan, and Germany. In 1990, the United States produced 150,600 tons of sodium dichromate and 53,300 tons of chromic acid (USPHS 1993).

Although natural mobilization of chromium by weathering processes is estimated at 32,000 tons/year, the amounts of chromium added to the environment as a result of anthropogenic activities are far greater. New York City alone contributes about 440 tons of chromium annually to the environment (Steven et al. 1976). In the 1970s, major atmospheric emissions of chromium were from the chromium alloy and metal-producing industries, and lesser amounts came from coal combustion, municipal incinerators, cement production, cooling towers (Towill et al. 1978), use of chromium-containing phosphate fertilizers, and landfill dumping of chromium-contaminated sewage sludge and consumer products (Outridge and Scheuhammer 1993). In the United States in the 1990s, atmospheric chromium emissions from anthropogenic sources average 2800 tons per year, mostly from combustion of coal and oil (60%) and chrome-plating (24%) sources (USPHS 1993). Atmospheric emissions contribute 4 to 6 times more chromium to aquatic ecosystems than do liquid wastes (Ecological Analysts 1981). In aquatic environments, the major sources of chromium are the electroplating and metal-finishing industries and publicly owned treatment plants; relatively minor sources (other than localized contamination) are iron and steel foundries, inorganic chemical plants, tanneries, textile manufacturing, and runoff from urban and residential areas (Towill et al. 1978; Ecological Analysts 1981). Chromium in phosphates used as fertilizers may be an important source of chromium in soil, water, and some foods (Langard and Norseth 1979). In general, elevated chromium levels in biological or other samples have been positively correlated with increased industrial and other uses of the element — especially uses associated with plating and foundry applications, chemical manufacturing, and corrosion inhibition (Taylor and Parr 1978).

Chromium in the crystalline form is a steel-gray, lustrous, hard metal characterized by an atomic weight of 51.996, an atomic number of 24, a density of 7.14 g/cm³, a melting point of 1857°C, and a boiling point of 2672°C. Four chromium isotopes occur naturally: Cr-50 (4.3%), -52 (83.8%), -53 (9.6%), and -54 (2.4%), and seven are man-made. Elemental chromium is very stable but is not usually found pure in nature. Chromium can exist in oxidation states ranging from -2 to +6, but is most frequently found in the environment in the trivalent (+3) and hexavalent (+6) oxidation states. The +3 and +6 forms are the most important because the +2, +4, and +5 forms are unstable and are rapidly converted to +3, which in turn is oxidized to +6 (Towill et al. 1978; Langard and Norseth 1979; Ecological Analysts 1981; USPHS 1993).

Most compounds prepared from chromite ore contain chromium in the more stable +3 and +6 states. The chromium in essentially all environmentally important chromium compounds is in one of these two oxidation states. Chromium in biological materials is usually in the +3 form (Langard and Norseth 1979) and is the form that functions as an essential element in mammals by maintaining efficient glucose, lipid, and protein metabolism (Steven et al. 1976; Outridge and Scheuhammer 1993; USPHS 1993). In general, the toxicity of trivalent chromium to mammals is low because its membrane permeability is poor and it is noncorrosive; further, there is little tendency for Cr⁺³ to biomagnify in food chains in the inorganic form. However, organo-trivalent chromium compounds may have significantly different accumulation tendencies although little is known about these compounds (Steven et al. 1976). Hexavalent chromium is more toxic than the +3 form because its oxidizing potential is high and it easily penetrates biological membranes (Steven et al. 1976; Taylor and Parr 1978; Langard and Norseth 1979; Ecological Analysts 1981; USPHS 1993).

All toxic effects of Cr⁺⁶ seem to be related to the strong oxidizing action of chromates, and all biological interactions of chromates seem to result in reduction to the Cr⁺³ form and subsequent coordination to organic molecules (Langard and Norseth 1979). It is difficult to distinguish between the effects caused by Cr⁺⁶ and those caused by Cr⁺³ since Cr⁺⁶ is rapidly reduced to Cr⁺³ after penetration of biological membranes and in the gastric environment. However, whereas Cr⁺⁶ can be readily transported into cells, Cr⁺³ is unable to cross cell membranes. The reduction of Cr⁺⁶ to Cr⁺³ may be the most important mechanism for the toxicity of chromium (USPHS 1993).

Most of the Cr⁺⁶ found in nature is a result of domestic and industrial emissions (Steven et al. 1976). Interaction of +6 chromic oxide, dichromate, or chromate compounds with organic compounds can result in reduction to the comparatively less toxic trivalent form (Taylor and Parr 1978).

Chromium compounds interact synergistically or antagonistically with many chemicals. For example, potassium dichromate administered by subcutaneous injection potentiated the effects of mercuric chloride, citrinin, and hexachloro-1,3-butadiene on rat kidneys (USPHS 1993). Chromium effects were lessened by ascorbic acid and Vitamin E, and N-acetyl cysteine was effective in increasing urinary excretion of chromium in rats (USPHS 1993).

Little is known about the relationship between concentrations of total chromium in a given environment and biological effects on the organisms living there. Depending on the physical and chemical state of the chromium, the same element concentration has a wide variety of mobilities and reactivities and thus has different effects (Steven et al. 1976). Chromium toxicity to aquatic biota is significantly influenced by abiotic variables such as hardness, temperature, pH, and salinity of water; and biological factors such as species, life stage, and potential differences in sensitivities of local populations (Ecological Analysts 1981; Holdway 1988). In both freshwater and marine environments, hydrolysis and precipitation are the most important processes that determine the fate and effects of chromium, whereas adsorption and bioaccumulation are relatively minor (Ecological Analysts 1981; Mayer 1988). Both Cr^{+3} and Cr^{+6} can exist in water with little organic matter; Cr^{+6} is usually the major species in seawater (Towill et al. 1978; Mayer 1988). Under oxygenated conditions, Cr^{+6} is the dominant dissolved stable chromium species in aquatic systems. The hexavalent form exists as a component of a complex anion that varies with pH and Eh and may take the form of chromate (CrO_4^{2-}), hydrochromate (HCrO_4^{-1}), or dichromate ($\text{Cr}_2\text{O}_7^{2-}$), with dichromate predominating at acidic pH's. These ionic Cr^{+6} forms are highly soluble in water and thus mobile in the aquatic environment. All stable Cr^{+6} anionic compounds strongly oxidize organic matter on contact and yield oxidized organic matter and Cr^{+3} (Ecological Analysts 1981; Mayer 1988; Saleh et al. 1989; Outridge and Scheuhammer 1993). Trivalent chromium tends to form stable complexes with negatively charged inorganic or organic compounds, and thus is unlikely to be found uncomplexed in aqueous solution if anionic or particulate compounds (such as decaying plant or animal tissues, or silt or clay particles) are present (Steven et al. 1976; Pfeiffer et al. 1980; Ecological Analysts 1981). Precipitated Cr^{+3} hydroxides remain in the sediments under aerobic conditions. Under low pH and anoxic conditions, however, Cr^{+3} hydroxides may solubilize and remain as ionic Cr^{+3} unless oxidized to Cr^{+6} through mixing and aeration (Ecological Analysts 1981; Mayer 1988). Among estuarine sediments, chromium content tends to be highest in those of small grain size and high organic and iron content. Concentrations in European estuaries ranged from 3.9 mg/kg in intertidal sands to 162.0 mg/kg in anaerobic muds (Rehm et al. 1984). Adsorption of chromium by sediments is salinity-dependent; adsorption is greatest at salinities of 0.1 to 1.0‰ (Mayer and Schick 1981). Colloidal iron strongly scavenges Cr^{+3} from river water; flocculation of the colloids when they are mixed with seawater, coupled with lack of removal of the colloids to the sediments by gravitational settling or scavenging by suspended sediments, promotes the flux of Cr^{+3} through the estuary to the open ocean (Mayer et al. 1981).

The solubility and potential bioavailability of chromium waste added to soils through sewage sludge, animal manures, and industrial wastewater are modified by soil pH and organic complexing substances (James and Bartlett 1983a, 1983b; Bartlett and James 1988). Although soil pH can affect oxidation rates of Cr^{+6} to Cr^{+3} , organic complexes appear to play a more significant role. For example, organically complexed Cr^{+3} added to soils may remain soluble for at least a year, whereas the free Cr^{+3} metal ion in the absence of soluble complexing ligands quickly becomes adsorbed, or hydrolyzed and precipitated. The biological effects of organochromium compounds, which are not well documented, appear to be high-priority subjects for further research.

In groundwater, hexavalent chromium tends to be mobile due to the lack of solubility constraints and the low adsorption of Cr^{+6} anion species by metal oxides in neutral to alkaline waters (Calder 1988). Above pH 8.5, no Cr^{+6} adsorption occurs in groundwater; Cr^{+6} adsorption increases with decreasing pH. Trivalent chromium species tend to be relatively immobile in most groundwaters because of the precipitation of low-solubility Cr^{+3} compounds above pH 4 and high adsorption of the Cr^{+3} ion by soil clay below pH 4 (Calder 1988).

Data on the environmental cycling of chromium are lacking, and those on the biochemistry of chromium are incomplete and sparse (Towill et al. 1978); it is clear that these two subjects merit additional research. Furthermore, there is increasing concern about the uncertainties in the analysis of some types of biological and environmental samples (Towill et al. 1978; Taylor and Parr 1978). For example, collaborating laboratories have reported order-of-magnitude differences in persistence of chromium in standard bovine liver. Until more is learned about the reasons for these differences, caution should be exercised in interpreting past analytical results.

2.3 CONCENTRATIONS IN FIELD COLLECTIONS

Chromium concentrations in selected nonbiological materials are elevated in the vicinity of industrial operations and municipal waste treatment facilities where chromium is a significant component of wastes discharged into the environment ([Tables 2.1](#) and [2.2](#)). It is generally agreed that suspended particulates are a major source of transport in aquatic systems, that most chromium in soil and sediment is unavailable to living organisms, that Cr⁺⁶ in air and water is hazardous to fish and wildlife, and that the grossly elevated levels of chromium (especially inorganic fractions) in sludge components may have serious implications to wildlife when the sludge is applied to croplands (Eisler 1986). Severe groundwater contamination, i.e., 40 mg Cr/L, is reported in Nassau County, New York, from an aircraft plant that used chromium solutions for anodizing and plating metals (Calder 1988). Chromium contamination of shallow aquifers is also reported near Telluride, Colorado, from heavy-metal mining and milling wastes discharged into a leaky holding pond, and from chromium wastes from automotive, electroplating, and wood treatment industries in Michigan (Calder 1988). Hexavalent chromium added to or found in soils may be leached, reduced, adsorbed, precipitated, or taken up by a living organism (Bartlett and James 1988). Chromium-contaminated sediments may act as a toxicant source by releasing chromium to interstitial sediment pore waters; the acute toxicity of chromium and other metals in sediments has been correlated with pore water concentrations (Gendusa et al. 1993).

Certain plants grown on serpentine soils containing 1000 to 50,000 mg Cr/kg DW may contain 10 to 100 mg Cr/kg DW — levels that may be toxic to wildlife, although no reports of this phenomenon are known (Outridge and Scheuhammer 1993). Most plant and invertebrate species die before accumulating amounts of chromium that are toxic to predators (Outridge and Scheuhammer 1993). Some species of terrestrial plants have been proposed for the removal of chromate from waste waters (Kleiman and Cigliatti 1997). Terrestrial plants, such as wheat (*Triticum aestivum*), accumulate the greatest amount of chromium under conditions of sulfate deficiency or deprivation. Because sulfate is a strong inhibitor of chromate uptake in terrestrial plants, the presence of sulfates in the environment negates the usefulness of this approach (Kleiman and Cigliatti 1997).

Concentrations of chromium in representative species of plants and animals collected worldwide are shown in [Table 2.3](#). Additional data were given by Jenkins (1980) and Eisler (1981, 1986). Chromium concentrations in species of individual taxonomic groups tended to be elevated when collection localities were near electroplating plants, tanneries, oil drilling operations, sewage outfalls, drift cooling towers, dump sites, or other sources of chromium-containing wastes that were being discharged into the environment. Among marine algae and invertebrates, for example, comparatively high concentrations of chromium were recorded in algae, clams, and annelids from the vicinity of electroplating plants; in crabs collected near an ocean dump site receiving large quantities of metals; and in algae and echinoderms near urbanized areas in Puerto Rico. Grossly elevated levels of chromium were also noted ([Table 2.3](#)) in selected plasma fractions of tunicate blood, in the scales from a few species of teleosts, and in corals from chromium-rich areas containing high concentrations of scandium and titanium. However, these accumulations were not attributed to anthropogenic activities. Studies demonstrate that fish and sediments in Florida stormwater ponds

^a 1, Ecological Analysts 1981; 2, Langard and Norseth 1979; 3, Towill et al. 1978; 4, Giblin et al. 1980; 5, Turekian and Scott 1967; 6, Pfeiffer et al. 1980; 7, Duval et al. 1980; 8, Bryan et al. 1983; 9, Eisler et al. 1977; 10, Mayer et al. 1981; 11, Steven et al. 1976; 12, Venugopal and Reddy 1992a; 13, Beyer 1990; 14, U.S. Public Health Service (USPHS) 1993.

do not have elevated concentrations of chromium (Campbell 1995), that chromium does not biomagnify in marine food chains in an Egyptian bay heavily contaminated with chromium (Dahab et al. 1990), that chromium from sediments containing 717 mg Cr/kg DW in a New Jersey wetlands is not biologically available to biota in the immediate vicinity (Hall and Pulliam 1995), and that elevated chromium residues in biota from a Texas estuary are not reflective of residues of other heavy metals (Custer and Mitchell 1993). Many factors are known to modify chromium levels. In marine molluscs, as one example, chromium concentrations tended to increase with the age of the organism (Eisler et al. 1978), although uptake was significantly inhibited at high salinities (Olson and Harrel 1973). Accidental contamination of field samples by metal particles in the samples, rust from stainless hydrowire, or flaking paint from the hull of the collecting ship may also constitute significant sources of elevated chromium residues in aquatic environments (Martin and Knauer 1973).

Waterfowl from areas contaminated by mining wastes and which consumed diets rich in chromium had elevated chromium concentrations in tissues, especially in gonads, gallbladder, and pancreas (van Eeden and Schoonbee 1992; Table 2.3). Chromium burdens were highest in livers of seed-eating species of birds from Baja California (Mora and Anderson 1995). In feathers of passerine birds, chromium concentrations were lowest in species that ate mostly fruit and highest in older adults of long-lived species (Burger et al. 1993a). Bones of 24 species of birds collected from southwestern Russia in 1993–95 contained 0.3 to 14.7 mg Cr/kg DW. Concentrations were higher in conspecifics collected in urban areas than in rural areas, highest in sparrows and other seed-eating species, lowest in owls, highest in bones of terrestrial species, and lowest in those of aquatic species (Lebedeva 1997). Elevated concentrations of chromium were measured in brain, lung, kidney, and liver of rock doves (*Columba livia*) from Mexico City when compared to conspecifics collected from a rural area (Gonzalez et al. 1994). In terrestrial ecosystems, elevated chromium levels were reported in cotton rats and plants collected near drift cooling towers and in earthworms and plants from sludge-amended soils (Table 2.3). However, the high levels of chromium reported in the hair of pronghorns and elk (Table 2.3) require verification.

A source of concern is the accuracy and precision of chromium analyses in biological samples. One interlaboratory calibration study, involving 87 laboratories, showed that an oyster homogenate averaged 1.1 mg/kg dry weight, with a standard deviation of 0.5 mg/kg (Fukai et al. 1978). This means that about 67% of the laboratories reporting were in the range of 0.6 to 1.6 mg/kg and about 33% were outside this range. It seems clear that more rigorous and standardized sample preparation techniques and analyses for chromium are needed.

2.4 BENEFICIAL AND PROTECTIVE PROPERTIES

Hexavalent chromium has no known essential function. However, trivalent chromium in the form of a dinicotinic acid-glutathione complex is an essential cofactor for insulin production, forms complexes with protein, amino acids, and other organic acids, and is the most biologically stable form of chromium. Dietary trivalent chromium deficiency results in an inability to clear glucose from the blood and pathology similar to diabetes (Outridge and Scheuhammer 1993; USPHS 1993). Although trivalent chromium is an essential nutrient, exposure to high levels via inhalation, ingestion, or dermal contact may cause adverse health effects (USPHS 1993; Domingo 1994). In humans, other mammals, and turkeys (*Meleagris gallopavo*), trivalent chromium is essential for the normal metabolism of carbohydrates, insulin, and glucose (Langard and Norseth 1979; Shiao and Chan 1993) and for regulating carbohydrate metabolism in mammals (Preston et al. 1976; Onkelinx 1977; Gale 1978; Towill et al. 1978; Langard and Norseth 1979; Post and Campbell 1980; Outridge and Scheuhammer 1993; USPHS 1993). Chromium deficiency has been described in rats, guinea pigs, and squirrel monkeys; signs include reduced growth, decreased life span, elevated serum cholesterol, increased formation of aortic plaques, and signs resembling those of diabetes mellitus. Subjecting chromium-deficient animals to stress can exacerbate the signs (Preston et al. 1976). In humans, chromium deficiency has been suggested as a possible factor in the incidence of diabetes and atherosclerosis. Autopsy data from 31 areas of the world suggest that many Americans, but few non-Americans, were deficient in chromium. One characteristic feature of chromium levels in human tissues is that they decline with increasing age (Onkelinx 1977).

Chromium is beneficial but not essential to growth in higher plants. Residues in plants seldom exceed a few mg/kg, except in plants living on infertile serpentine soils containing high chromium

concentrations, or grown on soils amended with sewage sludge. Plants with elevated chromium residues show no toxic effects, although concentrations in excess of 1 mg/kg in the aqueous medium may inhibit germination of the seed and growth of roots and shoots (Towill et al. 1978).

Chromium has proved effective in counteracting the deleterious effects of cadmium in rats and of vanadium in chickens. High mortality rates and testicular atrophy occurred in rats subjected to an intraperitoneal injection of cadmium salts; however, pretreatment with chromium ameliorated these effects (Stacey et al. 1983). The Cr-Cd relationship is not simple. In some cases, cadmium is known to suppress adverse effects induced in Chinese hamster (*Cricetus* spp.) ovary cells by Cr⁺⁶ (Shimada et al. 1998). In southwestern Sweden, there was an 80% decline in chromium burdens in liver of the moose (*Alces alces*) between 1982 and 1992 from 0.21 to 0.07 mg Cr/kg FW (Frank et al. 1994). During this same period in this locale, moose experienced an unknown disease caused by a secondary copper deficiency due to elevated molybdenum levels as well as chromium deficiency and trace element imbalance (Frank et al. 1994). In chickens (*Gallus* sp.), 10 mg/kg of dietary chromium counteracted adverse effects on albumin metabolism and egg shell quality induced by 10 mg/kg of vanadium salts (Jensen and Maurice 1980). Additional research on the beneficial aspects of chromium in living resources appears warranted, especially where the organism is subjected to complex mixtures containing chromium and other potentially toxic heavy metals.

2.5 LETHAL EFFECTS

2.5.1 General

Biocidal properties of chromium salts to aquatic organisms are modified, sometimes by an order of magnitude or more, by a variety of biological and abiotic factors. These include the species, age, and developmental stage of the organism; the temperature, pH, salinity, and alkalinity of the medium; interaction effects of chromium with other contaminants; duration of exposure; and the chemical form of the chromium tested. For hexavalent chromium, LC50 (96 h) values for sensitive freshwater and marine species were between 445 and 2000 µg/L. For trivalent chromium, LC50 (96 h) concentrations were 2000 to 3200 µg/L for sensitive freshwater organisms and 3300 to 7500 µg/L for marine biota.

Among warm-blooded organisms, hexavalent chromium was fatal to dogs in 3 months at 100 mg/kg in their food and killed most mammalian experimental animals at injected doses of 1 to 5 mg Cr/kg body weight, but it had no measurable effect on chickens at dietary levels of 100 mg/kg over a 32-day period. Trivalent chromium compounds were generally less toxic than hexavalent chromium compounds, but significant differences may occur in uptake of anionic and cationic Cr⁺³ species, and this difference may affect survival.

2.5.2 Aquatic Organisms

Records of acute toxicities of hexavalent and trivalent chromium salts to representative species of aquatic life (Table 2.4) make it clear that Cr⁺⁶ is the more toxic to freshwater biota in comparatively soft and acidic waters, that younger life stages are more sensitive than older organisms, and that 96 h is insufficient to attain stable mortality patterns. Euryhaline species of estuarine algae tested show increasing resistance to Cr⁺⁶ at increasing salinities (Wong and Trevors 1988). There are at least five ionic species of hexavalent chromium, of which two — the hydrochromate ion and the chromate ion — are the predominant species and probably the agents that are toxic to freshwater life (Van der Putte et al. 1981b). However, water pH dramatically affects the concentration of each: as pH decreased from 7.8 to 6.5, the hydrochromate ion increased by a factor of about 3, and the chromate ion decreased by a factor of about 6.8 (Van der Putte et al. 1981b). To some species of freshwater fishes, Cr⁺⁶ was 50 to 200 times more toxic at pH 6.4 to 7.4 than at pH 7.8 to 8.0 (Wepener et al. 1992). Hexavalent chromium interacts with other metals in solution to produce additive

or synergistic effects, as was the case with nickel salts in acute toxicity to guppies (Khangarot and Ray 1990). More research is needed to fully elucidate chromium's mode of action in solution. The organisms most sensitive to Cr^{+6} , as judged by 96-h LC50 values, were freshwater crustaceans and rotifers, and marine crustaceans, for which LC50 values were 445 to 3100 $\mu\text{g/L}$. Longer exposures of 28 to 84 days produced LC50 values of 200 to 500 $\mu\text{g/L}$ (Table 2.4). Other investigators had confirmed that Cr^{+6} is more toxic to freshwater daphnids and teleosts in water of comparatively low alkalinity, low pH, and low total hardness (Steven et al. 1976; Muller 1980). In marine teleosts, the toxicity of Cr^{+6} increased at elevated temperatures; furthermore, chromium was additive in toxicity when present as a component in a complex mixture of cadmium, zinc, and Cr^{+6} salts, (Negilski 1976).

For trivalent chromium and freshwater biota, toxicity was significantly increased in comparatively soft waters; this pattern was especially pronounced for daphnids (Table 2.4). Among freshwater teleosts, survival was reduced at comparatively low pH (U.S. Environmental Protection

^a 1, Sauter et al. 1976; 2, USEPA 1980; 3, Pickering 1980; 4, Reish 1977; 5, Stevens and Chapman 1984; 6, Dave et al. 1987; 7, Holdway 1988.

Agency [USEPA] 1980). Also, organisms exposed previously to Cr^{+3} salts were not unusually sensitive or resistant when subjected to additional Cr^{+3} , suggesting that they were unable to acclimatize or to become sensitized to Cr^{+3} (Stevens and Chapman 1984). As judged by 96-h LC50 values, Cr^{+3} was toxic to sensitive freshwater organisms at concentrations of 2000 to 3000 $\mu\text{g/L}$, or slightly less toxic than Cr^{+6} (Table 2.4). Toxicity of Cr^{+3} , like that of Cr^{+6} increased with increasing exposure in rainbow trout (*Oncorhynchus mykiss*). However, Cr^{+3} was significantly less toxic than Cr^{+6} in freshwater to salmon fingerlings, and was dramatically less toxic than Cr^{+6} to polychaetes and crustaceans (but not to molluscs or teleosts) in saltwater (Table 2.4).

Maximum acceptable toxicant concentrations (MATC) of chromium to aquatic life were derived from life cycle or partial life cycle exposures and expressed as the highest concentration tested having no significant adverse effect on the characteristics measured — usually survival, growth, and reproduction — and the lowest concentration at which these effects were observed. For chromium and freshwater teleosts, MATC values ranged from as low as 51 to 105 $\mu\text{g/L}$ in rainbow trout to as high as 1000 to 31,950 $\mu\text{g/L}$ in fathead minnows (Table 2.5). The most sensitive saltwater organism tested was a polychaete worm with a MATC range of 17 to 38 $\mu\text{g/L}$ (Table 2.5). For Cr^{+3} the MATC range for freshwater organisms was 47 to 1400 $\mu\text{g/L}$, which was quite similar to that for Cr^{+6} for freshwater life. No MATC data were available for Cr^{+3} and marine biota.

2.5.3 Terrestrial Invertebrates

Data on toxicity of chromium to terrestrial invertebrates are sparse. Studies conducted in India showed that a concentration of 10 to 15 mg/L of Cr^{+6} in irrigation water, when applied to soils for agricultural purposes, was lethal to two species of earthworms in 58 to 60 days (Soni and Abbasi 1981; Abbasi and Soni 1983).

2.5.4 Mammals and Birds

Acute and chronic adverse effects of chromium on warm-blooded organisms are caused mainly by Cr⁺⁶ compounds. There is little conclusive evidence of toxic effects caused by Cr⁺² or Cr⁺³ compounds (Langard and Norseth 1979). Most investigators agree that chromium in biological materials is probably always in the trivalent state, that greatest exposures to Cr⁺³ in the general human population are through the diet (but no adverse effects have been reported from such exposures), and that no organic trivalent chromium complexes of toxicological importance have been described. Studies with guinea pigs (*Cavia spp.*) fed Cr⁺³ for 21 weeks at concentrations up to 50 mg/kg dietary Cr⁺³ showed no adverse effects (Preston et al. 1976). Domestic cats were apparently unaffected after exposure to aerosol levels of 80 to 115 mg Cr⁺³/m³ for 1 h daily for 4 months, or after consuming diets with high amounts of chromic (Cr⁺³) salts over a similar period (Langard and Norseth 1979). When chromium was administered by injection, trivalent salts were substantially less toxic than hexavalent salts in producing effects in embryos of golden hamsters (Gale 1978). A similar pattern was evident in mice and in embryos of chickens. The LD50s for mice were 260 mg/kg body weight for Cr⁺³, but only 5 mg/kg body weight for Cr⁺⁶ (Steven et al. 1976). In rats (*Rattus sp.*), route of exposure and compound tested were important. Rats given a single dermal dose of various hexavalent chromium compounds had LD50 values that ranged from 400 mg Cr/kg BW for sodium dichromate to 680 mg Cr/kg BW for ammonium dichromate; potassium dichromate and sodium chromate were intermediate in toxicity (Outridge and Scheuhammer 1993). When the same four hexavalent chromium compounds were administered via inhalation, LD50s after 4 h of exposure ranged between 33 and 82 mg Cr/m³; females were more sensitive than males (Outridge and Scheuhammer 1993; USPHS 1993).

Steven et al. (1976), in studies with Cr⁺⁶ in dogs, showed that 100 mg/kg in food for 3 months was fatal, that 11.2 mg/L in drinking water was not lethal over a 4-year period (although significant accumulation was observed), and that 6.0 mg/L in drinking water for 4 years had no measurable effects. In rats, 1000 mg/kg dietary Cr⁺⁶ represented the toxic threshold, but all animals survived 134 mg/L of Cr⁺⁶ in drinking water for 3 months (Steven et al. 1976). For most mammalian experimental animals, including mice (*Mus sp.*), dogs (*Canis familiaris*), rabbits (*Oryctolagus sp.*), cats (*Felis domesticus*), and guinea pigs, the minimum injected fatal dose of Cr⁺⁶ ranged from 1 to 5 mg/kg body weight, although doses of 0.2 to 0.5 mg/kg body weight produced marked kidney damage (Steven et al. 1976). Repeated sublethal injections of Cr⁺⁶ did not promote tolerance in mice, but rather decreased the minimum lethal dose, suggesting that the animals were unable to develop tolerance to repeated chromium exposures (Steven et al. 1976). Investigators have not yet been able to identify a specific hexavalent chromium compound, or group of compounds, that could account for the most pronounced biological activity (Langard and Norseth 1979). A lethal oral dose of Cr⁺⁶ for a 14-year-old boy was estimated to be 10 mg/kg body weight — much lower than that tolerated by test animals on a repeated basis over a period of several months (Steven et al. 1976). A 44-year-old man who ingested 4.1 mg Cr⁺⁶/kg body weight as chromic acid died of severe gastrointestinal hemorrhage one month after ingestion (USPHS 1993).

Domestic chickens (*Gallus sp.*) appear to be more resistant than mammals. No adverse effects were observed in chickens exposed to 100 mg/kg dietary Cr⁺⁶ in a 32-day study (Rosomer et al. 1961), although embryolethal and teratogenic effects have been observed in the range of 0.2 mg/kg (Gilani and Marano 1979) to 1.7–22.9 mg/kg (Ridgeway and Karnofsky 1952), depending on the method of administration. For chicken embryos, the LD50 values (mg/kg body weight) were 22.9 for Cr⁺³ and 1.7 for Cr⁺⁶ (Ridgeway and Karnofsky 1952).

2.6 SUBLETHAL EFFECTS

2.6.1 General

Under laboratory conditions, chromium is mutagenic, carcinogenic, and teratogenic to a wide variety of organisms, and Cr⁺⁶ has the greatest biological activity. However, information is lacking

on the biological activities of water-soluble Cr⁺³ compounds, organochromium compounds, and their ionic states. Aquatic plants and marine polychaete worms appear to be the most sensitive groups tested. In exposures to Cr⁺⁶, growth of algae was inhibited at 10.0 µg/L, and reproduction of worms at 12.5 µg/L. At higher concentrations, Cr⁺⁶ is associated with abnormal enzyme activities, altered blood chemistry, lowered resistance to pathogenic organisms, behavioral modifications, disrupted feeding, histopathology, osmoregulatory upset, alterations in population structure and species diversity indices, and inhibition of photosynthesis. Not all sublethal effects observed were permanent, but the potential for acclimatization of organisms to chromium is not well documented. The great variability among species and tissues in the accumulation or concentration of chromium is attributed partly to the route of administration, partly to the concentration of chromium and its chemical species, and partly to numerous biotic and physicochemical modifiers. High accumulations of chromium have been recorded among organisms from the lower trophic levels, but there is little evidence of biomagnification through food chains. Marine bivalve molluscs, for example, accumulated measurable concentrations at ambient water concentrations of 5.0 µg/L of Cr⁺⁶, but the significance of chromium residues in molluscs and other organisms is not well understood. Depuration of accumulated chromium among organisms differs markedly, but usually follows a complex multicompartmental excretion pattern.

2.6.2 Aquatic Organisms: Freshwater

Bacteria

The role of sewage bacteria in chromium kinetics and cycling is unresolved and promises to be a fruitful field of research. Of 362 bacterial isolates from Cr⁺⁶ liquid sanitary sewage and chemical waste sludges, only 1 — an isolate of *Arthrobacter* sp. — could tolerate 400 mg/L of Cr⁺⁶ (Coleman and Paran 1983). However, this isolate could not effectively accumulate chromium at comparatively low ambient levels of 5 mg/L of Cr⁺⁶, whereas *Agrobacter* sp., another isolate, could. Hexavalent chromium in a wide array of forms showed dose-dependent responses for mutagenic activity in the bacterium *Salmonella typhimurium* (Del Carratore et al. 1984). Moreover, among 56 metal compounds tested, Cr⁺⁶ elicited the strongest mutagenic responses in *Bacillus subtilis* (Hatherill 1981). In some tests, Cr⁺³ was genetically active, but only when present as a stable organic complex (Del Carratore et al. 1984).

Algae and Macrophytes

Growth of freshwater algae was reduced at Cr⁺⁶ concentrations of 10 µg/L for *Chlamydomonas reinhardtii*, 20 µg/L for *Chlorella pyrenoidosa*, and >45 µg/L for other species tested. Effects were most pronounced in water of low alkalinity (USEPA 1980; Wong and Trevors 1988; Outridge and Scheuhammer 1993). Frond growth of the common duckweed, *Lemna minor*, the most sensitive aquatic plant tested, was reduced at 10 µg Cr⁺⁶/L in 14 days (Mangi et al. 1978). Jouany et al. (1982) reported that a green alga, *Chlorella vulgaris*, biomagnified Cr⁺⁶ from the medium about 1000 times in 28 days at ambient concentrations of 300 µg/L; growth was inhibited at 445 µg Cr⁺⁶/L in 96 h; and adenosine triphosphate (ATP) production was reduced at 470 µg/L in 24 h. At 10 µg Cr⁺⁶/L in the medium, bioconcentration factors for the chlorophytes *Hydrodictyon reticulatum* and *Oedogonium* sp. ranged from 200 to 600 in 14 days (Mangi et al. 1978). Accumulation of chromium by living and dead plant tissue is extensive, uptake linearly approximating concentration on a logarithmic basis (Mangi et al. 1978). Trivalent chromium is far less effective than Cr⁺⁶ in producing root weight inhibition in Eurasian watermilfoil, *Myriophyllum spicatum*: 9900 µg Cr⁺³/L vs. 1900 µg Cr⁺⁶/L (USEPA 1980). A similar case is made for terrestrial plants, such as barley, wherein hexavalent chromium at 100 µg/L and trivalent chromium at 1000 µg/L produced comparable growth inhibition (Outridge and Scheuhammer 1993).

Invertebrates

Hexavalent chromium was associated with adverse effects in invertebrates of widely separated taxa:

- Reduced survival and fecundity of the cladoceran *Daphnia magna* at a concentration of 10 µg/L and exposure for 32 days (USEPA 1980)
- Growth inhibition of the protozoan *Chilomonas paramecium* at 1100 to 3000 µg/L at temperatures of 10 to 30°C during exposures of 19 to 163 h (Honig et al. 1980)
- Abnormal movement patterns of larvae of the midge *Chironomus tentans* at 100 µg/L in 48 h (Catalan 1982)
- Temporary decrease in hemolymph glucose levels in the freshwater prawn *Macrobrachium lamarrei* surviving 1840 µg/L Cr⁺⁶ for 96 h (Murti et al. 1983)

Trivalent chromium was less effective than Cr⁺⁶ in reducing fecundity of *Daphnia magna*: 44 µg Cr⁺³/L vs. 10 µg Cr⁺⁶/L (USEPA 1980). Annelid worms (*Tubifex* sp.) accumulated about 1 mg total chromium/kg whole body during exposure for 2 weeks in sediments containing 175 mg Cr⁺³/kg, suggesting that benthic invertebrates have only a limited ability to accumulate chromium from sediments or clays (Neff et al. 1978).

Fishes

Among sensitive species of freshwater teleosts, Cr⁺⁶ concentrations of 16 to 21 µg/L in the medium resulted in reduced growth of rainbow trout and chinook salmon (*Oncorhynchus tshawytscha*) fingerlings during exposure of 14 to 16 weeks, and altered plasma cortisol metabolism in rainbow trout after 7 days (USEPA 1980). Rainbow trout avoid water containing 28 µg Cr⁺⁶/L; however, avoidance thresholds increased linearly if the fish were pre-exposed to 800 µg Cr⁺⁶/L for 7 to 20 weeks (Anestis and Neufeld 1986). Locomotor activity in bluegills (*Lepomis macrochirus*) increased after 2 weeks in 50 µg Cr⁺⁶/L (USEPA 1980). The avoidance threshold for golden shiner (*Notemigonus crysoleucas*) is 73 µg Cr⁺⁶/L (Hartwell et al. 1989). Exposure of cichlids (*Tilapia sparrmanii*) to 98 µg Cr⁺⁶/L for 96 h led to clotting defects that caused internal bleeding, with effects exacerbated by increasing water pH in the range pH 4 to 9 (van Pittius et al. 1992; Wepener et al. 1992). Long-term exposure of rainbow trout for 180 days to high, but environmentally realistic, concentrations of 200 µg Cr⁺⁶/L resulted in elevated levels of chromium in kidney (3.5 mg/kg fresh weight), liver (2.0), and muscle (0.6). After 90 days in chromium-free media, chromium levels were 1.6, 1.3, and 0.5 mg/kg FW, respectively (Calamari et al. 1982). Time required to reach median asymptotic uptake ranged from 36 to 55 days for various tissues; extrapolated values for almost complete equilibrium were 237 to 365 days (Calamari et al. 1982). In seaward-migrating coho salmon (*Oncorhynchus kisutch*), salinity tolerance and serum osmolality were impaired during exposure to 230 µg Cr⁺⁶/L for 4 weeks (Sugatt 1980a). In juvenile coho salmon, disease resistance and serum agglutinin production both decreased after 2 weeks in water containing 500 µg/L (Sugatt 1980b).

At high environmental concentrations of Cr⁺⁶ (i.e., 2.0 mg/L in water) and at alkaline pH, concentrations in rainbow trout tissues were greatest in gill, liver, kidney, and digestive tract. After transfer of the fish to chromium-free media, residues tended to remain high in kidney and liver. Concentration in gill tissues tended to be greater at pH 7.8 than at pH 6.5 (Van der Putte et al. 1981a). Studies with perfused gills showed that the transfer of chromium was directly coupled with the transfer of oxygen from the external solution to the internal perfusion medium and that this transfer was significantly more rapid at pH 6.5 than at alkaline pH (Van der Putte and Part 1982). Uptake rate of Cr⁺⁶ was rapid, equilibrium usually being reached in 2 to 4 days of exposure for various tissues, except for gill, which continued to accumulate chromium with increasing exposure

at acidic pH. In rainbow trout, the excretion pattern was biphasic. The biological half-life of the short-lived component (34% of the total chromium) was 1.0 day, and that of the long-lived component was 25.6 days (Van der Putte et al. 1981a). Exposure of isolated intestine tissues of rainbow trout to chromium leads to an initial dose-dependent inhibition of alkaline phosphatase activity; this enzyme is sensitive to chromium ion, especially Cr⁺⁶ (Boge et al. 1992).

Various effects are reported in freshwater teleosts following exposure to comparatively high sublethal concentrations of hexavalent chromium. In the snakehead (*Channa punctatus*), enzyme activities were altered in a wide variety of organs and tissues after exposure for 30 days to 2.6 mg/L (Sastry and Sunita 1984). The effects became life threatening after exposure for 120 days (Sastry and Tyagi 1982; Sastry and Sunita 1982, 1983). Gill histopathology was documented in the air-breathing catfish (*Saccobranchus fossilis*) after immersion in 5.6 mg Cr⁺⁶/L for 7 days (Khangarot and Tripathi 1990, 1992). Growth rate of larvae of the fathead minnow (*Pimephales promelas*) was reduced at 6 mg/L during exposure for 7 days (Pickering and Lazorchak 1995). The rudd (*Scardinus erythrophthalmus*), exposed to Cr⁺⁶ for 24 h, did not accumulate detectable levels of chromium in tissues during exposure to 16 mg/L, but did during exposures to 20 mg/L; the kidney contained the highest residues — 10.3 mg Cr/kg fresh weight (Van Hoof and Van San 1981). Climbing perch (*Anabas scandens*) exposed for 30 days to 25 mg Cr⁺⁶/L or 25 mg Cr⁺³/L showed depletion of glycogen and glucose reserves of liver and kidney, and decreased activity of respiratory enzymes (various dehydrogenases) and ATPases; in all cases, Cr⁺⁶ produced the greater effect (Venugopal and Reddy 1992a, 1992b, 1993). In the mudskipper (*Boleophthalmus dussumieri*), chromosomal aberrations in the gill increased after injection of 1.0 mg/kg body weight or exposure to 24 mg/L in the medium for 24 h (Krishnaja and Rege 1982). Mudskippers exposed to 30 to 60 mg Cr⁺⁶/L for 72 h had a dose-duration inhibition in specific activity of brain and muscle Na⁺, K⁺-ATPase and other ATPases (Kundu et al. 1995).

Chromium is considered to be a cofactor for insulin activity and part of an organic glucose tolerance factor (Shiau and Chan 1993). In common carp (*Cyprinus carpio*) fed low-protein diets, the addition of chromium chloride salts in the diet (equivalent to 60 µg Cr⁺³/kg BW) or injected intraperitoneally (2.5 µg/kg BW) significantly decreased plasma glucose levels (Hertz et al. 1989). Trivalent chromium supplementation in the diet improved glucose utilization in carp and tilapia when fed diets for 10 weeks containing 2 mg Cr/kg ration equivalent to 5% BW daily. Chromic oxide was more effective than chromium chloride, and both were more effective than sodium chromate tetrahydrate (Shiau and Chan 1993). Chromic oxide fed in the diet for 12 weeks at 0.5% and 2% to tilapia fingerlings improved glucose utilization and nutrient digestibility; the 0.5% diet was more efficient than the 2% diet (Shiau and Liang 1995).

Chromium uptakes and effects in teleosts were modified significantly by many biological and abiotic variables, including water temperature and pH, the presence of other contaminants or compounds, and sex and tissue specificity. In rainbow trout, only males showed significant changes in liver enzyme activity during exposure to 200 µg Cr⁺⁶/L for 6 months; the effects were intensified by the presence of nickel and cadmium salts in solution (Ariollo et al. 1982). Rainbow trout are able to regulate chromium somewhat, either actively, by reduced absorption or increased excretion, or passively, by the limitation of binding sites for chromium *in vivo* (Buhler et al. 1977). Tests with goldfish (*Carassius auratus*) and high Cr⁺⁶ concentrations indicated that lethal and sublethal effects were more pronounced at comparatively high water temperatures and reduced pH; further, chromium residue levels were abnormally high in dead or moribund fish, suggesting that residue values from dead or dying fish should be interpreted with extreme caution (Riva et al. 1981). In rainbow trout, acute chromium poisoning caused morphological changes in gills, kidney, and stomach tissues at pH 7.8, but only in the gills at pH 6.5 (Van der Putte et al. 1981b). Chromium uptake in trout increased when 10 µg/L of ionic cadmium was present in solution (Calamari et al. 1982) — again demonstrating that uptake patterns are not necessarily predictable for single components in complex mixtures.

2.6.3 Aquatic Organisms: Marine

Algae and Macrophytes

Algae and higher plants accumulated chromium from seawater by factors up to 8600 (Van As et al. 1973), and from solutions containing 50 mg/L of chromium by a factor of 18 in 48 h (Sivalingam 1978). Algae also accumulated chromium from sewage sludge, showing increases in chromium burdens of 25 to 60 mg/kg dry weight (Montgomery et al. 1978). The unusually high chromium concentrations observed in some species of algae and macrophytes from Narragansett Bay, Rhode Island (Phelps et al. 1975) and from Puerto Rico (Bernhard and Zattera 1975) almost certainly came from chromium wastes discharged from electroplaters (in Narragansett Bay) and from other anthropogenic sources (in Puerto Rico). A similar situation probably exists wherever grossly elevated chromium levels are observed.

Although chromium is abundant in primary producers, there is little evidence of biomagnification through marine food chains consisting of herbivores and carnivores (Osterberg et al. 1964). Baptist and Lewis (1969) followed the transfer of assimilated and unassimilated radiochromium through an experimental food chain that included phytoplankton, brine shrimp, postlarval fish, and adult fish. When chromium was successively transferred through each of the four trophic levels, concentrations declined after each transfer. Comparisons of the results from the food chain with laboratory studies on chromium uptake from seawater suggest that the food chain, despite the successive declines, was generally the more efficient pathway for uptake of chromium by all trophic levels.

Among sensitive species of marine algae, concentrations of 10 µg/L of Cr⁺⁶ partly inhibited growth of *Olisthodiscus lutens*. All cultures, including those in which growth was inhibited, contained viable, active (>75%) cells at the end of 10 days. Inhibitory effects were reversed by chelators such as EDTA (Mahoney 1982), suggesting that naturally occurring ligands and sequestering agents in seawater may alleviate the toxicity of Cr⁺⁶, and perhaps other metals. In the giant kelp (*Macrocystis pyrifera*), photosynthesis was inhibited 20% in 5 days at 1000 µg/L of Cr⁺⁶, and 50% in 4 days at 5000 µg/L (USEPA 1980); this kelp appears to be one of the more resistant aquatic plants.

Molluscs

Edible tissues of commercially important North American molluscs contained 0.1 to 0.6 mg Cr/kg fresh weight (Hall et al. 1978). Although this concentration is in general agreement with molluscan data from other geographic areas (Eisler 1981), Shuster and Pringle (1968) reported values (mg Cr/kg fresh weight) in edible portions as high as 3.4 in oysters (*Crassostrea virginica*), 5.8 in hardshell clams (*Mercenaria mercenaria*), and 5.0 in softshell clams (*Mya arenaria*). The ability of marine molluscs to accumulate chromium far in excess of that in ambient seawater was documented by Papadopoulou (1973), who found that the chromium concentration in 5 species of bivalves from Greek waters exceeded that in seawater by 16,000 times (*Pinna nobilis*) to 260,000 times (*Astralium rogosum*). No deleterious health effects have been reported among consumers of molluscs that contained occasional high chromium residues. Anthropogenic and natural chromium gradients in sediments or the water column were reflected in the wide range of values reported for this element in field collections of clams (Phelps et al. 1975; Eisler et al. 1978) and mussels (Alexander and Young 1976; Fowler and Oregoni 1976; Lande 1977; Karbe et al. 1977).

Two factors known to modify chromium accumulations in molluscs are the weight of the organism and the salinity of the medium. Concentrations of chromium in clams were reported to decrease with increasing body weight (Eisler et al. 1978) and increasing salinity (Olson and Harrel 1973). Accumulation of chromium by oysters (*Crassostrea gigas*) was independent of sediment chromium levels and dependent on organism size — suggesting some homeostatic regulation of

this metal (Ayling 1974). In a 20-week laboratory study of chromium accumulation rates by oysters (*C. virginica*), Shuster and Pringle (1969) continuously subjected the animals to seawater solutions containing 50 or 100 µg Cr⁺⁶/L. After 5, 10, or 20 weeks in 50 µg/L, maximum whole body concentrations (mg Cr/kg fresh weight) were 2.4, 3.7, and 6.3, respectively (up from control values of <0.12); in 100 µg/L, the values were 4.4 (5 weeks), 6.4 (10 weeks), and 11.5 (20 weeks). Preston (1971) concluded that *C. virginica*, under laboratory conditions, accumulated chromium more readily by direct absorption from the medium than from ingestion of radiochromium-labeled algae (*Chlamydomonas* spp.). In natural environments, however, chromium concentration is likely to be greater in the food supply than in the water. As a consequence, food might be the primary source of chromium to oysters, even though accumulation occurs more readily by direct absorption (Preston 1971).

Clams, oysters, and mussels accumulate chromium from the medium or from contaminated sediments at comparatively low concentrations. For example, oysters subjected to 5.0 µg Cr⁺⁶/L for 12 weeks contained 3.1 mg Cr/kg dry weight in soft parts and retained 52% of the accumulated chromium after they were transferred to chromium-free seawater for 28 weeks (Zaroogian and Johnson 1983). Mussels (*Mytilus edulis*) subjected to the same dose-time regimen contained 4.8 mg/kg, but retained only 39% after 28 weeks of depuration. Both oysters and mussels contained higher residues after exposure to 10.0 µg Cr⁺⁶/L for 12 weeks — 5.6 and 9.4 mg Cr/kg dry weight in soft parts, respectively — and both contained substantial (30 to 58%) residues after 28 weeks in a chromium-free environment (Zaroogian and Johnson 1983). In studies with mussels and softshell clams (*Mya arenaria*), Capuzzo and Sasner (1977) demonstrated that chromium in New Hampshire sediments (contaminated with Cr⁺³ from tannery wastes) was bioavailable to clams by diffusion from seawater, and that both diffusion and particulate uptake were important pathways for mussels. Accumulation was observed at sediment chromium concentrations as low as 150 mg/kg. Kaolinite sediments containing up to 1200 mg Cr⁺³/kg produced the most pronounced adverse effects on filtration rates and ciliary activity of bivalve molluscs, leading the authors to conclude that chromium that has accumulated in areas affected by industrial wastes might have serious consequences to filter-feeding bivalves.

It is emphasized that Cr⁺³, probably because of its very low solubility in seawater, appears to have a much lower bioavailability to most groups of marine animals than Cr⁺⁶, which is more water soluble (Carr et al. 1982). The clam *Rangia cuneata* appears to be an exception: it accumulated up to 19 mg Cr/kg in soft parts, on a dry weight basis, during exposure for 16 days to chromium-contaminated muds, and retained most of it for an extended period; the estimated biological half-time was 11 days (Carr et al. 1982). In general, benthic invertebrates rarely accumulate chromium from contaminated sediments (82 to 188 mg Cr⁺³/kg); only a few examples have been recorded (Neff et al. 1978).

Nematodes

Representatives of this phylum have been used extensively as indicators of stressed environments. Population structure and species diversity of free-living nematodes inhabiting sediments in the New York Bight were moderately influenced by the heavy-metal content of sands. In medium-grained sands, species diversity was inversely correlated with increased concentrations of chromium and other metals. Sands containing 3.0 to 21.5 mg Cr/kg were also marked by high relative abundances of one or two nematode species; the tolerance of these species to chromium stress probably exceeded that of the normal nematode inhabitants of such sediments (Tietjen 1980).

Crustaceans

In general, chromium seldom exceeds 0.3 mg/kg fresh weight in edible crustacean tissues (Eisler 1981). The highest value (0.6 mg Cr/kg fresh weight) reported in muscle of rock crab (*Cancer*

irroratus) was from specimens collected near an ocean dump site receiving large quantities of metals. Digestive glands and gills from these crabs also contained the highest chromium residues for these tissues in crustaceans (Greig et al. 1977).

Sather (1967) observed that uptake and loss of radiochromium by the crab *Podophthalmus vigil* was independent of sex and eyestalk hormone influences. Most of the radiochromium accumulated in gills. Equilibrium was reached in gill and muscle in 2 to 3 days, but in midgut and hemolymph in 4 to 5 days. Iron interfered with chromium uptake and retention. Tennant and Forster (1969) demonstrated that chromium concentrated in setae, gills, and hepatopancreas of Dungeness crab (*Cancer magister*) and suggested that surface adsorption and physiological processes were both instrumental in chromium accumulation. Barnacles (*Balanus* sp.) incorporated Cr⁺⁶ in soft tissues up to 1000 times over ambient concentrations, reaching equilibrium in 7 days (biological half-life for some components was 120 days); however, Cr⁺³, which precipitates in seawater, was quickly removed by filtering activity, was not concentrated in soft tissues, and was rapidly excreted by way of the digestive system (van Weerelt et al. 1984).

Sediment chromium concentrations of 3200 mg/kg in the New Bedford (Massachusetts) Acushnet estuary, and 100 mg/kg in the New York Bight have been recorded (Doughtie et al. 1983). Massive cuticular lesions suggestive of shell disease characterized up to 30% of the lobsters, crabs, and shrimp collected from the New York Bight, and these lesions could also be induced in crustaceans exposed to New York Bight sediments in the laboratory. This shell disease syndrome has been induced in 41% of grass shrimp (*Palaemonetes pugio*) during exposure to 0.5 mg Cr⁺⁶/L for 28 days (Doughtie et al. 1983). It is proposed that chromium interferes with the normal functions of subcuticular epithelium, particularly cuticle formation, and subsequently causes structural weaknesses or perforations to develop in the cuticle of newly molted shrimp. Because of these chromium-induced exoskeletal deficiencies, a viaduct for pathogenic bacteria and direct chromium influx is formed that perpetuates the development of the lesion.

Of the 65,000 tons of chromium compounds used annually in exploratory oil drilling, a significant portion enters the marine environment through the discharge of used drilling muds. It has been estimated that more than 225 tons of drilling mud may be used in a single 3000-m well (Carr et al. 1982). One of the most frequently used muds in offshore drilling operations is a chrome lignosulphonate mud containing barium sulphonate, bentonite clay, and ferrochrome or chrome lignosulphonates (Carr et al. 1982). The bioavailability of chromium to grass shrimp from used chrome lignosulphonate drilling muds is most pronounced at the mud aqueous layers. At chromium concentrations of 248 µg/L in the mud aqueous fraction, grass shrimp accumulated 23.7 mg Cr/kg dry weight whole body after 7 days (Carr et al. 1982). Concentrations of drilling mud of 1% or greater in seawater were toxic to sensitive species of crustaceans (Neff et al. 1981). Uptake of 4 to 5 mg/kg was reported in grass shrimp exposed to sediments containing 188 mg Cr/kg (Neff et al. 1978). The toxicity of chromium-contaminated drilling muds to grass shrimp may sometimes be attributable to large residuals of petroleum hydrocarbons in the sediments (Conklin et al. 1983).

Annelids

Studies of uptake and excretion of Cr⁺³ by *Hermione hystrix* (Chipman 1967) showed that Cr⁺³ was not readily accumulated from seawater, owing to the formation of particles and surface adsorption phenomena. Furthermore, little accumulation was evident on contact with contaminated sediments. Hexavalent chromium in the medium was readily accumulated by *Hermione*; the process was slow and only small amounts were taken up in 19 days — i.e., 0.03 to 0.10 mg/kg fresh weight from media containing 3 to 10 µg Cr⁺⁶/L. Higher body burdens of 0.5 to 1.8 mg Cr/kg fresh body weight were reported at 100 to 500 µg Cr⁺⁶/L, but some deaths were noted at these concentrations. Chromium accumulation by *Hermione* is a passive process and directly related to Cr⁺⁶ concentration in the medium. At least two rates of biological loss are involved, one of 8 days and another of 123 days. Chipman (1967) concluded that most of the chromium accumulated by *Hermione* from

long exposure is bound in a body component having a slow turnover rate and an estimated biological half-life of about 123 days.

Uptake of Cr⁺⁶ from seawater has been reported for *Neanthes arenaceodentata*. Whole *Neanthes* contained 30.0 mg Cr/kg dry weight after exposure for 150 days in 30 µg Cr⁺⁶/L (Mearns and Young 1977) and 0.5 to 1.6 mg Cr/kg fresh weight after exposure for 440 days (Oshida et al. 1976). Both of these observations were similar to those of Chipman (1967), after adjustment for wet and dry weights. Concentrations as low as 12.5 µg Cr⁺⁶/L decreased brood size in *Neanthes* (Mearns et al. 1976; Oshida et al. 1976), although no significant body residues were evident. Uptake of Cr⁺⁶ by *Neanthes* was related to dose at low ambient chromium concentrations. Worms subjected to 2.6, 4.5, 9.8, or 16.6 µg Cr⁺⁶/L for 309 days contained 0.5, 0.7, 2.2, and 2.5 mg Cr/kg whole fresh organism, respectively (Oshida and Word 1982). There was no direct relationship between tissue concentration and brood size, suggesting that chromium in *Neanthes* attaches to proteins in the body wall, gut, and parapodial regions (Oshida and Word 1982).

Neanthes arenaceodentata is the most sensitive marine organism yet tested. In worms exposed to sublethal concentrations of Cr⁺⁶, feeding was disrupted after 14 days at 79 µg/L (USEPA 1980), reproduction ceased after 440 days (three generations) at 100 µg/L (Oshida et al. 1981), brood size was reduced after 309 to 440 days at 12.5 to 16.0 µg/L (Oshida et al. 1981; Oshida and Word 1982), and abnormalities in larval development increased after 5 months at 25 µg/L (Reish 1977). On the other hand, exposure for 293 days (two generations) in 50,400 µg Cr⁺³/L caused no adverse effects on survival, maturation time required for spawning, or brood size (Oshida et al. 1981). The polychaete *Capitella capitata* was more resistant than *Neanthes*; a decrease in brood size was noted only after exposure for 5 months to 50 and 100 µg Cr⁺⁶/L (USEPA 1980).

Echinoderms

With the exception of two sea urchin samples collected from Puerto Rico, most chromium residues reported in echinoderms have been less than 1.0 mg/kg dry weight (Eisler 1981). The exceptions — elevated levels of 24 and 43 mg/kg fresh weight of whole organism in Puerto Rican sea urchins — were not reflected in sea cucumber muscle from the same vicinity (Fukai 1965), and thus should be viewed with caution. Echinoderms from the United Kingdom and environs were comparatively low in chromium; concentrations were less than 0.46 mg Cr/kg dry weight whole organism (Riley and Segar 1970). Embryos of a sea urchin (*Anthocidaris* sp.) developed normally in solutions containing 3.2 to 4.2 mg Cr/L, but failed to develop at 8.4 to 10.0 mg Cr/L (Okubo and Okubo 1962; Kobayashi 1971). Larvae of another species of sea urchin (*Hemicentrotus* sp.) were more sensitive, showing abnormal development or dying within 24 h at concentrations of less than 1.0 mg Cr/L (Okubo and Okubo 1962). Hexavalent chromium at 6.0 mg/L was associated with abnormal development in embryos of *Anthocidaris crassispina* (Kobayashi 1977).

Fishes

Trivalent chromium is relatively innocuous to the gray mullet (*Chelon labrosus*). Mullet held for 60 days in aquaria with sediments containing 46 mg Cr⁺³/kg dry weight and fed diets containing 4.4 to 13.8 mg Cr⁺³/kg dry weight ration had normal growth, survival, macroscopic physiology, and behavior; however, when compared to controls (6.4 mg Cr/kg sediments, 0.3 to 0.9 mg/kg DW ration), liver concentrations were elevated: 34 mg/kg DW vs. 2 (Walsh et al. 1994). Trivalent chromium, as chromic oxide, in the diet has been used as an indigestible marker to measure nutrient digestibility in American lobsters and freshwater-reared Arctic char (*Salvelinus alpinus*). The addition of 1% trivalent chromium to the diet of seawater-reared Arctic char results in altered intestinal microflora and increased lipids in the feces (Ringo 1993), and suggests that Cr⁺³ use for this purpose be discontinued.

Individual tissues of most species of marine finfishes contained between 0.1 and 0.6 mg Cr/kg fresh weight (Hall et al. 1978). For still unexplained reasons, chromium concentrated in the scales of some species collected in Greek waters, values ranging up to 97.0 mg Cr/kg dry weight (Papadopoulou and Kassimati 1977). Chromium concentrations also vary significantly among different species of fish collected from the same geographic area. For example, muscle chromium concentration was 1430 times greater in a porgy (*Pachymetopan grande*) than in a goosefish (*Lophius piscatorius*) from the same collection (Van As et al. 1973).

Accumulation of chromium under controlled conditions has been documented for speckled sanddab, *Citharichthys stigmaeus* (Mearns and Young 1977) and Atlantic croaker, *Micropogon undulatus* (Baptist et al. 1970). Sanddabs held in seawater solutions containing 3 to 5 mg Cr⁺⁶/L contained up to 100 mg Cr/kg intestine (dry weight), 10 in liver, and 3 in muscle (Mearns and Young 1977). Sanddabs accumulated significant concentrations of chromium in various tissues during long-term exposure in seawater concentrations as low as 16 µg Cr⁺⁶/L (Mearns and Young 1977). Baptist et al. (1970), who studied the retention of radiochromium-51 in croakers following a single intraperitoneal injection, wrote that retention was expressed as two exponential rate functions: 70 days for the long-lived component and 20 days for the short-lived component.

2.6.4 Birds

Male domestic chickens fed diets containing up to 100 mg Cr⁺⁶/kg ration for 32 days showed no adverse effects in survival, growth, or food utilization efficiency (Rosomer et al. 1961). However, teratogenic effects were documented in chicken embryos after eggs had been injected with Cr⁺⁶. Deformities included short and twisted limbs, microphthalmia, exencephaly, everted viscera, growth stunting, and parrot beaks (Ridgeway and Karnofsky 1952; Gilani and Marano 1979). The highest incidence of teratogenic effects was observed at Cr⁺⁶ concentrations that caused some deaths, and when the administration route was through the chorioallantoic membrane as opposed to the yolk. No teratogenic effects were observed with Cr⁺³ salts (Ridgeway and Karnofsky 1952).

Young American black ducks (*Anas rubripes*) absorbed anionic chromium species more readily than cationic forms from the intestines, strongly indicating that ionic chromium state should be considered when avian dietary toxicity studies are being planned (Eastin et al. 1980). In another study with black ducks, adults were fed diets containing 0, 20, or 100 mg/kg anionic Cr⁺³ and ducklings from these pairs were fed the same diets for 7 days; tests of avoidance responses of the ducklings to a fright stimulus showed that the chromium had no significant effect on their behavior (Heinz and Haseltine 1981).

2.6.5 Mammals

Chromium is causally associated with mutations and malignancy (Leonard and Lawerys 1980; Norseth 1981; Nieboer and Shaw 1988; Yassi and Nieboer 1988; USPHS 1993; Shimada et al. 1998). Under appropriate conditions, chromium is a human and animal carcinogenic agent; its biological effects depend on chemical form, solubility, and valence. In general, nearly all Cr⁺⁶ compounds are potent mammalian mutagens and all forms of Cr⁺⁶ — both water-soluble and water-insoluble compounds — are respiratory carcinogens in humans; metallic chromium and Cr⁺³ are essentially nontoxic (Gale 1978; Nieboer and Shaw 1988; Yassi and Nieboer 1988). However, exposure to water-solubilized Cr⁺³ has caused cancers and dermatitis in workers and toxicity in rabbits (Hatherill 1981). In the chromate-producing industry, workers who developed respiratory cancer had been exposed to 30 to 1100 µg/m³ chromium in air for periods of 4 to 24 years, and workers producing chromate pigment who developed respiratory cancer had been subjected to an estimated Cr⁺⁶ exposure of 500 to 1500 µg/m³ for 6 to 9 years. Carcinogens released in the chromate manufacturing process have not yet been identified (Post and Campbell 1980). Levels as low as 10 µg/m³ of Cr⁺⁶ in air produced strong irritation in nasal membranes, even after short exposures.

In some persons whose lower respiratory tissues became chromium-sensitized, asthmatic attacks occurred at levels of Cr⁺⁶ as low as 2.5 µg/m³ (Steven et al. 1976). Cancer risks in occupational exposure have declined over the past 50 years due to improvements in the production process and industrial hygiene (USPHS 1993). There is no evidence of chromium sensitization in mammals other than humans. In the only animal study demonstrating a carcinogenic effect of an inhaled chromate, adenocarcinomas were reported in the bronchial tree of mice exposed throughout life to CaCrO₄ dust at 13 mg/m³ (4330 µg Cr⁺⁶/m³) for 35 h weekly (Langard and Norseth 1979). Trivalent chromium compounds did not produce respiratory cancers (Steven et al. 1976). Interstitial fibrosis of the lungs was found in rats exposed via inhalation to 0.1 mg/m³ of Cr⁺⁶ or Cr⁺³ for 22 h daily over 18 months (USPHS 1993). In rabbits, both Cr⁺³ and Cr⁺⁶, given 1.7 mg/kg body weight daily for 6 weeks, adversely affected blood and serum chemistry, and both produced significant morphological changes in liver (Tandon et al. 1978); similar results were observed in rats (Laj et al. 1984). Although damage effects and residue accumulations were greater in rabbits treated with Cr⁺⁶, water-soluble Cr⁺³ compounds also may have significant biological activity (Tandon et al. 1978).

Hexavalent chromium compounds may cause skin ulceration, irritative dermatitis, ulcerations in mucous membranes, and perforations of the nasal septum. That inhalation of Cr⁺⁶ compounds may cause bronchial carcinomas has been well documented in humans (Langard and Norseth 1979; Yassi and Nieboer 1988). Inhalation exposure of mice to 1.8 mg Cr⁺⁶/m³ for 12 months, 2 days weekly, resulted in emphysema and nasal septum perforation (USPHS 1993). Skin lesions or ulcers were produced in guinea pigs when solutions containing 30,000 mg Cr⁺⁶/L were applied to abraded skin or if the natural oils were removed from the skin beforehand; Cr⁺³ in concentrations as high as 100,000 mg/L had no ulcerogenic effects (Steven et al. 1976). Allergic guinea pigs developed dermatitis when exposed to solutions of either Cr⁺⁶ or Cr⁺³ at concentrations as low as 10 µg/L (Steven et al. 1976). In nonallergic animals, these effects were observed after repeated exposures to solutions containing 1000 to 3000 mg/L of Cr⁺³ or Cr⁺⁶ salts. Local sarcomas in muscle and local carcinomas of the skin have also been demonstrated in small laboratory animals exposed to Cr⁺⁶ (Langard and Norseth 1979). Kidney and liver lesions in rats were observed when the drinking water contained 134 mg Cr⁺⁶/L for 2 to 3 months (Steven et al. 1976).

Hexavalent chromium has established its mutagenic activity in a wide array of screening tests, whereas insoluble Cr⁺³ forms appear to be inactive, in analogous evaluations — perhaps because Cr⁺³ absorption is poor in the systems analyzed (Hatherill 1981). Studies with tissue cultures of ovary cells of the Chinese hamster showed that the addition of 52 µg Cr⁺⁶/L not only induced sister chromatid exchanges but also inhibited cell proliferation. There was no measurable effect at 0.52 µg Cr⁺⁶/L. Trivalent chromium at 520 µg/L did not measurably affect cell proliferation or chromatid exchanges (Uyeki and Nishio 1983). Genotoxic effects of Cr⁺⁶ are reversed by the addition of reducing agents or ascorbic acid (Hatherill 1981; Uyeki and Nishio 1983). Chromosomal rearrangements and aberrations were recorded in rabbit cells after exposure to Cr⁺⁶ (Hatherill 1981).

Chromium compounds, especially hexavalent chromium compounds, are associated with spermidal, embryocidal, teratogenic, and other adverse effects on reproduction (Nieboer and Yassi 1988). Teratogenic effects induced by intravenous administration of 5 mg Cr⁺⁶/kg body weight to pregnant Syrian golden hamsters (*Mesocricetus auratus*) included cleft palates and defects in the ossification of the skeletal system (Gale 1978; Outridge and Scheuhammer 1993). Pregnant hamsters that received an oral dose of 15 mg Cr/kg body weight, as chromic trioxide, produced pups with a 64% malformation frequency (Domingo 1994). Pregnant mice given chromium-contaminated drinking water on gestation days 1 to 19 (equivalent to 57 mg Cr/kg body weight daily) had increased fetal absorption and postimplantation loss, and males had decreased spermatogenesis after eating diets for 7 weeks that contained 3.5 to 4.6 mg Cr⁺⁶/kg ration (USPHS 1993).

Chromium is the most common skin sensitizer known to human males (Haines and Nieboer 1988). Up to 26% of all males tested and 10% of females were sensitive to potassium dichromate patch tests. The highest frequency of chromium-sensitive individuals was found in Brazil, Belgium, and North America, especially Detroit and New Orleans. Frequency of chromium dermatitis was

highest in construction workers using cement. Other occupational exposures associated with chromium sensitivity include chromium plating, tanning of leather, application of anticorrosive agents, and printing. Oral ingestion of chromium compounds can sometimes lead to skin reactions in sensitive people (Haines and Nieboer 1988). Hexavalent chromium compounds are more potent inducers and elicitors of skin sensitivity than trivalent chromium compounds, probably because Cr⁺⁶ compounds can penetrate the skin more readily than Cr⁺³ compounds (Nieboer and Jusys 1988).

Accumulations of chromium in tissues and organs depend heavily on its chemical form, route of entry, and amount administered (Yamaguchi et al. 1983). Trivalent chromium is the normal form of chromium in the mammalian diet. It is localized primarily in blood, liver, spleen, kidney, and body soft tissues, with long-term storage in liver and spleen (Nieboer and Jusys 1988). Tissue accumulations were significant in dogs exposed to drinking water concentrations of 11.2 mg Cr/L; but were nil at 6 mg/L (Steven et al. 1976). Although both Cr⁺³ and Cr⁺⁶ accumulated in brain, kidney, and myocardium of rabbits, the accumulation of Cr⁺⁶ was highest in brain and that of Cr⁺³ in kidney; for both valence states there was no correlation between dose and concentration of stored chromium, or extent of tissue damage (Hatherill 1981). Tissue residues in mice given 0.1 mg Cr⁺⁶/kg in diet and water during lifetime exposure ranged from 0.1 mg Cr/kg fresh weight in liver to 0.7 in heart; mice given 5.1 mg/kg diet for a similar period contained 0.5 to 1.8 mg Cr/kg fresh weight in tissues, the residues being highest in the heart and spleen (Schroeder et al. 1964). Trivalent chromium was poorly absorbed from the intestinal tract of rats (<1% of an oral dose), whereas absorption of Cr⁺⁶ ranged from 3 to 6% (Langard and Norseth 1979). However, both Cr⁺³ and Cr⁺⁶ traverse placental barriers in mice when administered intravenously (Steven et al. 1976; Langard and Norseth 1979). All chemical forms of chromium, except chromates, cleared rapidly from the blood of rats. At dose levels of 60 to 250 µg/kg body weight, Cr⁺⁶ tended to accumulate in the reticuloendothelial system, liver, spleen, and bone marrow; at the much lower doses of 10 and 1 µg/kg body weight, major accumulation sites were bone, marrow, spleen, testes, and epididymis (Langard and Norseth 1979). Female rats given a single intravenous injection of radiochromium-51 depurated the isotope primarily by urinary clearance, and secondarily by fecal and residual clearances over an 11-day period. Retained radiochromium-51 accumulated over time in bone, kidney, spleen, and liver (Onkelinx 1977). For multicompartmental excretion patterns recorded in rats, biological half-lives of the three components were estimated to be 0.5, 5.9, and 83.4 days; in mammals, chromium is excreted primarily in urine (Langard and Norseth 1979). At least three distinct Cr⁺⁶ excretion patterns exist in rats:

- Blood has a single component, with a biological half-life of 13.9 days
- Testes, brain, kidney, and lung have two components
- Liver has three components with half-lives of 2.4 h, 52.8 h, and 15.7 days (Yamaguchi et al. 1983).

Excretion patterns for Cr⁺³ in rats were unpredictable and difficult to calculate (Yamaguchi et al. 1983). The excretion patterns for fecal chromium among 40 grazing Angus cows given 20 g dietary Cr₂O₃ (13.6 g Cr⁺³) daily for 72 days was diurnal; excretion was lowest at 8 p.m. and highest at 9 a.m. (Hopper et al. 1978).

2.7 FIELD INVESTIGATIONS

There is a wealth of data concerning the effects of chromium on living organisms under laboratory conditions simulating those encountered in the vicinity of high chromium discharges and accumulations typical of electroplating plants, tanneries, ocean dumping sites, and municipal waste outfalls. However, little research has been conducted under actual field conditions, except in three general fields: occupational exposures of humans in the chromate industry (discussed earlier),

accidental poisoning of livestock resulting from oil field activities, and chromium accumulations in ecosystems impacted by discharges associated with cooling waters or cooling towers.

All cases of accidental chromate poisoning in cattle have resulted from the exposure of animals to chromate compounds associated with oil field activities. Chromates are used as a corrosion inhibitor between the pipe and casing and are often added to drilling fluids (in the form of chromelignosulfonate) to improve thermal stability. One recorded case involved 20 mature cows and their 8-month-old calves, grazing in a native pasture where an oil well had just been completed. One cow and calf died and another cow and calf became uncoordinated and thin, and the feces contained bloody mucus. The calf soon died. The cow aborted, but appeared to recover completely. Liver from the dead calf had 14.8 mg Cr/kg fresh weight vs. 1.8 in controls; levels of arsenic and lead were not elevated (Reagor and McDonald 1980). The cause of death was the consumption by the animals of concentrated sodium chromate found near the well site. In other cases, 2 of 80 heifers died after consuming concentrated zinc chromate, and 10 cows and one calf died after they had ingested ammonium chromate. In poisoned cows, chromium concentrations were 500 mg/kg in stomach contents, 15.8 mg/kg fresh weight in kidney vs. 3.0 mg/kg in controls, and 1.1 mg/L in blood vs. 0.02 mg/L for controls (Kerr and Edwards 1981).

Chromium is widely used as a corrosion inhibitor in cooling waters by the electric power industry. Its use in this capacity involves addition of a Cr⁺⁶ salt, typically sodium dichromate, which forms an oxide on metal surfaces. Chromates are subsequently released to surface waters in high concentrations, compared with background levels of chromium in most freshwaters. In White Oak Lake (eastern Tennessee), which received chronic inputs of chromates from cooling towers located on two tributary streams, typical Cr⁺⁶ concentrations of 3 to 10 mg/L in waste effluents produced 100 to 300 µg/L of Cr⁺⁶ in White Oak Lake vs. 5 µg/L in a control area (Elwood et al. 1980). Concentrations of chromium in muscle of bluegills and largemouth bass from White Oak Lake did not differ significantly from those in fish from a control site — suggesting that these species either effectively regulated chromium concentration or that the elevated chromium levels in White Oak Lake (where 20 to 73% of the total chromium was Cr⁺⁶) were in a form that was unavailable for absorption into tissues. Elwood et al. (1980) suggested that chromium is an element with a determinant concentration in fish, and that accumulation is independent of environmental concentration. This concept requires validation. Noteworthy is the observation that chromium concentrations were lower in muscle and body of older freshwater teleosts — an observation consistent with the findings of Eisler (1984), who noted that liver chromium decreased with increasing age in marine teleosts.

Cooling towers of uranium enrichment facilities and gaseous diffusion plants, similar to those of 1000-MW conventional steam electric stations, contain a chromate zinc-phosphate compound to inhibit corrosion and fouling within the cooling system. A small fraction of the cooling water, containing about 20 mg Cr⁺⁶/L, becomes entrained within the exit air flow and is deposited as drift on the landscape, together with other salts found in the recirculating water system, such as sodium pentachlorophenate, chromated copper arsenate, and acid copper chromate. Effects of the chromium component on biological systems have been under investigation in Kentucky and Tennessee for many years (Taylor and Parr 1978; Taylor 1980; Taylor et al. 1975, 1979, 1983). Analysis of vegetation along distance gradients from the cooling towers identified areas of significant drift deposition, accumulation, and magnitude of atmospheric transport over the landscape. At 13 m downwind from the point source, plant foliar concentrations of chromium were highest in winter at 1390 mg/kg dry weight, decreasing to 190 in spring, and to 173 in summer as the demand for cooling — and hence the operation time of the facility — decreased. Decreased accumulations on foliage probably reflected high mobility due to leaching, and the short life span of individual leaves. In contrast, chromium concentrations in plant litter at 13 m increased from 894 mg/kg dry weight during winter to 1890 mg/kg in summer and 2140 mg/kg in autumn. Accumulation of chromium in the litter was probably related to the higher surface-to-volume ratio in the litter biomass resulting from seasonal senescence of foliage. Taylor and his coworkers emphasized that no adverse biological

effects were observed in native vegetation bearing high chromium residues. Concentrations in plants and litter decreased with increasing distance from the cooling towers: concentrations in foliage at 168, 530, and 923 m downwind were 157, 10, and 1.3 mg/kg (dry weight), respectively; for litter, these values were 421, 24, and 5.8. Potted tobacco plants (*Nicotiana tabacum*) proved to be sensitive indicators of chromium contamination. Tobacco plants placed 15 m from the towers contained 30 times background levels after 1 week and up to 237 mg/kg dry weight in 5 weeks; in plants placed 200 m downwind, leaf growth was reduced 75% after 7 weeks. Beetles and crickets collected near the towers contained 9 to 37 mg Cr/kg in gut contents (vs. 0.5 to 0.8 mg/kg for controls); however, assimilation rates were not measured. Cotton rats (*Sigmodon hispidus*) trapped in a fescue field adjacent to a large mechanical draft cooling tower contained up to 10 times more chromium in hair, pelt, and bone than controls, but accumulations were negligible in viscera and other internal organs. Licking of the coat by rats appeared to be a primary route of chromium uptake — a likelihood confirmed experimentally by Langard and Nordhagen (1980). Feeding of radiochromium-51 to cotton rats demonstrated low assimilation (0.8%) and rapid initial loss of Cr⁺⁶ (99% in 1 day) — suggesting that chromium is neither essential to cotton rats nor accumulated to any great extent through ingestion of drift-contaminated vegetation or inhalation of drift-contaminated air (Taylor 1980). Biological half times of chromium assimilated by man and cotton rats were similar: 616 and 693 days, respectively. The magnitude of the half times suggests that chromium derived from a chromate has a high potential for biological interaction, but that fractional assimilation is very low — thus reducing the likelihood of toxic effects.

Chromium does not appear to biomagnify in aquatic or terrestrial food chains. In virtually all studies in both marine and freshwater environments involving birds and mammals there was no biomagnification of chromium in the food web, but rather decreasing concentrations with increasing trophic level (Outridge and Scheuhammer 1993). Similar results were reported in freshwater and marine food webs involving invertebrates and fishes, and along the terrestrial food chain of soil–plant–animal (Holdway 1988; USPHS 1993).

Biomarkers that demonstrate chromium exposure under field conditions is under active investigation. Laboratory studies with Prussian carp (*Carassius auratus gibelio*) exposed for 3 to 9 days to 25 to 100 µg Cr⁺⁶/L or 50 to 200 µg Cr⁺³/L show a dose-dependent increase in the frequency of micronuclei in erythrocytes, and this increase is considered indicative of increasing DNA damage (Al-Sabti et al. 1994). Similar increases in micronuclei were observed in Prussian carp from the River Ljubjanica near chromium-containing outfalls from leather waste products in the Republic of Slovenia (Al-Sabti et al. 1994).

2.8 RECOMMENDATIONS

As reported here, sensitive species of freshwater aquatic organisms showed reduced growth, inhibited reproduction, and increased bioaccumulation at about 10.0 µg/L and higher of Cr⁺⁶, and other adverse effects at 30.0 µg/L and higher of Cr⁺³. Among marine organisms, measurable accumulations were recorded in oysters and worms at 5.0 µg/L of Cr⁺⁶, algal growth was reduced at 10.0 µg/L, and reproduction of polychaete annelid worms was inhibited at 12.5 µg/L; in all situations, Cr⁺³ was less damaging than Cr⁺⁶. For mammals, 5.1 mg Cr⁺⁶/kg dietary levels in food and water of mice was associated with elevated tissue residues. The significance of chromium residues is unclear, but available evidence suggests that organs and tissues of fish and wildlife that contain 4.0 mg total Cr/kg dry weight and higher should be viewed as presumptive evidence of chromium contamination. Aerosol concentrations in excess of 10.0 µg Cr⁺⁶/m³ are potentially harmful to human health; in the absence of supporting data, this value is recommended for protection of sensitive species of wildlife, especially migratory waterfowl. More research is recommended on carcinogenic and mutagenic properties of chromium on fish (Holdway 1988), and on algal and bacterial physiology (Wong and Trevors 1988).

The U.S. Public Health Service (USPHS 1993) recommends that occupational exposure to hexavalent chromium compounds should not exceed 1 µg/m³ air for a 10-h workday and 40-h workweek because all hexavalent chromium compounds are potential carcinogens. Other recommendations include more research on:

1. The nature of speciation of chromium in soil and water
2. Bioavailability of chromium compounds from environmental media
3. Food chain biomagnification
4. Release data of chromium from anthropogenic sources to the biosphere
5. Reliable and more recent monitoring data of chromium in air, water, and food, with emphasis on chromium levels in tissues and body fluids of animals living near hazardous waste sites
6. Methods for determining biomarkers of exposure and effect, for determining parent compounds and degradation products in environmental media (USPHS 1993)

Proposed criteria for the protection of various environmental compartments against chromium are numerous, disparate, and often contradictory (Table 2.6). Some of this confusion may be attributable to the general lack of confidence in analyses of chromium residues conducted some years ago, and some to the continued inability to quantify chemical species and ionic states of chromium. Uncertainties about the metabolic role of organochromium compounds, water-soluble Cr⁺³ species, and their interactions with other components in complex and potentially toxic mixtures, further confound the issue. The essentiality of chromium to some, but not all, species of mammals is recognized, but comparable data for other groups of organisms are missing. Finally, the wide range in sensitivities and accumulation rates documented between different taxonomic groups, and even among closely related species, to Cr⁺³ and Cr⁺⁶ salts merits elucidation.

Table 2.6 Proposed Chromium Criteria for Protection of Human Health and Natural Resources

Category and Criterion (units in parentheses)	Chromium Concentration	Reference ^a
FRESHWATER AQUATIC LIFE PROTECTION; WATER (µg/L)		
USA	<0.29 Cr ⁺⁶ as 24 h average; not to exceed 21 Cr ⁺⁶ at any time	1
Water hardness, in mg CaCO ₃ /L		
50	<2200 Cr ⁺³ at any time	1
100	<4700 Cr ⁺³ at any time	1
200	<9900 Cr ⁺³ at any time	1
Colorado	<25 Cr ⁺⁶ ; <100 Cr ⁺³	2
Florida		
Effluent discharges	<500 Cr ⁺⁶ ; <1000 total chromium	2
Recovery waters	<50 total chromium	
Indiana		
Most waters	Not to exceed 0.1 times the 96-h LC50 of aquatic species	2
Lake Michigan	<50 total chromium	2
Canada	<10 Cr ⁺⁶	8
MARINE AQUATIC LIFE PROTECTION; WATER (µg/L)		
USA	<18 Cr ⁺⁶ as 24-h average; not to exceed 1260 Cr ⁺⁶ at any time	1
USA	Insufficient database for Cr ⁺³ at this time, but presumably less stringent than Cr ⁺⁶	1
California	<2 total chromium, 6 month median; <8 total chromium, daily maximum; <20 total chromium, instantaneous mix	2

2.9 SUMMARY

Most authorities agree on eight points:

1. Chromium levels are elevated in soil, air, water, and biota in the vicinity of electroplating and metal-finishing industries, publicly owned municipal treatment plants, tanneries, oil drilling operations, and cooling towers
2. Hexavalent chromium (Cr^{+6}) is the most biologically active chromium chemical species, although little is known about the properties of organochromium compounds, water-soluble species, or their interactions in complex mixtures
3. Chromium chemistry is imperfectly understood, and existing analytical methodologies are inadequate for quantification of chromium species and ionic states
4. Trivalent chromium (Cr^{+3}) is an essential trace element in humans and some species of laboratory animals, but the database is incomplete for other groups of organisms
5. At high environmental concentrations, chromium is a mutagen, teratogen, and carcinogen
6. No biomagnification of chromium has been observed in food chains, and concentrations are usually highest at the lowest trophic levels
7. Toxic and sublethal properties of chromium are modified by a variety of biological and abiotic factors
8. Sensitivity to chromium varies widely, even among closely related species

As reported here, adverse effects of chromium to sensitive species have been documented at 10.0 µg/L (ppb) of Cr^{+6} and 30.0 µg/L of Cr^{+3} in freshwater and 5.0 µg/L of Cr^{+6} in saltwater and, to wildlife, 10.0 mg of Cr^{+6} per kilogram of diet (ppm). Tissue levels in excess of 4.0 mg total Cr/kg dry weight should be viewed as presumptive evidence of chromium contamination, although the significance of tissue chromium residues is unclear. Some of these findings are in sharp contrast to chromium criteria proposed by regulatory agencies.

CHAPTER 3

Copper

3.1 INTRODUCTION

Copper (Cu) is plentiful in the environment and essential for the normal growth and metabolism of all living organisms (Schroeder et al. 1966; Carbonell and Tarazona 1994). Abnormal levels of copper intake may range from levels so low as to induce a nutritional deficiency to levels so high as to be acutely toxic (U.S. Environmental Protection Agency [USEPA] 1980). Copper is probably the first metal worked by humans some 70 to 80 centuries ago (Schroeder et al. 1966). The earliest known artifacts of hammered copper date from about 6000 BCE. After 4000 BCE, melting and casting of copper was common in the Near East. Smelting was developed about 3000 BCE and bronze around 2500 BCE. Brass, a copper alloy, was developed in Roman times. Copper derives from the Latin *cuprum*, a corruption of *cyprium* — Cyprus being the source of Egyptian and Roman copper (Schroeder et al. 1966). Copper was identified in terrestrial plants in 1817 (Gallagher 1979), in marine invertebrates in 1833 (Schroeder et al. 1966), in vertebrates in 1838 (Gallagher 1979), and in hemocyanin — the blue respiratory pigment of molluscs and crustaceans — in 1880 (Schroeder et al. 1966). But the metabolic importance of copper in plants and animals was not suspected until the 1920s when diseases due to copper deficiency began to be recognized (National Academy of Sciences [NAS] 1977; Gallagher 1979). Copper deficiency in vertebrates, for example, is associated with anemia, gastrointestinal disturbances, aortic aneurisms, bone development abnormalities, and death (Aaseth and Norseth 1986).

Copper toxicosis in terrestrial higher plants is rare but occurs on mine spoils and where copper-rich manures or fungicides are used excessively (Schroeder et al. 1966; NAS 1977; Alva et al. 1995; Arduini et al. 1995). Copper is among the most toxic of the heavy metals in freshwater and marine biota (Schroeder et al. 1966; Betzer and Yevich 1975) and often accumulates and causes irreversible harm to some species at concentrations just above levels required for growth and reproduction (Hall et al. 1988). Birds and mammals, when compared to lower forms, are relatively resistant to copper, but diets containing elevated concentrations of copper are sometimes fatal to ducklings (Wood and Worden 1973) and livestock when fed for extended periods. Domestic sheep (*Ovis aries*) are the most susceptible farm animals to chronic copper poisoning, and effects include liver damage, impaired reproduction, reduced resistance to diseases, jaundice, and death (Gopinath and Howell 1975; Higgins 1981; Bires et al. 1993).

Many reviews and annotated bibliographies are available on copper ecology and toxicology, including those by Eisler (1973, 1979, 1998), Eisler and Wapner (1975), NAS (1977), Eisler et al. (1978, 1979), Nriagu (1979a, 1979b), USEPA (1980), Aaseth and Norseth (1986), and Agency for Toxic Substances and Disease Registry [ATSDR] (1990).

3.2 SOURCES AND USES

3.2.1 General

The United States is the major world producer and consumer of copper and its compounds. Most of the copper produced is used to manufacture electrical equipment, pipe, and machinery. Releases of copper to the global biosphere — which may approach 1.8 million metric tons per year — come mostly from anthropogenic activities such as mining and smelting, industrial emissions and effluents, and municipal wastes and sewage sludge. Copper compounds are widely used as biocides to control nuisance algae and macrophytes, freshwater snails that may harbor schistosomiasis and other diseases, ectoparasites of fish and mammals, marine fouling organisms, and mildew and other diseases of terrestrial crop plants. Copper compounds are also used in agricultural fertilizers, in veterinary and medical products, in the food industry, and as a preservative of wood and other materials.

3.2.2 Sources

Global copper production during the past 60 centuries is estimated at 307 million metric tons, most of which (79%) has occurred since 1900; annual global production of copper is now estimated at 13.6 million tons (Nriagu 1979c). Copper occurs naturally in many minerals and as uncombined metal. The three most important sources of copper are chalcocite (Cu_2S), chalcopyrite (CuFeS_2), and malachite ($\text{CuCO}_3 \cdot \text{Cu}(\text{OH})_2$; ATSDR 1990).

In 1986, domestic consumption of copper in the United States was 2.14 million metric tons, and mine production was 1.14 million metric tons, mostly from mines in Arizona, New Mexico, and Michigan. The major copper deposits in the United States are of hydrothermal origin and are uniformly distributed in fractures or veins (ATSDR 1990). Copper is the major toxic component in streams impacted by active placer mines (Buhl and Hamilton 1990). About 60% of copper metal is eventually recycled; in 1986, smelting of scrap copper produced an additional 0.9 million metric tons of copper. Also in 1986, 1.1 million tons of copper were imported into the United States, mostly from Canada, Chile, Peru, and Mexico (ATSDR 1990).

The amount of copper entering the global ecosystem annually is unknown, but estimates range from 211,000 metric tons (Nriagu 1979c) to 1.8 million metric tons (NAS 1977). About 80.7% of this copper is deposited in terrestrial compartments, 15.7% in the hydrosphere, and 3.6% to the atmosphere (Nriagu 1979c). The residence time for copper in the deep ocean is 1500 years; in soils it may be retained for as long as 1000 years; in air, copper persists for about 13 days (Nriagu 1979c). Copper in the atmosphere results mainly (73%) from human activities such as copper production and combustion of fossil fuels; the remainder is from natural sources that include seasalt sprays, windblown dusts, volcanic particles, and decaying vegetation (Nriagu 1979c, 1979d).

Input of copper into aquatic ecosystems has increased sharply during the past century and includes inputs from waste discharges into saline waters, industrial discharges into freshwater, and leaching of antifouling marine paints and wood preservatives (Nriagu 1979c). Present anthropogenic inputs of copper are two to five times higher than natural loadings. The atmosphere is a primary recipient of these inputs (Nriagu 1979d). In mining and industrial areas, precipitation of atmospheric fallout is a significant source of copper to the aquatic environment (USEPA 1980). More than 99.9% of oceanic copper falls as clay and manganese oxide particles in precipitation (NAS 1977). In the lower Great Lakes, direct atmospheric inputs of copper — in metric tons per year — range from 55 to 2300 for Lake Michigan, 120 to 330 for Lake Erie, and 72 to 123 for Lake Ontario. Regional disparities in atmospheric deposition of copper are related to the intensity of industrial activity and to the regional wind systems (Nriagu 1979d).

Copper in soils may come from a variety of anthropogenic sources:

- Mining and smelting activities
- Other industrial emissions and effluents
- Traffic
- Fly ash
- Dumped waste materials
- Contaminated dusts and rainfall
- Sewage and sludge
- Pig slurry
- Composted refuse
- Agricultural fertilizers, pesticides, and fungicides (Nriagu 1979c; Thornton 1979; Ma 1984; ATSDR 1990; Roncero et al. 1992; Alva et al. 1995).

In the case of Florida citrus groves, copper-containing fertilizers applied during the early 1900s accounted for as much as 34 kg Cu/ha annually, and routine fungicidal sprays contributed another 10 kg Cu/ha annually. Surface soils (0 to 15 cm) from some mature citrus groves contained as much as 540 kg Cu/ha (Alva et al. 1995). Copper deposition rates in soils are higher in cities and near highways, railroads, power plants, and industrial activities (Nriagu 1979d), but a Kansas landfill near a freshwater stream had no significant effect on copper concentrations in water, sediments, crayfish, and sunfish (Morrissey and Edds 1994).

3.2.3 Uses

Metallic copper end uses include electrical (70%), construction (15%), machinery (6%), transportation (4%), and ordnance (2%). The top domestic markets for copper and its alloys in 1986 were, in order of importance, plumbing, building wire, telecommunications, power utilities, in-plant equipment, air conditioning, automotive electrical, automotive nonelectrical, business electronics, and industrial valves and fittings (ATSDR 1990). A small percentage of copper production is used to manufacture chemicals, mainly copper sulfate. Of the copper sulfate used domestically, 65% is used in agriculture for fungicides, algicides, nutritional supplements, insecticides, and repellents; 28% is used industrially in froth flotation production of chromated copper arsenate wood preservatives, in electroplating, and in the manufacture of azo dyes; and 7% is used in water treatment to control nuisance algae (ATSDR 1990).

Copper is widely used to control unwanted species of freshwater algae and macrophytes (Bartley 1967; NAS 1977; USEPA 1980; Rowe and Prince 1983; Havens 1994). Chelated copper products are claimed to be effective algicides in hard water. The chelation of copper by organic compounds, such as ethanolamines or ethanalamine complexes, protects copper from precipitation and complexation (Straus and Tucker 1993). Copper sulfate is approved by the U.S. Environmental Protection Agency (USEPA) as an algicide in waters used to raise fish for human consumption (Straus and Tucker 1993). In algae, copper inhibits photosynthesis, nitrogen fixation, and phosphorus uptake. It selectively eliminates cryptophytes but spares diatoms (Havens 1994). Copper sulfate at low concentrations has been used to control freshwater algae in Wisconsin since 1918 without any conclusively proven effect on diversity or abundance of nontarget species (Mackenthun and Cooley 1952). But reduced abundance of freshwater benthos was noted in Lake Monona, Wisconsin, which received 771 metric tons of copper to control algae over a 26-year period and had sediment levels as high as 1093 mg Cu/kg DW (Mackenthun and Cooley 1952). Copper sulfate used to control algal blooms in Wisconsin lakes at 1.25 mg Cu/L killed nontarget fishes, crustaceans, snails, and amphibians in 14 days or less. However, 0.25 mg Cu/L was not fatal to these species in 20 days (Hasler 1949). Concentrations as low as 0.03 mg Cu/L inhibited growth in two of four species of nuisance aquatic weeds in Lake Mendota, Wisconsin, and 0.3 mg Cu/L was fatal to all four species (Hasler 1949). Copper sulfate controls algae in cranberry bogs at 0.4 mg Cu/L, but this concentration

also kills resident fishes (Deubert and Demoranville 1970). Copper was not measurable in the surface waters of cranberry bogs within 10 days of treatment, regardless of initial copper concentration; it is probable that copper was adsorbed onto bog soils (Deubert and Demoranville 1970). In England, copper sulfate was effective at 1.0 mg Cu/L in controlling algae and most species of aquatic weeds for 1.6 km downstream of treatment for 6 months during the summer; only 0.25 mg Cu/L was necessary in autumn and winter for effective aquatic weed control (Chancellor et al. 1960). During copper treatment to control plants, aquatic snails were greatly reduced or eliminated, but fishes seemed unaffected. Sensitive aquatic weeds included *Myriophyllum spicatum*, *Elodea canadensis*, *Potamogeton* spp., and *Lemna minor*; sensitive genera of algae included *Oedogonium*, *Spirogyra*, *Enteromorpha*, and *Mougeotia* (Chancellor et al. 1960).

In California, 4.23 million kg of copper compounds are used each year in agriculture, of which almost 1.4 million kg are applied as copper sulfate pentahydrate to flooded rice fields for control of algae and tadpole shrimp (Crosby 1999). Most of the copper precipitates as copper hydroxycarbonate within the first hour, with negligible loss to the atmosphere or from runoff. The remainder in rice field water is complexed with dissolved organic matter and is biologically unavailable to algae and shrimp. However, the major part accumulates in the soil, where it presents a threat to future plant agriculture at that site, although intentional mobilization may be possible (Crosby 1999).

In Iowa lakes, copper sulfate was used to control summer blooms of various species of toxic blue-green algae. Prior to treatment, blooms of *Anabaena flos-aquae*, *Aphanizomenon flos-aquae*, and *Microcystis aeruginosa* were associated with deaths of migratory waterfowl, game birds, songbirds, game, and domestic animals (Rose 1954). Most of these species of algae were controlled within 24 h by 1.0 mg Cu/L as copper sulfate. Copper treatment had no adverse effects on bottom fauna, but populations of crustaceans (daphnids, copepods, entomostracans) were reduced. One year after treatment, no deaths of birds or mammals were recorded (Rose 1954).

Copper salts are intentionally added to drinking water supplies of some municipalities to control growth of algae; concentrations as high as 59 µg Cu/L are maintained in New York City (USEPA 1980).

Copper compounds are used routinely and widely to control freshwater snails that serve as intermediate vectors of schistosomiasis and other diseases that afflict humans (Hasler 1949; NAS 1977; Rowe and Prince 1983; Winger et al. 1984; Al-Sabri et al. 1993). These compounds include copper sulfate, copper pentachlorophenate, copper carbonate, copper-tartaric acid, Paris green (copper arsenite-acetate), copper oxide, copper chloride, copper acetyl acetone, copper dimethyl dithiocarbamate, copper ricinoleate, and copper rosinate (Cheng 1979). Also, many species of oyster enemies are controlled by copper sulfate dips. All tested species of marine gastropods, tunicates, echinoderms, and crabs that had been dipped for 5 seconds in a saturated solution of copper sulfate died if held in air for as little as a few seconds to 8 h; mussels, however, were resistant (MacKenzie 1961).

Copper sulfate is used to control protozoan fish ectoparasites including *Ichthyophthirius*, *Trichodina*, and *Costia*. The effectiveness of the treatment diminishes with increasing total alkalinity and total hardness of the water (Straus and Tucker 1993). Copper compounds now used to control protozoan parasites of cultured red drum (*Sciaenops ocellatus*) include copper sulfate, copper sulfate plus citric acid, and chelated copper compounds (forms of copper bound by sequestering agents, such as ethanolamine); chelated copper compounds are considered less toxic to fish than copper sulfate and at least as effective in controlling parasites (Peppard et al. 1991).

Copper is the active agent in many antifouling paints applied to watercraft (Aaseth and Norseth 1986; Hall et al. 1988). The growing use of copper-based paints subsequent to the prohibition in 1982 of tributyltin-based paints (Hall et al. 1988) is associated with elevated copper concentrations in Pacific oysters (*Crassostrea gigas*) farmed in the Bay of Arcachon, France (Claisse and Alzieu 1993).

Copper compounds are used in agriculture to treat mildew and other plant diseases; in the food industry as preservatives, additives, or coloring agents; in preservatives of wood, leather, and fabrics; in coin manufacture; and in water treatment (ATSDR 1990; Roncero et al. 1992). The use of copper-containing pesticides is traditional along the Mediterranean Coast, especially the use of Bordeaux mixture, a copper sulfate-based fungicide that has been widely used for more than a century to

prevent mildew on grape vines (Romeu-Moreno et al. 1994). However, at current application rates of about 0.8 mg Cu/cm², Bordeaux mixture significantly reduces the life span and breeding rate of the fruit fly (*Drosophila melanogaster*) (Marchal-Segault et al. 1991).

Copper is widely used in veterinary clinics in medical products (Roncero et al. 1992). Copper sulfate is used by veterinarians to treat cattle and sheep for helminthiasis and infectious pododermatitis (NAS 1977). Cuprol (a 1% solution of cupric oleinate) is used to control lice (Aaseth and Norseth 1986). Copper is routinely used as a growth supplement in the diets of swine (*Sus* sp.) in the United Kingdom and elsewhere; diets may contain as much as 250 mg Cu/kg ration (USEPA 1980). The intensity of pig farming within about 10 km from the coast may influence copper content in estuarine sediments. For example, intensive pig farming in coastal Brittany, France, increased soil copper concentrations by 0.6 kg/ha annually and increased coastal sediment copper concentrations to as high as 49.6 mg/kg DW (Arzul and Maguer 1990).

In human medicine, metallic copper is used in some intrauterine devices, and various copper compounds are used as emetics and to treat rheumatoid arthritis (USEPA 1980; Aaseth and Norseth 1986). Some individuals wear copper bracelets as treatment for arthritis although its therapeutic value has little support (USEPA 1980).

3.3 CHEMICAL AND BIOCHEMICAL PROPERTIES

3.3.1 General

This section demonstrates that (1) free ionic copper (Cu²⁺) is the most toxic chemical species of copper and that copper bioavailability is modified by many biological and abiotic variables; (2) copper metabolism and sensitivity to copper of poikilotherms differs from that of mammals; and (3) copper interactions with inorganic and organic chemicals are substantial and must be considered when evaluating copper hazards to natural resources.

3.3.2 Chemical Properties

Copper is a soft heavy metal, atomic number 29, a density in elemental form at 20°C of 8.92 g/cc and a melting point of 1083.4°C (USEPA 1980; Aaseth and Norseth 1986; [Table 3.1](#)). Copper has two natural isotopes: Cu-63 (69.09%) and Cu-65 (30.91%) (NAS 1977).

Table 3.1 Some Properties of Copper and Copper Sulfate

Property	Copper	Copper Sulfate
Chemical and other names	Copper	Cupric sulfate, blue vitriol, cupric sulfate, Roman vitriol, Salzburg vitriol, blue copperas, copper (II) sulfate
Chemical formula	Cu	CuSO ₄
Oxidation state	0	2+
CAS (Chemical Abstract Services) number	7440-50-8	7758-98-7
Molecular weight	63.546	159.60
Color and form	Reddish solid	Blue crystals
Melting point	1083.4°C	Decomposes slightly at >200°C
Boiling point	2567°C	Decomposes to CuO at 650°C
Density	8.92	3.603
Solubility		
Water	Insoluble	143 g/L
Organic solvents	Insoluble	Soluble in methanol, slightly soluble in ethanol

From Agency for Toxic Substances and Disease Registry (ATSDR). 1990. Toxicological Profile for Copper. U.S. Pub. Health Serv., Atlanta, Georgia, TP-90-08. 143 pp.

Copper exists in four oxidation states: Cu⁰, Cu⁺¹, Cu⁺², and Cu⁺³ (ATSDR 1990). Elemental copper (Cu⁰) is readily attacked by organic and mineral acids that contain an oxidizing agent and is slowly soluble in dilute ammonia; halogens attack elemental copper slowly at room temperature to yield the corresponding copper halide (USEPA 1980). Elemental copper is not oxidized in water (Aaseth and Norseth 1986). Cuprous copper (Cu⁺¹) exists only in water solution when complexed, usually in a tetrahedral form, with affinity for sulfur and nitrogen ligands (Schroeder et al. 1966). Cuprous copper is unstable in aerated aqueous solution over the pH range 6 to 8 and will undergo auto-oxidation-reduction into elemental copper (Cu⁰) and cupric ion (Cu⁺²) (USEPA 1980; Aaseth and Norseth 1986). The only cuprous ion (Cu⁺¹) compounds that are stable in water are extremely insoluble ones such as cuprous chloride, CuCl (ATSDR 1990). Cuprous ion-complexes may be formed in seawater by photochemical processes and persist for several hours. The cupric ion (Cu⁺²) is the one generally encountered in water. Cupric ions are coordinated with six water molecules in solution (ATSDR 1990). Cupric ion ordinarily forms planar, less stable chelates with nitrogen and oxygen ligands (Schroeder et al. 1966). In seawater and sediment interstitial waters, the free cupric ion (Cu⁺²) is the most readily available and toxic inorganic species of copper; however, the free ion concentration is sensitive to complexation and is less available to aquatic biota in the presence of natural organic chelators and high salinities (Bryan and Langston 1992). Cupric ions account for about 1% of the total dissolved copper in seawater and less than 1% in freshwater (Boyle 1979). Trivalent copper (Cu⁺³) probably does not occur naturally (Schroeder et al. 1966). It is strongly oxidizing and occurs only in a few compounds; none of these compounds is now considered industrially important or environmentally significant (ATSDR 1990).

Copper speciation in freshwater is figured in detail by Leckie and Davis (1979). In freshwater, the solubility of copper salts is decreased under reducing conditions and is further modified by water pH, temperature, and hardness; size and density of suspended materials; rates of coagulation and sedimentation of particulates; and concentration of dissolved organics. The chemical form of copper in freshwater is important in controlling geochemical and biological processes. But the lack of knowledge on the adsorption characteristics of most cupric (Cu⁺²) ion complexes contributes to uncertainties about the behavior of known copper species (Leckie and Davis 1979). Ionic copper (Cu⁺²) and some copper hydroxyl species are correlated with high toxicity to aquatic life; however, carbonato species (CuHCO₃⁺, CuCO₃, Cu(CO₃)₂⁻) are much less toxic than other copper complexes (Meador 1991). The major chemical species of copper in freshwater are Cu(CO₃)₂⁻ and CuCO₃ (Boyle 1979). Cupric ion is the dominant toxic copper species at pH less than 6; the aqueous copper carbonate complex is dominant from pH 6.0 to 9.3 (USEPA 1980). This equilibrium is altered in the presence of humic acids, fulvic acids, amino acids, cyanide, certain polypeptides, and detergents (USEPA 1980). Most cupric salts dissolve readily in freshwater to produce the aquo ion, Cu(H₂O)₆⁺² (Leckie and Davis 1979). Divalent copper chloride, nitrate, and sulfate are highly soluble in water (USEPA 1980; Table 3.1), but copper carbonate, cupric hydroxide, cupric oxide, and cupric sulfide will precipitate from solution or form colloidal suspensions when excess cupric ions are present (USEPA 1980).

In seawater, the major chemical species of copper are Cu(OH)Cl and Cu(OH)₂ and these account for about 65% of the total copper in seawater (Boyle 1979). The levels of copper hydroxide (Cu(OH)₂) increase from about 18% of the total copper at pH 7.0 to 90% at pH 8.6; copper carbonate (CuCO₃) dropped from 30% at pH 7.0 to less than 0.1% at pH 8.6 (USEPA 1980). The dominant copper species in seawater over the entire ambient pH range are copper hydroxide, copper carbonate, and cupric ion (USEPA 1980). Bioavailability and toxicity of copper in marine ecosystems is promoted by oxine and other lipid soluble synthetic organic chelators (Bryan and Langston 1992).

Copper concentrations in sediment interstitial pore waters correlate positively with concentrations of dissolved copper in the overlying water column and are now used to predict the toxicity of test sediments to freshwater amphipods (Ankley et al. 1993). Sediment-bound copper is available to deposit-feeding clams, especially from relatively uncontaminated anoxic sediments of low pH (Bryan and Langston 1992). The bioavailability of copper from marine sediments, as judged by increased copper in sediment interstitial waters, is altered by increased acid volatile sulfide (AVS)

content (Casas and Crecelius 1994). But acid volatile sulfide is not an appropriate partitioning phase for predicting copper bioavailability of freshwater sediments (Ankley et al. 1993).

3.3.3 Metabolism

Copper is part of several essential enzymes including tyrosinase (melanin production), dopamine beta-hydroxylase (catecholamine production), copper-zinc superoxide dismutase (free radical detoxification), and cytochrome oxidase and ceruloplasmin (iron conversion) (Aaseth and Norseth 1986). All terrestrial animals contain copper as a constituent of cytochrome *c* oxidase, monophenol oxidase, plasma monoamine oxidase, and copper protein complexes (Schroeder et al. 1966). Excess copper causes a variety of toxic effects, including altered permeability of cellular membranes. The primary target for free cupric ions in the cellular membranes are thiol groups that reduce cupric (Cu^{+2}) to cuprous (Cu^{+1}) upon simultaneous oxidation to disulfides in the membrane. Cuprous ions are reoxidized to Cu^{+2} in the presence of molecular oxygen; molecular oxygen is thereby converted to the toxic superoxide radical O^{-2} , which induces lipoperoxidation (Aaseth and Norseth 1986).

Aquatic Organisms — Bioavailability and toxicity of copper to aquatic organisms depends on the total concentration of copper and its speciation (Hung et al. 1990). In hard, moderately polluted waters, 43 to 88% of the copper is associated with suspended solids and not available to biota (Shaw and Brown 1974). Copper toxicity to aquatic biota is related primarily to the dissolved cupric ion (Cu^{+2}) and possibly to some hydroxyl complexes (NAS 1977; Hall et al. 1988; Hung et al. 1990). Soluble copper is largely complexed with carbonate, amino acids, or humic substances. Cupric copper — one of the most toxic forms — constitutes 0.1 to 0.2% of this soluble material (Shaw and Brown 1974). The toxicity of copper in its complexed, precipitated, or adsorbed form is less than that of the free ionic form (Hall et al. 1988; Hung et al. 1990). In aquatic invertebrates, copper causes gill damage at high concentrations, and in fishes it interferes with osmoregulation (Hodson et al. 1979). Elevated concentrations of copper interfere with oxygen transport and energy metabolism; tissue hypoxia is the cause of death and is associated with reductions in the activities of regulatory enzymes of ATP-synthesizing pathways (Hansen et al. 1992b).

In freshwater algae, movement of copper into cells occurs mainly by physical transport; the plasmalemma is the initial site of copper binding. Copper on the plasmalemma increases its permeability, as shown by the leakage of potassium and other ions from copper-treated cells and entry of copper into intracellular sites (Stokes 1979).

Marine prosobranch gastropods, like several other groups of molluscs and arthropods, normally accumulate and store copper and use it in the synthesis of hemocyanin, a blood pigment (Betzer and Yevich 1975). In gastropods, copper may elicit secretions of mucus by goblet cells; bind to hydrophilic regions of the external membranes of epithelial cells, altering their biochemical and biophysical properties; or disrupt the normal functioning of peroxidase and ferritin (Cheng 1979). Peroxidation products, such as hydroperoxides and malondialdehyde, are toxic to vital functions of membranes and cells. Bivalve molluscs challenged with ionic copper show significant increases in these products (Chelomin and Belcheva 1992). Exposure of gastropods to high sublethal concentrations of copper completely inhibits succinic dehydrogenase activity at whole-body concentrations between 4.7 and 11.9 mg Cu/kg DW soft parts, causes a measurable decrease in heart beat rate, and adversely affects surface epithelia, especially those covering the head-foot and rectal ridge, disrupting osmoregulation and producing water accumulation in tissues (Cheng 1979). The primary lethal effect of copper in gastropod molluscs is caused by disruption of the transporting surface epithelium (Cheng 1979).

In crabs, the gills are a major target organ of copper toxicity; waterborne copper decreases hemocyanin–oxygen affinity (Truchot and Boitel 1992). Exposure of shore crabs (*Carcinus maenas*) to lethal concentrations of copper is associated with reductions in activity of glycolytic enzymes but, unlike fishes, did not involve cellular energy deprivation (Hansen et al. 1992b). Copper-tolerant

strains of aquatic mayflies (*Baetis thermicus*) have evolved in Japan. Tolerance is attributed to the ability to induce a metal-binding protein that preferentially sequesters copper over cadmium and zinc (Suzuki et al. 1989).

In fishes, the gill surface's low affinity for metal allows greater entry of the metal to the intracellular compartment. Once there, more complex binding sites are present. Binding to these ligands causes one or more of the following toxic mechanisms: (1) blocking of the essential biological functional groups of biomolecules; (2) displacing the essential metal ion in molecules; or (3) modifying the active conformation of biomolecules. These mechanisms may account for the specific inhibition of ion transport from ionic (Cu^{+2}) copper exposure (Reid and McDonald 1991). Studies with radiocopper-64 and rainbow trout (*Oncorhynchus mykiss*) show that the external gill epithelial surface has a relatively low affinity for copper, allowing copper to penetrate intracellular compartments. Copper disrupts gill function of rainbow trout by impairing transepithelial ion exchange, for example, impairing or upsetting electrolyte balance by inhibiting active uptake or stimulating passive loss (Reid and McDonald 1991). Copper toxicity to rainbow trout in hard water is related to the total concentration of soluble copper (copper carbonate, $CuCO_3$; cupric ion, Cu^{+2}) in the test medium rather than to either of these two forms alone (Shaw and Brown 1974). Long-term retention of copper accumulations in fish tissues is characterized by high half-time persistence after copper administration and binding of copper to proteins in a nonexchangeable or slowly exchangeable pool (Carbonell and Tarazona 1994).

Copper detoxifying mechanisms in fishes include the induction of metallothioneins, allowing copper retention for weeks or months after absorption without producing toxic effects (Hogstrand et al. 1991; Hylland et al. 1992; Carbonell and Tarazona 1994; Marr et al. 1995). Hepatic metallothionein contents of individual fishes usually reflect the accumulation of copper in that organ (Hogstrand et al. 1991). This strongly supports the use of metallothionein as an indicator of copper stress (Hogstrand 1991).

In tench (*Tinca tinca*), hepatic alterations observed after exposure to lethal concentrations of copper (75 mg/L for 4 to 12 days) include accumulation of various pigments in Kupffer cells and hepatocytes. Death was attributed to deficient oxygen transport and consumption and to the lytic effect of copper on various cell membranes, eventually causing massive necrosis in large areas of the liver parenchyma (Roncero et al. 1992). In rapidly growing juvenile flounders (*Paralichthys* spp.), copper blocks calcium transport, possibly through interference with gill chloride cells. Copper inhibition of calcium accumulation is alleviated by removing copper from the medium (Dodoo et al. 1992).

Mammals — Copper homeostasis plays an important role in the prevention of copper toxicity. After copper requirements are met, excess copper absorbed into gastrointestinal mucosal cells is bound to metallothionein and excreted when the cell is sloughed. Copper that eludes the intestinal barrier is stored in the liver or incorporated into bile and excreted in feces. The most likely pathway for the entry of toxic amounts of copper would be long-term inhalation or entry through the skin. Both of these pathways allow copper to pass unimpeded into the blood (ATSDR 1990). The levels of copper in the mammalian body are held constant by alterations in the rate and amount of copper absorbed, its distribution, and rate and route of excretion (ATSDR 1990). Many factors interfere with copper absorption, including competition for binding sites, as with zinc; chelation, as with phytates; and interaction with ascorbic acid, which aggravates copper deficiency by decreasing copper absorption and — with excess copper — reduces the toxic effects (USEPA 1980; ATSDR 1990).

Two inherited human diseases that represent abnormal copper metabolism are Menkes' syndrome and Wilson's disease. Menkes' syndrome, with symptoms similar to those of copper deficiency, is characterized by a progressive brain disease, abnormally low copper concentrations in liver and other tissues, and diminished ability to transfer copper across the absorptive cells of the intestinal mucosa (USEPA 1980; Aaseth and Norseth 1986). Wilson's disease (hepatolenticular degeneration) is the only significant example of copper toxicity in humans. Wilson's disease is an autosomal recessive disorder that affects normal copper homeostasis and is characterized by excessive

retention of hepatic copper, decreased concentration of serum ceruloplasmin, impaired biliary copper excretion, and hypercupremia. Systemic manifestations of Wilson's disease are hepatic and renal lesions and hemolytic anemia (Schroeder et al. 1966; Goresky et al. 1968; Baker 1969; USEPA 1980; Aaseth and Norseth 1986; ATSDR 1990). Certain strains of mutant rats with reduced excretion of biliary copper spontaneously develop hepatitis because of the extremely gross deposition of copper in the liver (Sugawara et al. 1994). Most humans afflicted with Wilson's disease usually die before puberty, although some survive to age 35 (Schroeder et al. 1966). Postmortems of Wilson's patients show that livers had as much as 7.5% copper and kidney ash had up to 2.7%. There is no evidence, however, that persons with normal homeostatic mechanisms are subject to any chronic degenerative disorders resulting from modern exposures to copper (Schroeder et al. 1966). Unusually susceptible human populations to copper poisoning include those afflicted with Wilson's disease, infants and children under one year of age, those with liver damage or chronic renal disease, individuals undergoing dialysis (excess copper in the dialysate), and those with an inherited deficiency of the enzyme glucose-6-phosphate dehydrogenase (ATSDR 1990).

Ingested copper travels through the gastrointestinal (GI) tract, where some of it is absorbed into the blood and becomes associated with plasma albumin and amino acids (Sugawara et al. 1994) or is used to maintain copper levels in erythrocytes (USEPA 1980). Albumin-bound copper is eventually transported to the liver; however, minor fractions are transported into the bone marrow, the erythrocytes, or other tissues (Aaseth and Norseth 1986). Most of the circulating copper is translocated within minutes. During the next few hours, blood copper concentrations increase, and Cu becomes an integral part of the ceruloplasmin molecule (Goresky et al. 1968). Gastrointestinal absorption is normally regulated by the copper status in the body. In general, up to 50% of small doses (i.e., less than 1 µg in rats) are absorbed, whereas large doses are absorbed to a lesser extent (Aaseth and Norseth 1986). In humans, about 40% of the dietary copper is absorbed (USEPA 1980). Absorbed copper is freely exchangeable with copper loosely bound to the alpha-globulin ceruloplasmin, where it is exchanged in the cupric form (Schroeder et al. 1966). Copper is stored mainly in liver, brain, heart, kidney, and muscle; in tissues and blood cells, copper is bound to proteins, including many enzymes (Aaseth and Norseth 1986). Amino acids facilitate the entry of Cu into liver cells, and a small proportion of copper in serum is bound to amino acids (Goresky et al. 1968). About 80% of the absorbed copper is bound to metallothionein in the liver; the remainder is incorporated into compounds such as cytochrome *c* oxidase (USEPA 1980; ATSDR 1990). Copper accumulations in animals are associated with increased number and increased size of copper-containing lysosomes in hepatocytes. In liver, copper is initially bound to a metallothionein-like, low-molecular-weight protein, and later it appears in a high-molecular-weight protein, ceruloplasmin, which reenters the circulation. Ceruloplasmin transports copper to tissues and also functions as an oxidase (Aaseth and Norseth 1986). The amount of copper absorbed is usually far in excess of metabolic requirements (Sugawara et al. 1994). Of the copper retained in the body, almost all plays a particular physiological role in the function of at least 12 specific copper proteins, such as cytochrome *c* oxidase and tyrosinase. Thus, only extremely small concentrations of free copper ions are normally found in body fluids (NAS 1977).

Retention of radiocopper injected into humans is high; only 10% is excreted within 72 h in urine and feces, and 50% in four weeks (Aaseth and Norseth 1986). Most (72%) of the unabsorbed copper is excreted in the feces primarily by way of the biliary duct, the salivary glands, or the intestinal mucosa; a minor portion is excreted by way of sweat and menses (Schroeder et al. 1966; USEPA 1980; ATSDR 1990). In mammals, copper is excreted mainly via the bile in association with glutathione or unidentified high-molecular-weight molecules. However, the transport mechanisms of copper from liver cells into bile are essentially unknown (Aaseth and Norseth 1986). In rats, biliary excretion of copper is increased by increased flow of bile, increased body temperature, or administration of adrenal steroids (Sugawara et al. 1994).

Mechanisms implicated in copper poisoning include free radical production, alteration in activities of several enzymes, and interference with metallothionein synthesis. At the cellular level,

copper has several primary mechanisms of toxicity that alter protein configuration and biological activity. These include the catalysis of peroxidation reactions and subsequent generation of free radicals that damage lipids and proteins, interactions with R groups of proteins — particularly SH groups, and acting as a substituent for other metals in metalloproteins (Sanders et al. 1994). Copper, in relative excess, is a cytotoxic metal with injury related to the process of lipid peroxidation. Isolated rat hepatocytes exposed to copper solutions for as long as 90 min show a concentration- and time-related decrease in cell viability as judged by loss of intracellular potassium and aspartate aminotransferase, an increase in lipid peroxidation, and a decrease in glutathione (Stacey and Klaassen 1981). Falling disease in cattle, dogs, and chickens is associated with a cardiovascular disorder caused by reduced activity of lysal oxidase, a Cu-requiring enzyme necessary for elastic tissue formation and maintenance (USEPA 1980). Metallothionein synthesis acts as a protective mechanism against buildup of excessive amounts of the essential, but potentially toxic, copper ions, possibly before the development of other control processes. In livers of newborn lambs, rabbits, mice, and hamsters, copper concentrations are usually directly related to the metallothionein content in cytoplasmic fractions (Bakka and Webb 1981). In sheep, elevated serum glutamic oxaloacetic transaminase (SGOT) levels were linked to elevated copper concentrations in blood at least 1 to 6 weeks before obvious external signs of copper poisoning. SGOT measurements in sheep serum seem to constitute an adequate early warning of the approach of the hemolytic crisis and eventual death of the animal from chronic copper poisoning (MacPherson and Hemingway 1969).

3.3.4 Interactions

Copper interacts with numerous compounds normally found in natural waters. The amounts of the various copper compounds and complexes present in solution depend on water pH, temperature, and alkalinity and on the concentrations of bicarbonate, sulfide, and organic ligands (USEPA 1980). In animals, copper interacts with essential trace elements such as iron, zinc, molybdenum, manganese, nickel, and selenium and also with nonessential elements including silver, cadmium, mercury, and lead; interactions may be either beneficial or harmful to the organism (Kirchgessner et al. 1979). The patterns of copper accumulation, metabolism, and toxicity from these interactions frequently differ from those produced by copper alone. Acknowledgment of these interactions is essential to understanding copper toxicokinetics.

Aluminum

Mixtures of copper and aluminum were more than additive in toxicity to ova of brown trout, *Salmo trutta* (Sayer et al. 1991)

Cadmium

Exposure of algae to low sublethal concentrations of copper (0.03 µg/L) increases their sensitivity toward additional copper challenge and to cadmium (Cd) salts (Visviki and Rachlin 1994a). In freshwater clams (*Anodonta cygnea*) exposed for 46 days to a mixture of high concentrations of copper (139 µg/L) and cadmium (122 µg/L), cadmium accumulation is reduced 90% and copper accumulation reduced 50% (Holwerda 1991). Exposure of crayfish (*Cambarus bartoni*) to 12.5 µg Cd/L for 72 h results in significantly increased copper stores in the hepatopancreas; however, isopods similarly exposed had decreased copper stores in antennal glands (Mwangi and Alikhan 1993). In the presence of copper, barnacles tend to accumulate cadmium (Powell and White 1990). In fishes, copper–cadmium interactions occur in Mozambique tilapia (*Oreochromis mossambicus*) during single and combined exposures. Waterborne copper tends to increase whole-body cadmium content of tilapia at all tested copper concentrations and exposure durations (as high as 400 µg Cu/L for 96 h); however, cadmium exposure tends to lower copper concentrations in tissues of tilapia (Pelgrom et al. 1994).

In birds, copper concentrations in kidneys of the willow ptarmigan (*Lagopus lagopus*) are positively correlated with concentrations of cadmium (Wren et al. 1994).

In mammals, cadmium inhibits copper absorption across the intestinal mucosa (Aaseth and Norseth 1986). Intercorrelations of copper with cadmium and zinc in livers of polar bears (*Ursus maritimus*) are probably mediated by metallothioneins, which may contain all three metals (Braune et al. 1991). In rats, copper protects against nephrotoxicity induced by cadmium, provided that copper is administered 24 h prior to cadmium insult. Specifically, rats given 12.5 mg Cu/kg BW by way of subcutaneous injection 24 h before receiving 0.4 mg Cd/kg BW — when compared to a group receiving Cd alone — did not have excessive calcium in urine and renal cortex or excessive protein in urine. Thus, 2.8 mg Cu/kg BW protects against 0.25 mg Cd/kg BW (Liu et al. 1992).

Iron

Iron-reducing bacteria from a copper-contaminated sediment were more tolerant of copper adsorbed to hydrous ferric oxide (HFO) than were pristine-sediment bacteria (Markwiese et al. 1998). Copper-tolerant bacteria were more efficient in reducing contaminated HFO, with greater potential for copper mobilization in aquatic sediments (Markwiese et al. 1998).

Mixtures of copper and iron salts were more than additive in toxicity to ova of brown trout (Sayer et al. 1991).

In muscle of Weddell seals (*Leptonychotes weddelli*), copper is positively correlated with iron (Szefer et al. 1994). In general, concentrations of copper in all tissues of all marine vertebrates examined are positively correlated with concentrations of iron (Eisler 1984).

The primary function of the mammalian red blood cell is to maintain aerobic metabolism while the iron atom of the heme molecule is in the ferrous (Fe^{+2}) oxidation state; however, copper is necessary for this process to occur (USEPA 1980). Excess copper within the cell oxidizes the ferrous iron to the ferric (Fe^{+3}) state. This molecule, known as methemoglobin, is unable to bind oxygen or carbon dioxide and is not dissociable (Langlois and Calabrese 1992). Simultaneous exposure of sheep to mixtures of cupric acetate, sodium chlorite, and sodium nitrite produced a dose-dependent increase in methemoglobin formation (Calabrese et al. 1992; Langlois and Calabrese 1992).

The addition of iron to diets of domestic pigs increases their resistance to copper poisoning (USEPA 1980), but this is an exception. High intake of iron, in general, adversely affects copper status in ruminants, guinea pigs, and rats; the mechanisms for this phenomenon are unknown (Yu et al. 1994). Genetically anemic and normal strains of rats fed high-iron diets had reduced kidney copper concentrations in both groups. This was associated with decreased absorption and biliary excretion of copper (Yu et al. 1995).

Manganese

Copper in livers and muscles of Weddell seals was positively correlated with manganese (Szefer et al. 1994). In general, manganese and copper are positively correlated in tissues of marine vertebrates (Eisler 1984). Uptake of copper from copper-contaminated freshwater sediments by annelid worms is related to the amount of reducible manganese oxide in the sediments (Diks and Allen 1983).

Molybdenum

In terrestrial vegetation, molybdenum and sulfur interfere with copper-induced deficiencies (Gupta 1979). Copper poisoning in cattle and other ruminants is governed by dietary concentrations of molybdenum and sulfate (Lewis et al. 1967; Todd 1969; Buckley and Tait 1981; Eisler 1989). Molybdenum and sulfur in mammalian diets cause a decrease in the availability of copper because of the formation of the biologically unavailable copper–thiomolybdate complex (Aaseth and Norseth 1986). Cattle die when grazing for extended periods on pastures where the ratio of copper to molybdenum

is less than 3 to 1, or if they are fed low-copper diets containing molybdenum at 2 to 20 mg Mo/kg ration (Eisler 1989). Wilson's disease is induced in rabbits by feeding a diet high in molybdates and sulfates, suggesting that the disease is not solely the result of copper intoxication (Goresky et al. 1968).

Zinc

Copper is positively correlated with zinc in gills of two species of fishes from the Mediterranean Sea (Romeo et al. 1994). Mixtures of copper and zinc salts in marine or freshwater fishes are more-than-additive in toxicity, producing more deaths in 96 h than expected on the basis of individual components (Eisler and Gardner 1973; Birge and Black 1979; Hodson et al. 1979). Mixtures of copper and zinc are generally acknowledged to be more-than-additive in toxicity to a wide variety of aquatic organisms (Birge and Black 1979; Hodson et al. 1979; Fernandez and Jones 1990; Eisler 1993). But mixtures of copper (0 to 90 µg/L) and zinc (0 to 1200 µg/L) are only additive in action to a marine bacterium (*Photobacterium phosphoreum*), decreasing its luminescence after exposure for 30 min (Parrott and Sprague 1993). Sometimes mixtures of copper and zinc salts are less-than-additive in action, as judged by DNA, RNA, and protein contents of newly hatched fathead minnows (*Pimephales promelas*) exposed for 4 days (Parrott and Sprague 1993).

In birds, copper and zinc concentrations are positively correlated in kidneys of the willow ptarmigan (*Lagopus lagopus*; Wren et al. 1994) and in kidneys and livers of common murres (*Uria aalge*; Stewart et al. 1994).

In mammals, copper absorption across the intestinal mucosa is inhibited by concomitant high oral intake of zinc (Aaseth and Norseth 1986). In livers from Weddell seals, copper is positively correlated with zinc (Szefer et al. 1994). The addition of zinc to swine diets protects against copper toxicosis caused by eating diets containing 250 mg Cu/kg ration (USEPA 1980).

Other Inorganics

Copper interacts with lead, magnesium, silver, and other elements. Dose-dependent frequency of deformities were observed in chironomid larvae held in water containing 1 to 100 µg Cu/L for 5 generations; copper and lead mixtures — up to 500 µg Pb/L — interacted to produce more-than-additive deformity frequency (Janssens de Bisthoven et al. 1998). In mammals, supplemental copper promotes urinary excretion of lead from the body and loss of lead from tissues (Flora 1991). In shore crabs (*Carcinus maenas*), ionic copper displaces ionic magnesium in gills, leading to inhibition of phosphoryl transfer (Hansen et al. 1992b). In embryos of the Pacific oyster (*Crassostrea gigas*), silver — at 0.5 to 15.5 µg silver/L — enhances adverse effects when copper concentrations exceed 6.0 µg Cu/L (Coglianese and Martin 1981). Silver positively correlates with copper in livers of Weddell seals, but the correlation is negative in muscles (Szefer et al. 1994).

In fishes, additive or more-than-additive toxicity occurs with mixtures of salts of copper and mercury, copper-zinc-phenol, and copper-nickel-zinc (Birge and Black 1979). Accumulation of copper in gills of fathead minnows during exposure to 16 µg Cu/L is reduced by added ionic calcium, which competes with Cu for gill binding sites (Playle et al. 1992).

Organic Compounds

Sequestering agents, increasing salinity, sediments, and other variables all reduce toxicity and accumulation of copper in tested species of aquatic plants and invertebrates. Chelating agents, such as nitrilotriacetic acid, reduce the toxicity of ionic copper to six species of estuarine phytoplankton (Erickson et al. 1970). Sensitivity of freshwater zooplankton communities varies seasonally. Communities are most sensitive to copper stress (20 or 40 µg Cu/L) during exposure for 5 weeks in spring rather than in summer or autumn because, in part, of reduced dissolved organic carbon concentrations in the spring (Winner et al. 1990). Adverse effects of copper on survival of marine copepods are reduced or eliminated by the presence of clay minerals, diatoms, ascorbic acid, sewage

effluents, water extracts of humic acids, and certain soil types (Lewis et al. 1972). Chelators, such as EDTA, and more alkaline pH increase the survival and larval developmental rates of copepods challenged with copper through increased complexation of cupric ions (Sunda et al. 1990). Natural fulvic acids, which comprise 75% of dissolved humic substances, reduce the acute toxicity of copper to rotifers (Porta and Ronco 1993). A significant reduction in radiocopper-64 accumulation by clams (*Macoma balthica*) occurs at high concentrations of dissolved organic ligands. Reduction is more pronounced at 3.0% salinity than 1.0% salinity (Absil et al. 1993). The presence of sediments in assay containers reduces the toxicity of copper to freshwater gastropods (Winger et al. 1984). Copper uptake by brine shrimp (*Artemia franciscana*) increases with decreasing pH and decreasing carbonate complexation (Blust et al. 1991). Studies with a freshwater shrimp (*Paratya australiensis*) and copper salts show that uncomplexed cupric ions are the most toxic chemical species in solutions containing nitrilotriacetic acid or glycine; however, the singly charged copper-glycine⁺ complex also appears to be mildly toxic (Daly et al. 1990a). Shrimp (*Paratya* sp.) are more resistant to copper in higher alkalinity waters (Daly et al. 1990b) and under conditions of increasing dissolved organic matter (Daly et al. 1990c).

In freshwater fishes, mixtures of copper with anionic detergents or various organophosphorus insecticides cause more-than-additive toxicity (Hodson et al. 1979). In marine vertebrates, copper in tissues is positively correlated with metal-binding proteins (Eisler 1984). Accumulations of copper in gills of fathead minnows during exposure to 16 µg Cu/L is reduced by added EDTA, which reduces bioavailability of copper through complexation (Playle et al. 1992). Copper LC50 (96 h) values (i.e., concentrations of ionic copper in solution at start of the test estimated to kill 50% of the test species in 96 h, to larval fathead minnows) range from a low of 2 µg/L at low pH and low dissolved organic carbon to 182 µg/L at pH 6.9 and dissolved organic carbon of 15.6 mg/L (Welsh et al. 1993). Acidification and the removal of dissolved organic carbon increases the toxicity of copper to fathead minnows in natural waters of low alkalinity and explains 93% of the variability in field toxicity data for that species (Welsh et al. 1993).

In mammals, phenobarbital and phenytoin increase serum ceruloplasmin concentrations (Aaseth and Norseth 1986). Chronic copper poisoning in sheep is exacerbated when diets contain heliotrope plants (*Heliotropium* sp., *Echium* spp., *Senecio* sp.). Aggravated effects of the heliotrope plants include reduced survival and a twofold to threefold increase in liver and kidney copper concentrations when compared to control animals fed copper without heliotropes (Howell et al. 1991). Rats given acutely toxic doses of 2,3,7,8-tetrachlorodibenzo-para-dioxin had elevated concentrations of copper in liver and kidney because of impaired biliary excretion of copper (Elsenhans et al. 1991). Morphine increases copper concentrations in the central nervous system of rats, and dithiocarbamates inhibit biliary excretion (Aaseth and Norseth 1986). In human patients, urinary excretion of copper is increased after treatment with D-penicillamine, calcium disodium EDTA, or calcium trisodium diethylenetriamine penta acetic acid (Flora 1991).

3.4 CARCINOGENICITY, MUTAGENICITY, AND TERATOGENICITY

3.4.1 General

No definitive evidence exists demonstrating that copper or copper compounds at environmentally realistic concentrations are the causative agents in the development of carcinogenicity, mutagenicity, or teratogenicity (USEPA 1980; Aaseth and Norseth 1986; ATSDR 1990). However, under controlled conditions of grossly elevated exposures, some studies suggest that copper is a potential carcinogen in rodents (USEPA 1980; ATSDR 1990; Toussaint and Nederbragt 1993); a mutagen in rodents (Aaseth and Norseth 1986; ATSDR 1990), sheep (Bires et al. 1993), and grasshoppers (Bhunya and Behura 1986); and a teratogen in fish (Birge and Black 1979), rodents, and other small laboratory animals (Aaseth and Norseth 1986).

3.4.2 Carcinogenicity

The carcinogenic classification of copper is Group 3 or D; that is, it is not classifiable as to its carcinogenicity in humans (ATSDR 1990). No definitive evidence exists showing that copper or copper compounds cause cancer in mammals (USEPA 1980; Aaseth and Norseth 1986; ATSDR 1990). Although hypercupremia is sometimes associated with neoplasms (USEPA 1980), some copper compounds seem to have an inhibitory effect on the development and growth of malignant tumor cells (Aaseth and Norseth 1986). Copper is not associated with an elevated incidence of cancer in humans or animals exposed by way of inhalation, oral, dermal, or intramuscular injection routes. A slightly increased incidence of reticulum cell sarcoma was noted in mice 18 months after a single subcutaneous injection of copper 8-hydroxyquinoline, but this needs to be verified (ATSDR 1990).

Sensitivity of cancerous cells to copper may reflect cell DNA content. Two closely related rat hepatoma cell lines differed in sensitivity to copper toxicity by a factor of four; DNA content in each cell line decreased with increasing copper concentrations, but at different rates. Severity of toxicity was associated with increasing accumulations of copper in the cell nucleus and with decreasing DNA (Toussaint and Nederbragt 1993).

3.4.3 Mutagenicity

Grasshoppers (*Oxya velox*) injected intra-abdominally with relatively high concentrations of soluble copper showed a 1.6% frequency of chromosomal anomalies in meiotic cells of testes 24 h after injection (Bhunya and Behura 1986); however, no control data were presented. Copper-induced DNA strand breaks in rats and chromosomal aberrations and sperm abnormalities in mice suggest that copper is a potential human mutagen (ATSDR 1990). Copper salts affect chromosomes *in vitro* in the presence of hydrogen peroxide and ascorbic acid and can also increase the frequency of noncomplementary nucleotides in the synthesized DNA double helix (Aaseth and Norseth 1986). Sheep, age 1.5 years, given about 10.7 mg Cu/kg BW daily — in addition to other metals — until they died (65 to 84 days later) show a significant increase in sister chromatid exchanges in bone marrow (Bires et al. 1993). However, the specific role of copper on survival and mutagenicity is unclear and requires verification.

3.4.4 Teratogenicity

Grossly elevated concentrations of dissolved copper produce teratogenicity in fish embryos. A significant number of malformed fish larvae came from eggs treated with 500 µg Cu/L (Birge and Black 1979). In studies with laboratory animals and elevated concentrations of copper salts, copper penetrates the placental barrier into the fetus; intramuscular injection of 4 mg Cu/kg BW early in pregnancy adversely affects fetal central nervous system development (Aaseth and Norseth 1986). In humans, no definitive data are available on whether copper can cause birth defects; however, incubation of human spermatozoa with metallic copper results in loss of sperm motility (Aaseth and Norseth 1986).

3.5 CONCENTRATIONS IN FIELD COLLECTIONS

3.5.1 General

Copper concentrations in air, soil, water, sediments, and other abiotic materials are elevated as a result of human activities, especially near copper smelters and mines, urban areas, municipal and industrial wastewater outfalls, marinas containing copper-based antifouling paints, and agricultural soils receiving prolonged applications of copper-based fungicides (Table 3.2). Maximum copper

Table 3.2 Copper Concentrations in Selected Abiotic Materials

Material, Units of Concentration, and Other Variables	Concentration^a	Reference^b
AIR, µg/m³		
Near copper smelters	1–2; Max. 5.0	1, 2
Nonurban locations	0.16–0.21; Max. 1.2	3
Remote locations	Usually <0.001; sometimes 0.001–0.003; Max. 0.012	4
South Pole	0.00004	5
Urban locations	0.15–0.18; Max. 1.6	4
United States	0.01–0.67	5
U.S. cities	Usually 0.09–0.81; sometimes 0.81–2.4; infrequently >2.4	2, 6
Uncontaminated	0.001–0.2	1, 7
COAL, µg/kg dry weight (DW)	17,000	7
DRINKING WATER, µg/L		
Conducted via copper pipes	Max. 1000	1
Private houses		
White Plains, New York	540	6
Bridgeport, Connecticut	185	6
Vermont		
Private houses	75–1400	6
Hospital	17–730	6
United States	134; Max. 8350;	1, 2
	0.2	7
GLACIERS, µg/kg fresh weight (FW)		
GROUNDWATER, µg/L		
New Jersey	About 5.0	1
LAKES AND RIVERS, µg/L		
Canada	1–8	1
Contaminated vs. noncontaminated	50–100 vs. 1–7	6
Lake Ascosa, Nicaragua, 1991–92	Usually <2.0; mean 3.1; Max. 13.1	8
Ligurian Sea drainage	<0.3–1.75 (equivalent to 3.5–7.1 tons annually)	22
New Jersey	3.0	1
Sweden; near brassworks vs. reference site	9.4 vs. 1.0	21
United States	5.3 (0.83–105.0); usually <2.0–4.2	1, 5, 7
MANURE, µg/kg DW		
Cattle	5000	1
MINE TAILINGS, mg/kg DW		
Butte Lake, Canada, 1982	7100	9
MUNICIPAL WATER SUPPLIES, µg/L	8.3 (0.6–250.0)	6
OIL, µg/kg FW		
Crude	140	7
Shale	70,000	7
POND WATER, µg/L		
Massachusetts	(<10–105)	1
POULTRY LITTER, mg/kg DW	1196	10
PRECIPITATION, µg/L		
Soluble vs. total	6.0 vs. 12.3	4
ROCKS, µg/kg DW		
Crustal and sedimentary	24,000–45,000	6, 7
Sandstones	10,000–40,000	11
Shales	30,000–150,000	11
Marine black shales	20,000–300,000	11
SEAWATER, µg/L		
Central Texas coast	Max. 50.0	12
Chesapeake Bay, Maryland; 1985–86; dissolved	11.7 (ND-80.0)	13
In water flowing through copper pipes	45.0	6
Mediterranean, northwestern coast	Max. 22.4	12
North Sea	0.2–2.6	14
Oceanic

^b 1, ATSDR 1990; 2, USEPA 1980; 3, Nriagu 1979a; 4, Nriagu 1979d; 5, Aaseth and Norseth 1986; 6, Schroeder et al. 1966; 7, Nriagu 1979c; 8, Cruz et al. 1994; 9, Pedersen 1983; 10, van der Watt et al. 1994; 11, NAS 1977; 12, Neff and Anderson 1977; 13, Hall et al. 1988; 14, Bryan and Langston 1992; 15, Hung et al. 1990; 16, Beyer 1990; 17, Thornton 1979; 18, Turgeon and O'Connor 1991; 19, Johnson et al. 1992; 20, Arduini et al. 1995; 21, Hogstrand et al. 1991; 22, Migon 1993.

concentrations in selected abiotic materials are 5 µg/m³ in air, 5 µg/L in groundwater, 12 µg/L in rainwater, 300 mg/kg DW in black shales, 1200 mg/kg DW in poultry litter, 6500 mg/kg DW in marine sediments, 7000 mg/kg DW in soils, and 7700 mg/kg DW in sewage sludge ([Table 3.2](#)).

Copper concentrations in field collections of plants and animals are usually elevated in areas treated with copper-containing herbicides, near smelters, and from heavily urbanized and industrialized areas (Stokes 1979; Eisler 1984; Winger et al. 1984; Read and Martin 1993; Swiergosz et al. 1993; Fishelson et al. 1994; Storm et al. 1994). The amount and distribution of copper in animal tissues varies with tissue, organism age, sex, and amount of copper in the diet (Cuill et al. 1970; NAS 1977; USEPA 1980; Fishelson et al. 1994). Additional and more detailed information on copper concentrations in field collections of plants and animals is found in Jenkins (1980) and Eisler (1979, 1981).

In terrestrial vegetation, copper is usually less than 35 mg/kg DW except near smelters, where it may approach 700 mg/kg DW, and in copper-accumulator plants that may normally contain as much as 13,700 mg/kg DW ([Table 3.3](#)). In aquatic vegetation, copper is elevated in metals-contaminated water bodies, reaching concentrations as high as 1350 mg/kg DW in eelgrass (*Zostera* spp.) from contaminated bays vs. 36 mg/kg DW in conspecifics from reference sites ([Table 3.3](#)).

Copper concentrations in terrestrial invertebrates range from 137 to 408 mg/kg DW. Soil invertebrates are not likely to accumulate copper but are important in recycling copper through terrestrial food webs. Aquatic invertebrates seldom contain as much as 95 mg Cu/kg DW, regardless of collection locale. Exceptions include whole amphipods and lobster hepatopancreas (335 to 340 mg/kg DW) from copper-contaminated sites and many species of molluscs that normally contain 1100 to 6500 mg Cu/kg DW ([Table 3.3](#)).

Maximum concentrations of copper in elasmobranchs and teleosts from all collection sites range from 7 to 15 mg/kg DW in eyeballs, intestines, muscle, scales, vertebrae, heart, and gonads and from 16 to 48 mg/kg DW in gills, kidneys, skin, and spleens. They reach 53 mg/kg DW in whole animals, 155 mg/kg DW in stomach contents, 208 mg/kg DW in feces, and 245 mg/kg DW in livers ([Table 3.3](#)).

Data on copper concentrations in field collections of amphibians and reptiles are scarce. Crocodile eggs contain as much as 60 mg Cu/kg DW; however, some toads (*Bufo* spp.) may contain as much as 2100 mg Cu/kg DW in livers without apparent adverse effects ([Table 3.3](#); Goldfischer et al. 1970).

Birds from contaminated sites may contain as much as 9 to 28 mg Cu/kg DW in eggs, muscle, and stomach contents; 43 to 53 mg/kg DW in kidneys, feces, and feathers; and 367 mg/kg DW in livers ([Table 3.3](#)).

Marine mammals usually contain less than 44 mg Cu/kg DW in all tissues except livers. Copper in livers seldom exceeds 116 mg/kg DW except in polar bears (146 mg/kg DW), and manatees, *Trichechus manatus*, (1200 mg/kg DW) from a copper-contaminated site ([Table 3.3](#)). Maximum copper concentrations in terrestrial mammals from all collection sites are usually less than 29 mg/kg DW in all tissues except kidneys (108 mg/kg DW) and livers (1078 mg/kg DW; [Table 3.3](#)).

3.5.2 Abiotic Materials

Copper concentrations in abiotic materials are comparatively elevated near copper smelters and urban areas ([Table 3.2](#)). Copper concentrations are also elevated in drinking water from copper pipes, in poultry and livestock manures, mine tailings, fossil fuels, shales ([Table 3.2](#)), sewage sludge, and in wastes from plating industries, foundries, and coking plants (ATSDR 1990). Drinking waters from certain locales contain elevated concentrations of copper added intentionally to control algal growth; drinking water may account for 10 to 20% of the daily intake of copper in humans (USEPA 1980).

Copper is found in the rocks and minerals of the earth's crust, occurring usually as sulfides and oxides, and sometimes as metallic copper (USEPA 1980). The mean concentration of copper in the upper lithosphere ranges from 70 to 100 mg/kg, ranking 14th among the trace elements in this

Table 3.3 Copper Concentrations (milligrams of copper per kilogram fresh weight [FW], dry weight [DW], or ash weight [AW]) in Field Collections of Representative Plants and Animals

Taxonomic Group, Organism, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
TERRESTRIAL PLANTS		
Red maple, <i>Acer rubrum</i> ; leaf; Ontario, Canada; distance from smelter		
1.6 km	37 DW	1
2.6 km	26 DW	1
10.4 km	19 DW	1
28.9 km	16 DW	1
Copper plant mint, <i>Aeolanthus biformifolius</i> ; Zaire		
Leaf	2150–2600 DW	1
Flower stem	2150–3500 DW	1
Corm	2600–13,700 DW	1
Whole	10,000–13,700 DW	1
Agricultural crops, various		
Hair grass, <i>Deschampia flexuosa</i> ; Ontario, Canada; distance from smelter	3–36 DW	2
1.7 km	726 DW	1
2.1 km	121 DW	1
7.4 km	103 DW	1
52.7 km	13 DW	1
Ferns, seven species; leaves	0.51 (0.22–0.98) FW	1
Fungi		
Seven species, whole	2.4 (1.5–3.0) FW	3
Various species		
Cap	Max. 131.7 DW	1
Spore	Max. 165.0 DW	1
Stalk	Max. 14.2 DW	1
Whole	Max. 95.9 DW	1
Grasses, various species	5 DW	2
Moss, <i>Hypnum cupressiforme</i>		
Wales; distance downwind from smelter		
Up to 3 km	All dead	1
8 km	62–68 DW	1
25 km	18–19 DW	1
Control site	11 DW	1
Sweden; near industries		
Legumes, various	Max. 265–580 DW	1
Lichens, various species	15 DW	2
Arctic		
Near copper smelter; Sudbury, Ontario	5 DW	4
(15–20) DW		4
Tomato, <i>Lycopersicon esculentum</i> ; United States		
Fruit	14 (8–34) DW	1
Leaf	(3–12) DW	1
Terrestrial plants, various species; seeds	1.1 (0.6–2.9) FW	3
Poppy, <i>Papaver orientale</i> ; pods	14.3 FW	3
Lichen, <i>Parmelia baltimorensis</i> ; Washington, D.C.; various years		
1938	17 DW	1
1958	22 DW	1
1970	32 DW	1
Norway spruce, <i>Picea abies</i>		
Connecticut		
Leaf	6.0 DW	1
Twig	15.0 DW	1
England		
Bark	5.0 DW	1
Wood	0.6 DW	1

Table 3.3 (continued) Copper Concentrations (milligrams of copper per kilogram fresh weight [FW], dry weight [DW], or ash weight [AW]) in Field Collections of Representative Plants and Animals

Taxonomic Group, Organism, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
Sweden		
Bark	25.0 DW	1
Needle	(4.4–8.1) DW	1
Root	(8–21) DW	1
Twig	(42–76) DW	1
Wood	2.0 DW	1
Trees, various species; leaves	1.8 (0.6–5.2) FW	3
Tundra plants; whole; Spitsbergen, Norway; 1987		
Lichens, 14 species	1.8–36.7 DW	5
Mosses, four species	3.4–33.0 DW	5
Vascular plants, five species	3.9–10.0 DW	5
Elm, <i>Ulmus americana</i> ; wood	7.9 FW	3
Corn <i>Zea mays</i>		
Grain		
East Asia	1.6 FW	1
Lower Dahomey	(1.0–2.9) DW	1
United States	8 (4–17) DW	1
From soils with Cu additions of 360 kg Cu/ha		
Grain	1.7–2.8 DW	6
Leaves	7.8–12.5 DW	6
AQUATIC PLANTS		
Algae and macrophytes; 11 species; Brazil; November 1989; whole	2.4–6.9 DW	14
Alga, <i>Ascophyllum nodosum</i>		
England; polluted bay vs. reference site	68 (46–96) DW vs. 12 (6–18) DW	1
Norway; polluted fjord vs. reference site	(45–240) DW vs. 5.5 (4–8) DW	1
Freshwater macrophytes; various species	2.5–256.0 DW	15
Water milfoil, <i>Myriophyllum</i> spp.	10.0–41.3 DW	1
Brown alga, <i>Pelvetia canaliculata</i> ; whole		
Norway	55 DW	1
Scotland	5–16 DW	1
Pondweed, <i>Potamogeton</i> spp.; whole; Pennsylvania	5.0–102.9 DW	1
Eelgrass, <i>Zostera</i> spp.		
Denmark; 1979–80; metals-contaminated site vs. reference site		
Leaves	9–13 DW vs. 5–6 DW	16
Roots	27.4 DW vs. 6–7 DW	1
Portugal and Spain; contaminated bay vs. reference site	1350 DW vs. (9–36) DW	1
PORIFERA		
Sponges; three species; whole	13–34 DW	1
COELENTERATES		
Jellyfish, <i>Cyanea capillata</i> ; whole		
New England	8.2 DW	1
Sweden	68.0 DW	1
Octacorals; Venezuela; whole; five species	0.9–3.1 DW	17
TERRESTRIAL INVERTEBRATES		
Honeybee, <i>Apis mellifera</i> ; Czechoslovakia; industrial locations vs. reference site; 1986–87		
Foraging workers	32–37 DW vs. 20–24 DW	7
Honey	1.1–1.7 DW vs. 0.6 DW	7
Pollen	6.1–8.2 DW vs. 5.4 DW	7

Table 3.3 (continued) Copper Concentrations (milligrams of copper per kilogram fresh weight [FW], dry weight [DW], or ash weight [AW]) in Field Collections of Representative Plants and Animals

Taxonomic Group, Organism, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
Landsnail, <i>Arianta arbustorum</i> ; urban areas vs. reference site; Innsbruck, Austria; 1987; soft parts	188 (30–408) DW vs. 84 (46–104) DW	8
Bumblebee; four species of <i>Bombus</i> ; queens; whole; Sweden; April 1991	18–23 (11–38) DW	9
Pine moth, <i>Bupalus piniarius</i> ; pupae; whole; Finland, 1987; industrialized area vs. reference site	Max. 137 DW vs. 53 DW	10
Earthworm, <i>Lumbricus rubellus</i> ; Cardiff, Wales; 1984; contaminated soils (2740 mg Cu/kg DW soil) vs. reference site (26 mg Cu/kg DW soil)		
Anterior alimentary canal	85.4 DW vs. 18.2 DW	11
Posterior alimentary canal	64.4 DW vs. 21.1 DW	11
Remainder	23.2 DW vs. 10.1 DW	11
17-year cicadas, <i>Magicicada</i> spp.; Maryland; 1987; whole	(33.2–60.3) DW	12
Pine noctuid, <i>Panolis flammea</i> ; pupae; whole; Finland, 1987; industrialized area vs. reference site	Max. 89 DW vs. 20 DW	10
Cuckoo bumblebee, <i>Psithyrus bohemicus</i> ; queens; Sweden; April, 1991; whole	19 (12–29) DW	9
Spiders, whole; from old-field subjected to 11 years of nutrient enrichment (3410 g Cu/ha yearly) vs. reference site (2–3 g Cu/ha yearly)		
Garden orb weaver, <i>Argiope aurantia</i>	110 DW vs. 80 DW	13
Wolf spiders, Lycosidae	130 DW vs. 85 DW	13

AQUATIC MOLLUSCS

Antarctic scallop, <i>Adamussium colbecki</i> ; Ross Sea; 1987–88 vs. 1990		
Digestive gland	12.6 vs. 3.5 FW	18, 19
Gills	6.5 DW vs. 1.4 FW	18, 19
Gonad	4.7 DW vs. ND	18
Kidney	4.0 DW vs. ND	18
Mantle	3.5 DW vs. ND	18
Muscle	1.6 DW vs. ND	18
Freshwater mussel, <i>Amblema</i> sp.; Texas		
Digestive gland	9.5 FW	1
Foot	2.9 DW	1
Gill	6.1 DW	1
Mantle	3.6 DW	1
Blood clam, <i>Anadara granosa</i> ; soft parts; Malaysia	0.7–0.8 FW; 6.3 (4.5–8.0) DW	20, 21
Freshwater mussel, <i>Anodonta grandis</i> ; soft parts; Manitoba, Canada; 1986	45.3 (5–80) DW	22
Lake mussel, <i>Anodonta piscinalis</i> ; gills		
No glochidia	5.4 DW	23
With glochidia	8.0 DW	23
Ocean quahog, <i>Arctica islandica</i>		
Soft parts		
Block Island Sound	10.0 DW	24
Chesapeake Bay	5.4 DW	24
Georges Bank	3.5–10.3 DW	24
New York Bight	11.3 DW	24
Western Baltic Sea, 1992–93		
Adductor muscle	1.8–2.2 DW	24
Digestive gland	13.5 DW	24
Foot	3.1 DW	24
Gills	6.7 DW	24
Kidney	40.1 DW	24
Mantle	5.0 DW	24
Soft parts	14.3–15.3 DW	24

Table 3.3 (continued) Copper Concentrations (milligrams of copper per kilogram fresh weight [FW], dry weight [DW], or ash weight [AW]) in Field Collections of Representative Plants and Animals

Taxonomic Group, Organism, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
Whelk, <i>Buccinum undatum</i> ; soft parts		
Irish Sea	180 DW	1
Scotland	78 DW	1
Channeled whelk, <i>Busycon canaliculatum</i>		
Digestive gland	(32–1135) FW	1
Muscle	(12–21) FW	1
Cephalopods; liver	150 FW	3
Scallop, <i>Chlamys operculis</i>		
Kidney	240.0 FW	1
Shell	2.1 FW	1
Soft parts	1.7 FW	1
Pacific oyster, <i>Crassostrea gigas</i>		
Shell	(1.6–2.9) DW	1
Hong Kong, 1989; various locations		
Gill	840 DW	25
Mantle	509 DW	25
Muscle	750 DW	25
Soft parts	344–422 DW; max. 1071 DW	25
Visceral mass	383 DW	25
Arcachon Bay, France, soft parts		
1979–82	48.3–63.8 DW	26
1983–87	67.7–116.2 DW	26
1988–91	101.8–135.0 DW	26
Soft parts		
England	(340–6480) DW	1
South Africa	33.0 DW	1
Tasmania	(9.4–84.4) DW	1
United States	(7.8–38.0) FW	1
Taiwan		
Soft parts; 1989; seawater had 5.0–23.6 µg Cu/L from discharges of copper recycling facility	4401 DW; green in color	27
Soft parts		
From copper-contaminated environment	2225 DW	28
As above; after 6 days in clean seawater	746 DW	28
As above; after 32 days in clean seawater	344 DW	28
American oyster, <i>Crassostrea virginica</i>		
Florida, soft parts		
From a canal lined with chromated-copper-arsenate wood vs. reference site	150–200 FW vs. 10 FW; elevated concentrations were associated with greenish color and higher frequency of histopathology of digestive gland diverticula	29
Reference site oysters transplanted into above canal		
After 3 months	130 FW	29
After 4 months	220 FW; no increase in frequency of digestive gland lesions	29
North Carolina, soft parts		
Marina sites	36.7 FW	30
Open water sites	7.1 FW	30
At 12‰ salinity	6.0 FW	31
At 33‰ salinity	2.0 FW	31
Soft parts		
Alabama	20 (4–78) FW	1
Chesapeake Bay	(5–240) FW	1
Eastern USA	91 (7–517) FW	1
Georgia	(48–261) DW	1
Gulf of Mexico states	16 (6–27) FW	1

Table 3.3 (continued) Copper Concentrations (milligrams of copper per kilogram fresh weight [FW], dry weight [DW], or ash weight [AW]) in Field Collections of Representative Plants and Animals

Taxonomic Group, Organism, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
Maryland (green oysters)	Max. 1120 DW	1
NW Atlantic	46 (11–110) DW	1
Rhode Island	121 (92–140) FW	1
Texas	161 DW	1
Virginia; 1972–73		
At 7.5‰ salinity	29 FW	31
At 9.5‰ salinity	16 FW	31
At 12‰ salinity	12 FW	31
At 13.5‰ salinity	3 FW	31
Zebra mussel, <i>Dreissena polymorpha</i> ; soft parts; caged for 15–60 days; water contained 0.8–1.4 µg Cu/L and particulates had 0.3–3.2 µg Cu/L	12.6–17.7 DW	32
Zebra mussel; soft parts; the Netherlands; 1994; Rhine-Meuse delta vs. reference site	1.9–2.7 FW vs. 1.1 FW	133
Freshwater mussels; two species; soft parts; St. Lawrence River; 1989–90; sediment copper ranged from 4 to 148 mg/kg DW	7.8–16.2 DW	33
Octopus, <i>Eledone cirrhosa</i> ; English Channel; October, 1987		
Branchial hearts	335 DW	34
Digestive gland	448–463 DW	34
Genital tract	60–66 DW	34
Gill	268 DW	34
Kidney	594 DW	34
Mantle	102 DW	34
Muscle	17 DW	34
Whole	122 DW	34
Mud snail, <i>Ilyanassa obsoleta</i> ; soft parts; North Carolina		
Marina sites	402.2 FW	30
Open-water sites	219.5 FW	30
Baltic clam, <i>Macoma balthica</i> ; soft parts; The Netherlands; 1990–92		
Acid-soluble fraction	4.1 (2.7–6.7) DW	35
Total copper	13.8–22.6 DW	35
Lagoon mussel, <i>Mytella strigata</i> ; soft parts; Baja California, Mexico; 1989–91	Max. 3.9 DW	36
Common mussel, <i>Mytilus edulis</i>		
Shell		
California	(<5.8–8.6) DW	1
England	9.6 DW	1
Japan	(1.2–2.8) DW	1
New Zealand	3.0 DW	1
Soft parts		
California	(5.0–11.2) DW	1
Canada, Halifax	13.7–154.3 DW	39
England	(7–11) DW	1
Long Island Sound, New York		
1983	1.0–2.3 FW	38
1986–87	15 DW	37
Norway	(3.0–130.0)	1
Portugal and Spain	(6.5–14.0) DW	1
Mussel, <i>Mytilus smaragdium</i> ; soft parts; copper-contaminated environment vs. 6 days in clean seawater	20.2 DW vs. 1.8 DW	28
Mussels; <i>Mytilus</i> spp.; soft parts; United States; 1970s vs. 1980s		
Bodega Bay, California	6.9 DW vs. 7.7 DW	40
Narragansett Bay, Rhode Island	11.0 DW vs. 14.0 DW	40
Octopus, <i>Octopus vulgaris</i> ; hepatopancreas	4880 DW	1

Table 3.3 (continued) Copper Concentrations (milligrams of copper per kilogram fresh weight [FW], dry weight [DW], or ash weight [AW]) in Field Collections of Representative Plants and Animals

Taxonomic Group, Organism, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
Squid, <i>Ommastrephes bartrami</i> ; liver	195 (17–696) DW	1
Clam, <i>Paphia undulata</i> ; soft parts; Malaysia; 1993	0.9–1.1 FW	20
Scallop, <i>Pecten jacobaeus</i> ; Adriatic Sea; June 1988		
Digestive gland	16.6 DW	18
Gills	6.3 DW	18
Gonad	10.3 DW	18
Kidney	17.5 DW	18
Mantle	3.3 DW	18
Muscle	1.1 DW	18
Green-lipped mussel, <i>Perna viridis</i> ; Hong Kong; soft parts; March, 1986	Max. 35.1 DW	41
Tropical rock oyster, <i>Saccostrea cucullata</i> ; soft parts		
Australia, 1983–84; near sewage discharge vs. reference site	285 DW vs. 34 DW	42
Hong Kong, March 1986	Max. 556 DW	41
Sydney rock oyster, <i>Saccostrea commercialis</i> ; soft parts; Georges River, Australia; 1970s vs. 1980s	20–46 FW vs. 14–93 FW	43
Cuttlefish, <i>Sepia officinalis</i> ; English Channel; October, 1987		
Branchial hearts	256 DW	34
Digestive gland	313–317 DW	34
Genital tract	55–56 DW	34
Gill	183 DW	34
Kidney	185 DW	34
Mantle	141 DW	34
Muscle	9 DW	34
Whole	59 DW	34
Freshwater clam, <i>Sphaerium</i> sp.; soft parts; Illinois	10.1 DW	1
Squid, <i>Symplectoteuthis ovalaniensis</i> ; liver	1720 DW	1
Freshwater mussel, <i>Unio</i> sp.; soft parts	11.9–19.3 DW	32

AQUATIC ARTHROPODS

Amphipods, various species; whole; Antarctica; 1989	31.3 (30.7–32.0) DW	44
Crayfish, <i>Astacus astacus</i> ; raw vs. cooked		
Hepatopancreas	52.0 FW vs. 31.0 FW	45
Muscle	5.7 FW vs. 11.0 FW	45
Mayfly, <i>Baetis thermicus</i> ; whole; larvae; Japan; metal-contaminated river (28.6 µg Cu/L) vs. reference site	73.5 FW vs. 4.0 FW; Cu localized in midgut epithelial cells	46
Crustaceans; 17 species; whole; Antarctic Ocean; 1985–88		
Two species	5.5–7.7 DW	47
Three species	37–42 DW	47
Six species	53–68 DW	47
Four species	81–107 DW	47
Two species	123–149 DW	47
Benthic crab, <i>Dorippe granulata</i> ; Hong Kong (contaminated harbor)		
Exoskeleton	7.7 DW	48
Gills	123.9 DW	48
Hemolymph	53.2 FW	48
Midgut gland	114.9 DW	48
Muscle	36.6 DW	48
Euphausiids; Antarctic and Atlantic Oceans; 1985–86; whole		
<i>Euphausia superba</i>	55 (30–86) DW	49
<i>Meganyctiphanes norvegica</i>	58 (40–83) DW	49

Table 3.3 (continued) Copper Concentrations (milligrams of copper per kilogram fresh weight [FW], dry weight [DW], or ash weight [AW]) in Field Collections of Representative Plants and Animals

Liver	4.6 (0.5–22.0) FW	1
Muscle	0.4 (0.3–1.2) FW	1
Blue marlin, <i>Makaira nigricans</i> ; muscle		
Japan	0.4 (0.1–0.7) FW	1
Puerto Rico	1.3 (0.4–2.6) FW; 2.7 (1.5–10.0) DW	1
Red mullet (Mullidae), <i>Mullus barbatus</i> ; gills; Coutou, France	17.6–48.1 DW	59
Hump rock cod (Nototheniidae), <i>Notothenia gibberifrons</i> ; Antarctica; 1989; muscle	0.85 DW	44
Kelp bass, <i>Paralabrax clathratus</i> ; California; Los Angeles site near effluent discharge of steam utility plant vs. Catalina Island (reference site)		
Eyeball	8.0 DW vs. 4.0 DW	1
Gonad	6.0 DW vs. 5.0 DW	1
Heart	1.5 DW vs. 12.0 DW	1
Liver	5.0 DW vs. 6.0 DW	1
Muscle	5.0 DW vs. 2.0 DW	1
Southern flounder, <i>Paralichthys lethostigma</i> ; South Carolina; 1990–93; whole	1.1–1.9 (0.0–22.2) FW	55
Yellow perch, <i>Perca flavescens</i> ; Michigan; 1993; Torch Lake (34 µg Cu/L) vs. reference site (10 µg Cu/L)		
Ovaries	5.0 DW vs. 2.1 DW	60
Testes	3.5 DW vs. 1.3 DW	60
Southern mouth brooder, <i>Pseudocrenilabrus philander</i> ; South Africa; whole fish; mine-polluted impoundment	9 (4–26) DW	61
Winter flounder, <i>Pleuronectes americanus</i>		
New York		
Muscle	(0.5–1.1) FW	1
Liver	(2.7–13.8) FW	1
Texas		
Muscle	1.0 (0.6–1.5) DW	1
Skin	1.7 (1.2–2.1) DW	1
Atlantic guitarfish, <i>Rhinobatos lentiginosus</i>		
Liver	6.6 DW	1
Muscle	2.2 DW	1
Stomach	6.2 DW	1
Red drum, <i>Sciaenops ocellatus</i> ; South Carolina; 1990–93; whole	0.4–9.2 (0.0–52.9) FW	55

Table 3.3 (continued) Copper Concentrations (milligrams of copper per kilogram fresh weight [FW], dry weight [DW], or ash weight [AW]) in Field Collections of Representative Plants and Animals

Taxonomic Group, Organism, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
Spanish mackerel, <i>Scomberomorus maculatus</i>		
Liver	3.3 DW	1
Muscle	2.3 DW	1
Painted comber, <i>Serranus cabrilla</i> ; gills; Coutou, France	5.3–27.2 DW	59
Sharks, 10 species; British and Atlantic waters; 1984–88		
Gills	0.05–2.2 FW	62
Gonads	0.1–4.9 FW	62
Heart	0.03 FW	62
Jaws	1.7–3.3 FW	62
Kidney	0.02–4.0 FW	62
Liver	0.2–7.8 FW	62
Muscle	0.2–2.4 FW	62
Pancreas	0.7 FW	62
Skin	0.6–12.1 FW	62
Spleen	0.03–2.5 FW	62
Vertebra	0.5–5.9 FW	62
Spiny dogfish, <i>Squalus acanthias</i>		
Liver	4.5 DW	1
Muscle	2.3 DW	1
Spleen	16.0 DW	1
Bluefin tuna, <i>Thunnus thynnus</i> ; Spain		
Heart	4.2 FW; 18.1 DW	1
Intestine	1.4 FW; 5.8 DW	1
Kidney	8.6 FW; 27.8 DW	1
Liver	74.0 FW; 245.0 DW	1
Ovary	(1.4–2.3) FW; (5.4–11.0) DW	1
Spleen	1.2 FW; 4.4 DW	1
Red hake, <i>Urophycis chuss</i>		
Liver	(3.2–6.0) FW	1
Muscle	(0.5–0.7) FW	1
Swordfish, <i>Xiphias gladius</i> ; muscle	(0.3–1.4) FW	1
AMPHIBIANS AND REPTILES		
Frogs; Maryland, 1990–91; tadpoles		
Northern cricket frog, <i>Acris crepitans</i> ; whole	9.8–15.7 DW	131
Gray treefrog, <i>Hyla versicolor</i> ; whole	7.4–12.6 DW	131
Green frog, <i>Rana clamitans</i>		
Gut vs. remainder	21.5 DW vs. 6.7 DW	131
Frogs and toads; Yugoslavia; liver; near mercury mines		
European toad, <i>Bufo bufo</i>	56.2–81.4 FW	1
Toad, <i>Bombina variegata</i>	(5.0–5.6) FW	1
European frog, <i>Rana temporaria</i>	318.9 FW	1
Giant toad, <i>Bufo marinus</i> ; liver		
Australia	Max. 1640 DW	63
Dominican Republic		
Black livers	1248–2091 DW	63
Yellow livers	367–469 DW	63
American crocodile, <i>Crocodylus acutus</i> ; egg; Florida	(0.9–15.0) FW	1
BIRDS		
Western grebe, <i>Aechmophorus occidentalis</i> ; Puget Sound, Washington; 1985–86; sediments had 52 mg Cu/kg DW		
Diet (fish muscle)	0.3–0.5 FW	64
Liver	12.7–17.6 DW	64

Table 3.3 (continued) Copper Concentrations (milligrams of copper per kilogram fresh weight [FW], dry weight [DW], or ash weight [AW]) in Field Collections of Representative Plants and Animals

Taxonomic Group, Organism, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
Mallard, <i>Anas platyrhynchos</i> ; Canada; 1975; feathers; near smelter vs. reference site	23 DW vs. 7–14 DW	65
Black duck, <i>Anas rubripes</i> ; Canada; 1975; feathers; near smelter vs. reference site	53 DW vs. 10 DW	65
Ducks, <i>Anas</i> spp.; Poland; 1988–91		
Kidney	9.9 (3.5–30.0) FW	66
Liver	58.0 (11.0–200.0) FW	66
Muscle	4.5 (2.1–10) FW	66
Lesser snow geese, <i>Anser c. caerulescens</i> ; Wrangel Island, Russia; June 1992; 2 subpopulations		
Subpopulation that overwintered in British Columbia and northern Washington, feeding mainly on vegetative plant parts		
Eggs	3.0 DW	135
Liver	47 (20–87) DW	135
Subpopulation that overwintered in Central Valley of California feeding mainly on rice seeds		
Eggs	3.0 DW	135
Liver	78 (25–627) DW	135
Geese, <i>Anser</i> spp.; Poland; 1988–91		
Liver	80 (29–160) FW	66
Muscle	4.0 (1.6–8.8) FW	66
Antarctica; February–March 1989		
Blue eyed cormorant, <i>Phalacrocorax atriceps</i> ; muscle	10 DW	67
Southern giant petrel, <i>Macronectes giganteous</i> ; muscle	7.2 DW	67
Adelie penguin, <i>Pygoscelis adeliae</i>		
Liver	11.9 (11.0–12.6) DW	67
Muscle	7.9 (6.5–8.5) DW	67
Chinstrap penguin, <i>Pygoscelis antarctica</i>		
Feces	37.6 (35.1–49) DW	67
Liver	12.6 (12–13) DW	67
Muscle	9.7 (9.5–10.1) DW	67
Gentoo penguin, <i>Pygoscelis papua</i>		
Liver	26.5 (24.0–27.6) DW	67
Muscle	8.2 (7.7–8.9) DW	67
Redhead, <i>Aythya americana</i> ; Louisiana and Texas; 1987–88; liver	7.3 (3.9–11.5) DW	68
Canvasback, <i>Aythya valisineria</i> ; Louisiana; 1987–88; liver; females	Usually 76–187 DW	69
Ruffed grouse, <i>Bonasa umbellus</i> ; liver	5.2 FW	3
Willet, <i>Catoptrophorus semipalmatus</i> ; San Diego Bay; 1994; sediment vs. stomach contents		
Naval Air Station	3 DW vs. 17 DW	136
Tijuana Slough National Wildlife Refuge	12 DW vs. 34 DW	136
Lesser kestrel, <i>Falco naumanni</i> ; nonviable eggs; Spain; 1988–91	3.1 (0.2–7.1) FW	3
Bald eagle, <i>Haliaeetus leucocephalus</i> ; eggs		
Florida	(0.7–1.2) FW; (4.8–8.0) DW	1
Maine	(0.3–0.6) FW; (2.0–5.0) DW	1
Wisconsin	(0.5–1.2) FW; (3.0–9.0) DW	1
Willow ptarmigan, <i>Lagopus lagopus</i> ; Norway; winter 1986–87; kidney; adults vs. juveniles	2.8–4.9 FW (Max. 8.0 FW) vs. 1.9–3.6 FW (Max. 5.5 FW)	71
Lesser black-backed gull, <i>Larus fuscus</i>		
Egg	1.0 FW	1
Kidney	14.0 DW	1

Table 3.3 (continued) Copper Concentrations (milligrams of copper per kilogram fresh weight [FW], dry weight [DW], or ash weight [AW]) in Field Collections of Representative Plants and Animals

Taxonomic Group, Organism, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
Liver	17.0 DW	1
Muscle	14.0 DW	1
Marine birds, New Zealand; 1975–83		
Albatrosses, eight species; adults vs. juveniles		
Feather	44.0 FW vs. 18.4–32.3 FW	72
Liver	5.0–8.6 FW vs. 12.2–225.3 FW	72
Gulls, <i>Larus</i> spp.; adults vs. juveniles		
Feather	13.1–20.0 FW vs. 25.3–60.5 FW	72
Liver	5.0–6.6 FW vs. 23.8–35.0 FW	72
Penguins, three species; liver; adults vs. juveniles	4.3–13.2 FW vs. 8.5–18.5 FW	72
Petrels, 19 species; adults vs. juveniles		
Feather	14–40 FW vs. 20–79 FW	72
Liver	4–45 FW vs. 8–75 FW	72
Shearwaters, three species of <i>Puffinus</i> ; liver; adults vs. juveniles	6.4–7.2 FW vs. 4.6–446.3 FW	72
Surf scoter, <i>Melanitta perspicillata</i> ; San Francisco Bay; 1985; liver; January vs. March	37.8 (29.3–47.0) DW vs. 50.1 (41.3–58.3) DW	73
Turkey, <i>Meleagris gallopavo</i> ; Poland; 1988–91		
Kidney	3.0 (2.3–5.2) FW	66
Liver	4.7 (3.1–13.0) FW	66
Muscle	0.3 (0.2–0.4) FW	66
Brown pelican, <i>Pelecanus occidentalis</i>		
Egg		
Florida	(0.9–1.1) FW	1
South Carolina	(0.7–1.3) FW	1
Liver; Florida, Georgia; South Carolina	(4.3–9.0) FW	1
Flamingo, <i>Phoenicopterus ruber roseus</i> ; France; 1988		
Blood serum, nestlings	0.25 (0.13–0.51) FW	74
Feather, adults	Max. 7.43 DW	74
Seabirds, 19 species; pelagic; North Pacific Ocean; 1982–87		
Kidney	4.7 FW	75
Liver	5.9 FW; Max. 7.7 FW	75
Muscle	5.1 FW	75
Seabirds		
Liver; 11 species	Means 14–64 DW	137
3 species		
Bone, fat	<1.0 DW	137
Lung, pancreas, spleen, gonads, uropygial gland, skin, eyeball	1–5 DW	137
Brain, heart, stomach, intestine, muscle	7–10 DW	137
Liver, gall bladder, kidney	11–15 DW	137
Shorebirds; Chile; November 1981–March 1982; near abandoned copper mine; liver vs. stomach contents		
Sanderling, <i>Calidris alba</i>	(9.2–11.5) FW vs. no data	76
Oyster catcher, <i>Haematopus ostralegus</i>	8.0 (6.8–8.6) FW vs. (24.4–27.2) FW	76
Kelp gull, <i>Larus dominicanus</i>	(3.8–6.3) FW vs. (0.8–3.4) FW	76
Grey gull, <i>Larus modestus</i>	6.2 (4–7.4) FW vs. (30–46.7) FW	76
Franklin's gull, <i>Larus pipixcan</i>	(4.7–5.5) FW vs. no data	76
Whimbrel, <i>Numenius phaeopus</i>	(3.9–17.8) FW vs. (6.1–86.4) FW	76
Eider, <i>Somateria mollissima</i> ; Norway		
Egg	4.0 DW	1
Kidney	43.0 DW	1
Liver	367.0 DW	1
Muscle	13.0 DW	1

Table 3.3 (continued) Copper Concentrations (milligrams of copper per kilogram fresh weight [FW], dry weight [DW], or ash weight [AW]) in Field Collections of Representative Plants and Animals

Taxonomic Group, Organism, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
Tree swallow, <i>Tachycineta bicolor</i> ; nestlings; acidified (pH 4.8) vs. reference (pH 6.7) lakes; Ontario, Canada; 1986–89		
Kidney	12.8 DW vs. 10.4 DW	77
Liver	42.6 DW (elevated metallothionein) vs. 17.3 DW	77
Redshank, <i>Tringa totanus</i> ; liver; feeding on sandworms (<i>Nereis diversicolor</i>) containing 500–1000 mg Cu/kg DW	30 DW	78
Waterfowl; livers; 46 species		
20 species	6–50 DW	135
16 species	51–100 DW	135
7 species	101–200 DW	135
Ring-necked duck, <i>Aythya collaris</i> ; Chesapeake Bay	263 DW	135
Pochard, <i>Aythya ferina</i> ; England	603 DW	135
Eider, <i>Somateria mollissima</i> ; Spitsbergen	900 DW	135

MARINE MAMMALS

Gray whale, *Eschrichtius robustus*; stranded along North American west coast; 1988–91

Brain	2.4 FW	79
Kidney	2.4 (0.5–4.9) FW	79
Liver	9.2 (0.6–25.0) FW	79
Stomach contents	21.0 (3.0–66.0) FW	79

Pilot whale, *Globicephala melaena*; stranded on Cape Cod, Massachusetts, 1986–90

Adults		
Brain	9.1 (5.7–12.3) DW	80
Kidney	14.7 (7.4–21.0) DW	80
Liver	15.5 (9.9–20.3) DW	80
Ovary	5.5 (2.8–8.4) DW	80
Fetuses		
Brain	5.1 (4.4–6.2) DW	80
Kidney	20.0 (8.1–28.1) DW	80

Gray seal, *Halichoerus grypus*; British Isles and vicinity; 1988–89

Blubber	<0.1 FW	81
Kidney	(3.2–27.0) FW	81
Liver	(4.0–26.0) FW	81, 82
Muscle	2.5 FW	81

Leopard seal, *Hydrurga leptonyx*; Antarctic; 1989

Kidney	32.6 (22.5–43.8) DW	83
Liver	105.0 (98.0–116.0) DW	83
Muscle	4.0 (2.5–8.4) DW	83
Stomach contents	14.4 (13.3–16.4) DW	83

Pygmy sperm whale, *Kogia breviceps*; Argentina; found dead

Heart	6.9 FW	84
Kidney	7.4 FW	84
Liver	10.3 FW	84
Other tissues	<2.3 FW	84

Weddell seal, *Leptonychotes weddelli*; Antarctic; 1989

Kidney	22.8 (21.7–24.5) DW	83
Liver	57.4 (28–87) DW	83
Muscle	2.8 (2.1–3.1) DW	83

Crabeater seal, *Lobodon carcinophagus*; Antarctic 1989

Kidney	25.6 (18.9–39.5) DW	83
Liver	71.1 (42–105) DW	83
Muscle	3.3 (2.7–4.3) DW	83

Table 3.3 (continued) Copper Concentrations (milligrams of copper per kilogram fresh weight [FW], dry weight [DW], or ash weight [AW]) in Field Collections of Representative Plants and Animals

Taxonomic Group, Organism, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
Baikal seal, <i>Phoca sibirica</i> ; Siberia; 1992; immatures vs. adults		
Kidney	7.3 FW vs. 5.1 FW	138
Liver	4.9 FW vs. 3.5 FW	138
Muscle	1.4 FW vs. 1.0 FW	138
Harbour seal, <i>Phoca vitulina</i> ; British Isles; 1988–89; liver	7–21 FW	82
Common harbour porpoise, <i>Phocoena phocoena</i>		
England; 1988–89; liver	6–160 FW	82
Greenland; 1988–89		
Kidney	5.5 (3.7–8.0) FW	85
Liver	12.0 (5–50) FW	85
Muscle	2.0 (1.1–5.4) FW	85
Skin	1.0 (0.6–1.9) FW	85
Whales; unidentified; 1989; found dead		
Blubber	0.2–1.7 FW	81
Liver	6.6–8.7 FW	81
Muscle	3.0 FW	81
La Plata river dolphin, <i>Pontoporia blainvillii</i> ; Argentina; found dead		
Kidney	14 FW	84
Liver	16 FW	84
Other tissues	<2.8 FW	84
Striped dolphin, <i>Stenella coeruleoalba</i> ; Wales; 1989; found dead		
Blubber	0.3–0.7 FW	81
Muscle	2.1 FW	81
Manatee, <i>Trichechus manatus</i> ; Florida; 1977–81; liver	175.0 (4.4–1200.0) DW	86
Dolphin, <i>Tursiops gophysurus</i> ; Argentina; found dead		
Blubber	4.0 FW	84
Kidney	29.5 FW	84
Liver	77.7 FW	84
Melon	2.7 FW	84
Muscle	6.3 FW	84
Stomach contents	1.2 FW	84
Bottlenose dolphin, <i>Tursiops truncatus</i>		
England; 1988–89; liver	4–12 FW	82
Wales; 1989		
Blubber	0.9–1.1 FW	81
Muscle	2.5 FW	81
Polar bear, <i>Ursus maritimus</i>		
Canada, Northwest Territories; 1982–84; liver	81–146 DW	87
Svalbard (Arctic Ocean region); 1978–89; adults vs. juveniles		
Kidney	8.3 FW vs. 6.2 FW	88
Liver	42 FW vs. 33 FW	88
Welsh coast and Irish Sea; adults of 17 species of marine mammals; found dead; 1989–91; liver	Usually between 3.2 and 30.0 FW	89

TERRESTRIAL MAMMALS

Impala, <i>Aepyceros melampus</i> ; Kruger National Park, South Africa; 1989		
Kidney	(3–141) FW	90
Liver	(3–444) FW	90
Moose, <i>Alces alces</i>		
Alaska		
Hair	(5.2–11.7) DW	1
Hoof	(3.2–5.3) DW	1

Table 3.3 (continued) Copper Concentrations (milligrams of copper per kilogram fresh weight [FW], dry weight [DW], or ash weight [AW]) in Field Collections of Representative Plants and Animals

Taxonomic Group, Organism, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
Estonia; 1980–82		
Kidney	5.1 FW	91
Liver	3.1 FW	91
Poland; 1977–87; muscle	(0.9–2.6) FW	91
Sweden; 1979–80		
Kidney	(2.2–7.4) FW	91
Liver	(3.2–96.0) FW	91
Arctic fox, <i>Alopex lagopus</i> ; Norway; 1984–86; liver	6.0 (2.4–26.0) FW	92
Wood mouse, <i>Apodemus sylvaticus</i>		
Kidney	(3.7–6.0) FW	1
Liver	(2.6–18.1) FW	1
Testes	(12.2–18.7) FW	1
Whole	(2.8–5.5) FW	1
Bison, <i>Bison bison</i> ; Canada; 1986		
Kidney	6.7 (5.5–8.0) FW	91
Liver	35 (13–52) FW	91
European bison, <i>Bison bonasus</i> ; Poland; 1987		
Kidney	4.4 FW	91
Liver	3.4 FW	91
Muscle	2.0 FW	91
Cattle, <i>Bos</i> spp.		
Poland; 1987–91		
Kidney	5.6 FW	93
Liver	29.0 FW	93
Muscle	1.2 FW	93
South Africa; 1989; found dead near copper smelter; surface soil had 103 mg Cu/kg DW (14 at reference site)		
Kidney	36 (6–83) FW; 108 DW	90
Liver	359 (161–600) FW; 1078 DW	90
Various locations; liver	38.2–156.1 DW	94
Water buffalo, <i>Bubalus</i> sp.; Kruger National Park, South Africa; 1989; liver	Usually 18–80 FW; (6–144) FW	90
Bactrian camel, <i>Camelus bactrianus</i> ; China; 1992		
Normal		
Blood	0.86 FW	95
Hair	6.4 DW	95
Camels with sway disease (severe copper deficiency)		
Nonpregnant females		
Blood	0.36 FW	95
Hair	4.3 DW	95
Pregnant camels vs. post-partum		
Blood	0.17 FW vs. 0.26 FW	95
Hair	3.0 DW vs. 3.3 DW	95
Dog, <i>Canis familiaris</i>		
Brain	3.9 FW; 19 DW	96
Kidney	6.9 FW; 26 DW	96
Liver	82 FW; 336 DW	96
Muscle	1.1 FW; 3.7 DW	96
Serum	0.7 FW	96
Whole body	2.3 FW	96
Coyote, <i>Canis latrans</i> ; kidney	5.2 FW	97
Goat, <i>Capra hircus</i> ; mother vs. newborn		
Hair	8.9 DW vs. 8.3 DW	1
Kidney	9.8 DW vs. 19.0 DW	1
Liver	11.3 DW vs. 63.3 DW	1

Table 3.3 (continued) Copper Concentrations (milligrams of copper per kilogram fresh weight [FW], dry weight [DW], or ash weight [AW]) in Field Collections of Representative Plants and Animals

Taxonomic Group, Organism, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
Roe deer, <i>Capreolus capreolus</i> ; Poland; 1987–91		
Kidney	7.8 FW	91
Liver	28.0 FW	91
Muscle	4.5 FW	91
European red deer, <i>Cervus elaphus</i>		
The Netherlands; 1989–92		
Kidney	54–86 DW	98
Liver	14–18 DW	98
Poland; 1986–91		
Kidney	5.4 FW	91
Kidney	9.4 DW	99
Liver	12.0 FW	91
Muscle	6.3 FW	91
Muscle	19.0 DW	99
Bank vole, <i>Clethrionomys glareolus</i>		
Poland; 1990; whole, less stomach and gastrointestinal tract	5.7–9.5 DW	100
Poland; 1985; various sites		
Bone	18.2–22.7 DW	101
Fur	12.0–14.5 DW	101
Kidney	43.4–73.8 DW	101
Liver	27.6–31.2 DW	101
Remainder	12.5–28.8 DW	101
Horse, <i>Equus caballus</i> ; liver	10.3–51.5 DW	94
North American porcupine, <i>Erethizon dorsatum</i>		
Heart	8.4 FW	97
Lung	4.7 FW	97
Human, <i>Homo sapiens</i>		
Healthy adults vs. adults with Wilson's Disease

Deer, <i>Odocoileus</i> spp.		
Brain	0.3–2.4 FW	97
Hooves	0.6 FW	97
Kidney	5.8–8.4 FW	97
White-tailed deer, <i>Odocoileus virginianus</i> ; Texas; 1979–80; uranium mining district vs. reference site		
Antlers	16.7 (0.5–71.0) FW vs. 18.0 (0.6–94.0) FW	104
Liver	0.5–94.0 FW vs. <1.0–>70.0 FW	104
Muskrat, <i>Ondatra zibethicus</i> ; Virginia; 1986–88; contaminated site (many chemicals; 68 mg Cu/kg DW sediment) vs. reference site (26 mg Cu/kg DW sediment); kidney	12.9 DW vs. 11.1 DW	105
Rabbit, <i>Oryctolagus</i> sp.; Poland; 1990; industrialized area vs. reference site		
Heart	5.9 FW vs. 3.0 FW	106
Kidney	6.6 FW vs. 2.6 FW	106
Liver	5.8 FW vs. 3.1 FW	106
Muscle	2.4 FW vs. 1.2 FW	106
Muskox, <i>Ovibus moschatus</i> ; Canadian Arctic; 1985–90		
Kidney	11 DW	107
Liver	67 DW	107
Domestic sheep, <i>Ovis aries</i>		
Copper-poisoned vs. normal sheep		
Blood	1.74–9.1 FW vs. 0.6–1.6 FW	108
Kidney	60 FW vs. 5 FW	109
Liver	432 FW vs. 12 FW	109
Muscle	2.5 FW vs. 2.1 FW	109
Spleen	19 FW vs. 5 FW	109
England; in paddock near heavily traveled highway for 150 days vs. reference site		
Blood	0.98 FW vs. 0.97 FW	110
Wool, tip	28.6 DW vs. 12.4 DW	110
Poland; 1988–91		
Kidney	5.7 (3.1–13.0) FW	66
Liver	41 (7–98) FW	66
Muscle	0.9 (0.8–1.3) FW	66
Raccoon, <i>Procyon lotor</i> ; fat	1.2 FW	97
Caribou, <i>Rangifer tarandus</i> ; Canadian Arctic; 1985–90		
Kidney	29 DW	107
Liver	68 DW	107

Table 3.3 (continued) Copper Concentrations (milligrams of copper per kilogram fresh weight [FW], dry weight [DW], or ash weight [AW]) in Field Collections of Representative Plants and Animals

Taxonomic Group, Organism, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
Rat, <i>Rattus</i> spp.		
Mature and aged		
Brain	6.6 FW	97

6.5–31 km	14–22 DW	115
India; river near Madras; receives industrial wastes		
Sediments	760–930 DW	116
Water	0.01–0.04 FW	116
Alga, <i>Enteromorpha intestinalis</i> ; whole	12.3 FW	116
Oyster, <i>Crassostrea madrasensis</i> ; soft parts	4.2 FW	116
Crustaceans, whole	Max. 18.4 FW	116
Fishes, muscle	Max. 0.09 FW	116
Israel; Acre Valley; 1988–91		
Molluscs; soft parts		
Bivalves	9.4–13.3 DW	117
Gastropods	31.0–48.0 DW	117
African sharp-tooth catfish, <i>Clarias gariepinus</i> ; liver	Max. 92.0 DW	117
Italy; Goro Bay; 1991–92		
Sediments	42–54 DW	118
Seawater	0.0005–0.0022 FW	118
Mussel, <i>Mytilus galloprovincialis</i> ; soft parts; purged for 48 h in aerated synthetic seawater vs. not purged	6.9 DW vs. 13.1 DW	118
New Zealand; pasture soil contaminated by runoff from an adjacent timber treatment plant; 1993; copper-contaminated soils (70–1233 mg Cu/kg DW soil) vs. reference site (25 mg Cu/kg DW soil)	In less-contaminated soils, plant-feeding nematodes were predominant. With increasing copper loadings, bacterial-feeding and predatory nematodes dominated; at highest loadings, microbial biomass declined	119
New Zealand; pasture contaminated by runoff from chromated copper arsenate timber preservation facility; 1991; control surface soils contained an average of 19 mg Cu/kg DW, low contamination 109 mg/kg, medium contamination 425 mg/kg, and high contamination 835 mg/kg DW soil		
Vegetation	Herbage yield decreased with increasing copper loadings; after 35 days roots had 10.5 mg Cu/kg DW in controls, 14.6 in low group, 18.4 in medium group and 23.9 in high group	120
Earthworms, <i>Lumbricus rubellus</i> , <i>Aporrectodea rosea</i>	Earthworms absent from plats with medium and high contamination. Surface casts of <i>L. rubellus</i> had 17.5 mg/kg DW in low contamination soils vs. 7.0 in controls; for <i>A. rosea</i> . These values were 13.3 vs. 7.0	120

category (Schroeder et al. 1966). Copper in the environmental crust averages 50 mg/kg, but is higher (140 mg/kg) in ferromagnesium minerals (NAS 1977). Soil contamination by copper occurs around all known smelter locations; contamination may persist for decades, and plants and animals are often unable to survive the harsh chemical environments created (Hutchinson 1979). Italian soils have higher copper concentrations (51 mg/kg DW) than those of other European counties, probably as a result of the widespread and prolonged application of copper-based fungicides in Italian orchards and vineyards (Arduini et al. 1995).

Copper concentrations in lake sediments within a radius of 80 km from a smelter in northern Sweden are positively correlated with proximity to the smelter (Johnson et al. 1992). In some cases, lake sediments are sinks for copper, with little release to the overlying lake water. For example, copper-bearing mine tailings in Butte Lake, British Columbia, do not undergo oxidative diagenesis because of a rapid rate of accumulation and short exposure time to dissolved oxygen in bottom waters (Pedersen 1983). In Michigan, lakes with elevated concentrations of copper (34 µg/L) have low densities of fish populations (Ellenberger et al. 1994). In the Elizabeth River estuary of southern Chesapeake Bay, anthropogenic copper and other chelatable metals are present at concentrations sufficient to adversely affect growth and survival of the copepod *Acartia tonsa* (Sunda et al. 1990). In Norway, freshwater fish are present only when copper is less than 60 µg/L and some humic acids are present (Hodson et al. 1979). Successful reproduction of the spotted salamander (*Ambystoma maculatum*) occurs at low water concentrations of copper (<10 µg/L), lead, and aluminum, and high concentrations of silicon. Failed reproduction occurs at low water concentrations of silicon, and elevated concentrations of copper (>25 µg/L), lead, and aluminum (Blem and Blem 1991).

In marine ecosystems, the high copper levels measured in heavily contaminated coastal areas sometimes approach the incipient lethal concentrations for some organisms (Neff and Anderson 1977). Elevated copper concentrations in marine and estuarine environments may result from atmospheric deposition, industrial and municipal wastes, urban runoff, rivers, and shoreline erosion. Chesapeake Bay, for example, receives more than 1800 kg of copper daily from these sources (Hall et al. 1988). Copper concentrations in abiotic marine materials are generally higher near shore than

off shore. Copper is elevated in sediments of many marinas, probably from the copper antifouling bottom paints used on boats housed there (Hall et al. 1988). In New Zealand, copper concentrations in contaminated inshore sediments frequently exceed 100 mg Cu/kg DW vs. 14 mg Cu/kg DW at noncontaminated sites (Roper and Hickey 1994). The fine particle fraction of sediments collected near bulkheads made of chromated copper arsenate (CCA)-treated wood contain elevated concentrations of copper, chromium, and arsenic; metal concentrations decreased with increasing distance from the bulkhead. Sediments, for example, decreased from 11 mg Cu/kg DW in the vicinity of treated bulkheads to less than 2 mg/kg DW at more distant sites (Weis and Weis 1994).

3.5.3 Terrestrial Plants and Invertebrates

In general, copper concentrations in terrestrial vegetation seldom exceed 35 mg/kg DW, except near point sources of copper contamination and in certain copper-tolerant species (Table 3.3). The highest copper concentration recorded in nonaccumulator plants is 726 mg/kg DW in hair grass (*Deschampia flexuosa*) near a smelter (Table 3.3). Several species of terrestrial plants accumulate spectacular concentrations of copper. Mint plants (*Aeolanthus* spp., *Elsholtzia* spp.) growing in copper-rich soils contain unusually high concentrations and are used as economic indicators of copper deposits in the former Soviet Union and the People's Republic of China (Jenkins 1980). The copper plant mint (*Aeolanthus biformifolius*), for example, normally contains as much as 13,700 mg Cu/kg DW whole plant (Table 3.3). Copper-tolerant species of mosses, lichens, fungi, and higher plants occur in Greenland, Canada, the former Soviet Union, Africa, and elsewhere. In Zambia and Rhodesia, the copper-tolerant *Becium homblei* is found only in soils containing more than 1000 mg Cu/kg and is believed responsible for the discovery of copper deposits in those nations (Hutchinson 1979). Some species of copper-indicator plants in Zambia tolerate as much as 70,000 mg Cu/kg in the soil and accumulate as much as 3000 mg Cu/kg in leaves (Hutchinson 1979).

Copper is not accumulated from soils by most crop plants, suggesting a soil–plant barrier for copper (Levine et al. 1989). Thus, corn (*Zea mays*) did not accumulate copper from soils treated with 365 kg of copper per surface hectare (as copper-rich pig manure or copper sulfate) over a 13-year period. Corn yield is not affected under these conditions (Reed et al. 1993).

Copper burdens in terrestrial invertebrates are highest in organisms collected near industrial locations and urban areas or from copper-contaminated soils. The highest copper concentration recorded among terrestrial invertebrates is 408 mg Cu/kg DW soft parts in gastropods from urban areas (Table 3.3). Copper concentrations in pine moths (*Bupalus piniarius*) and pine noctuids (*Panolis flammea*) from industrialized areas range from 89 to 137 mg/kg DW, but are lower than dietary concentrations and suggest negligible accumulation (Heliovaara and Vaisanen 1990). Accumulations of as much as 60 mg Cu/kg DW in 17-year cicadas (*Magicicada* spp.) pose no apparent dietary threat to insectivorous birds (Clark 1992).

Earthworms from soils heavily contaminated with copper (2740 mg/kg DW soil) can regulate copper more efficiently than cadmium and lead. However, copper is more toxic to earthworms than lead or zinc in the soil, due, in part, to the inability of most soft tissues to synthesize copper-binding ligands when challenged with copper (Morgan and Morgan 1990).

In woodland ecosystems, copper concentrations in the litter horizon are rarely exceeded by those in soil animals — which play a key role in copper cycling (Wieser 1979). Meiofaunal feces comprise an efficient distributing system through which copper and other nutrients are cycled through the food web of woodland ecosystems. During a 12-month cycle the total copper bound in litter progresses through a cycle of chemical binding states. It may be released from a strongly chelated organic complex as the litter is attacked by the digestive juices of animals, or it may be discharged in soluble form with the feces and become complexed again by the activity of micro-organisms in these feces. When feces are ingested by coprophagous animals, such as isopods, the copper may become trapped in proteins or membrane-bound vesicles (Wieser 1979).

3.5.4 Aquatic Organisms

Copper is essential for the successful growth and development of many species of aquatic organisms, but its rate and extent of accumulation and retention are modified by numerous biological and abiotic variables. Abiotic variables known to modify copper concentrations in tissues of aquatic biota include water temperature, pH, salinity, and depth; the presence of other inorganics, organics, and chelators; the chemical species of copper; and proximity to anthropogenic point sources of copper. Biological variables affecting copper accumulations in marine organisms include the organism's age, size, and developmental stage; physiological or genetic adaptation to high copper substrates; inherent species differences; and tissue specificity, such as the thorax of barnacles, gill and osphradium of gastropods, and livers of teleosts (Eisler 1979). Among marine organisms, the highest accumulations are generally found in molluscan tissues and soft parts, especially those of cephalopods and oysters. In order of decreasing copper accumulations, molluscs are followed by crustaceans, macrophytes, annelids, tunicates, algae, echinoderms, and coelenterates. Lowest concentrations of copper were consistently found among the vertebrates — elasmobranchs, fishes, mammals — and strongly indicates a discrimination against copper among the highest marine trophic levels examined (Eisler 1979, 1981). Aquatic molluscs and arthropods that possess hemocyanin — a copper-containing respiratory pigment — have elevated tissue and plasma copper concentrations when compared to the ambient medium (Neff and Anderson 1977). Unlike many species of invertebrates, no vertebrate animal has a copper pigment as the main metallic constituent of blood (Schroeder et al. 1966). Marine organisms without hemocyanin have lower tissue concentrations of copper than those with it (Neff and Anderson 1977).

Diet is the most important route of copper accumulation in aquatic animals, and food choice influences body loadings of copper. For example, whole-body copper concentrations in aquatic insects from copper-contaminated rivers are highest in detritivores (as high as 102 mg/kg DW), followed by predators (54 mg/kg DW) and omnivores (43 mg/kg DW; Cain et al. 1992). Little or no biomagnification of copper is evident in freshwater food chains (Stokes 1979).

Copper concentrations in freshwater macrophytes near mining areas are elevated (as much as 256 mg/kg DW) compared to conspecifics collected from more remote sites (Stokes 1979). Bioconcentration factors (ratio of milligrams of copper per kilogram fresh weight organism to milligrams of copper per liter of ambient water) for copper by various species of freshwater algae range from 770 to 83,000. In general, copper accumulations in algae are higher at pH 8 than at pH 5; under conditions of low oxygen and reduced illumination; at low ambient concentrations of calcium, cobalt, zinc, magnesium, manganese, and organic chelators; and at high ambient concentrations of fluoride (Stokes 1979). Benthic communities in the vicinity of bulkheads made of chromated copper arsenate-treated wood had elevated concentrations of these elements, reduced species richness and diversity, and reduced numbers of total organisms when compared to reference sites (Weis and Weis 1994). American oysters (*Crassostrea virginica*) from a canal lined with chromated copper arsenate-treated wood had 150 mg Cu/kg FW soft parts vs. 20 mg Cu/kg FW in oysters from a more distant site (Weis and Weis 1993).

Copper concentrations in cephalopod molluscs are, in general, higher than those in bivalve molluscs. In cephalopods, 50 to 80% of the copper is localized in the digestive gland (Miramand and Bentley 1992). Copper concentrations in tissues of clams (*Macoma balthica*) in San Francisco Bay are associated with seasonal variations in tissue weight, concentrations of copper in the sediments, and anthropogenic inputs from nearby sources (Cain and Luoma 1990). In cockles (*Cerastoderma edule*), copper concentrations in tissues decrease with increasing age, decrease in summer when compared to other seasons, and increase with increasing sediment copper concentrations (Savari et al. 1991). In the cockle (*Anadara trapezium*), tissue copper concentrations are positively related to dissolved copper concentrations in the water column and independent of sediment copper concentrations (Scanes 1993). Small freshwater clams (*Anodonta grandis*) have higher copper concentrations in soft tissues than large clams because small clams take up copper

at a greater rate and excrete it more slowly than large clams (Pip 1990). A similar case is made for oysters and other bivalve molluscs (Weis et al. 1993a). Zebra mussels (*Dreissena polymorpha*) regulate body copper concentrations at water copper levels of 13 µg Cu/L and lower (Camusso et al. 1994). Proximity to point sources, such as sewage discharge plants, is associated with elevated copper burdens in common mussels, *Mytilus edulis* (Ward 1990). Copper concentrations increased in mussels (*Mytilus* spp.) analyzed in the coastal mussel watch program between the late 1970s and the late 1980s. This may be due to increased availability of copper from anthropogenic sources; however, concentrations of other metals (silver, nickel, cadmium, lead, zinc) in mussels analyzed during this period showed a decrease (Lauenstein et al. 1990).

Pacific oysters near a copper recycling facility in Taiwan have elevated concentrations of copper (as high as 4400 mg/kg DW soft parts), a characteristic green color, and low survival after exposure to waste effluents for 3 months (Hung et al. 1990). Diet is the major pathway by which greenish-colored Pacific oysters accumulate copper. Initial daily accumulation rates are as high as 214 mg Cu/kg DW soft parts (Han and Hung 1990). Elimination of 50% of the copper from green Pacific oysters with elevated copper loadings takes only 11.6 days vs. 25.1 days in reference oysters (Han et al. 1993). Elevated concentrations of copper in Pacific oysters (135 mg/kg DW soft parts) near a marina in Arcachon Bay, France, are attributed to the ban on tributyltin antifouling paints in 1982 and the subsequent growth of the use of copper-based antifouling paints (Claisse and Alzieu 1993). Copper concentrations in soft tissues of the American oyster are higher in oysters from low-salinity waters than those from more saline waters; accumulations are not related to sediment copper concentrations in the immediate environment (Huggett et al. 1975). In Maryland, copper concentrations in tissues of the American oyster are seasonally highest in July and lowest in October and higher in low-salinity waters than in high-salinity waters (Roesijadi 1994). In Australia, copper concentrations in oyster soft parts from the Georges River, New South Wales, rose from 20 mg/kg FW to 46 mg/kg FW in the 1970s to as high as 93 mg/kg FW in 1987, possibly as a result of urban and industrial discharges; this concentration exceeds the recommended limit of 70 mg Cu/kg FW in shellfish edible tissues for protection of human health in Australia (Brown and McPherson 1992).

In amphipod (*Orchestia gammarellus*) crustaceans, copper concentrations vary seasonally due to variable copper loadings, are higher in organisms from contaminated sites than reference sites, and higher in females with juveniles in the brood pouch than females without juveniles (Moore et al. 1991). The existence of copper-rich granules is common to all invertebrate phyla; these granules are usually found in the digestive gland or its evolutionary equivalent, and their formation is related to high concentrations of copper in the immediate environment (Weeks 1992). The tolerance of talitrid amphipods to high concentrations of ambient copper is attributable, in part, to the formation of intracellular granules within the cells of the ventral caeca (Weeks 1992). In the crab (*Carcinus mediterraneus*), tissue copper concentrations are lower in winter than in summer and correlate positively with total protein and hemolymph copper contents (Devescovi and Lucu 1995). Elevated copper burdens in hemolymph of crabs probably reflects the incorporation of copper atoms in the structure of hemocyanin, the major hemolymph protein (Depledge et al. 1993). Marine decapod crustaceans regulate tissue copper concentrations within the range of 25 to 35 mg/kg DW (Neff and Anderson 1977).

In *Limnodrilus* sp., an oligochaete worm, copper bioavailability from surficial freshwater sediments is associated with the amount of copper present in the manganese oxide fraction of the sediment. The redox potential and pH in the gut of *Limnodrilus* allows the dissolution of the manganese oxide coating, making copper and other metals available for uptake (Diks and Allen 1983).

Copper concentrations in freshwater fishes collected nationwide in the United States have not changed significantly since 1978 (Schmitt and Brumbaugh 1990). In 1984, samples with the highest copper concentrations were Mozambique tilapia (*Tilapia mossambica*) from Hawaii and white perch (*Morone americana*) from the Susquehanna River in Maryland. These locations have historically

yielded fish with relatively high concentrations of copper. In Hawaii, this may develop from copper-containing pesticides (Schmitt and Brumbaugh 1990). Copper concentrations in fishes are usually higher in liver than other tissues, higher in fish from copper-contaminated lakes than reference lakes, and higher in small fish than large fish of the same species (Cuill et al. 1970; Eisler 1984; ATSDR 1990; de Wet et al. 1994; Table 3.3). Residue data on copper in fish that are dead on collection are probably worthless for purposes of risk assessment owing to copper accumulation after death (Eisler and Gardner 1973). Among sharks collected in British waters, copper concentrations in all tissues are highest from inshore demersal species and lowest from offshore pelagic species, with males having higher copper concentrations in liver than females (Vas 1991).

Copper concentrations in tissues of marine vertebrates tend to decrease with increasing age of the organism (Law et al. 1992; Watanabe et al. 1998). Concentrations of copper in marine and coastal vertebrates — including elasmobranchs, teleosts, and pinniped mammals — are related to the age of the animal. Regardless of species or tissues, except brain, concentrations decrease with increasing age of the organism; brain copper concentrations in marine mammals increase with organism age (Eisler 1984). Decreases in tissue copper content are also associated with spawning migrations of salmonids when entering freshwater from the sea and with reproductive cycles of cod and other gadoids (Eisler 1984). In the copper-contaminated Miramichi River, Canada, populations of Atlantic salmon (*Salmo salar*) are reduced in numbers due to poor survival and reproduction (Sprague et al. 1965). Copper-containing mine wastes entering the Northwest Miramichi River cause many adult Atlantic salmon on their normal upstream spawning migration to return prematurely downstream; about 62% do not reascend. Downstream returns of salmon rose from 1% to 3% before pollution to 10% to 22% during 4 years of pollution. During some periods, dissolved copper and zinc concentrations exceed the lethal levels for immature salmon and the avoidance concentrations for subadults (Sprague et al. 1965; Saunders and Sprague 1967).

In polar bears, concentrations of copper in liver are 3 to 5 times higher than their seal diet (Braune et al. 1991). Copper concentrations in liver and kidney of polar bears are lower in juveniles than adults (Norheim et al. 1992), which is contrary to a reverse trend noted in most species of vertebrates. Neonatal marine mammals, for example, have higher concentrations of copper in liver than those found in the mother (Law et al. 1992). The use of copper herbicides in Florida to control aquatic plants may be hazardous to the endangered manatee. Copper concentrations in livers of these aquatic herbivores from areas of high copper herbicide use are as high as 1200 mg/kg DW. The maximum copper concentrations in livers of copper-challenged manatees are higher than any copper concentration measured in any species of free-ranging mammalian wildlife and are comparable to copper concentrations in livers of some species of domestic animals poisoned by copper (O’Shea et al. 1984).

3.5.5 Amphibians and Reptiles

Eggs of the Jefferson salamander (*Ambystoma jeffersonianum*) from a series of ponds that contain 1 to 25 µg Cu/L have — at the higher copper concentrations — a reduction in hatching success and an increase in embryonic mortality (Horne and Dunson 1995).

For reasons unknown, livers of some adult giant toads (*Bufo marinus*) normally contain grossly elevated concentrations of copper (>2000 mg/kg DW). The toads’ livers are undamaged by this level of copper, and this lack of effect is in sharp contrast to human patients with Wilson’s disease (2000 mg Cu/kg DW liver) wherein hepatocyte degeneration, necrosis, and ultimately cirrhosis result (Goldfischer et al. 1970). In toad livers, the copper is sequestered in lysosomes, which seems to protect the cell from the toxic effects of copper. In contrast, copper in liver of humans with Wilson’s disease is diffusely distributed in the cytoplasm of hepatocytes and is associated with severe and often fatal pathological changes (Goldfischer et al. 1970).

3.5.6 Birds

Season of collection and organism age affect copper concentrations in avian tissues. In livers of surf scoters (*Melanitta perspicillata*) from San Francisco Bay, copper concentrations are higher in March than in January; in livers of canvasbacks (*Aythya valisineria*) from Louisiana, concentrations are lower in November than later months; and in primary flight feathers of mallards (*Anas platyrhynchos*) and black ducks (*Anas rubripes*) from the vicinity of a smelter in Sudbury, Ontario, copper concentrations are highest in autumn (Ranta et al. 1978). Copper concentrations in tissues of coastal seabirds tend to decrease with increasing age (Eisler 1984). In New Zealand, younger marine birds have higher concentrations of copper in livers than adults (Lock et al. 1992), but juveniles and adults of common murres (*Uria aalge*) from Scotland have similar concentrations of copper in kidneys, livers, and muscle (Stewart et al. 1994).

In general, birds retain a very small portion of copper and other metals ingested (Bryan and Langston 1992). It is therefore noteworthy that livers of some canvasbacks collected in Louisiana (Custer and Hohman 1994) and livers of some mute swans (*Cygnus olor*) from England (Bryan and Langston 1992) both contain more than 2000 mg Cu/kg DW. In the case of mute swans, several thousands of milligrams of copper per kilogram dry weight occur in the blackened livers; blackening is attributed to ingestion of flakes of copper-based antifouling paints (Bryan and Langston 1992). Tree swallows (*Tachycineta bicolor*) nesting near acidified aquatic ecosystems accumulate sufficient copper from the diet to induce elevated hepatic metallothionein concentrations (St. Louis et al. 1993). Copper concentrations in stomach contents of willets (*Catoptrophorus semipalmatus*) from San Diego Bay tend to reflect sediment copper concentrations (Hui and Beyer 1998). However, there is no evidence of copper biomagnification in the sediment food chain of sediment–pond-weed–red-knobbed coot (*Fulica cristata*; van Eeden and Schoonbee 1993).

3.5.7 Mammals

Impalas (*Aepyceros melampus*) found dead in Kruger National Park, South Africa, had elevated concentrations of copper in livers (maximum 444 mg/kg FW) and kidneys (maximum 141 mg/kg FW); authors assert that copper poisoning is the most likely cause of death (Gummow et al. 1991), but this needs verification. Copper concentrations in bones, kidneys, and livers of white-tailed deer (*Odocoileus virginianus*) near a copper smelter and from distant sites are about the same. However, deer near the smelter have significantly elevated concentrations of cadmium in kidneys and livers, lead in bone, and zinc in kidneys (Storm et al. 1994).

Only a small portion (0.037%) of copper mining wastes discharged into riparian wetlands is bioavailable to resident rodents, as judged by measurements of copper in carcasses of mice and voles (Pascoe et al. 1994). Populations of brown-backed voles (*Clethrionomys rufocanus*) and other microtine rodents (*Microtus* spp., *Lemmus*) are low or absent in the vicinity of Russian copper–nickel smelters (Kataev et al. 1994). The reasons for this decline are unknown but may be due to a decrease in the abundance of important food plants (lichens, mosses, seed plants), and — as shown in preference studies — to an avoidance of plants from the contaminated area (Kataev et al. 1994). Bank voles (*Clethrionomys glareolus*) from areas of Poland subjected to various degrees of industrial contamination have copper concentrations in tissues comparable to those in animals from polluted sites in North America and the United Kingdom (Sawicka-Kapusta et al. 1990). Compared to animals from a reference site, muskrats (*Ondatra zibethicus*) from a site contaminated by copper and other chemicals have higher concentrations of copper in kidneys, smaller spleens, larger adrenals, less fat, and lower body weight (Halbrook et al. 1993).

In Poland near copper foundries, livers from cattle (*Bos* sp.) have higher copper concentrations (35 to 140 mg/kg FW) than cattle from agricultural regions (7 to 32 mg/kg FW); however, kidney copper concentrations are comparable for both regions (Falandysz 1993a). Cattle found dead in South Africa near a copper smelter have elevated levels of copper in liver (600 mg/kg FW;

1078 mg/kg DW); airborne copper from the smelter is considered the most likely cause of death (Gummow et al. 1991). Sheep held for 150 days in a paddock near a heavily-travelled highway have significantly elevated copper concentrations in wool; these differences are not as pronounced in hair from horses (*Equus caballus*) and alpacas (*Lama pacos*) held under similar conditions (Ward and Savage 1994).

Interspecies differences in copper contents are considerable. Serum from domestic dogs (*Canis familiaris*) lacks the strong copper binding site available on the serum albumin molecule of humans and rats. Accordingly, copper concentrations in livers from dogs (82 mg/kg FW; 336 mg/kg DW) are normally about 12 times higher than those of human livers and 19 times higher than those of rat livers (Goresky et al. 1968).

Human foods that are particularly rich in copper (20 to 400 mg Cu/kg) include oysters, crustaceans, beef and lamb livers, nuts, dried legumes, dried vine and stone fruits, and cocoa (USEPA 1980). In humans, copper is present in every tissue analyzed (Schroeder et al. 1966). A 70-kg human male usually contains 70 to 120 mg of copper (USEPA 1980). The brain cortex usually contains 18% of the total copper, liver 15%, muscle 33%, and the remainder in other tissues — especially the iris and choroid of the eye. Brain gray matter (cortex) has significantly more copper than white matter (cerebellum); copper tends to increase with increasing age in both cortex and cerebellum. In newborns, liver and spleen contain about 50% of the total body burden of copper (USEPA 1980). Liver copper concentrations were usually elevated in people from areas with soft water (Schroeder et al. 1966). Elevated copper concentrations in human livers are also associated with hepatic disease, tuberculosis, hypertension, pneumonia, senile dementia, rheumatic heart disease, and certain types of cancer (Schroeder et al. 1966).

3.6 COPPER DEFICIENCY EFFECTS

3.6.1 General

Adverse effects of copper deficiency can be documented in terrestrial plants and invertebrates, poultry, small laboratory animals, livestock — especially ruminants — and humans. Data are scarce or missing on copper deficiency effects in aquatic plants and animals and in avian and mammalian wildlife. Copper deficiency in sheep, the most sensitive ruminant mammal, is associated with depressed growth, bone disorders, depigmentation of hair or wool, abnormal wool growth, fetal death and resorption, depressed estrous, heart failure, cardiovascular defects, gastrointestinal disturbances, swayback, pathologic lesions, and degeneration of the motor tracts of the spinal cord (NAS 1977).

3.6.2 Terrestrial Plants and Invertebrates

Copper is an essential micronutrient of all higher plants studied, being a cofactor for the enzymes polyphenol oxidase, monophenol oxidase, laccase, and ascorbic acid oxidase (Schroeder et al. 1966). In copper-deficient soils, copper is strongly held on inorganic and organic exchange sites and in complexes with organic matter (Thornton 1979), causing reduced availability of copper to vegetation in these soils. Copper deficiency in terrestrial plants is usually associated with reduced growth, abnormally dark coloration in rootlets, and chlorotic leaves (Gupta 1979). In agricultural crops, copper deficiency occurs at <1.6 mg dissolved Cu/kg DW soil (Thornton 1979), and in sensitive plants at <2 to <5 mg total Cu/kg DW leaves (Gupta 1979). In fruit trees, copper deficiency is characterized by death of apical buds, formation of multiple buds, and yellowing (chlorosis) of the leaf margins (NAS 1977). Copper deficiency in alfalfa (*Medicago sativa*) and clover (*Trifolium* spp.) is associated with a faded green leaf color, growth inhibition, and withering (Gupta 1979). In grasses, copper deficiency is characterized by chlorosis, stunting, and necrosis, and in cereals by pale color, reduced growth, and a reduction in the number of pollen grains (Gupta 1979).

Increased yields of various crops occur when copper salts are added to fertilizers at 300 to 800 mg Cu/m³ (NAS 1977). In corn (*Zea mays*) and other vegetables, younger plants are more sensitive to copper deficiency than mature plants; in all cases, copper-deficient vegetables show chlorosis, reduced growth and reproduction, and low survival (Gupta 1979).

No evidence of copper deficiency exists in terrestrial species of invertebrates examined. However, relatively low concentrations of copper stimulated growth and reproduction. Reproduction in mites (*Platynothrus peltifer*) increases when fed diets containing 28 mg Cu/kg DW (vs. 13 mg/kg in controls) for 3 months (Denneman and van Straalen 1991). Also, juveniles of earthworms (*Eisenia andrei*) show increased growth at 18 mg Cu/kg DW soil after 12 weeks (van Gestel et al. 1991).

3.6.3 Aquatic Organisms

No documented report of fatal copper deficiency is available for any species of aquatic organism, and no correlation is evident in aquatic biota for the presumed nutritional copper requirements of a species and its sensitivity to dissolved copper (Neff and Anderson 1977). Extremely low copper concentrations (5.5 and 6.7 mg/kg DW) in whole bodies of 2 of 17 species of crustaceans from the Antarctic Ocean support the hypothesis that certain Antarctic species may show copper deficiencies or reduced metal requirements (Petri and Zauke 1993).

3.6.4 Birds and Mammals

Copper deficiency is not a major public health concern in the United States (Percival 1995). It is rarely observed in humans except in cases of severely malnourished children or those with Menkes' disease — an X-linked recessively inherited disorder. This disease is a severe congenital copper deficiency marked by slow growth, progressive cerebral degeneration, convulsions, temperature instability, bone alterations, and peculiar steel-like hair (ATSDR 1990; Yoshimura et al. 1995). Treatment of Menkes' disease is now restricted to parenteral administration of copper salts, although complete prevention of neurodegradation is difficult to obtain (Yoshimura et al. 1995). Copper deficiency is sometimes reported in humans after intestinal resection surgery (reduced absorptive surface), in people who consume high levels of zinc (zinc induces intestinal metallothionein that blocks copper transport), in infants who consume a diet based on cow milk (cow milk is a poor source of copper), and in genetic cases (Percival 1995). Moderate copper deficiency also exists in burn and trauma patients, two groups at high risk for sepsis (DiSilvestro et al. 1995).

An inherited abnormal copper metabolism has been established in certain strains of mice, rats, and dogs (Sugawara and Sugawara 1994). Feeding a copper-deficient diet to these animals may prevent acute hepatitis. In rats with abnormal copper metabolism and hereditary hepatitis, feeding a copper-deficient diet (0.5 mg Cu/kg ration for 35 days) prevents copper accumulation (94 to 139 mg Cu/kg DW liver) and dysfunction. Feeding a normal diet of 30 mg Cu/kg DW ration to these rats produces liver Cu concentrations of 375 mg/kg DW (Sugawara and Sugawara 1994). Administered copper protects copper-deficient strains of mice against neurodegradation, and protects ponies against selenium poisoning when pretreated with 20 or 40 mg Cu/kg BW (Stowe 1980).

Chickens (*Gallus domesticus*) given diets deficient in copper (less than 2.7 mg Cu/kg ration) have anemia, poor growth, low survival, and a high frequency of cardiovascular and skeletal lesions (Carlton and Henderson 1963, 1964a, 1964b). It is emphasized, however, that copper deficiency does not usually arise from eating a copper-poor diet because copper is found ubiquitously in foods (Percival 1995). Chickens, turkeys (*Meleagris gallopavo*), cattle, and pigs deficient in copper are prone to sudden death (Gallagher 1979). Sudden death in some copper-deficient species is sometimes associated with rupture of a major blood vessel or rupture of the heart (Carlton and Henderson 1964b; NAS 1977; ATSDR 1990; Saari et al. 1994). Male weanling rats given a copper-deficient diet of 0.13 mg Cu/kg ration (vs. copper-normal diet of 5.7 mg Cu/kg ration) for 7 weeks show high mortality (24%) from cardiac rupture; ruptured hearts had elevated concentrations of sodium,

potassium, and calcium, and depressed magnesium (Saari et al. 1994). Copper deficiency in weanling rats is confirmed by low activities of ceruloplasmin in serum and superoxide dismutase in liver and serum (DiSilvestro et al. 1995). Skeletal deformities and leg fractures occur in copper-deficient chickens, dogs, pigs, sheep, cattle, and children because of decreased tensile strength of bones (Carlton and Henderson 1964a; NAS 1977; Gallagher 1979). In lambs from copper-deficient ewes, locomotor disturbances of gait or posture occur because of lesions of excessive myelination of the central nervous system (Gallagher 1979).

Copper deficiency in humans and other mammals is characterized by slow growth, hair loss, anemia, weight loss, emaciation, edema, altered ratios of dietary copper to molybdenum and other metals, impaired immune response, decreased cytochrome oxidase activity, central nervous system histopathology, decreased phospholipid synthesis, fetal absorption, and eventually death (NAS 1977; Gallagher 1979; Kirchgessner et al. 1979; USEPA 1980; ATSDR 1990; Percival 1995).

In laboratory white rats, signs of copper deficiency include reductions in tissue copper concentrations; reduced activities of cytochrome oxidase, superoxide dismutase, succinoxidase, and ceruloplasmin; increased activity of 7-ethoxyresorufin O deethylase (EROD) in small intestines; anemia associated with low hematocrit and hemoglobin; increased acute inflammatory response; increased sensitivity to endotoxins; central nervous system lesions; and reduced phospholipid synthesis (Gallagher 1979; Johnson and Smith 1994; Schuschke et al. 1994; DiSilvestro et al. 1995). Copper-deficient rats also have prolonged sleeping times and significant reductions in activities of aniline hydroxylase and hexobarbital oxidase in liver (Moffitt and Murphy 1973). Earliest signs of copper deficiency in rats include low concentrations of copper in livers (1.4 to <3.0 mg/kg DW vs. 12.6 to 15.0 mg/kg DW in controls); profound reductions in activities of cytochrome oxidase and succinoxidase; and reductions in hematocrit, hemoglobin, ceruloplasmin, and phospholipid synthesis (Gallagher 1979; Johnson and Smith 1994). Severe copper deficiency in rats results in anemia characteristic of defective hemoglobin synthesis resulting from abnormal use of iron by mitochondria in heme synthesis (Johnson and Smith 1994). Copper-deficient rats are extraordinarily sensitive to endotoxins and die after receiving normally sublethal doses of various endotoxins (DiSilvestro et al. 1995). Copper deficiency-induced lesions in the central nervous system are produced experimentally in rats and guinea pigs and are a characteristic feature of Menkes' disease (Gallagher 1979).

Sway disease of Bactrian camels (*Camelus bactrianus*) — characterized by anemia, emaciation, falling, fractures, and death — is caused by copper deficiency associated with high molybdenum content in soils and forage. Deficiency effects are aggravated during reproduction (Zong-Ping et al. 1994).

Sheep fed copper-deficient diets of less than 2.5 mg Cu/kg DW ration (vs. a normal diet of 11.0 mg Cu/kg DW) produce a high frequency of swaybacked lambs. Swaybacks have lower concentrations of copper in liver than nonswaybacked lambs from copper-deficient ewes. Both groups have lower concentrations of copper in livers than normal lambs (Lewis et al. 1967; Buckley and Tait 1981).

Copper deficiency effects are reported in mink (*Mustela vison*) and domestic swine. Copper deficiency in mink, as judged by reduced survival, occurs by feeding rations containing the equivalent of 3.5 mg Cu/kg BW daily for a period of 50 weeks (ATSDR 1990). Swine, which seem to have higher copper requirements than mink, given low copper diets equivalent to 15 to 36 mg Cu/kg BW daily for 7 days have decreased hemoglobin, hematocrit, and growth rate (ATSDR 1990).

Dietary copper deficiency increases the acute inflammatory response in rats and other small laboratory animals (Schuschke et al. 1994). The release of inflammatory mediators, such as histamine and serotonin, from mast cells increases the vascular permeability of postcapillary venules and results in edema. In copper-deficient rats, release of histamine from mast cells correlates positively with frequency of the acute inflammatory response. Copper-deficient rats (0.6 mg Cu/kg DW ration for 4 weeks) have more mast cells in muscle than copper-adequate controls given diets containing 6.3 mg Cu/kg DW ration; however, histamine content of mast cells is not affected (Schuschke et al. 1994). An early clinical sign of copper deficiency is a reduction in the number of circulating neutrophils; the mechanism for copper-deficient neutropenia (leukopenia in which

the decrease in white blood cells is chiefly neutrophils) is unknown (Percival 1995). Proposed mechanisms to account for neutropenia from copper deficiency include:

1. Early destruction of bone marrow progenitor cells
2. Impaired synthesis of neutrophils from progenitor cells
3. A decrease in the rate of cellular maturation in the bone marrow
4. Impaired secretion of neutrophils from the bone marrow
5. Rapid clearance of circulating copper-deficient neutrophils (Percival 1995)

3.7 LETHAL AND SUBLETHAL EFFECTS

3.7.1 General

Copper is toxic to sensitive species of terrestrial vegetation at >40 µg/L nutrient solution (seedlings of pines, *Pinus* spp.), at >10 mg/kg DW leaves (cucumber, *Cucumis sativus*), and >60 mg extractable Cu/kg DW soil (sweet orange, *Citrus sinensis*; Table 3.4). Among sensitive species of terrestrial invertebrates, adverse effects on survival, growth, or reproduction occur at 2 µg Cu/cm² on paper discs (earthworms), >50 mg Cu/kg diet (larvae of gypsy moth, *Lymantria dispar*), and 53 to 70 mg Cu/kg DW soil (earthworms and soil nematodes; Table 3.4).

Table 3.4 Effects of Copper on Representative Terrestrial Plants and Invertebrates

Organism, Copper Concentration or Dose, and Other Variables	Effects	Reference ^a
PLANTS		
Agricultural crops from soils containing dissolved copper		
0.0–1.6 mg/kg soil	Copper deficiency in susceptible crops	1
1.7–2.4 mg/kg soil	Slight deficiency	1
2.5–4.0 mg/kg soil	Deficiency unlikely	1
>4.0 mg/kg soil	Soil well supplied with copper	1
Sweet orange, <i>Citrus sinensis</i> ; 4-year-old trees; M3 extractable soil copper >60 mg/kg DW (from treated plots containing about 120 kg Cu/ha)	Growth adversely affected; positive correlation between copper concentrations in feeder roots (4 to 450 mg Cu/kg DW) and M3 extractable soil copper	17
Cucumber, <i>Cucumis sativus</i> ; leaves		
<2 mg/kg dry weight (DW)	Deficient	2
2–10 mg/kg DW	Sufficient	2
>10 mg/kg DW	Toxic	2
Soybean, <i>Glycine max</i> ; leaves		
<4 mg/kg DW	Deficient	2
10–30 mg/kg DW	Sufficient	2
>50 mg/kg DW	Toxic	2
Pasture grasses; above-ground portions		
<5 mg/kg DW	Deficient	2
5–12 mg/kg DW	Sufficient	2
>12 mg/kg DW	Toxic	2
Seedlings of stone pine, <i>Pinus pinea</i> and maritime pine, <i>Pinus pinaster</i> ; exposed to nutrient solutions containing 0.4 (controls) 4, 40, or 200 µg Cu/L for as long as 4 weeks		
4 µg/L	Slight to no enhancement of root elongation	16
40 µg/L	Taproot elongation reduced but partial growth recovery in 7 days; cell membrane damage evident after 10 days	16
200 µg/L	Root growth completely inhibited within 3 days in both species	16

Table 3.4 (continued) Effects of Copper on Representative Terrestrial Plants and Invertebrates

Organism, Copper Concentration or Dose, and Other Variables	Effects	Reference ^a
Faba bean, <i>Vicia faba</i> ; cultured hydroponically with nutrient solutions containing 100 mg Cu/L for 24 days; shoots analyzed before (day 4) and after (day 24) 20-day infestation by the black bean aphid, <i>Aphis fabae</i> . Controls were raised in copper-free nutrient solutions	Aphid infestation caused a significant reduction in copper content of shoots from 51 mg Cu/kg DW to 17 mg/kg; copper in control was 25 mg/kg DW prior to aphid infestation and 14 mg/kg after 20-day infestation	3
INVERTEBRATES		
Earthworm, <i>Aporrectodea caliginosa</i> ; cocoons; exposed to aqueous solutions of copper chloride at 0–20 mg Cu/L for 14 days at 20°C and 100% relative humidity, and then to either desiccation or frost for 14 days	No adverse effects at 6 and 12 mg Cu/L. At 20 mg Cu/L, none survived at –3°C and 95% survived at 0°C; embryos contained up to 200 mg Cu/kg DW — comparable to concentrations found in various earthworm tissues from copper-contaminated soils	18
Soil nematode, <i>Caenorhabditis elegans</i>		
70 mg/kg DW sandy soil for 24 h	LC50	4
105 mg/L for 24 h; no soil	LC50	4
1061 mg/kg loam substrate for 24 h	LC50	4
2476 mg/L for 24 h; loam substrate	LC50	4
Soil ciliate, <i>Colpoda steini</i>		
250 µg/L for 24 h	Growth reduced 50%	5
Fruitfly, <i>Drosophila melanogaster</i>		
In culture medium containing 80 µg Cu/cm ² for 4 weeks	Survival reduced 35%; copper elevated in cytoplasm, Malpighian tubule epithelial cells, and other tissues	6
Earthworms, three species; 40–238 mg/kg soil; exposure duration unknown	No effect on growth, survival, or reproduction	7
Earthworm, <i>Eisenia andrei</i> ; juveniles; exposure for 12 weeks		
18 mg/kg DW soil	Growth stimulated	8
56 mg/kg DW soil	No effect on growth or reproduction	8
100 mg/kg DW soil	<50% effective in reducing growth; inhibited sexual development	8
Earthworm, <i>Eisenia fetida</i>		
32 mg/kg DW soil for 56 days	No effect on cocoon production	9
53.3 (32.5–186.0) mg/kg DW soil for 56 days	Cocoon production reduced 50%	9
210 mg/kg DW soil for 56 days	No deaths	9
555 (460–678) mg/kg DW soil for 56 days	50% dead	9
683 (570–812) mg/kg DW soil for 14 days	50% dead	9
Earthworm, <i>Eisenia fetida andrei</i>		
Adults held in soil containing as much as 300 mg Cu/kg DW for 3 weeks; resultant cocoons incubated in uncontaminated soil for 5 weeks to assess hatchability	No adverse effects on cocoon production or hatchability in soil containing 60–120 mg Cu/kg DW; adult growth retarded during exposure at 300 mg/kg DW	10
Earthworm, <i>Lumbricus rubellus</i>		
100–150 mg/kg DW soil	Decreased cocoon production	11
150–300 mg/kg DW soil	Decrease in litter breakdown activity	11
>300 mg/kg DW soil	Reduced growth and increased mortality	11
1000 mg/kg DW soil for 6 weeks	Lethal to 50%	11
Earthworm, <i>Lumbricus terrestris</i>		
Exposed for 5 days to filter paper disc containing 0.5, 1, 2, 4, or 8 µg Cu/cm ²	At 4 µg/cm ² and higher, mortality was >90%; 20% were dead at 2 µg/cm ² , and none were dead at lower concentrations. Whole worms contained, in mg Cu/kg DW, 5.9 in controls, 28.5 in the 0.5 group, and 73.1 in the 1.0 group. At sublethal concentrations, worms had decreased lysozyme activity in coelomic fluid and coelomocytes	12

Table 3.4 (continued) Effects of Copper on Representative Terrestrial Plants and Invertebrates

Organism, Copper Concentration or Dose, and Other Variables	Effects	Reference ^a
Gypsy moth, <i>Lymantria dispar</i> Larvae were fed diets containing 10, 50, 250, or 1250 mg Cu/kg ration from first instar to pupation; effects measured on development rate, growth, survival, and reproductive success	No adverse effects at 10 mg/kg diet. Significant adverse effects at 50 mg/kg and higher on development and reproductive success and at 250 mg/kg and higher on growth	13
Oribatid mite, <i>Platynothrus peltifer</i> Fed diets with 13 (control), 28, 64, 168, 598, or 1498 mg Cu/kg DW diet for 3 months	No deaths at any dose.	7
84 mg/kg DW soil Soil faunal communities Forest soil treated to contain 100, 200, 400, or 600 mg Cu/kg DW; nematodes and macroarthropods enumerated after 7 days	Reproduction increased at 28 mg/kg but decreased steadily with increasing dose. The no-observable-effect-concentration (NOEC) for reproduction was 168 mg/kg diet; the NOEC for growth was 598 mg/kg. Copper concentrations in whole mites increased significantly at dietary loadings >168 mg/kg NOEC on growth, survival, or reproduction	7
Termites, subterranean; Karachi, Pakistan; termite-infested area (<i>Microtermes</i> spp., <i>Heterotermes</i> spp., <i>Coptotermes</i> spp., <i>Odontotermes</i> spp.) Fir (<i>Abies pindrow</i>) wooden stakes coated with 5% copper sulfate in gelatin solution vs. uncoated stakes	Sensitive species of nematodes and mites were reduced in number at 100 mg/kg soil; total nematode and arthropod numbers declined at 200 mg/kg and higher Copper-treated stakes prevented termite attack in soil up to 4 years vs. severe termite damage within 6 months in control stakes	14 15

^a 1, Thornton 1979; 2, Gupta 1979; 3, Crawford et al. 1990; 4, Donkin and Dusenberry 1993; 5, Forge et al. 1993; 6, Marchal-Segault et al. 1991; 7, Denneman and van Straalen 1991; 8, van Gestel et al. 1991; 9, Spurgeon et al. 1994; 10, van Gestel et al. 1989; 11, Ma 1984; 12, Goven et al. 1994; 13, Gintenreiter et al. 1993; 14, Parmelee et al. 1993; 15, Roomi et al. 1990; 16, Arduini et al. 1995; 17, Alva et al. 1995; 18, Holmstrup et al. 1998.

Sensitive species of representative freshwater plants and animals die within 96 h at waterborne copper concentrations of 5.0 to 9.8 µg/L (Hodson et al. 1979; Table 3.5). The most sensitive freshwater species have LC50(96 h) values between 0.23 and 0.91 µg Cu/L and include daphnids (*Daphnia* spp.), amphipods (*Gammarus pseudolimnaeus*), snails (*Physa* spp.), and chinook salmon (*Oncorhynchus tshawytscha*; USEPA 1980; Table 3.5). In general, mortality of tested aquatic species is greatest under conditions of low water hardness (as measured by CaCO₃), starvation, elevated water temperatures, and among early developmental stages (Hodson et al. 1979; Table 3.5). Toxicity testing of copper-contaminated sediments to amphipods (*Hyalella azteca*) and daphnids (*Daphnia magna*) using techniques of enzyme inhibition and growth rate show that these variables are more sensitive in accurately predicting copper sensitivity than LC50(48 h) values (Kubitz et al. 1995) and should be considered when assessing risk of contaminated sediments to freshwater systems. The most sensitive saltwater species to copper have LC50(96 h) values from 28 to 39 µg/L and include summer flounders (*Paralichthys dentatus*), copepods (*Acartia tonsa*), and softshell clams (*Mya arenaria*; USEPA 1980; Eisler 1995; Table 3.5). Adverse sublethal effects of copper on representative species of estuarine algae, molluscs, and arthropods frequently occur at 1 to 10 µg/L (Bryan and Langston 1992; Table 3.5).

No data are available on copper toxicity to avian wildlife. Experiments with domestic poultry show that copper accumulates in livers of mallard ducklings at dietary concentrations as low as 15 mg/kg DW ration; that gizzard histopathology and a reduction in weight gain of chicks (*Gallus* sp.) occur at 250 to 350 mg Cu/kg DW ration; and that growth of turkey poult is improved at

60 mg Cu/kg DW ration and inhibited at 120 mg/kg DW ration, with signs of gizzard histopathology at 500 mg/kg DW ration (Wood and Worden 1973; Poupolis and Jensen 1976; NAS 1977; Kashani et al. 1986; [Table 3.6](#)).

Copper is lethal to mammals through a variety of routes ([Table 3.7](#)). Single oral doses of 6 to 637 mg Cu/kg BW are fatal to humans. A single oral dose of 200 mg/kg BW is usually fatal to cattle. Dietary copper is lethal when eaten for extended periods at more than 80 mg Cu/kg ration in sheep (equivalent to 5.1 to 10.7 mg Cu/kg BW daily), more than 238 mg/kg ration in pigs, and more than 4000 mg/kg ration in rats (equivalent to more than 133 mg Cu/kg BW daily; [Table 3.7](#)).

Adverse sublethal effects of copper to sensitive mammals occur in human infants at drinking water concentrations more than 3 mg Cu/L; in cattle at dietary levels greater than 20 mg Cu/kg BW by way of intraperitoneal injection and more than 4.2 mg Cu/kg BW via drinking water; in sheep given daily oral doses of 7.5 to 15.0 mg Cu/kg BW or fed diets containing more than 37.3 mg Cu/kg ration; in rats at >100 mg Cu/kg ration (equivalent to >7.9 mg Cu/kg BW daily), >400 mg Cu/L drinking water, or >2.0 to 2.5 mg Cu/kg BW daily via injection; and in pigs at more than 14.5 mg Cu/kg BW daily via diet. Elevated copper concentrations (328 mg Cu/kg DW) occur in livers of surviving cattle fed diets containing 8.2 mg Cu/kg ration; of sheep (1109 mg/kg DW liver) fed diets containing 37.3 mg Cu/kg ration; and of rats (710 mg/kg FW liver) given intraperitoneal injections of 3.75 mg Cu/kg BW daily for 18 weeks ([Table 3.7](#)).

3.7.2 Terrestrial Plants and Invertebrates

Copper is toxic to sensitive plants when plant nutrient solutions contain >40 to 200 µg Cu/L, when leaves have >10 to 12 mg Cu/kg DW, and when extractable copper in soils is >60 mg/kg DW soil ([Table 3.4](#)). Excess copper inhibits root elongation and branching and reduces the ability of the plant to explore the soil for water and nutrients (Arduini et al. 1995). Root damage occurs in pine seedlings (*Pinus* spp.) after exposure for 10 days to nutrient solutions that contain 40 µg Cu/L. A lower concentration of 4 µg Cu/L has no adverse effects on root growth and morphology, while a higher concentration of 400 µg Cu/L completely inhibits root growth within 3 days (Arduini et al. 1995).

Severely reduced crop growth was measured in soils treated with 750 kg Cu/ha annually for 13 years wherein the soil pH declined from 6.1 to 4.7 during this period (Boon et al. 1998). Laboratory studies showed that planting of copper-tolerant grass (*Agrostis capillaris*) on these soils resulted within 10 weeks in faster bacterial growth, more protozoans, and more nematodes in comparison to fallow controls. Boon et al. (1998) concluded that metal-tolerant plant species can reestablish the necessary food base to support organism growth and can reverse the loss of soil function due to high copper levels under acidic conditions.

Poultry litter is a useful agricultural by-product with high nitrogen and phosphorus content and is frequently added to agricultural soils. Poultry litter from northern Georgia containing 1196 mg Cu/kg DW and applied at a final rate of 5 to 15 mg Cu/kg soil to fields of Sudex (*Sorghum bicolor* × *S. sudanense*) did not affect copper levels of treated Sudex or produce any evidence of toxicity (van der Watt et al. 1994). However, most terrestrial vegetation in the United States, Sweden, Wales, and other locales is usually adversely affected by emissions from copper mines, brass foundries, and copper smelters (Hutchinson 1979). Damage to vegetation persists for at least 50 years after closure of a copper smelter because of copper, arsenic, and lead in the soil. Particularly sensitive to copper in the soils are white pine (*Pinus strobus*) and red maple (*Acer rubrum*). Less sensitive are Douglas fir (*Pseudotsuga menziesii*) and lodgepole pine (*Pinus contorta*; Hutchinson 1979).

Earthworms (*Eisenia fetida*) held in soils containing 53 mg Cu/kg DW show a 50% reduction in cocoon production in 56 days; 32 mg Cu/kg soil had no effect on cocoon production (Spurgeon et al. 1994). The LC50 (56 days) value for earthworms is 555 mg Cu/kg DW soil; no deaths occur at 210 mg/kg soil during this period. Copper is more toxic to *Eisenia fetida* than are salts of cadmium, zinc, or lead (Spurgeon et al. 1994). Copper adversely affects the earthworm *Lumbricus rubellus* (Ma 1984). Concentrations of 150 mg Cu/kg surface soil from an accidental spill of copper

sulfate in grasslands reduced earthworm populations by about 50%; surface soil concentrations of 260 mg Cu/kg kill almost 100% of the *Lumbricus*. Copper is most toxic to *Lumbricus* at low soil pH (4.8 to 7.1) and at low temperatures (Ma 1984). Earthworm cocoons, however, were relatively unaffected by copper at concentrations <12 mg Cu/L, and at 20°C unless stressed by desiccation or frost (Holmstrup et al. 1998). Cocoons of *Aporrectodea calignosa* were unaffected at 20 mg Cu/L except under conditions of low relative humidity (95% relative humidity vs. 97.5% or 100%), and temperatures of -3, and -6°C, but not 0°C (Holmstrup et al. 1998).

Tests show that the presence of soil reduces the toxicity of copper to the soil-dwelling nematode *Caenorhabditis elegans*; copper toxicity to nematodes increases with increasing densities of bacteria and increasing concentrations of sodium chloride or potassium chloride (Donkin and Dusenberry 1993). Terrestrial isopods efficiently assimilate and store copper as detoxified granules in the hepatopancreas; this activity is in contrast to many species of marine crustaceans that are unable to assimilate, detoxify, or otherwise regulate copper (Weeks and Rainbow 1993).

3.7.3 Aquatic Organisms

Plants

Photosynthesis and growth in sensitive species of freshwater algae are inhibited by copper concentrations of 1 to 6 µg/L (NAS 1977; [Table 3.5](#)). For sensitive species of estuarine phytoplankton, copper is lethal at 50 µg/L and most toxic under conditions of decreasing salinity, pH, and concentrations of chelators (Erickson et al. 1970). Sensitivity to copper varies widely among species of estuarine algae (Erickson et al. 1970; [Table 3.5](#)). Some species, for example, grow normally at concentrations as high as 10 mg Cu/L during exposure for 9 days (Piccinni and Coppelotti 1982). In mesocosm studies, 50 µg Cu/L caused a reduction of about 80% in total zooplankton and total algal biovolumes; the algal assemblage that persisted was dominated by diatoms (Havens 1994). Copper-resistant strains of *Euglena gracilis* challenged with high sublethal concentrations of copper for 5 days had an altered cysteine metabolism (Coppelotti 1989).

Some species of aquatic plants absorb or adsorb dissolved copper at extremely high rates ([Table 3.5](#)). Bioconcentration factors for copper and freshwater alga (*Chlorella* sp.) range from 203 to 2000 after exposure for 14 to 30 h (USEPA 1980). Seagrass (*Heterozostera tasmanica*) in seawater containing 42 µg Cu/L for several weeks contain 2700 mg Cu/kg DW; seagrasses in media containing 0.3 µg Cu/L contain 2.5 mg Cu/kg DW; and intermediate values are reported for 10 µg Cu/L (306 to 564 mg/kg DW) and 20 µg/L (1280 mg/kg DW; Ahsanullah and Williams 1991). Some freshwater aquatic macrophytes accumulate as much as 54,500 mg Cu/kg DW, as was the case for *Lemna* sp. during exposure to 1000 µg Cu/L; a lower dose regimen of 35 µg Cu/L results in 256 mg Cu/kg DW *Lemna* (Stokes 1979).

Table 3.5 Effects of Copper on Representative Aquatic Plants and Animals

Taxonomic Group, Organism, Copper Concentration, and Other Variables	Effects	Reference ^a
PLANTS		
Algae; mixed culture; 5 µg/L	Photosynthesis reduced	1
Aquatic weeds, fresh water 170 µg/L for 99 days, continuous exposure	Eliminated or controlled most submerged species; adverse effects first noted at day 34. Weeds contained 360 to 4280 mg Cu/kg dry weight (DW)	2
250–1000 µg/L for 99 days, continuous exposure	Unsuccessful in controlling emergent aquatic weeds; successful in eliminating filamentous algae and most submerged species	2

Table 3.5 (continued) Effects of Copper on Representative Aquatic Plants and Animals

Taxonomic Group, Organism, Copper Concentration, and Other Variables	Effects	Reference ^a
Marine alga, <i>Chlamydomonas bulloso</i> ; 49.9 µg/L for 96 h	Growth reduced 50%	3
Green alga (fresh water), <i>Chlamydomonas reinhardtii</i>		
18 µg/L for 24 h	Reduction in number of cells bearing flagella	4
21 µg/L for 7 days	Growth normal	5
32 µg/L for 7 days	Growth reduced 50%	5
60 µg/L for 10 min	Flagella shed; flagellar refabrication inhibited for 24 h	4
79 µg/L for 72 h	Growth inhibited 50%	5
Freshwater alga, <i>Chlorella</i> spp.		
1.0 µg/L	Growth reduced	1
6.3 µg/L	Photosynthesis inhibited	1
Marine alga, <i>Dunaliella salina</i>		
0.031 µg/L for 8 months	Minor adverse effects on lipid metabolism	6
380 µg/L for 96 h	Growth reduced 50%; negligible effects on cellular ultrastructure	3, 6
Marine alga, <i>Dunaliella tertiolecta</i>		
8000 µg/L for 48 h	Growth normal	7
12,000–16,000 µg/L for 48 h	Adverse effects on photosynthesis, cell division rates, and pigment metabolism	7
Euglena, <i>Euglena gracilis</i> ; 10,000 µg/L for 5 days	Adverse sublethal effects, including altered free cysteine metabolism	8
	Complete inhibition of growth	1
Freshwater diatom, <i>Nitzschia palea</i> ; 5 µg/L Alga, <i>Ochromonas danica</i>		
10,000 µg/L for as long as 9 days	Growth normal	11
Aquatic moss, <i>Rhynchostegium riparioides</i> ; 4.5 (controls), 9, 21, or 50 µg/L for 27 days followed by 14 days in clean media	Copper accumulation plateaued after 18 days. Maximum concentrations reached, in mg/kg DW, were 900 (9 µg/L group) 2000 (20 µg/L group) and 3500 (50 µg/L group). At end of depuration mosses had lost about 50% of accumulated copper	12
Freshwater alga, <i>Scenedesmus acutiformis</i> ; 100 µg/L for 20 min at pH 4.8, 5.8, or 6.8	Copper concentrations, in mg/kg DW, increased from 400 (pH 4.8) to 750 (pH 5.8) to 4000 (pH 6.8)	10
Freshwater alga, <i>Scenedesmus subspicatus</i>		
56 µg/L for 72 h	Growth normal	5
120 µg/L for 72 h	Growth reduced 50%	5
Marine alga, <i>Scrippsiella faeroense</i> ; 5 µg/L for 5 days	Growth inhibited 50%	1
Marine alga, <i>Thalassiosira pseudonana</i> ; 5 µg/L for 72 h	Growth inhibited 50%	1
PROTISTS		
Freshwater protozoan ciliate, <i>Tetrahymena pyriformis</i>		
3818 µg/L for 96 h	Growth normal	5
8000 µg/L for 48 h	Growth inhibited 50%	5
Marine protozoan, <i>Euplotes vannus</i> ; exposure for 6 days		
100 µg Cu/L	Growth stimulated	170
200 µg Cu/L	Tolerated; growth normal	170
400 µg/L	Accumulations of 239 mg Cu/kg DW; depressed growth; morphological cell alterations	170

Table 3.5 (continued) Effects of Copper on Representative Aquatic Plants and Animals

Taxonomic Group, Organism, Copper Concentration, and Other Variables	Effects	Reference ^a
CNIDARIANS		
Sea anemone, <i>Anemonia viridis</i> ; 50 or 200 µg/L for 5 days	Immediate tentacle retraction; copious production of mucus; progressive visible bleaching and loss of zooxanthellae	13
Hydroid, <i>Campanularia flexuosa</i>		
1.4 µg/L for 11 days	Enzyme disruption	1
10–13 µg/L for 11 days	Growth rate reduced	1
Ctenophore, <i>Pleurobrachia pileus</i> ; 33 µg/L for 24 h	Fatal to 50%	1
PLATYHELMINTHES		
Trematode, <i>Posthodiplostomum minimum</i>		
Cercariae		
26 µg Cu/L	LC50 in 12 h	173
32 µg Cu/L	LC50 in 9 h	173
<i>Posthodiplostomum</i> -infected snail (<i>Physa gyrina</i>) intermediate host		
38.0 µg Cu/L	LC50 in 7 days	173
44.6 µg Cu/L	64% dead in 96 h	173
89.2 µg Cu/L	87% dead in 96 h	173
ROTIFERS		
Freshwater rotifer, <i>Brachionus calyciflorus</i>		
2.5–5.0 µg/L	MATC ^b	14
14 µg/L for 5 h	Swimming behavior impaired 50%	14
25 µg/L for 5 h	All immobilized	14
26 µg/L for 24 h	Fatal to 50%	14, 15
34 µg/L for 5 h	Feeding rate reduced 50%	15
43 µg/L for 24 h	Feeding rate reduced 50%	16
80 µg/L for 24 h	No deaths when molar ratio of fulvic acid to copper was 1:1	17
NEMATODES		
Free-living nematode, <i>Caenorhabditis elegans</i>		
260 µg/L for 96 h	LC50	18
22,000 µg/L for 24 h	LC50	18
MOLLUSCS		
Freshwater unionid mussel, <i>Anodonta cygnea</i>		
2.1 (95% confidence interval [CI] of 0.01–7.2) µg/L for 72 h	Reduction by 50% in valve closure of glochidia; ability to infect fish reduced	19
5.3 µg/L for 48 h	Valve closure rate reduced 50%	19
Freshwater mussel, <i>Anodonta grandis</i>		
17 µg/L for 24 h	Valve closure normal	20
33 µg/L for 24 h	Valve closure rate reduced 50%	20
44 µg/L for 24 h	Fatal to 50%	20
Bay scallop, <i>Argopecten irradians</i>		
5.0 µg/L for 119 days	All dead	1
5.8 µg/L for 42 days	Growth rate reduced 50%	1
Freshwater snail, <i>Biomphalaria glabrata</i> ; 60 µg/L for 60 h	Lethal; epithelial cell histopathology	21
Freshwater snail, <i>Bulinus globosus</i> ; 707 µg/L for 24 h	LC50	22

Table 3.5 (continued) Effects of Copper on Representative Aquatic Plants and Animals

Taxonomic Group, Organism, Copper Concentration, and Other Variables	Effects	Reference ^a
Channeled whelk, <i>Busycon canaliculatum</i> 100 µg/L for 54 days	Copper concentrations, in mg/kg FW, were 43 (vs. 35 in controls) in gills and 25 (vs. 16) in osphradium	23
500 µg/L for 16 days	All dead	23
Snail, <i>Campeloma decisum</i> >30 µg/L for 24 h	Motility inhibited	24
1700 µg/L for 96 h	LC50	24
Asiatic clam, <i>Corbicula fluminea</i> 5.5 µg/L for 30 days	Growth normal; soft tissues contained 80 mg Cu/kg DW (vs. 40–60 in controls)	25
8.4–26.7 µg/L for 30 days	Some deaths; growth reduction in juveniles and adults; soft parts had 205–278 mg Cu/kg DW	25
19.2 µg/L for 30 days	LC50	25
Pacific oyster, <i>Crassostrea gigas</i> Adults		
10 µg/L for 14 days	LC20	27
100 µg/L	No deaths in 96 h; 30% dead in 14 days	27
560 µg/L for 96 h	LC50	27
Embryos, exposed for 48 h 5 µg/L	94–98% normal development vs. 97–99% in controls	28
6.5 µg/L	8–25% abnormal (retarded shell size, reduced growth, erratic swimming behavior)	28
10 µg/L	26–79% abnormal	28
18 µg/L	No embryos developed normally	28
American oyster, <i>Crassostrea virginica</i> ; adults with soft parts containing 837 mg/kg DW were held in flowing seawater of 1–2 µg Cu/L for 56 weeks	No significant depuration; soft parts contained 746–1526 mg/kg DW during exposure	26
Clam, <i>Donax incarnatus</i> 4.0 µg/L for 4 h		
26.1 µg/L for 96 h	Increased oxygen consumption and increased ammonia excretion	29
Zebra mussel, <i>Dreissena polymorpha</i> 4.5, 9, 21, or 50 µg/L for 27 days followed by 14 days in clean media	LC50	29
13 µg/L for 9 weeks	No deaths. Filtration rate reduced in 50 µg/L group during exposure but not afterwards. Maximum concentrations, in mg/kg DW soft parts, were about 30 (9 µg/L), 70 (21 µg/L), and 100 (50 µg/L); about 18% of the accumulated copper was lost during depuration	12
>28 µg/L for 48 h	No effect on survival or filtration rate	30
41–43 µg/L for 48 h to as long as 9 weeks	Copper accumulation	31
90 µg/L for 9 weeks	Filtration rate reduced 50%	30, 31
Black abalone, <i>Haliotis cracherodii</i> ; 50 µg/L for 96 h	28% dead; 78% reduction in filtration rate	30
Red abalone, <i>Haliotis rufescens</i> ; 86 µg/L for 96 h	LC50	1
Freshwater mussel, <i>Lamellidens marginalis</i> 250 µg/L for 96 h	LC50	1
250, 500, 750, or 1000 µg/L for 30 days	Moribund; complete dissolution of crystalline style in 9.8 h: style reforms in 2.5 h on transfer to uncontaminated media and this may be useful as indicator of copper stress	32
5000 µg/L for 96 h	No deaths. Initial dose-dependent increase in respiratory rate and decrease in growth rate; similar to controls by day 30	33
	LC50	32, 33

Table 3.5 (continued) Effects of Copper on Representative Aquatic Plants and Animals

Taxonomic Group, Organism, Copper Concentration, and Other Variables	Effects	Reference ^a
Baltic clam, <i>Macoma balthica</i> ; 40 µg/L for 48 h	Copper in soft parts was 23.5 mg/kg DW vs. 20.0 in controls	34
Clam, <i>Macoma liliana</i> ; juveniles held in sediments containing <1 (controls), 5, 10, 15, 25, 30, 50, 70, or 140 mg/kg DW. Effects on avoidance in 96 h, burial rate in 90 min, and survival in 10 days were measured	Maximal avoidance was in sediments containing 25 mg/kg and higher (interstitial water had 113 µg Cu/L). Ability to bury in sediments was inhibited in sediments containing 15 mg/kg and higher (pore water of 120 µg/L). Reduced survival at 30 mg/kg DW sediment and higher	35
Quahog clam, <i>Mercenaria mercenaria</i> 25 µg/L for 77 days 640–6400 µg/L	53% dead Dose-dependent increase in cytotoxicity by isolated brown cells	1 36
Scallop, <i>Mizuhopecten yessoensis</i> ; 25 µg/L for 21 days	Hepatopancreas had 513 mg/kg DW (vs. <50 in controls); accumulations accompanied by a significant increase in hydroperoxide and malondialdehyde contents in microsomal membranes and alterations in lipid peroxidation rates	37
Softshell clam, <i>Mya arenaria</i> 35 µg/L for 168 h 39 µg/L for 96 h 86 µg/L for 504 h 3000 µg/L for 336 h	LC50 at 22°C LC50 LC50 at 17.5°C No deaths at 4°C	38, 160 1 38, 160 38, 160
Common mussel, <i>Mytilus edulis</i> 0, 1, 3.2, 10, 32, or 100 µg/L for 7 days; mantle tissue analyzed for heat shock protein 60	Adverse effects on growth in the 32 and 100 µg/L groups; dose-dependent protein increase at 3.2 µg/L and higher	39
Mussels age 2.5 months continuously exposed to 0, 1, 5, or 10 µg/L for 21 months. Growth, histopathology, and residues in soft parts measured after 12, 18, and 21 months	Growth adversely affected in the 10 µg/L group; histopathology evident in the 5 and 10 µg/L groups. After 21 months, concentrations in soft parts, in mg/kg FW, were 5.5 in controls and the 1.0 µg/L group, 19.2 in the 5 µg/L group, and 62 in the highest exposure group	40
1, 3.2, 10, 32, or 100 µg/L for 7 days	No effect on protein activity in gill and mantle at 32 µg/L and lower; increased accumulations at 100 µg/L. At 32 µg/L and higher growth was reduced. At 100 µg/L survival decreased and copper concentrations increased from 24 to 89 mg/kg DW in gill and from 14 to 54 mg/kg DW in mantle	41
2 µg/L for 30 days 5–6 µg/L for 10 days 50 µg/L for 6 days, then transferred to clean seawater	Spawning frequency reduced 50% Growth reduced 50% Lysosomal destabilization in all age groups; ability to recover declined with increasing age	42 42 43
430 µg/L for 120 h	Cardiac activity reduced 50% within 4 h and reduction persisted for 120 h	44
Dipped for 5 sec in CuSO ₄ solutions containing 5, 10, 25, or 50 grams/L and stored in air for 6, 24, or 48 h	Fatal at 5 to 10 g/L if kept out of water for 24 h; fatal at 10–20 g/L if stored only a few hours. Oysters (<i>C. virginica</i>) survived this treatment	45
Mussel, <i>Mytilus galloprovincialis</i> 15 µg/L for 5 days	Stimulates the synthesis of thionein-like copper-binding proteins in gill, mantle, and digestive gland	46

Table 3.5 (continued) Effects of Copper on Representative Aquatic Plants and Animals

Taxonomic Group, Organism, Copper Concentration, and Other Variables	Effects	Reference ^a
40 µg/L for 6 days	Gills contained 22.3 mg Cu/kg FW (vs. 2.4 in controls); digestive gland had 6.8 mg/kg FW (3.0). Exposed mussels show stimulated lipid peroxidation rates in tissues	47
80 µg/L for 2 h	Induces the synthesis of copper-binding proteins similar to that of metallothioneins in gills and mantle	46
Common limpet, <i>Patella vulgata</i> ; 10 µg/L for 6 h Brown mussel, <i>Perna indica</i>	Pedal mucus production reduced 40%	48
2–6 µg/L for 4 h 21.8 µg/L for 96 h	Increased oxygen consumption LC50	29 29
Green mussel, <i>Perna viridis</i>	Reduction in filtration rate, growth, and oxygen to nitrogen ratio; histopathology of digestive cells and tissues. Residues, in mg/kg FW, were 38.2 in digestive gland vs. 2.6 in controls and 24.7 in total soft parts vs. 1.3 in controls	49
25 µg/L for 2 weeks	LC50	49
86 µg/L for 96 h		
Snail, <i>Physa integra</i>	No adverse effects on growth, survival, or feeding	24
15 µg/L for 6 weeks		
39 µg/L for 96 h	LC50	1, 24
Apple snail, <i>Pomacea paludosa</i> ; 24–57 µg/L for 96 h	LC50	50
Cuttlefish, <i>Sepia officinalis</i> ; eggs; 4 (control), 50, 100, or 200 µg/L for 8 weeks	Dose-dependent decrease in hatching time and survival; no external malformations	51
Freshwater snail, <i>Thiara tuberculata</i>		
450 µg/L for 20 days	Progressive decline over time in oxygen consumption	52
2180 µg/L for 72 h	LC50; survivors had decreased oxygen consumption	52
Giant clam, <i>Tridacna derasa</i> ; embryos age 1 h; exposed at 27°C		
0.1 µg/L for 72 h	LC50	53
1.0 µg/L for 72 h	LC65	53
10.0 µg/L for 72 h	LC91	53
Clam, <i>Villorita cyprinoides</i>		
450 µg/L for 120 h	No deaths	54
1000, 3000, or 5000 µg/L for 120 h	No deaths. Hemolymph protein levels reduced at 1000 and 3000 µg/L, but not in 5000 µg/L	54, 161
Freshwater mussel, <i>Villosa iris</i>		
24 µg/L for 24 h	Valve closure normal	55
27–29 µg/L for 24 h	50% reduction in valve closure	55
83 µg/L for 24 h	LC50	55
CRUSTACEANS AND ARACHNOIDS		
Copepod, <i>Acartia clausi</i> ; 52 µg/L for 96 h	LC50	1
Copepod, <i>Acartia tonsa</i> ; 31 µg/L for 96 h	LC50	1
Amphipod, <i>Allorchestes compressa</i>		
3.7 µg/L for 4 weeks	Extrapolated concentration causing detectable decreases in survival and biomass	9
10 µg/L for 4 weeks	Lowest concentration tested causing adverse effects on growth and survival; bioconcentration factor (BCF) of 51,500	9
500 µg/L for 96 h	LC50	9

Table 3.5 (continued) Effects of Copper on Representative Aquatic Plants and Animals

Taxonomic Group, Organism, Copper Concentration, and Other Variables	Effects	Reference ^a
Cladoceran, <i>Bosmina longirostris</i>		
1.4 µg/L for 48 h; starved	50% immobilized	56
3.7 µg/L for 48 h; fed	50% immobilized	56
16 µg/L for 15 days	Growth rate reduced	158
18 µg/L for 15 days	Survival reduced	158
Lesser blue crab, <i>Callinectes similis</i>		
50 µg/L for 118 days	No effect on survival or molting during exposure	57
250 µg/L; juveniles	LC50 (30 days); LC100 (68 days)	57
500 µg/L	50% of megalops dead in 3.7 days; 50% of juveniles dead in 7.7 days; all juveniles dead in 49 days	57
Crayfish, <i>Cambarus bartoni</i> ; copper-tolerant strain exposed to 19 (controls), 125, 250, or 500 µg/L for 4 weeks; concentrations in controls (mg/kg DW) vs. all experimental groups (mg/kg DW)		
Exoskeleton	54 DW vs. 78–116 DW	58
Gills	368 DW vs. 571–1167 DW	58
Hepatopancreas	1778 DW vs. 1494–2346 DW	58
Muscle	88 DW vs. 99–129 DW	58
Viscera	92 DW vs. 158–276 DW	58
Shore crab, <i>Carcinus maenas</i>		
500 µg/L for 5–18 days	Gill histopathology; some recovery after exposure	59
500 µg/L for 28 days		
Controls (fed) vs. exposed (fed); values in mg/kg DW		
Carapace	5 DW vs. 51 DW	60
Midgut gland	26 DW vs. 474 DW	60
Controls (starved) vs. exposed (starved); values in mg/kg DW		
Carapace	4 DW vs. 72 DW	60
Midgut gland	298 DW vs. 583 DW	60
2000 µg/L for 5 days	Some deaths; severe gill cellular hyperplasia	59
Daphnid, <i>Ceriodaphnia dubia</i>		
9.5 µg/L for 48 h	LC50 at pH 6.0–6.5	61
28 µg/L for 48 h	LC50 at pH 7.0–7.5	61
200 µg/L for 48 h	LC50 at pH 8.0–8.5	61
Chironomid, <i>Chironomus riparius</i> ; larvae; 5 generations exposed from egg to fourth instar at medium concentrations of 0, 1, 10, or 100 µg Cu/L	Mandible and mentum deformities were positively associated with increasing concentration and generation	169
Cladoceran, <i>Chydorus sphaericus</i>		
3.3 µg/L for 48 h; starved	50% immobilized	56
7.6 µg/L for 48 h; fed	50% immobilized	56
Amphipod, <i>Corophium volutator</i> ; exposed to <0.1, 50, or 100 µg/L for 14 days in seawater under conditions of normoxia, moderate hypoxia (29% oxygen saturation), and hypoxia (19% oxygen saturation)	Exposure to increasing levels of copper resulted in a significant increase in total body copper concentrations (from 76 to 174 mg/kg DW), and a lowering of egg production; mortality was higher at low oxygen saturations and high copper concentrations (max. 35% dead at 100 µg/L and 19% saturation)	62
Brown shrimp, <i>Crangon crangon</i> ; 330 µg/L for 96 h	LC50	1
Daphnids, <i>Daphnia ambigua</i> , <i>D. parvula</i> , <i>D. pulex</i> ; 49 µg/L for lifetime exposure	Reduced productivity	1
Daphnid, <i>Daphnia carinata</i> ; 28 µg/L for 96 h	LC50	63
Daphnid, <i>Daphnia magna</i>		

Table 3.5 (continued) Effects of Copper on Representative Aquatic Plants and Animals

Taxonomic Group, Organism, Copper Concentration, and Other Variables	Effects	Reference ^a
5.9 µg/L for 21 days	Growth reduced 10%; bioconcentration factor (BCF) of 4900; maximum whole-body concentration of 43 mg/kg DW	64
10 µg/L for 96 h	LC50 at 45 mg CaCO ₃ /L	1
10 µg/L, life cycle	Inhibited reproduction	1
11.4–16.3 µg/L	MATC ^b at 51 mg CaCO ₃ /L	1
16.1 µg/L for 21 days	Growth reduced 50%	64
20–43 µg/L	MATC ^b at 104 mg CaCO ₃ /L	1
26–59 µg/L for 48 h; fed	LC50; no weight loss among survivors	65
28–58 µg/L for 48 h; starved	LC50; survivors had significant weight loss	65
59 µg/L for 26 h	Feeding rate reduced 50%	16
69 (37–110) µg/L for 21 days	LC50	64
200 µg/L for 96 h	LC50 at 226 mg CaCO ₃ /L	1
Daphnid, <i>Daphnia pulex</i>		
0.003–0.3 µg/L for 21 days	Increased reproduction	66
3 µg/L for 21 days	Impaired reproduction	66
5 µg/L for 70 days	Decreased survival beginning at day 58; no effect on reproduction	67
20–37 µg/L for 48 h	LC50	66, 67, 68
20 µg/L for 6 h daily for 70 days	Decreased survival and brood size	67
30 µg/L for 15 days	No significant effect on growth or survival	158
Daphnid, <i>Daphnia pulicaria</i>		
7.2–11.4 µg/L for 96 h	LC50 at 44–48 mg CaCO ₃ /L	1
17.8–27.3 µg/L for 96 h	LC50 at 95–245 mg CaCO ₃ /L	1
Amphipod, <i>Gammarus pseudolimnaeus</i>		
<4.6 µg/L for 15 weeks (two generations)	No adverse effects	24
4.6–8 µg/L	MATC ^b at 45 mg CaCO ₃ /L	1
6.2–12.9 µg/L for 5 weeks	Decreased survival	24
20 µg/L for 96 h	LC50	24
Amphipod, <i>Gammarus pulex</i>		
Immersed in solutions containing 2.6 (controls), 11, 14.6, 18.2 or 23.1 µg/L for 100 days	Population density doubled in the controls and the 11 µg/L group. Rate of increase was adversely affected at 14.6 and 18.2 µg/L; the high-dose group lost population. Low-dose groups were composed mainly of juveniles; at 14.6 µg/L and higher, the number of juveniles decreased; and at 18.2 µg/L and higher, number of adults decreased	69
33 µg/L for 240 h	LC50	69
Mysid shrimp, <i>Holmesimysis costata</i> ; 17 µg/L for 96 h	LC50	70
American lobster, <i>Homarus americanus</i>		
48 µg/L for 96 h	Larval LC50	1
100 µg/L for 96 h	Adult LC50	1
Amphipod, <i>Hyalella azteca</i>		
1.3 (control), 5.6, 10, 18, 32, 56, or 100 µg/L for 10 weeks beginning at age 1-week	Survival reduced at 32 µg/L and higher; no significant copper accumulations over controls in all groups	71
1.3 (control), 5.6, 10, 18, 32, 56, 100, or 180 µg/L for 4 weeks; adults	Copper residues, in mg/kg DW, were 98 in controls; 122–150 for the 5.6–32 µg/L groups, and >196 for the high dose groups	71
17 µg/L for 96 h	LC50 at pH 6.0–6.5, adults	61
31 (28–35) µg/L for 10 days	LC50, juveniles	73
34 µg/L for 96 h	LC50; age 6–8 days	72
52 µg/L for 96 h	LC50; age 20–24 days	72
87 µg/L for 96 h	LC50 at pH 8.0–8.5	61

Table 3.5 (continued) Effects of Copper on Representative Aquatic Plants and Animals

Taxonomic Group, Organism, Copper Concentration, and Other Variables	Effects	Reference ^a
Horseshoe crab, <i>Limulus polyphemus</i>		
Embryos		
2 mg Cu/L	LC50 (72 h), Sandy Hook Bay, New Jersey	171
171 mg Cu/L	LC50(72 h), Delaware Bay, Delaware	171
Larvae, Sandy Hook		
100 mg Cu/L	Normal survival and molting	171
637 mg Cu/L	LC50 (72h)	171
Freshwater prawn, <i>Macrobrachium rosenbergii</i> ; 12 µg/L for 96 h	LC50	74
Freshwater prawn, <i>Macrobrachium rude</i> ; 18–65 µg/L for 96 h	LC50–LC84	63, 75
Macroinvertebrate communities; 11.3 µg/L for 10 days	Abundance was reduced by 75% in laboratory studies vs. 44% in field experimental streams; number of taxa was reduced 56% in the laboratory vs. 10% in field streams	76
Peneid Shrimp, <i>Metapenaeus ensis</i>		
160 µg/L for 48 h	LC50 for larvae	77
250 µg/L for 2 h	Feeding inhibited >50%	77
4760 µg/L for 48 h	LC50 for postlarvae	77
Cladoceran, <i>Moina irrasa</i>		
1.4 µg/L for 24 h	LC50 at pH 5.0, 30°C	78
2.8 µg/L for 24 h	LC50 at pH 6.5, 30°C	78
3.3 µg/L for 96 h	LC50 at pH 5.0, 20°C	78
5.5 µg/L for 48 h	LC50 at pH 5.0, 25°C	78
6.5 µg/L for 96 h	LC50 at pH 6.5, 20°C	78
7.5 µg/L for 96 h	LC50 at pH 8.0, 20°C	78
11.8 µg/L for 48 h	LC50 at pH 8, 25°C	78
19.7 µg/L for 24 h	LC50 at pH 8, 20°C	78
Mysid shrimp, <i>Mysidopsis bahia</i> ; 38–77 µg/L	MATC ^b	1
Norway lobster, <i>Nephrops norvegicus</i>		
10 µg/L for 30 days; 4.9 cm in length	Copper concentrations were elevated in most tissues, especially ovary (to 393 from 115 mg/kg DW), but not hepatopancreas or external eggs	79
100 µg/L for 14 days	LC100	79
Crab, <i>Paragrapuspus quadridentatus</i>		
110–250 µg/L for 96 h	LC16–LC84 for larvae	80
170 µg/L for 96 h	LC50 for larvae	80
Freshwater shrimp, <i>Paratya australiensis</i>		
15 µg/L, continuous exposure	Mean molt period of 23 days (range 20–27 days) vs. 25 days (18–36 days) for controls	81
40 µg/L for 96 h	LC50	81
Amphipod <i>Parhallella natalensis</i> ; 72 µg/L for 48 h	LC50	82
Crayfish, <i>Procambarus clarkii</i>		
120 µg/L for 20 days	LC50 for larvae	83
1300 µg/L for 20 days	LC50 for adults; increased copper concentrations at >480 µg/L in gills but not other tissues	83
3700 µg/L for 20 days	LC50 for embryos	83
Copepod, <i>Pseudodiaptomus coronatus</i> ; 138 µg/L for 96 h	LC50	1
Barnacle, <i>Semibalanus balanoides</i> ; 20–90 µg/L for 100 days	Dose-dependent increase in copper loadings in bodies and egg masses	84
Copepod, <i>Tigriopus japonicus</i> ; 487 µg/L for 96 h	LC50	1
Copepod, <i>Tisbe furcata</i> ; 37–57 µg/L	MATC ^b	85

Table 3.5 (continued) Effects of Copper on Representative Aquatic Plants and Animals

Taxonomic Group, Organism, Copper Concentration, and Other Variables	Effects	Reference ^a
AQUATIC INSECTS		
Midge, <i>Chironomus ninevah</i> ; 0, 20, 100, 150, or 200 µg/L for 21 days (eggs through fourth stage larvae)	Statistically significant, dose-dependent decrease in gene activity of salivary gland chromosomes at 20 µg/L and higher	86
Midge, <i>Chironomus</i> sp.; 30 µg/L for 96 h	LC50 at 50 mg CaCO ₃ /L	1
Midge, <i>Tanytarsus dissimilis</i> ; 16.3 µg/L for 10 days	LC50	1
Various species; 25 µg/L for 10 days in outdoor experimental streams	Mayflies were the most sensitive group with 67–100% reduction in numbers; chironomids had 80% reduction, and caddisflies were reduced by 16–30%	87
ANNELIDS		
Lugworm, <i>Arenicola marina</i> ; held on copper-contaminated sediments		
182–204 mg Cu/kg DW sediment	Inhibitory effects on digestive processes	172
1113 mg Cu/kg DW sediment	Lethal in 48 h	172
Ragworm, <i>Hediste diversicolor</i>		
5, 10, or 20 µg/L at four salinities and three temperatures; 1-day-old larvae	20 µg/L caused high mortality at all thermosaline regimens tested; some adverse effects noted at lower concentrations	88
247–513 µg/L for 96 h; no sediments in assay containers	LC50s at various thermosaline regimens	89
3200–4100 µg/L for 96 h; sediments present in assay containers	LC50s at various thermosaline regimens	89
Oligochaete, <i>Lumbriculus variegatus</i>		
130 µg/L for 96 h	LC50 at pH 6.0–6.5	61
500 µg/L for 96 h	LC50 at pH 8.0–8.5	61
Marine worm, <i>Nereis diversicolor</i> ; 500 µg/L at three salinities and three temperatures	Mortality was greatest at 5‰ salinity (50% dead in 44 h vs. 66–82 h at higher salinities), and at 20°C (50% dead in 32 h vs. 88–106 h at lower temperatures)	90
ECHINODERMS		
Echinoid, <i>Echinometra mathaei</i> ; 20 µg/L for 4 days	Skeletal development of larvae suppressed	1
Sea urchin, <i>Paracentrotus lividus</i> ; 10–20 µg/L for 4 days	Pluteal growth retarded	1
Sea urchin, <i>Strongylocentrotus nudus</i> ; adults held in seawater containing 25 µg Cu/L for 30 days; resultant embryos reared in uncontaminated seawater for 30 days	Food consumption of adults decreased after day 16; accelerated development of pluteal stages; all developmental stages had increased activities of acid phosphatase	91
FISH		
Topsmelt, <i>Atherinops affinis</i>		
53 µg/L for 15 min; sperm	No effect on fertilization in 48 h	92
100 µg/L for 7 days; larvae, age 5–20 days	No effect	93
109 µg/L for 15 min; sperm	Egg fertilization reduced 50% in 48 h	92
123 µg/L for 96 h; larvae	No deaths	92
137 µg/L for 7 days; larvae, age 7–20 days	LC50	93
146 µg/L for 48 h; embryos	50% abnormal development	92
180 µg/L for 7 days; larvae, age 1–3 days	No deaths	93
238 µg/L for 96 h; larvae	LC50	92
365 µg/L for 7 days; larvae, age 0–5 days	LC50	93

Table 3.5 (continued) Effects of Copper on Representative Aquatic Plants and Animals

Taxonomic Group, Organism, Copper Concentration, and Other Variables	Effects	Reference ^a
Zebrafish, <i>Brachydanio rerio</i>		
0.05 µg/L for 16 days; eggs and larvae	Delayed hatch	94
0.25 µg/L for 16 days; eggs and larvae	No deaths	94
1.0 µg/L for 16 days; eggs	<50% hatched	94
1.0 µg/L; adults	No avoidance but inhibition of attraction response to L-alanine	95
50–150 µg/L for 7 days; adults	No adverse effects on survival or behavior; dose-dependent decrease in kidney leukocyte numbers and phagocytic response	96
Goldfish, <i>Carassius auratus</i>		
36 µg/L for 96 h	LC50 at 20 mg CaCO ₃ /L	1
300 µg/L for 96 h	LC50 at 52 mg CaCO ₃ /L	1
368 µg/L for 96 h	LC50 at 272 mg CaCO ₃ /L	97
White sucker, <i>Catostomus commersoni</i> ; 12.9–33.8 µg/L	MATC ^b at 45 mg CaCO ₃ /L	1
Murrel, <i>Channa punctatus</i> ; 50 or 100 µg/L for 7 days	Liver pathology	98
Catfish, <i>Clarias</i> sp.		
27, 55, or 110 µg/L for 8 weeks; whole fish analyzed for total copper at end of exposure	Copper concentrations, in mg/kg DW, were 15.7 for the low-dose group, 21.8 for the 55 µg/L group, and 31.2 for the high-dose group vs. 6.9 DW in controls	99
425 µg/L for 96 h	LC50; nonresistant strain	99
4301 µg/L for 96 h	LC50; copper-resistant strain	100
African sharp-tooth catfish, <i>Clarias gariepinus</i> ; Olifants River (water of 32–55 µg Cu/L), South Africa		
767–991 µg/L for 96 h	10–20% dead	101
1240–1380 µg/L for 96 h; adults and juveniles	LC50 at 21–28°C	101
Pacific herring, <i>Clupea harengus pallasi</i> ; 33 µg/L for 6 days; embryos	LC50	1
Common carp, <i>Cyprinus carpio</i> ; 100 µg/L for 43 days	Skin histopathology	102
Northern pike, <i>Esox lucius</i> ; 34.9–104.4 µg/L	MATC ^b at 45 mg CaCO ₃ /L	1
Freshwater fishes; eight species; embryos and larvae; 31.7–43.5 µg/L for 30–60 days	Reduced survival	103
Mummichog, <i>Fundulus heteroclitus</i>		
1000 µg/L for 96 h	Renal and lateral line canal lesions	104
1700–8000 µg/L for 96 h	LC30–LC50	104, 105
Indian catfish, <i>Heteropneustes fossilis</i>		
250 µg/L; 5 h daily for 30 days	Time-dependent increase in adverse effects on blood chemistry, liver metabolism, and respiration	106
5000 µg/L for 48–96 h	After 48 h, decreased hematocrit, erythrocyte number, and hemoglobin; after 96 h, increased liver glycogen	107, 108
10,500–25,500 µg/L for 72–96 h	LC50	107, 108
Brown bullhead, <i>Ictalurus nebulosus</i>		
4, 8, 16, 32, 64, or 104 µg/L for as long as 600 days; blood chemistry analyzed periodically	Some deaths at 104 µg/L; no deaths at lower doses; no adverse biochemical effects at 16 µg/L and lower	109
4 to 512 µg/L for as long as 20 months	Increases in liver and gill copper concentrations in survivors at 275 µg/L and higher; equilibrium reached within 30 days. Copper levels in blood were the same as in controls	110
170 to 190 µg/L for 96 h; juveniles	LC50	110

Table 3.5 (continued) Effects of Copper on Representative Aquatic Plants and Animals

Taxonomic Group, Organism, Copper Concentration, and Other Variables	Effects	Reference ^a
Channel catfish, <i>Ictalurus punctatus</i> ; fingerlings Exposed for 96 h at 16 mg CaCO ₃ /L 51–65 µg/L 54–55 µg/L	LC50; chelated copper LC50; nonchelated copper	111 111
Exposed for 96 h at 239 mg CaCO ₃ /L 925–1041 µg/L 1603–1878 µg/L	LC50; nonchelated copper LC50; chelated copper	111 111
Spot, <i>Lepostomus xanthurus</i> ; 280 (240–330) µg/L for 96 h; adults	LC50	112
Green sunfish, <i>Lepomis cyanellus</i> ; 937 (686–1281) µg/L for 96 h	LC50	97
Bluegill, <i>Lepomis macrochirus</i> 21–40 µg/L 31 µg/L 40–162 µg/L for 90 days; larvae 40–162 µg/L for 24 months; adults	MATC ^b at 45 mg CaCO ₃ /L Consumed 27% fewer prey than controls Reduced survival At 162 µg/L, survival was reduced, growth retarded, and spawning inhibited. Maximum copper concentrations, in mg/kg FW, in treated fish (vs. controls) were 13 in gills (3), 480 in liver (7), and 44 in kidneys (22)	1, 114 113 114 114
236–892 µg/L for 96 h; adults 261 µg/L for 7 days, then subjected to a drop in dissolved oxygen over 60 min from 7.8 to 1.3 mg/L and then allowed to recover in copper-free aerated water	LC50 No deaths during copper exposure. During hypoxia; 2 of 77 died; survivors had hyperglycemia, lower plasma sodium, lower liver ATP, and higher plasma potassium than did nonexposed controls. Authors concluded that previous copper exposure causes some hypoxia responses to be accentuated in an additive manner	97, 115, 173 115
1100 µg/L for 96 h; larvae 4300 µg/L for 48 h	LC50 LC50	114 116
Atlantic silverside, <i>Menidia menidia</i> ; 136 µg/L for 96 h; larvae	LC50	1
Tidewater silverside, <i>Menidia peninsulae</i> ; 140 (110–180) µg/L for 96 h; larvae	LC50	112
Striped bass, <i>Morone saxatilis</i> 50–100 µg/L for 96 h; larvae 150 µg/L for 96 h; fingerlings 2680 µg/L for 96 h; fingerlings; 5‰ salinity 7880–8080 µg/L for 96 h; fingerlings; 10–15‰ salinity	LC50 at 68 mg CaCO ₃ /L LC50 at 68 mg CaCO ₃ /L LC50 LC50	1 1 117 117
Cutthroat trout, <i>Oncorhynchus clarkii</i> 37 µg/L for 96 h 232 µg/L for 96 h	LC50 at 18 mg CaCO ₃ /L LC50 at 204 mg CaCO ₃ /L	1 1
Coho salmon, <i>Oncorhynchus kisutch</i> 0, 15, 60, or 90 µg/L for 170 h; yearlings	No deaths; distress noted at 60 and 90 µg/L. Dose-dependent elevation in serum cortisol. When challenged with seawater, copper-exposed salmon had lowered survival and dose-dependent depression in serum chloride levels	118
5–30 µg/L for as long as 172 days; yearlings	Altered downstream migration patterns, lowered gill ATPase activity, and reduced survival. When subjected to >20 µg/L, appetite was depressed for several weeks to months	119
15.1–31.9 µg/L for 96 h; juveniles	LC50	120

Table 3.5 (continued) Effects of Copper on Representative Aquatic Plants and Animals

Taxonomic Group, Organism, Copper Concentration, and Other Variables	Effects	Reference ^a
18.2 µg/L for 31 days then challenged with seawater	Reduced survival during adaptation to seawater	121
24.6 µg/L for 31 days; fingerlings	Reduced survival; survivors unable to adapt to seawater	121
26 µg/L for 96 h; alevins	LC50 at 25 mg CaCO ₃ /L	1
46 µg/L for 96 h; adults	LC50 at 20 mg CaCO ₃ /L	1
60 µg/L for 96 h; smolts	LC50 at 95 mg CaCO ₃ /L	1
60–74 µg/L for 96 h; yearlings	LC50 at 95 mg CaCO ₃ /L	1, 119
70 or 140 µg/L for 14 weeks; fingerlings	Loss of appetite and reduced growth. Copper concentrations, in mg/kg DW, at end of study for the controls, the 70 µg/L group, and the 140 µg/L group were 2.9, 5.6, and 9.8 in gills, and 5.7, 6.1, and 7.5 in kidneys	122
70 or 140 µg/L for 14 weeks; liver cytosol samples from fingerlings	Copper concentrations in the low-molecular-weight fractions of the 70 µg/L group were higher than controls after 6 weeks and increased rapidly; those of the 140 µg/L group increased in the first 2–4 weeks then leveled off. Increasing levels of metallothioneins were detected in low-molecular-weight fractions of copper-exposed salmon. In the high-molecular-weight fractions, copper concentrations in both groups increased after 8–10 weeks	123
140 or 210 µg/L for 78 h; yearlings	Median survival times were 60 h for the low-dose group and 48 h for the high-dose group; survivors had elevated serum cortisol. Livers were normal but kidney and gill histopathology was evident in both groups	118
220–280 µg/L for 168 h; fingerlings	LC50	122
310 µg/L for 168 h; prior exposure to 70 µg/L for 16 weeks; fingerlings	LC50	122
550 µg/L for 168 h; prior exposure to 140 µg/L for 16 weeks; fingerlings	LC50	122
Rainbow trout, <i>Oncorhynchus mykiss</i>		
0.1 µg/L for 1 h	Avoidance by fry	1
Yearlings exposed to 6.4, 16, or 26.9 µg Cu/L for up to 21 days	Adverse effects on survival during first 48 h and decrease in respiratory burst activity at all concentrations tested. At high dose, percentage of monocytes increased and lymphocyte percent decreased	168
7.0 µg/L for 200 h; smolts	LC10	1
8.0 µg/L for 2 h	Depressed olfactory bulbar electrical responses to the standard stimulant L-serine	124
9.0 µg/L for 200 h; swimup stage	LC10	1
11.4–31.7 µg/L	MATC ^b at 45 mg CaCO ₃ /L	1
13.8 µg/L for 96 h; juveniles	LC50	120
19.0 µg/L for 200 h; alevins	LC10	1
20–30 µg/L for 96 h	LC50 at 30–32 mg CaCO ₃ /L	1
21.5 µg/L for 30 days; juveniles	No adverse effects; no altered susceptibility to <i>Aeromonas hydrophila</i> infections	125
22 µg/L for 37 to 41 weeks; two groups: age 14 days postfertilization and posthatch. Controls were held in water containing 4 µg/L	Survival of embryo group reduced 30%. Alterations in cell architecture in both treated groups were noted as early as week 8 posthatch. Both groups had	126, 127

Table 3.5 (continued) Effects of Copper on Representative Aquatic Plants and Animals

Taxonomic Group, Organism, Copper Concentration, and Other Variables	Effects	Reference ^a
36 µg/L for 96 h; alevins	irreversible histopathology of the olfactory organ after 7 months; no histopathology in controls. After 8 months, controls preferred their own rearing water but both copper-exposed groups showed no preference; some recovery 2 to 10 weeks after removal from copper	120
50 µg/L for 24 h; adults	LC50 No deaths; some degeneration of sensory receptors	128
50 µg/L for 21 days; juveniles	Rapid and sustained elevation of plasma cortisol levels; altered plasma cholesterol and sodium levels	129
55 µg/L for 28 days; juveniles	Initial inhibition of sodium uptake and whole body sodium content that were normal by day 28. Abnormal liver enzyme activity. Liver copper increased from 23 mg/kg FW at start to 113 mg/kg FW at day 28	164, 165
70 µg/L	Avoidance by juveniles	166
70–514 µg/L for 96 h	LC50 at 194–370 mg CaCO ₃ /L	1
75 µg/L for 24 h	LC50; survivors had complete degeneration of olfactory receptors	128
90 (50–150) µg/L; embryo through posthatch	LC50 at 28 days	162
130–140 µg/L for 24 h	LC50 at pH 6.5–pH 7.5	130
308 µg/L for 24 h in freshwater vs. 400 µg/L for 24 h in 35‰ seawater	All dead in freshwater vs. no deaths in seawater and no major changes in plasma Na ⁺ , Cl ⁻ , K ⁺ , or Ca ²⁺	131
500 or 1000 µg/L for 2 or 24 h; fingerlings	Gill histopathology in low-dose, low-exposure group; damage more severe with increasing dose and exposure	131
500 µg/L for 9 days; weight 400 g; under conditions of normal and low dissolved oxygen	No signs of respiratory dysfunction; no difference in copper uptake due to dissolved oxygen levels	133
1200 µg/L for 6 h	LC50	130
4560 µg/L	Juveniles attracted	166
Fed diet containing 13 or 684 mg/kg ration for 42 days and simultaneously exposed to waterborne-copper concentrations of 5, 32, 55, or 106 µg/L (low-copper diet) or 13, 38, 62, or 127 µg/L (high-copper diet)	No adverse effects on growth, survival, or food conversion efficiency. Elevated dietary copper increased copper concentrations in liver, kidney, gill, and digesta; increasing waterborne-copper concentrations produced increasing copper concentrations in liver and kidney. For fish in the high-copper diet, the diet provided 99% of the liver copper in the 38 µg/L group, 85% in the 62 µg/L group, and 73% in the 127 µg/L group	134
Fed diets containing 25.8 mg/kg DW ration (vs. 15.8 mg/kg DW in controls) for 28 days; equivalent to 69.2 mg/kg fish (130 g) daily	Fish readily ate copper-contaminated food. Elevated copper levels in gill, liver, and muscle. Some food regurgitation on days 20–28	135
Juveniles fed diet containing 200 mg/kg DW for 32 days followed by normal (15.8 mg/kg DW) diet for 12 days	No deaths. After 32 days whole fish contained 1.5 mg/kg FW vs. 1.2 at start; copper concentrations were elevated in gill, gut, blood, skin, and mucus, but not in muscle, liver, or kidney. Copper concentrations in gill and kidney tissues were elevated 12 days after exposure, but other tissues were normal	136

Table 3.5 (continued) Effects of Copper on Representative Aquatic Plants and Animals

Taxonomic Group, Organism, Copper Concentration, and Other Variables	Effects	Reference ^a
Single intravenous injection of 80 µg/kg BW; juveniles, 100–300 g in body weight	Half-time persistence in plasma was 7.2 min for the short-lived component and 3.2 h for the long-lived component. Plasma copper concentration fell from 1.1 mg/L shortly after administration to about 200 µg/L after 7.5 h	137
Chinook salmon, <i>Oncorhynchus tshawytscha</i>		
10–38 µg/L for 96 h	LC50 in soft water	1
19 µg/L for 200 h; swimup stage	LC50	1
20 µg/L for 200 h; alevins	LC50	1
26 µg/L for 200 h; smolts	LC50	1
30 µg/L for 200 h; parr	LC50	1
54–60 µg/L for 96 h; fry	LC50	138
78–145 µg/L for 24 h; fry	LC50	138
85–130 µg/L for 96 h	LC50 in hardwater	1
Green snakehead, <i>Ophiocephalus punctatus</i> ; weight 15–18 g		
5000–7500 µg/L for 24 h	Sublethal. Disrupted kidney and liver alkaline phosphatase and acid phosphatase activity	139
70,000 µg/L for 48 h	LC50	139
Nile tilapia, <i>Oreochromis niloticus</i>		
50, 100, or 200 µg/L for 8 weeks	At end of exposure, whole fish contained 34.7 and 36.1 mg/kg DW in the two lowest-dose groups and 81.0 mg/kg DW in the high-dose group (vs. 17.4 mg/kg DW in controls)	140
964 µg/L for 96 h	LC50	140
Summer flounder, <i>Paralichthys dentatus</i> ; embryos; 28 µg/L for 96 h	LC50	1
Flounder, <i>Paralichthys</i> spp.; juveniles		
6.4 µg/L for 14 days	Interference with calcium metabolism	157
448 µg/L for 14 days	LC50	157
Fathead minnow, <i>Pimephales promelas</i>		
2 µg/L for 96 h; larvae	LC50 at pH 5.6 and dissolved organic carbon (DOC) of 0.2 mg/L	141
10.6–18.4 µg/L	MATC ^b at 30 mg CaCO ₃ /L	142
14.5–33.0 µg/L	MATC ^b at 200 mg CaCO ₃ /L	142
15 µg/L for 96 h	LC50 at pH 6.6.5	143
23 µg/L for 96 h	LC50 at 20 mg CaCO ₃ /L	1
44 µg/L for 96 h	LC50 at pH 7.0–7.5	143
75–84 µg/L for 96 h	LC50 in soft water; continuous flow and static assays	142
182 µg/L for 96 h	LC50 at pH 6.9 and dissolved organic carbon of 15.6 mg/L	141
>200 µg/L for 96 h	LC50 at pH 8.0–8.5	143
210 µg/L for 96 h	LC50 at 100 mg CaCO ₃ /L	163
390 µg/L for 96 h	LC50 at 250 mg Ca/CO ₃ /L	163
430–470 µg/L for 96 h	LC50 in hard water; continuous flow and static assays	142
European flounder, <i>Platichthys flesus</i>		
Seawater-adapted; exposure for 42 days; experimentals (170 µg/L) vs. controls (3 µg/L; values in mg/kg DW tissue		
Gill	7.7 vs. 2.7	167
Kidney	13.1 vs. 4.1	167
Liver	640.2 vs. 15.6	167
Muscle	7.7 vs. 2.7	167

Table 3.5 (continued) Effects of Copper on Representative Aquatic Plants and Animals

Taxonomic Group, Organism, Copper Concentration, and Other Variables	Effects	Reference ^a
Freshwater-adapted; exposure for 37 days; experimentals (15 µg/L) vs. controls (5 µg/L); values in mg/kg DW tissue		
Gill	16.2 vs. 6.5	167
Kidney	28.7 vs. 14.3	167
Liver	295.6 vs. 157.8	167
Muscle	4.9 vs. 1.8	167
Guppy, <i>Poecilia reticulata</i>		
36 µg/L for 96 h	LC50 at 20 mg CaCO ₃ /L	1
112–138 µg/L for 96 h	LC50 at 67–82 mg CaCO ₃ /L	1
Winter flounder, <i>Pleuronectes americanus</i>		
129 µg/L for 96 h; embryos	LC50	1
180 µg/L for 29.1 days; adults	Gill histopathology	144
560–3200 µg/L for 29.2 days; adults	Copper-induced histopathology of kidney, liver, and gill; reduced food intake	144
Mangrove rivulus, <i>Rivulus marmoratus</i> ; 1400 µg/L for 96 h	LC50	145
Air-breathing catfish, <i>Saccobranchus fossilis</i> ; 56, 100, or 320 µg/L for 28 days	Dose-dependent decrease in red and white blood cell numbers, hemoglobin, and hematocrit; histopathology in gill, skin, spleen, and kidney	146
Atlantic salmon, <i>Salmo salar</i>		
2.4 µg/L	Avoidance threshold in laboratory	147
12.8–621.0 µg/L	Dose-dependent inhibition of olfactory response; toxic effect mainly on transduction mechanisms of the olfactory receptor cells	148
16.9–20.6 µg/L	Avoidance threshold in field	147
32–125 µg/L for 96 h	LC50 at 8–20 mg CaCO ₃ /L	1, 147
Brown trout, <i>Salmo trutta</i>		
22.0–43.2 µg/L	MATC ^b at 45 mg CaCO ₃ /L	1
103–148 (91–165) µg/L	LC50 at 48 h, juveniles	159
Brook trout, <i>Salvelinus fontinalis</i>		
2.7 (control), 4.5, 6.1, or 9.4 µg/L for two generations	No adverse effects on growth, survival, or reproduction; no elevated copper concentrations in gill, liver, kidney, muscle, or eggs	152
3.4, 5.7, 9.5, 17.4, or 32.5 µg/L for 337 days	No significant changes in blood chemistry except for measurable decrease in plasma glutamic oxalacetic transaminase activity at 17.4 and 32.5 µg/L	149
6–15 µg/L for 2–24 h; yearlings	Increased cough frequency, increased locomotor activity, and decreased feeding response	150
9.5–17.4 µg/L	MATC ^b at 45 mg CaCO ₃ /L and pH 7.5	151
23, 39, or 68 µg/L for 6 or 21 days	At 39 and 68 µg/L, adverse effects on blood chemistry; decreases in plasma chloride and osmolarity	149
100 µg/L for 96 h; age 14 months	LC50	151
Lake trout, <i>Salvelinus namaycush</i> ; 22.0–42.3 µg/L	MATC ^b at 45 mg CaCO ₃ /L	92
Red drum, <i>Sciaenops ocellatus</i>		
250 µg/L for 96 h; juveniles	No deaths	153
520 µg/L for 96 h; juveniles	LC50 at 25°C and 8‰ salinity	153
Pearl dace, <i>Semotilus marginata</i> ; 1000–279,000 µg/L for as long as 7 h then transferred to clean water for 48 h	Decreasing survival and coordination with increasing concentration or duration of exposure after exposure to 1000 µg/L for 6 h, 9000 µg/L for 1 h, 74,000 µg/L for 0.33 h, or 279,000 µg/L for 0.25 h	154
Walleye, <i>Stizostedion vitreum</i> ; 13–21 µg/L	MATC ^b at 35 mg CaCO ₃ /L	1

Table 3.5 (continued) Effects of Copper on Representative Aquatic Plants and Animals

Taxonomic Group, Organism, Copper Concentration, and Other Variables	Effects	Reference ^a
Florida pompano, <i>Trachinotus carolinus</i> ; 360–510 µg/L for 96 h	LC50	1
Arctic grayling, <i>Thymallus arcticus</i>		
2.65 µg/L for 96 h; swimup fry	LC50	120
9.6 µg/L for 96 h; fry	LC50	120
23–131 µg/L for 96 h; alevins	LC50	120
AMPHIBIANS		
Marbled salamander, <i>Ambystoma opacum</i> ; 50 µg/L for 96 h; embryos	97% survival 4 days posthatch	155
American toad, <i>Bufo americanus</i> ; tadpoles		
10 µg/L	Avoidance	166
930 µg/L	Attraction	166
Fowler's toad, <i>Bufo fowleri</i> ; 2696 µg/L for 7 days; embryos	LC50	155
Two-lined salamander, <i>Eurycea bislineata</i> ; 1120 µg/L for 48 h; juveniles	LC50	156
Narrow-mouthed toad, <i>Gastrophryne carolinensis</i>		
10 µg/L for 4 days; embryos	34% dead 4 days after hatching	155
40 (30–50) µg/L; embryos through posthatch	LC50 (7 days)	162
50 µg/L for 72 h; embryos	LC50	155
Southern gray treefrog, <i>Hyla chrysoscelis</i>		
10 µg/L for 96h; embryos	39% dead 4 days after hatching	155
40 µg/L for 7 days; embryos	LC50	155
60 µg/L for 72 h; embryos	LC50	155
Northern leopard frog, <i>Rana pipiens</i>		
10 µg/L for 96h; embryos	34% dead 4 days after hatching	155
50 µg/L for 8 days; embryos	LC50	155

^b MATC = Maximum acceptable toxicant concentration. Lower value in each MATC pair indicates highest concentration tested producing no measurable effect on growth, survival, reproduction, and metabolism during chronic exposure; higher value indicates lowest concentration tested producing a measurable effect.

Cnidarians

Sea anemones (*Anemonia viridis*) in seawater solutions containing 50 or 200 µg Cu/L regulate copper by expelling zooxanthellae, which are shown to accumulate copper (Harland and Nganro 1990).

Molluscs

Initial effects of copper on mussels (*Mytilus* spp.) include valve closure, a reduction in filtration rates, and cardiac inhibition; these responses all serve to slow the uptake of copper through a reduction in mussel contact with the ambient environment and a reduction in blood flow within the organism (Gaine and Kenyon 1990). Copper impairs the structure and function of cellular membranes in mussels by stimulating the peroxidation of membrane lipids. End products of lipid peroxidation contribute to the formation of lipofuscins (Viarengo et al. 1990). Copper-induced lysosomal lipofuscin accumulations, together with metallothioneins, control copper residues at the cellular levels and are responsible for the short half-time persistence (6 to 8 days) of copper in the digestive gland of mussels (Vairengo et al. 1990). Concentrations of heat shock protein (hsp60) in mantle tissues of mussels exposed to copper increased in a dose-dependent manner; hsp60 may have potential as a biomarker of copper insult (Sanders et al. 1991). Copper-stressed common mussels (*Mytilus edulis*) die more quickly under conditions of anoxia, high temperatures, and low salinities (Weber et al. 1992). Concentrations of copper that cause a decrease in yields of normal larvae in populations of *Mytilus edulis* from unpolluted or mildly contaminated sites did not affect embryonic development of mussels from polluted sites. Cross breeding of mussels from these sites suggests that copper tolerance in mussels is mostly maternally determined (Hoare et al. 1995a). Embryos of common mussels are more sensitive to copper than veliger larvae or postlarval spat stages (Hoare et al. 1995b). A copper-induced decrease in glochidial viability is a possible explanation for the disappearance of freshwater unionid mussels from acid- and metals-contaminated waters (Huebner and Pynnonen 1992). Hole et al. (1993) state that mussels of all ages are equally susceptible to copper and that their capacity to recover declines with increasing age; however, this phenomenon needs verification.

Bioconcentration factors for marine bivalves (ratio of milligrams of copper per kilogram fresh weight soft parts to milligrams of copper per liter of medium) vary from 85 to 28,200. Bioconcentration factors for copper are highest for American oysters after exposure for 140 days (20,700 to 28,200), and lowest for bay scallops (*Argopecten irradians*) after exposure for 112 days (3310) and for softshell clams after exposure for 35 days (3300; USEPA 1980). Copper is more toxic to embryos of the tropical giant clam (*Tridacna derasa*) than to embryos of bivalves from temperate regions (Soria-Dengg and Ochavillo 1990), possibly because many tropical species of shellfish live

near their upper lethal thermal limits and are unable to withstand additional environmental stressors. Juveniles of Asiatic clams (*Corbicula fluminea*) are more sensitive than adults to ionic copper (Belanger et al. 1990).

On exposure to lethal concentrations of copper the channeled whelk (*Busycon canaliculatum*), a marine gastropod, accumulates the metal in gill and osphradium. These tissues show progressive histopathology including swelling of the gill filaments, amoebocytic infiltration of the connective tissue, and necrosis and sloughing of the mucosa (Betzer and Yevich 1975). Copper-resistant strains of freshwater gastropods are found in media containing elevated concentrations of 35 µg Cu/L (Ebele et al. 1990), suggesting physiological or genetic adaptation. Fine suspensions of copper and kaolinite mixtures are more toxic to freshwater gastropods than copper alone. Toxicity is greater at pH 8 than at pH 7 (Al-Sabri et al. 1993). The authors conclude that copper is strongly adsorbed by kaolinite in alkaline media and that the acidic pH of the snail gut enhances release of ionic copper. In freshwater gastropods, ionic copper causes hypersynthesis of lysosomal enzymes and acid and alkaline phosphatases; immature gastropods are more sensitive than adults (Winger et al. 1984).

Arthropods

Life-cycle exposures of four species of *Daphnia* to graded concentrations of copper show reductions in survival at more than 40 µg/L and reductions in growth and reproduction at 40 to 60 µg/L; heavier and larger species are the most resistant to copper (Winner and Farrell 1976; Table 3.5). Starvation increases the sensitivity of most species of freshwater cladocerans to copper (Koivisto et al. 1992); however, there is no difference in LC50(48 h) values between fed and starved *Daphnia magna* (Lazorachak and Waller 1993). Bioavailability and toxicity of copper to *D. magna* and other tested arthropods are usually higher under conditions of increasing acidification, ionic copper, alkalinity, and temperature, or of decreasing dissolved organic carbon (Meador 1991; Taylor et al. 1994; Zou and Bu 1994). Mixtures of copper and other metals produce additive or more-than-additive effects in *D. magna* than would be expected on the basis of individual components (Enserink et al. 1991). The concept that chronic exposures to pulses of the LC50 concentrations of copper or cadmium causes no damage to freshwater organisms — provided that the average daily concentration never exceeds the no-observable-effect concentration — was tested in daphnids. The concept was true for cadmium but not copper, and the use of pulsed exposures for establishing water-quality criteria to protect aquatic life needs to be reexamined (Ingersoll and Winner 1982).

Copper uptake by aquatic arthropods occurs usually by way of the gut after eating or from the gills and other permeable surfaces in contact with the ambient medium (Weeks and Rainbow 1993). Copper accumulations by crustaceans are greatest at elevated (summer) temperatures and during molting (Powell and White 1990). A relatively high bioconcentration factor of 2000 is documented for copper and freshwater stoneflies (*Pteronarcys californica*; USEPA 1980), but the reasons for this phenomenon are unknown. The high tolerance to copper and other metals of mayfly larvae (*Baetis thermcius*), and high copper accumulations, is attributed, in part, to the selective induction of metal binding proteins in the gut (Sumi et al. 1991). Marine amphipods readily accumulate dissolved copper from seawater in a dose-dependent manner (Weeks and Rainbow 1991). But some species of talitrid amphipods are unable to meet their copper requirements from seawater alone and depend on dietary sources of copper (Weeks and Rainbow 1993). Mesocosm studies with freshwater zooplankton assemblages show that increasing copper concentrations in the range 0 to 50 µg/L cause a reduction in total zooplankton and changes in diversity. Within 4 days, copepods became dominant at the expense of cladocerans (Havens 1994).

Soldier crabs (*Mictyris longicarpus*) accumulate copper mostly from sediments rather than the water column (Weimin et al. 1994). The fine particles of sediment trapped as food contain bioavailable fractions of copper and other metals, and these significantly correlate with metal concentrations in the body of the crab. However, copper accumulations from sediments by soldier crabs

occurs only at an artificially high concentration (1900 mg Cu/kg DW sediment), which also had toxic effects. Soldier crabs seem unable to regulate copper within their body (Weimin et al. 1994).

In shore crabs, several days of exposure to sublethal concentrations of waterborne copper cause extensive damage to gill epithelium; at lethal concentrations, tissue hypoxia is probably the major effect of copper (Nonnotte et al. 1993). Starved shore crabs show a reduction in carapace copper concentrations and heavier midgut glands; starvation in combination with copper exposure (500 µg/L) results in an increase in copper in the carapace and a decrease in carapace calcium (Scott-Fordsmand and Depledge 1993). Shore crabs in seawater with high (10 mg/L) levels of waterborne copper show reductions in hemolymph sodium, gill sodium-potassium-ATPase activity, activities of various midgut gland enzymes (hexokinase, phosphofructokinase, pyruvate kinase), and hemolymph electrolytes (Hansen et al. 1992a, 1992b).

In the rusty crayfish (*Orconectes rusticus*), toxicity of copper at high concentrations is due to the coagulatory action on cellular proteins and to interference with respiratory processes; at low concentrations, copper causes degenerative changes in certain tissues and interferes with glutathione equilibrium (Hubschman 1967). Larvae of the red crayfish (*Procambarus clarkii*) exposed to copper as embryos are less sensitive than those exposed after hatching, suggesting acclimatization (Rice and Harrison 1983).

Annelids

Aquatic oligochaetes (*Lumbriculus variegatus*) do not accumulate significant amounts of copper when compared to controls after exposure for 30 days in sediments containing as much as 90.1 mg Cu/kg DW or in water containing as much as 2.3 µg Cu/L (Ankley et al. 1994). Adult lugworms (*Arenicola marina*) living in sediments containing 182 to 204 mg Cu/kg DW sediment had inhibited digestive processes; authors concluded that the digestive systems of lugworms, and perhaps other deposit feeders, are vulnerable to copper-contaminated sediments (Chen and Mayer 1998). Larvae of the sandworm (*Nereis diversicolor*) are more resistant to copper with increasing organism age and with increasing temperature and salinity of the medium (Ozoh and Jones 1990). In adult sandworms, whole-body loadings of copper usually increase with increasing temperature in the range of 12 to 22°C and with decreasing salinity in the range 0.7 to 3.1% (Ozoh 1992b). However, copper–temperature–salinity interactions are significant and complex in this species (Ozoh 1994).

Fishes

Adverse sublethal effects of copper on behavior, growth, migration, and metabolism occur in representative species of fishes at nominal water concentrations between 4 and 10 µg/L. In sensitive species of teleosts, copper adversely affects reproduction and survival from 10 to 20 µg Cu/L (Hodson et al. 1979; [Table 3.5](#)). Copper exerts a wide range of physiological effects in fishes, including increased metallothionein synthesis in hepatocytes, altered blood chemistry, and histopathology of gills and skin (Iger et al. 1994). At environmentally realistic concentrations, free copper:

- Adversely affects resistance of fishes to bacterial diseases
- Disrupts migration (that is, fishes avoid Cu-contaminated spawning grounds)
- Alters locomotion through hyperactivity
- Impairs respiration
- Disrupts osmoregulation through inhibition of gill Na⁺-K⁺-activated ATPase
- Is associated with tissue structure and pathology of kidneys, liver, gills, and other hematopoietic tissues
- Impacts mechanoreceptors of lateral line canals
- Impairs functions of olfactory organs and brain
- Is associated with changes in blood chemistry, enzyme activities, and corticosteroid metabolism (Hodson et al. 1979).

Copper-induced cellular changes or lesions occur in kidneys, lateral line, and livers of several species of marine fishes (Gardner and LaRoche 1973).

Copper-induced mortality in teleosts is reduced in waters with high concentrations of organic sequestering agents and in genetically resistant species (Hodson et al. 1979). At pH values less than 4.9 (that is, at pH values associated with increased aluminum solubility and toxicity), copper may contribute to the demise of acid-sensitive fishes (Hickie et al. 1993). Copper affects plasma Na^+ and gill phospholipid activity; these effects are modified by water temperature and hardness (Hansen et al. 1993). In red drum, copper toxicity is higher at comparatively elevated temperatures and reduced salinities (Peppard et al. 1991). Copper is acutely toxic to freshwater teleosts in soft water at concentrations between 10 and 20 $\mu\text{g/L}$ (NAS 1977). In rainbow trout, copper toxicity is markedly lower at high salinities (Wilson and Taylor 1993). Comparatively elevated temperatures and copper loadings in the medium cause locomotor disorientation of tested species (Kleerekoper 1973). Copper may affect reproductive success of fish through disruption of hatch coordination with food availability or through adverse effects on larval fishes (Ellenberger et al. 1994). Chronic exposure of representative species of teleosts to low concentrations (5 to 40 $\mu\text{g/L}$) of copper in water containing low concentrations of organic materials adversely affects survival, growth, and spawning; this range is 66 to 120 $\mu\text{g Cu/L}$ when test waters contain enriched loadings of organic materials (Hodson et al. 1979).

Larval and early juvenile stages of eight species of freshwater fishes are more sensitive to copper than embryos (McKim et al. 1978) or adults (Hodson et al. 1979). But larvae of topsmelt (*Atherinops affinis*) are increasingly sensitive to copper with increasing age. Topsmelt sensitivity is associated with increasing respiratory surface area and increasing cutaneous and branchial uptake of copper (McNulty et al. 1994).

Sublethal exposure of fishes to copper suppresses resistance to viral and bacterial pathogens (Rougier et al. 1994) and, in the case of the air-breathing catfish (*Saccobranchus fossilis*), affects humoral and cell-mediated immunity, the skin, and respiratory surfaces (Khangarot and Tripathi 1991). Rainbow trout exposed to 50 $\mu\text{g Cu/L}$ for 24 h — a sublethal concentration — show degeneration of olfactory receptors that may cause difficulties in olfactory-mediated behaviors such as migration (Klima and Applehans 1990). The primary site of sublethal copper toxicity in rainbow trout is the ion transport system of the gills (Hansen et al. 1993). In European sea bass (*Dicentrarchus labrax*), copper compromises the defense system of red blood cells against active forms of oxygen, leading to increased membrane lipid peroxidation (Roche and Boge 1993).

Dietary copper is more important than waterborne copper in reducing the survival and growth of rainbow trout larvae (Woodward et al. 1994). Simultaneous exposure of rainbow trout to dietary and waterborne copper results in significant copper assimilation. Diet is the main source of tissue copper; however, the contribution of waterborne Cu to tissue burdens increases as water concentrations rise (Miller et al. 1993).

Rate and extent of copper accumulations in fish tissues are extremely variable between species and are further modified by abiotic and biological variables. Copper accumulations in fish gills increase with increasing concentrations of free copper in solution, increasing dissolved organic carbon (DOC), and decreasing pH and alkalinity (Playle et al. 1993a, 1993b). Starved Mozambique tilapia accumulated significantly more copper from the medium in 96 h than did tilapia fed a diet containing 5.9 mg Cu/kg DW ration (Pelgrom et al. 1994). The bioconcentration factor for whole larvae of the fathead minnow was 290 after exposure for 30 h, but only 0.1 in muscle of bluegills after 660 h (USEPA 1980). Prior exposure of brown bullheads (*Ictalurus nebulosus*) to sublethal copper concentrations for 20 days before exposure to lethal copper concentrations produces higher copper concentrations in tissues of dead bullheads than in those not previously exposed; however, the use of tissue residues is not an acceptable autopsy procedure for copper (Brungs et al. 1973). Rising copper concentrations in blood plasma of catfish (*Heteropneustes fossilis*) seem to reflect copper stress, although the catfish appear outwardly normal. Plasma copper concentrations of catfish

increase from 290 µg Cu/L in controls at start to 380 µg Cu/L in survivors at 72 h (50% dead); a plasma copper concentration of 1060 µg Cu/L at 6 h is associated with 50% mortality (Banerjee and Homechaudhuri 1990). In rainbow trout, copper is rapidly eliminated from plasma; the half-time persistence is 7 min for the short-lived component and 196 min for the long-lived component (Carbonell and Tarazona 1994).

Attraction to waters containing low (11 to 17 µg/L) concentrations of copper occurs in several species of freshwater teleosts, including goldfish (*Carassius auratus*) and green sunfish (*Lepomis cyanellus*). However, other species, including white suckers (*Catostomus commersonii*), avoid these waters (Kleerekoper 1973). In avoidance/attraction tests, juvenile rainbow trout avoided waters containing 70 µg Cu/L but were significantly attracted to water containing 4560 µg Cu/L. A similar pattern was observed in tadpoles of the American toad, *Bufo americanus* (Birge et al. 1993). Copper concentrations in the range of 18 to 28 µg/L interfere with bluegill growth and prey choice (Sandheinrich and Atchison 1989). Copper interferes with the ability of fish to respond positively to L-alanine, an important constituent of prey odors; concentrations as low as 1 µg Cu/L inhibit this attraction response in some species (Steele et al. 1990).

Increased tolerance to copper was observed in fathead minnows after prolonged exposure to sublethal concentrations, but tolerance was not sustained on removal to clean water. Copper tolerance in fathead minnows is attributed to increased production of metallothioneins (Benson and Birge 1985). Copper tolerance in rainbow trout seems dependent on changes in sodium transport and permeability (Lauren and McDonald 1987a).

Integrated Studies

Bioconcentration and biomagnification of copper occurs in the food chain of diatom (*Skeletonema costatum*) to clam (*Donax cuneatus*) to prawn (*Penaeus indicus*). All species accumulate copper from the medium, and clams and shrimp from the diet. Maximum concentrations after exposure to 200 µg Cu/L and diets for 10 days, in mg Cu/kg FW, are 2.8 in whole diatoms, 13.6 in clam soft parts, and 33.9 in whole shrimp (Rao and Govindarajan 1992). In the marine food chain of phytoplankton to clam (*Tellina tenuis*) to juvenile plaice (*Pleuronectes platessa*), copper accumulates in a concentration-dependent manner in viscera of plaice. All organisms held in 10, 30, or 100 µg Cu/L solutions for 100 days had reduced growth. Copper concentrations, in mg Cu/kg DW at day 100, in soft parts of clams *T. tenuis* were 270 in the 10 µg/L group, 470 in the 30 µg/L group, and 1100 in the 100 µg/L group vs. less than 50 in the controls. For plaice viscera, these values were 30 in controls, 71 in the 10 µg/L group, 147 in the 30 µg/L group, and 467 mg/kg DW in the 100 µg/L group (Saward et al. 1975). Accumulations in Pacific oysters held in copper-loaded sediments are similar to those of oysters contaminated through ingestion of diatoms (*Haslea ostrearia*). However, accumulations are highest in Pacific oysters when exposed through the medium (Ettajani et al. 1992). In that study, a concentration of 30 µg Cu/L medium for 21 days resulted in copper concentrations of 137 mg/kg DW in diatoms and 1320 mg/kg DW in oyster soft parts. Oysters fed contaminated diatoms in the study had 419 mg Cu/kg DW soft parts. Oysters held in sediments containing 108 mg Cu/kg DW — a level reached after exposure for 21 days to 300 µg Cu/L — had 401 mg Cu/kg DW (Ettajani et al. 1992). Copper-induced changes in population density and community metabolism occur in an aquatic mesocosm of algae, protozoans, rotifers, oligochaetes, and bacteria; death of rotifers, algae, and oligochaetes occur at concentrations as low as 700 µg Cu/L. Adverse effects occur at 300 to 700 µg Cu/L but are negated by increasing concentrations of dissolved organic matter (Sugiura et al. 1982).

Transfer of copper from wood treated with chromated copper arsenate (CCA) occurs in estuarine algae (*Ulva*, *Enteromorpha*), American oysters, mud snails (*Nassarius obsoletus*), and fiddler crabs (*Uca* spp.; Weis and Weis 1992). Algae, barnacles, and mussels from CCA-treated lumber show elevated concentrations of copper when compared to reference sites. The epibiotic estuarine community that

forms on CCA-treated wood has lower species richness, diversity, and biomass when compared to untreated lumber (Weis et al. 1993b). Copper is trophically transferred from CCA-exposed American oysters to predatory gastropods (*Thais* sp.), resulting in reduced gastropod feeding and growth (Weis and Weis 1993).

3.7.4 Birds

No data are available on the toxicity of copper to avian wildlife. All studies with birds and copper use domestic chickens, ducks, or turkeys (Table 3.6). Copper, however, may indirectly affect avian wildlife by curtailing certain prey species. Winger et al. (1984), for example, show that apple snails (*Pomacea paludosa*) are not only extremely susceptible to copper (LC₅₀ of 24 to 57 µg/L in 96 h; immatures most sensitive), but are the primary food of the snail kite (*Rostrhamus sociabilis*), an endangered species. The decline of the apple snail in southern Florida coincided with the use of copper-diquat to control hydrilla aquatic weeds (*Hydrilla verticillata*), with serious implications for the snail kite (Winger et al. 1984).

In the domestic chicken, adverse effects of copper occur in chicks fed diets containing 350 mg Cu/kg ration for 25 days (reduced weight gain) and in adults given a dietary equivalent of more than 28 mg Cu/kg BW (Table 3.6). Chicks fed diets of 500 mg Cu/kg ration show damage to the gizzard lining; damage effects are attributed to the shedding of gizzard glandular cells into the keratin-like koilin layer, disrupting koilin production (Bremner 1979). Copper-induced gizzard histopathology in growing chicks is not reversed by zinc or Vitamins B₁₂ or E (Poupoulis and Jensen 1976). Supplementing chick diets with copper did not prove markedly advantageous (Poupoulis and Jensen 1976), provided that normal rations had about 4 mg Cu/kg and adequate iron (Carlton and Henderson 1964b). Unlike mammals, chicks fed copper-supplemented diets do not have elevated copper concentrations in liver or signs of liver damage (Bremner 1979). Broiler hens housed on slats made of lumber pressure-treated with chromated copper arsenate show severe foot-pad dermatitis and excessive mortality after 17 weeks. However, arsenic and cresylic acid — not copper — may be the responsible agents (Sander et al. 1994).

Ducklings (*Anas* spp.), unlike chicks, accumulate copper in livers when fed diets supplemented with high loadings of copper (Wood and Worden 1973). Domesticated mallards show a dose-time dependent increase in copper liver concentrations, with a maximum concentration of 254 mg Cu/kg DW liver (Table 3.6). Mallards seem to prefer drinking water containing 100 mg Cu/L over distilled water (Table 3.6); however, these birds were molting and this may have influenced their response because trace mineral requirements rise during molting (Rowe and Prince 1983).

In turkeys, natural diets with as much as 800 mg Cu/kg ration have no adverse effects on growth or survival. But purified diets are toxic to turkeys in three weeks, and purified diets that contain as little as 50 mg Cu/kg ration produce adverse effects (Waibel et al. 1964). Turkeys fed purified diets with supplemented copper show a dose-dependent increase in mortality and decrease in growth; these effects are attributed to a copper-accelerated dietary deterioration (Supplee 1964). Turkey growth and survival are acceptable when fed purified diets supplemented with as much as 800 mg Cu/kg ration provided that effective levels of added antioxidant (0.02% ethoxyquin) and stabilized sources of Vitamins A and D are present (Supplee 1964).

3.7.5 Mammals

Wilson's disease is the only naturally occurring neuropathological condition in humans and other mammals in which copper poisoning is implicated. People with Wilson's disease have severe pathological changes in the brain, especially in the basal ganglia, and in the liver. Pathology is associated with excess copper in tissues (Doherty et al. 1969). Copper concentrations in tissues from children who die from Wilson's disease are as much as 2217 mg/kg DW in liver and 1245 mg/kg DW in kidney (Table 3.7). Long-term exposure of humans to copper dust irritates the nose, eyes,

Table 3.6 Effects of Copper on Selected Birds

Organism, Copper Dose, and Other Variables	Effects	Reference ^a
MALLARD, <i>Anas platyrhynchos</i>		
Fed diets containing 15 or 135 mg/kg ration for 18 days; ducklings	Livers from low-dose group had 30 mg/kg dry weight (DW) at day 4 and 107 mg/kg at day 18; values for the high-dose group were 45 mg/kg at day 4, 74 mg/kg at day 7, and 254 mg/kg DW at day 18	1
For 15 days adults were given a choice of distilled water or water with 30, 60, or 100 mg/L	Ducks consumed significantly more water treated at 100 mg/L than distilled water; no preference was evident at lower doses	2
DUCKS, <i>Anas</i> spp.		
Ducklings fed diets containing 15 or 50 mg/kg ration for 51 days	Livers from control ducklings had 9.3 mg/kg DW. Livers from both treated groups had about 17 mg/kg DW at day 9, 37 mg/kg at day 30, and 47 mg/kg DW at day 51	1
Ducklings fed diet containing 200 mg/kg DW ration for 58 days	Copper concentrations in livers increased from 23 mg/kg DW at day 23 to 141 at day 44; at day 58 it had declined to 80 mg/kg DW	1
DOMESTIC CHICKEN, <i>Gallus</i> spp.		
Chicks age 1-day fed copper-deficient diet of 0.7 mg/kg ration or copper-adequate diet of 8.0 mg/kg ration for 46 weeks	Chicks fed copper-deficient diet had >50% mortality and high frequency of cardiovascular and skeletal lesions. Chicks on copper-adequate diet had negligible mortality, no histopathology, and normal growth 95% dead of copper deficiency	3, 4
Chicks fed diet containing 1.5 mg/kg ration for 60 days	Normal growth but high frequency of vascular rupture	5
Chicks fed diet containing 2.7 mg/kg ration for 60 days	Good survival and growth	5
Chicks fed diet containing 8.7 mg/kg feed for 60 days	Reduced weight gain in the 350 mg/kg group; other groups same as controls	6
Day-old chicks fed diets containing 10 (control), 100, 200, or 350 mg/kg ration for 25 days	Livers from controls had 5.9 mg/kg DW; treated groups were similar to controls, with copper concentrations in livers between 4.3 and 8.5 mg/kg DW	1
Chicks fed diets containing 15 or 50 mg/kg ration for 51 days	After 2 to 6 weeks, chickens were weak, anorectic, and lethargic; 35% were anemic	6
Adults were fed diets equivalent to 28 mg/kg body weight (BW) daily for the first week, 42 mg/kg BW daily for week 2, and 100 mg/kg BW daily until anemia, toxicosis, or death occurred	Maximum copper concentration in liver was 17.2 mg/kg DW at day 20; by day 58 it had dropped to 7.2 mg/kg DW	1
Chicks fed diet containing 200 mg/kg DW for 58 days	No gizzard erosion in controls; chicks fed the 250 mg/kg diet grew better than other treated groups but some had gizzard erosion. Chicks fed the 500 and 1000 mg/kg diets had decreased growth, decreased feed efficiency, and a high frequency of gizzard erosion. Severity of gizzard erosion was significantly reduced in the 500 mg/kg group (but not the 1000 mg/kg group) by adding 0.35% cholic acid	7
Chicks fed diets supplemented with 250, 500, or 1000 mg/kg ration for 4 weeks	Controls and the 250 mg/kg group had lower concentrations of copper in liver than those fed diets containing 500 mg/kg and higher. Copper concentration in the 2000 mg/kg group increased from 3 mg/kg DW at day 3 to 1790 mg/kg at day 48 (vs. 11.3 mg/kg DW in controls)	8
Laying hens fed diets supplemented with 250, 500, 1000, or 2000 mg/kg ration for 48 days		

Table 3.6 (continued) Effects of Copper on Selected Birds

Organism, Copper Dose, and Other Variables	Effects	Reference ^a
TURKEY, <i>Meleagris gallopavo</i>		
Day-old pourets fed diets containing 0, 60, 120, or 240 mg/kg ration and adequate levels of methionine for 24 weeks	Diets containing 60 mg/kg improved body weight at age 8 weeks; the 120 and 240 mg/kg diets inhibited growth for the first 8 weeks but not during the next 16 weeks	9
Week-old pourets fed a purified corn starch, isolated soy protein diet supplemented with 50 to 800 mg/kg ration for 3 weeks	Dose-dependent increase in mortality and decrease in growth	10
Week-old pourets fed corn-soybean meal supplemented with 100 to 800 mg/kg ration	No adverse effects on survival; growth reduced only at 800 mg/kg diet	10
Day-old pourets fed diet containing 500 mg/kg ration for 24 weeks	Reduced growth and increased gizzard histopathology	9

^a 1, Wood and Worden 1973; 2, Rowe and Prince 1983; 3, Carlton and Henderson 1963; 4, Carlton and Henderson 1964a; 5, Carlton and Henderson 1964b; 6, National Academy of Sciences 1977; 7, Poupoulis and Jensen 1976; 8, Stevenson and Jackson 1978; 9, Kashani et al. 1986; 10, Supplee 1964.

and mouth and causes headaches, dizziness, nausea, and diarrhea (USEPA 1980; ATSDR 1990). Drinking water that contains higher than normal concentrations of copper may cause vomiting, diarrhea, stomach cramps, nausea, and greenish or bluish stools and saliva. Intentionally high intakes of copper may result in liver and kidney damage, and sometimes death, especially in children. The seriousness of the effects of copper is expected to increase with increasing dose and duration of exposure (USEPA 1980; ATSDR 1990). Human tissues directly exposed to copper or copper salts will suffer adverse effects because of copper absorption. This is the case for copper bracelets on sweaty skin, for certain intrauterine devices, and for copper dental fillings (USEPA 1980). In monkeys, copper used as dental fillings in deciduous teeth caused more severe pulp damage than did other materials studied (USEPA 1980).

Mammals and birds are 100 to 1000 times more resistant to copper than other animals (Schroeder et al. 1966). But excessive dietary intakes of copper by 20- to 50-fold over normal levels may have serious effects in mammals. Depending on the species, growth and food intake may be reduced, anemia may develop, and liver, kidney, brain, and muscle may degenerate, often resulting in death (Bremner 1979; ATSDR 1990). Copper poisoning in mammals may result from consumption of plants treated with copper-containing pesticides, from the veterinary use of copper sulfate to control helminthiasis and infectious pododermatitis in cattle and sheep, and from the ingestion of contaminated soils and vegetation near copper mining and refining operations (NAS 1977). Emissions from copper mines and smelters are often associated with deaths of horses, cows, and sheep; pasture lands, in some cases, are fit for grazing only after heavy rains (Hutchinson 1979).

Ruminant mammals are significantly more sensitive to copper than nonruminant mammals and poultry (Schroeder et al. 1966; NAS 1977). Signs of copper poisoning in ruminants include vomiting, excessive salivation, abdominal pain, diarrhea with greenish-tinted feces, pathology of internal organs, elevated copper concentrations in livers, altered enzyme activities in liver and serum, and collapse and death within 24 to 48 h (NAS 1977). Young calves may develop copper toxicosis at relatively low copper intakes, especially when receiving milk-based diets. Goats, however, seem resistant to copper toxicosis (Bremner 1979). Among ruminants, domestic sheep are particularly susceptible to copper insult from grazing on pastures treated with copper-containing fungicides and molluscicides or from inadvertently consuming diets specially formulated for pigs that contain large amounts of copper as a swine growth stimulant (Todd 1969; Bremner 1979).

Chronic copper poisoning in domestic sheep is first characterized by a period of passive accumulation of copper in the tissues. This period varies from a few weeks to more than a year. During this time the animal appears outwardly normal although the liver may contain more than 1000 mg Cu/kg DW and plasma activities of aspartate transaminase, sorbitol dehydrogenase, lactic

dehydrogenase, and arginase increase, indicating that liver damage has occurred. During the last few weeks of the passive phase, and prior to the so-called toxic phase, liver histopathology of parenchymal cells and copper-containing Kupffer cells occurs. The toxic phase, which is an acute illness and referred to as the hemolytic crisis, usually results in death 2 to 4 days later. During this phase sheep refuse to eat but have an excessive thirst. The eyes are usually sunken. The venous blood is chocolate colored. The liver is jaundiced. The kidneys are completely gorged with hemoglobin breakdown products and the medulla and cortex are black. The spleen is enlarged, with the parenchyma a deep brown to black color. The onset of these signs in sheep is associated with liberation of copper from the liver and a massive increase in blood copper concentrations. The increased blood copper concentrations lead to an increase in blood methemoglobin and a sudden fall in the erythrocyte glutathione level immediately followed by massive hemolysis and kidney damage, leading to uremia and death. At the time of crisis, elevated serum creatine phosphokinase activity suggests that muscle cell membranes are affected, and elevated serum glutamic oxaloacetate transaminase (SGOT) and lactic dehydrogenase activities indicate progressive liver necrosis (Doherty et al. 1969; Todd 1969; Thompson and Todd 1974; Bremner 1979). It is emphasized that (1) blood copper status and liver function in sheep experimentally poisoned with copper sulfate are linked to elevated SGOT activities 1 to 6 weeks in advance of obvious external signs (MacPherson and Hemingway 1969); (2) copper chloride is 2 to 4 times more toxic than copper sulfate to sheep (NAS 1977); and (3) the use of copper-enriched feeding stuffs increases the risk of chronic copper poisoning in sheep fed purified rations (Froslie et al. 1983). Also, sheep that accumulate higher than normal amounts of copper in the liver (i.e., 1900 mg Cu/kg DW) are more severely affected by lupinosis (acute liver atrophy due to poisoning by ingestion of plants of *Lupinus* spp.) than sheep with normal (40 mg/kg DW) concentrations of copper in the liver (Gardiner 1967).

Copper toxicosis in lambs of domestic sheep occurs at dietary concentrations between 8 and 60 mg Cu/kg ration. The wide range of dietary concentrations is a function of copper availability. Availability, in turn, is influenced by dietary composition, genetic influence, age, breed, sex, physiological state, and interactions with other dietary constituents including iron, zinc, and molybdenum (Bremner 1979). Chronic copper poisoning in lambs occurs at dietary levels as low as 27 mg Cu/kg DW ration (Buckley and Tait 1981). During the passive phase, lambs — like adults — have normal plasma copper concentrations and seem outwardly unaffected. Unlike adults, copper accumulates in livers of lambs during a shorter period (several weeks to months vs. months to years). Signs of hemolytic crisis and death within a few days are similar for both adults and lambs. Elevated plasma aspartate aminotransferase (AAT) activity in lambs — up to 10 times higher than controls — occurs 4 to 8 weeks before the hemolytic crisis (Buckley and Tait 1981) and strongly indicates a need for more research on the usefulness of AAT and other enzymes as early indicators of copper stress. A recommended treatment for lambs diagnosed with chronic copper poisoning is 20 mL of a mixture containing 100 mg of ammonium molybdate and 1 g of sodium sulfate administered orally 5 days weekly (Doherty et al. 1969).

In domestic pigs, copper toxicosis results from eating diets containing 250 mg Cu/kg ration and is characterized by anemia, jaundice, elevated levels of Cu in serum and liver, and elevated serum AAT activity (USEPA 1980). Shortly before death, copper-poisoned pigs had white noses, poor balance, stomach histopathology, orange cirrhotic livers, anorexia, and anemia (Higgins 1981).

In rodents, copper administered by single intraperitoneal or subcutaneous injection is lethal at 3 to 7 mg Cu/kg BW ([Table 3.7](#)). Mice died when their drinking water contained 640 mg Cu/L ([Table 3.7](#)). In rats, copper accumulation in kidneys and lungs is similar regardless of route of administration (Romeu-Moreno et al. 1994). Concentrations of copper in serum of rats (*Rattus* sp.) reflect dietary copper; concentrations in liver and kidney are directly related to serum Cu and ceruloplasmin (Petering et al. 1977). As serum Cu concentrations rise in rats, levels fall for serum cholesterol, triglycerides, and phospholipids (Petering et al. 1977).

Table 3.7 Effects of Copper on Selected Mammals

Organism, Copper Dose, and Other Variables	Effects	Reference ^a
CATTLE, <i>Bos</i> spp.		
Fed diet containing 8.2 mg/kg ration for 333 days	Copper concentration in liver increased from 111 to 328 mg/kg dry weight (DW)	1
Fed diets containing 20 to 125 mg/kg ration for extended period	Intoxication	2
Single dose; 200 mg/kg body weight (BW)	Lethal	2
PONY, <i>Equus</i> sp.		
Ponies given a single oral dose of 20 or 40 mg/kg BW were challenged 24 h later with oral doses of 2, 4, 6, or 8 mg selenium/kg BW	All ponies given 20 or 40 mg/kg BW were unaffected by selenium, regardless of dosage; without copper pretreatment, signs of severe Se toxicosis — including lethargy, colic, and death — developed in ponies given 6 or 8 mg Se/kg BW	3
Fed diet containing 800 mg/kg ration for 6 months	No adverse effects	4
HUMANS, <i>Homo sapiens</i>		
3 mg/L drinking water for 9 months	Liver damage in infants	5
30 mg/L drinking water; single exposure; total intake unknown	Vomiting, diarrhea, stomach cramps	5
6 to 637 mg/kg BW; single exposure (attempted suicides)	13 of 53 patients died; death attributed to shock and hepatic or renal complications	5
Children who died from Wilson's disease vs. normal children		
Brain	2090 mg/kg ash weight (AW), equivalent to 31 mg/kg fresh weight (FW) or 129 mg/kg DW vs. 290 mg/kg AW	6
Heart	6800 mg/kg AW, equivalent to 75 mg/kg FW or 298 mg/kg DW vs. 340 mg/kg AW	6
Kidney	27,160 mg/kg AW, equivalent to 299 mg/kg FW or 1245 mg/kg DW vs. 250 mg/kg AW	6
Liver	74,570 mg/kg AW, equivalent to 820 mg/kg FW or 2217 mg/kg DW vs. 1300 mg/kg AW	6
Pancreas	1200 mg/kg AW vs. 160 mg/kg AW	6
Spleen	1930 mg/kg AW vs. 100 mg/kg AW	6
MICE, <i>Mus</i> spp.		
Strain genetically deficient in copper (Menkes disease) given subcutaneous injections of 50 µg copper chloride (CuCl_2) on postnatal days 7 and 10. Before therapy, liver copper concentration was 3.1 mg/kg FW (vs. 30.1 mg/kg FW in normal mice)	Seven months postinjection there was some reduction in neurodegeneration; copper was distributed normally in liver; in intestine, copper accumulated in histiocytes	7
120 µg/m ³ air for 1–2 weeks	Alveoli thickening	5
<3.3 mg/kg BW; single intraperitoneal (ip) injection	No effect on oxygen consumption or body temperature	8
3.3–8.0 mg/kg BW; single ip injection	Dose-dependent reduction in oxygen consumption and body temperature	8
4.02 mg/kg BW; single ip injection	50% dead	8
Drinking water equivalent of 4.2 mg/kg BW daily for 850 days	Decreased growth and survival	5
Drinking water equivalent of 42.5 mg/kg BW daily as copper glutamate; lifetime exposure	Maximal lifespan reduced from 986 days to 874 days	5
640 mg/L drinking water for 850 days	Decreased survival	5

Table 3.7 (continued) Effects of Copper on Selected Mammals

Organism, Copper Dose, and Other Variables	Effects	Reference ^a
MINK, <i>Mustela vison</i>		
Dietary equivalent of 3.5 mg/kg BW daily for 50 weeks	Decreased survival (deficiency)	5
Dietary equivalent of 13.5 mg/kg BW daily for 50 weeks	Some deaths; no adverse effect on reproduction of survivors	5
RABBIT, <i>Oryctolagus</i> sp.		
600 µg/m ³ air for 4 to 6 weeks	No adverse systemic or immunological effects	5
DOMESTIC SHEEP, <i>Ovis aries</i>		
Ewes were fed a copper-deficient diet of 1.3 to 2.5 mg/kg DW ration. At mating, livers contained 20 to 106 mg/kg DW; after lambing, livers contained 3 to 12.3 mg/kg DW	22 of 54 (41%) lambs from ewes fed a copper-deficient diet developed swayback; these lambs had liver concentrations of 5.9 (1.5–11.0) mg/kg DW vs. 6.9 (2.5–14) mg/kg DW in non-swaybacked lambs	11
Ewes from vicinity of copper production plant receiving daily dietary intake of 465 mg/ewe (10.7 mg/kg BW daily) vs. control ewes with average daily dietary intake of 29 mg Cu/ewe (0.67 mg Cu/kg BW daily)	All ewes near copper facility were dead by day 89 vs. none dead in controls. At day 35, ewes near copper production plant had 11.8 mg/kg DW in wool vs. <7 mg/kg DW in controls	9
Merino sheep, 6 to 9 months old; given 5.1 mg/kg BW 5 times weekly for 28 weeks through the mouth as copper sulfate. Heliotrope and nonheliotrope diets	Some deaths. Yellow discoloration of sclera of eye; passing of red-colored urine. Copper concentrations, in mg/kg DW, from sheep fed nonheliotrope diets were 1394 in liver (824 in controls) and 132 in kidney (20 in controls). Sheep on heliotrope diet had 2783 mg/kg DW in liver and 321 mg Cu/kg DW in kidney	10
Oral administration of 7.5 mg/kg BW daily for 83 days, as copper sulfate	Severe morphological changes in liver, kidney, and brain; tissue damage continued after cessation of copper and was sufficiently severe to lead to repeated hemolytic crises. Maximum copper concentrations at day 83 were 3289 mg/kg DW in liver (138 in controls), and 683 in kidney (15 in controls)	12
Lambs fed diets containing 9.1 (control) or 37.3 mg/kg ration for 11 weeks	Normal growth and survival. At slaughter, liver copper concentrations, in mg/kg DW, were 372 in controls and 1109 in the treated group; plasma aspartate aminotransferase was elevated in the high-dose group	13
Lambs fed diets containing 11 (control), 18, or 25 mg/kg ration for 10 weeks	Survival and growth normal in all groups. Liver concentrations, in mg/kg DW, were 239 (11 mg/kg group), 454 (18 mg/kg group), and 721 (25 mg/kg group)	13
Rams, age 4.5 to 5.5 years; daily intake of 15 mg/kg BW for 50 days	Increased concentrations of copper in ejaculates (16 mg/kg DW vs. 2 in controls) and liver (1435 mg/kg DW vs. 63). Sperm motility in test rams was significantly decreased, abnormalities were increased, and testes copper was elevated (96–101 mg/kg DW vs. 60–69 in controls)	14
Equivalent of 20 mg/kg BW daily for 9 weeks Lambs fed diet containing 80 mg/kg DW ration for 6 weeks	Hemolysis Postmortem examination of 17 lambs that died suddenly showed brain histopathology, particularly in white matter of midbrain, pons, and cerebellum. Severe liver cirrhosis and necrosis of kidney tubules. Liver copper elevated at 3225 to 4325 mg/kg DW	15 16

Table 3.7 (continued) Effects of Copper on Selected Mammals

Organism, Copper Dose, and Other Variables	Effects	Reference ^a
LABORATORY WHITE RAT, <i>Rattus</i> sp.		
Dietary route		
Male weanlings fed copper-deficient (0.13 mg/kg ration) or copper-adequate (5.7 mg/kg ration) diets for 49 days	24% of the copper-deficient rats died of cardiac rupture; ruptured hearts had lower magnesium and higher sodium, phosphorus, and calcium. Copper-adequate rats had 21.7 mg/kg DW liver vs. 2.2 in copper-deficient rats in which hearts had ruptured	17
Low copper diet of 1 mg/kg DW ration vs. 5 mg/kg diet for 12 weeks	Dose-dependent increase in copper concentrations in kidney, liver, and plasma. Low Cu status increases retention of cadmium in liver	18
100 mg/kg diet for 20 weeks	Increased blood pressure	5
250 mg/kg diet for 3 months	No deaths	5
500 mg/kg diet for 3 months	Kidney damage	5
1000 mg/kg diet for 3 months	Stomach and liver damage	5
2000 mg/kg diet for 1 to 3 weeks	Liver and kidney damage	5
4000 mg/kg diet (133 mg/kg BW daily) for 1 week	Increased mortality	5
6000 mg/kg diet (300 mg/kg BW daily) for 2 weeks	Weanlings died from extensive centrilobular necrosis	5
Equivalent to 7.9 mg/kg BW daily for 90 days	Increased serum glutamic oxaloacetic transaminase enzyme activity	5
Equivalent to 10 mg/kg BW daily for 20 weeks	Increased blood pressure; increased hemoglobin	5
Equivalent to 40 mg/kg BW daily for 30 days	Anemia, increased liver enzyme activity, increased cholesterol and urea	5
Equivalent to 130 mg/kg BW daily for 18 weeks	Decreased body growth; decreased testes weight	5
Equivalent to 144 mg/kg BW daily for 4 weeks	Decrease in rate of body weight gain	5
Drinking water route		
0.25, 2, or 16 mg/L for 109 to 119 days	Serum copper rose from 44 µg/L (controls) to 106 µg/L (0.25 mg/L group) to 848 (2 mg/L) to 943 µg/L (16 mg/L group); dose-dependent decrease in serum cholesterol, triglycerides, and phospholipids	19
50 or 150 mg/L for 15 to 30 days	No adverse effect on liver microsomal activity	20
398 to 450 mg/L for 15 to 30 days	Reduction in liver aniline hydroxylase activity; liver histopathology	5, 20
Inhalation route		
Copper sulfate spray containing 330 g/L for daily exposures of 1 h for as long as 10 days	Concentrations of copper in liver, in mg/kg FW, were 32 after 6 hr, 84 after 5 days, and 285 after 10 days	27
Injection route		
0.26 mg/rat daily as copper sulfate for 60 days; subcutaneous (sc) injection	Treated rats had 1000 mg/kg FW liver (vs. 4.7 in controls); lowered hemoglobin, hematocrit, and red cell counts; mean survival time of 67 days; hepatic and renal histopathology	15
0.625, 1.25, 2.5, or 3.75 mg/kg BW daily for 18 weeks; intraperitoneal injection	Dose-time-dependent increase in copper concentrations in liver, spleen, and lung; little accumulation in muscle and skin. Reduced growth at 2.5 and 3.75 mg/kg BW daily; reduced survival at 3.75 mg/kg BW. Maximum copper concentrations recorded, in mg/kg FW (vs. saline controls,) were 710 in liver (<5), 212 in kidney (<10), 7 in lung (<1.5), 27 in spleen (<2.0) 6 in bone (<2.0) and 2.2 in testes (<1.6)	21
Adult males given 2 mg/kg BW daily as copper acetate for 14 days; intra-peritoneal injection	Increased serum ceruloplasmin and white blood cell number	22

Table 3.7 (continued) Effects of Copper on Selected Mammals

Organism, Copper Dose, and Other Variables	Effects	Reference ^a
Other routes Isolated cells from adrenal and testes held in media containing 0.065, 0.65, or 6.5 mg/kg for 2 h	No effect at lowest doses. High dose caused decreased survival of cells from both organs and reduced testosterone production	23
RODENTS, various species		
3–7 mg/kg BW; single ip or sc injection	50% dead	15
COMMON SHREW, <i>Sorex araneus</i>		
Newly weaned shrews fed diets equivalent to 2.13 mg copper/shrew daily for 12 weeks; uncontaminated diets contained 25.1 mg/kg DW ration	No effect on growth, survival, or tissue copper burdens; kidney and liver copper concentrations increased in response to cadmium dosing	24, 25
DOMESTIC PIG, <i>Sus</i> spp.		
Dietary equivalent of 14.6 mg/kg BW daily for 54 days	Decreased hemoglobin and hematocrit; decreased growth rate	5
Dietary equivalent of 36 mg/kg BW daily for 7 weeks	Decreased hemoglobin, altered serum enzyme activity	5
Fed diets containing <150 mg/kg ration for 9 months	No copper accumulations over controls in liver (16–48 mg/kg DW) or kidney (20–49 mg/kg DW); growth promoting effects	26
Fed diets supplemented with 238–250 mg/kg ration, as copper sulfate, from age 3 weeks for 9 months	High mortality, usually between age 14 and 20 weeks. Dead pigs had 1300 mg/kg DW in liver and 95 mg/kg in liver; survivors had as much as 2100 mg/kg DW liver, 670 mg/kg DW kidney, and 3.3 mg/L serum	26
Fed diets containing 700 mg/kg ration for several months	High mortality; survivors had anemia, gastric ulcers, liver pathology, and 100–170 mg/kg FW in liver	15

3.8 PROPOSED CRITERIA AND RECOMMENDATIONS

Proposed copper criteria for the protection of agricultural crops, aquatic life, terrestrial invertebrates, poultry, laboratory white rats, livestock, and human health are summarized in Table 3.8.

Copper is essential to normal plant growth, and copper deficiency is known in various agricultural crops, such as vegetables and grains (Gupta 1979). Crops seem to be protected against copper deficiency when growing soils contain >10 mg Cu/kg DW and leaves >6 mg Cu/kg DW (Table 3.8). With some exceptions, agricultural crops are protected against copper toxicosis when irrigation waters contain <1.0 mg Cu/L and soils <170 mg Cu/kg DW (Table 3.8), but adverse effects occur on root development of seedling pines at irrigation water concentrations as low as 200 µg Cu/L (Arduini et al. 1995) and on growth of citrus trees when extractable copper in the soil exceeds 60 mg/kg DW (Alva et al. 1995). States allow application of sewage sludge to agricultural soils if total copper in the sludge does not exceed 1000 mg/kg DW (100 mg/kg DW in Florida), or if the application rate for sludge does not exceed 280 kg sewage sludge per surface acre (50 kg/ha in Wisconsin; Table 3.8). The practice by some localities of applying raw sewage sludge to crop soils

on the basis of kg sludge/surface acre ratio should be discouraged unless the sludge is periodically analyzed for copper and other contaminants.

Proposed criteria to protect most species of freshwater aquatic life from copper toxicity or deficiency include maximum water concentrations over a 24-h period of 12 µg Cu/L in soft water and 43 µg/L in hard water, sediment concentrations <480 mg Cu/kg DW, and, in rainbow trout, a zinc/copper ratio in gill or opercle >1.5 (Table 3.8). However, the proposed maximum water concentration range of 12 to 43 µg Cu/L exceeds the 5 to 10 µg/L range that is lethal or teratogenic to sensitive species of fishes and amphibians (Birge and Black 1979) and overlaps the 18 to 28 µg/L range that inhibits growth and ability to discriminate prey for other species (Sandheinrich and Atchison 1989). Some scientists state that laboratory studies tend to overestimate the adverse effects of copper on freshwater abundance and diversity and suggest more research on field mesocosms receiving water directly from the system under investigation (Clements et al. 1990). In marine ecosystems, copper concentrations should not exceed 23 µg Cu/L at any time, and sediments should contain less than 200 mg Cu/kg DW (Table 3.8). But adverse sublethal effects of copper to representative species of estuarine algae, molluscs, and arthropods frequently occur at less than 10 µg Cu/L (Bryan and Langston 1992). Also, extrapolation of laboratory data on copper and marine benthos to actual field conditions is difficult because of changing environmental conditions, such as thermosaline regimes and the nature of the sediment substrate (Ozoh 1992c).

Among sensitive species of terrestrial invertebrates, earthworms show disrupted enzyme activities at whole-body concentrations as low as 28.5 mg Cu/kg DW (Table 3.8). Soil copper concentrations between 53 and 100 mg/kg DW kill soil nematodes and soil faunal communities (Parmelee et al. 1993; Donkin and Dusenberry 1993) and cause a reduction in cocoon production of earthworms (Ma 1984; Spurgeon et al. 1994). Diets that contain between 50 and 63 mg Cu/kg ration inhibit development and reproduction in gypsy moths and oribatid mites (Denneman and van Straalen 1991; Gintenreiter et al. 1993). The wood louse (*Porcellio scaber*), an isopod, is proposed as a bioindicator of copper contamination in terrestrial ecosystems because whole-body concentrations seem to reflect copper loadings in the isopod's immediate environment (Hopkin et al. 1993; Table 3.8). More research is recommended on isopods and other sentinel organisms.

Quantitative data are missing on copper effects on avian and mammalian wildlife, and this represents a high-priority research need. Some data are available for copper and poultry and livestock, but extrapolation of these results to wildlife species is contraindicated in view of the wide range in sensitivities to copper between species. Domestic chickens show good growth and survival when their diets contain adequate iron and more than 4 and less than 200 mg Cu/kg ration (Carlton and Henderson 1964b). In sheep — and some other mammals — prior knowledge of copper stress would allow adequate time for treatment (i.e., prophylactic dosing with ammonium molybdate plus sodium sulfate or intravenous injection of chelating agents) to prevent sudden death during copper-induced hemolytic crisis (MacPherson and Hemingway 1969). In sheep, for example, elevated SGOT activity is an early indicator of copper poisoning and is measurable 1 to 6 weeks before the hemolytic crisis stage (MacPherson and Hemingway 1969). Providing prophylactic licks containing zinc sulfate and sulfur to African cattle, buffaloes, and impalas seems to be successful in protecting against the lethal effects of excess airborne copper in the grazing area (Gummow et al. 1991).

The proposed domestic drinking water criterion of <1.0 mg Cu/L for the protection of human health is not based on copper toxicosis but on the unpleasant taste which develops with higher levels of copper in drinking water (USEPA 1980). Increased copper levels (>1.3 mg Cu/L) in household water supplies caused by corrosion of copper plumbing materials may adversely affect infants and young children among residents of newly constructed or renovated homes (Knobeloch et al. 1994). Human groups at greatest risk to copper toxicosis now include young children subjected to unusually high concentrations of copper in soft or treated water held in copper pipes or vessels, medical patients with Wilson's disease, medical patients treated with copper-contaminated fluids in dialysis or parenteral administration, people with a glucose-6-phosphate dehydrogenase (G-6-PD)

deficiency (about 13% of the Afro-American male population has a G-6-PD deficiency) who drink water containing >1.0 mg Cu/L, and occupationally exposed workers (USEPA 1980).

Other copper research areas that seem to merit additional effort include:

1. Establishment of specific biomarkers for copper toxicity (ATSDR 1990)
2. Development of a national system to verify incidents of deficiency and excess of copper and interrelated trace elements in species of concern (NAS 1977)
3. Clarification of copper interactions with molybdenum, sulfate, iron, and zinc in plant and animal metabolisms (NAS 1977; Eisler 1989, 1993)
4. The role of copper in carcinogenesis, mutagenesis, and teratogenesis (NAS 1977; ATSDR 1990) because preliminary evidence suggests that exposures to grossly elevated concentrations of copper produces teratogenicity in fish (Birge and Black 1979) and mammals (Aaseth and Norseth 1986), carcinogenicity in rodents (USEPA 1980; ATSDR 1990; Toussaint and Nederbragt 1993), and mutagenicity in rodents (ATSDR 1990), sheep (Bires et al. 1993), and grasshoppers (Bhunya and Behura 1986)
5. Mechanisms by which copper deficiency results in neutropenia, with emphasis on the process of cellular differentiation and the viability of neutrophils in blood and marrow (Percival 1995)
6. Copper status effects on resistance to endotoxin-induced injuries because burn and trauma patients show moderate copper deficiency and high risk to sepsis, and copper deficient rats are sensitive to endotoxins causing sepsis (DiSilvestro et al. 1995)
7. The role of aquatic organisms in copper cycling in aquatic ecosystems (Stokes 1979)
8. Mechanisms of copper tolerance or acclimatization to high doses of copper (ATSDR 1990)
9. The relation between copper toxicosis, copper absorption rates, and copper retention (Stokes 1979; ATSDR 1990)
10. Effects on reproduction, neurotoxicity, and immune response (ATSDR 1990)
11. Biochemistry and physiology of copper proteins (NAS 1977)
12. Measurement of flux rates of ionic copper from metallic copper (ATSDR 1990)
13. Determination of safe levels of copper in livestock and poultry feeds (NAS 1977), and in diets of avian and mammalian wildlife

Table 3.8 Proposed Copper Criteria for the Protection of Natural Resources and Human Health

Resource, Criteria, and Other Variables	Effective Copper Concentration	Reference ^a
AGRICULTURAL CROPS		
Irrigation water	<1.0 mg/L	1
Leaves		
Severe deficiency	<4 mg/kg dry weight (DW)	2
Deficient	<5 mg/kg DW	1, 3
Mild to moderate deficiency	4 to 5 mg/kg DW	1, 3
Deficiency rare	>6 mg/kg DW	2
Sewage sludge		
Europe, acidic soils	50 to 140 kg/ha	4
United States		
All agricultural lands	<1000 mg/kg DW	5
Florida	<100 mg/kg DW	4
Illinois	<280 kg/ha	4
Maryland, Massachusetts	140 to 280 kg/ha ^b	4
Minnesota, Missouri	140 to 560 kg/ha ^c	4
New York		
Agricultural soils	<125 kg/ha	4
Forests	<280 kg/ha	4
Wisconsin, acidic soils	50 to 140 kg/ha	4
Soils		
Deficient	<10 mg/kg DW	6
Safe	<280 kg/ha ^d	7
M-3 extractable soil copper	<60 mg/kg DW	8

Table 3.8 (continued) Proposed Copper Criteria for the Protection of Natural Resources and Human Health

Resource, Criteria, and Other Variables	Effective Copper Concentration	Reference^a
Canada		
Agricultural lands	<100 mg/kg DW	4
Acidic soils, Alberta	<200 mg/kg DW	4
Industrial and other lands	<300 mg/kg DW	4
Former Soviet Union, maximum allowable concentration	3 mg/kg DW when extracted with ammonium acetate buffer	4
The Netherlands		
Normal	50 mg/kg DW	4
Moderately contaminated	100 mg/kg DW	4
Requires remediation	>500 mg/kg DW	4
United States, New Jersey	<170 mg/kg DW	4
AQUATIC LIFE, FRESHWATER		
Sediments		
Great Lakes		
Nonpolluted	<25 mg/kg DW	4
Moderately polluted	25 to 50 mg/kg DW	4
Heavily polluted	>50 mg/kg DW	4
Reduced abundance of benthos	480 to 1093 mg/kg DW	9
Toxic to benthos	>9000 mg/kg DW	9
Tissue concentrations; rainbow trout, <i>Oncorhynchus mykiss</i> ; ratio of zinc to copper in gill or opercle		
Normal	Ratio >1.5	10
Probably copper-poisoned	Ratio 0.5 to 1.5	10
Acute copper poisoning	Ratio <0.5	10
Water		
Safe. No adverse effects on rainbow trout exposed from fertilization through 4 days after hatching		
In soft or medium water	2 to 5 µg/L	11
In hard water	5 to 8 µg/L	11
Death or teratogenicity in eggs of sensitive species of fishes and amphibians	5 to 10 µg/L	11
United States		
Safe; total recoverable copper; 24 h average	<5.6 µg/L	12
Maximum allowable concentration at 50 mg CaCO ₃ /L	12 µg/L	12
Maximum allowable concentration at 100 mg CaCO ₃ /L	22 µg/L	12
Maximum allowable concentration at 200 mg CaCO ₃ /L	43 µg/L	12
Inhibits fish growth and ability of fish to discriminate prey	18 to 28 µg/L	13
Chesapeake Bay; proposed for protection of 90% of species tested		
Acute exposures		
All species	<6.3 µg/L ^f	35
Benthos	<6.9 µg/L	35
Fishes	<10.8 µg/L	35
Chronic exposures		
All species	<3.8 µg/L ^f	35
Fishes	<3.9 µg/L	35
The Netherlands; total recoverable copper; maximum allowable concentration	<50 µg/L	14
AQUATIC LIFE, MARINE		
Seawater		
Safe. Total recoverable copper, 24 h average	<4.0 µg/L; not to exceed 23 µg/L at any time	12
Safe. Maximum concentration	<5.0 µg/L	15

Table 3.8 (continued) Proposed Copper Criteria for the Protection of Natural Resources and Human Health

Resource, Criteria, and Other Variables	Effective Copper Concentration	Reference^a
Chesapeake Bay; recommended for protection of 90% of species tested		
Acute exposures		
All species	<6.3 µg/L ^f	35
Benthos	<4.1 µg/L	35
Fishes	<16.1 µg/L	35
Chronic exposures		
All species	<6.4 µg/L ^f	35
Sediments		
Avoidance by clams	>5 mg/kg DW	16
Clam burrowing ability inhibited (water concentrations of 113 to 120 µg Cu/L)	>15 mg/kg DW	16
Not polluted	<40 mg/kg DW	15
Moderately polluted	40 to 60 mg/kg DW	15
Very polluted	>60 mg/kg DW	15
Reduced species diversity; sensitive species absent	>200 mg/kg DW	17
Toxic to juvenile bivalve molluscs	>2000 mg/kg DW	17
TERRESTRIAL INVERTEBRATES		
Earthworms, whole; disrupted lysozyme activity in coelomic fluid and coelomocytes	>28.5 mg/kg DW	18
Isopod, <i>Porcellio scaber</i> ; whole		
Deficiency	Unknown	19
Uncontaminated	<250 mg/kg DW	19
Low contamination	250 to 400 mg/kg DW	19
Medium contamination	400 to 600 mg/kg DW	19
High contamination	600 to 1000 mg/kg DW	19
Very high contamination	>1000 mg/kg DW	19
POULTRY, DIETS		
Deficient	<8.7 mg/kg DW ration; some deaths at 0.7 to 1.5 mg/kg DW ration; high frequency of vascular rupture at 2.7 mg/kg DW ration	3, 20, 33
Safe	<200 mg/kg DW feed	17
Recommended for growing chickens	>4 mg/kg DW diet plus adequate iron	20
LABORATORY WHITE RAT, <i>Rattus</i> sp.		
Minimal	3 to 6 mg/kg FW diet; 0.15–0.3 mg/kg body weight (BW) daily	5
Adequate	10 mg/kg DW diet	21
LIVESTOCK		
All species except sheep; diet		
Deficient	<5 mg/kg DW	2
Minimal	>5 to <15 mg/kg DW	1
Adequate	20 to 30 mg/kg DW	2
Cattle, <i>Bos</i> sp.; liver, copper-poisoned	>150 mg/kg fresh weight (FW); >450 mg/kg DW	22
Sheep, <i>Ovis aries</i>		
Toxic	20 to 30 mg/kg DW diet	2
Pig, <i>Sus</i> sp.		
Diet		
Safe	3 to 5 mg/kg DW	5
United Kingdom, maximum	200 mg/kg DW ^e	23

Table 3.8 (continued) Proposed Copper Criteria for the Protection of Natural Resources and Human Health

- ^b Soil cation exchange capacity less than 5 meq/100 g for 140 kg/ha and more than 5 meq/100 g for 280 kg/ha.
- ^c Soil cation exchange capacity ranges from less than 5 to more than 15 meq/100 g.
- ^d Higher levels of 365 kg Cu/ha had no effect on corn yield or copper content in corn.
- ^e Diet should also contain 150 mg Zn/kg and 200 mg Fe/kg to further reduce the chances of copper toxicity to pigs.
- ^f Concentrations >50 µg Cu/L are routinely measured in the Chesapeake and Delaware Canal and infrequently in other portions of Chesapeake Bay.

3.9 SUMMARY

Copper discharges to the global biosphere are due primarily to human activities, especially mining, smelting, and refining copper and the treatment and recycling of municipal and industrial wastes. Some copper compounds, especially copper sulfate, also contribute to environmental copper burdens because they are widely and intensively used in confined geographic areas to control nuisance species of aquatic plants and invertebrates, diseases of terrestrial crop plants, and ectoparasites of fish and livestock.

Copper concentrations in field collections of abiotic materials and living organisms are usually elevated in the vicinity of human activities and intensive copper use. Maximum copper concentrations recorded in selected abiotic materials are 5 µg/m³ in air, 5 µg/L in groundwater, 12 µg/L in rainwater, 1200 mg/kg DW in poultry litter, 7000 mg/kg DW in soils, and 7700 mg/kg DW in sewage sludge. In terrestrial vegetation, copper is usually less than 35 mg/kg DW except near smelters, where it may approach 700 mg/kg DW and in certain copper-accumulator plants that may normally contain as much as 13,700 mg/kg DW. Aquatic vegetation from copper-contaminated sites contain as much as 1350 mg Cu/kg DW vs. 36 mg/kg DW in conspecifics from reference sites. Terrestrial invertebrates from industrialized areas may contain from 137 to 408 mg Cu/kg DW whole organism. Aquatic invertebrates seldom contain as much as 95 mg Cu/kg DW, regardless of collection locale. Exceptions include whole amphipods and lobster hepatopancreas (335 to 340 mg/kg DW) from copper-contaminated sites and many species of molluscs that normally contain 1100 to 6500 mg Cu/kg DW. Data are scarce on copper concentrations in field populations of amphibians and reptiles: crocodile eggs may contain as much as 60 mg Cu/kg DW and livers of some toads may contain as much as 2100 mg Cu/kg DW without apparent adverse effects. Maximum copper concentrations in tissues of fishes, elasmobranchs, birds, and marine mammals from all collection sites are low when compared to more primitive organisms and never exceed 53 mg Cu/kg DW, except liver (146 to 367 mg/kg DW); an exception is liver from endangered manatees (1200 mg/kg DW) collected at a site treated with a copper-containing herbicide. Maximum copper concentrations in all tissues of terrestrial mammals, regardless of collection locale, are low and seldom exceed 29 mg/kg DW, except kidneys (108 mg/kg DW) and livers (1078 mg/kg DW) from animals near a copper refinery.

Copper deficiency is not a major public health concern in the United States, although skeletal deformities and leg fractures may occur in some copper-deficient children. Copper deficiency effects occur, however, in various species of terrestrial plants (reduced growth, necrosis, reduction in number of pollen grains, death), chickens (poor growth, high frequency of cardiovascular and skeletal lesions, low survival), turkeys (sudden death), rats (defective hemoglobin synthesis, lesions of the central nervous system, low survival, altered blood and liver enzyme activities), guinea pigs (lesions of the central nervous system), dogs (leg fractures), sheep and other ruminant mammals (sudden death, skeletal deformities), pigs (poor growth, decreased hemoglobin and erythrocytes, skeletal deformities), mink (reduced survival), and camels (anemia, emaciation, falling, fractures, death).

Data are scarce or missing on copper deficiency effects in aquatic flora and fauna and in avian and terrestrial mammalian wildlife; additional studies of copper deficiency in these groups are merited. In sensitive terrestrial agricultural crops, copper deficiency occurs at less than 1.6 mg

dissolved Cu/kg DW soil and less than 5 mg total Cu/kg DW leaves. For domestic chickens, copper deficiency occurs when diets containing less than 2.7 mg Cu/kg ration are fed. Male weanling rats show deficiency effects when fed diets containing 0.13 mg Cu/kg ration vs. a copper-normal diet of 5.7 mg Cu/kg ration; earliest signs of copper deficiency in rats include low concentrations of copper in livers (less than 3.0 mg/kg DW vs. 12.6 to 15.0 mg/kg DW in controls), reductions in activities of cytochrome oxidase and succinoxidase, and prolonged sleeping times. Ewes of Bactrian camels fed copper-deficient diets of less than 2.5 mg Cu/kg DW ration (vs. normal diet of about 11.0 mg Cu/kg DW) produce a high frequency of swaybacked lambs. Copper deficiency in mink is produced at daily intake rates equivalent to 3.5 mg Cu/kg BW for 50 weeks. Swine require high intakes of copper to avoid deficiency; daily intakes of less than 36 mg Cu/kg BW are associated with reductions in growth rate, hemoglobin, and hematocrit.

Copper and its compounds are not carcinogenic, mutagenic, or teratogenic at environmentally realistic concentrations, but under controlled conditions of grossly elevated exposures some studies suggest that copper is a potential carcinogen in rodents; mutagen in rodents, sheep, and grasshoppers; and teratogen in fish and small laboratory animals. More research is needed in this area.

Bioavailability and toxicity of copper to aquatic organisms depends on the total concentration of copper and its speciation. Both availability and toxicity are significantly reduced by increased loadings of suspended solids and natural organic chelators and increased water hardness. Toxicity to aquatic life is related primarily to the dissolved cupric ion (Cu^{+2}) and possibly to some hydroxyl complexes. Cupric copper (Cu^{+2}) is the most readily available and toxic inorganic species of copper in fresh water, seawater, and sediment interstitial waters. Cupric ion accounts for about 1% of the total dissolved copper in seawater and less than 1% in fresh water. In fresh water, cupric copper and some copper hydroxyl species are correlated with high toxicity to aquatic life, although carbonato species are much less toxic than other copper complexes. More research seems needed on the adsorption characteristics of most cupric ion complexes. In solution, copper interacts with numerous inorganic and organic compounds resulting in altered bioavailability and toxicity. Acknowledgment of these interactions is essential to the understanding of copper toxicokinetics. In aquatic invertebrates, copper disrupts gill epithelium at high concentrations, and in fishes it interferes with osmoregulation; death is caused by tissue hypoxia associated with disrupted ATP synthesis. Copper detoxifying mechanisms in fishes include the induction of metallothioneins, allowing copper retention for weeks or months after absorption without toxicity. In higher vertebrates, excess copper is cytotoxic and alters protein configuration and lipid peroxidation rates. Mechanisms implicated in copper poisoning of mammals include free radical production, alteration in activities of several enzymes, and inhibited metallothionein synthesis. In mammals, copper is normally excreted via the bile in association with glutathione or unidentified high-molecular-weight proteins.

Excess copper is toxic to representative species of plants and animals. Significant adverse effects in terrestrial plants occur at concentrations as low as 40 μg Cu/L of nutrient solution, more than 10 mg Cu/kg DW in leaves, and greater than 60 mg extractable Cu/kg DW of soil. Sensitive species of terrestrial invertebrates show a reduction in growth, survival or reproduction at more than 50 mg Cu/kg diet or 53 to 70 mg Cu/kg DW of soil. Many species of freshwater plants and animals die within 96 h at waterborne copper concentrations of 5.0 to 9.8 μg Cu/L, and sensitive species of freshwater molluscs, crustaceans, and fishes die at 0.23 to 0.91 μg Cu/L within 96 h. The most sensitive tested species of marine molluscs, crustaceans, and fishes have an LC50 (96 h) range from 28 to 39 μg Cu/L; significant sublethal effects to representative species of estuarine algae, molluscs, and arthropods frequently occur at 1 to 10 μg Cu/L. Mammals and birds are at least 100 times more resistant to copper than other organisms, but ruminant mammals are significantly more sensitive to copper than nonruminant animals and poultry. Excessive dietary intakes of copper by 20- to 50-fold over normal levels may, however, have serious adverse effects on birds and mammals. No data are available on copper toxicity to avian wildlife. Studies with poultry demonstrate that copper accumulates in livers at dietary concentrations as low as 15 mg Cu/kg DW ration, inhibits growth at 120 mg Cu/kg DW ration, and causes gizzard histopathology at 250 mg Cu/kg DW ration.

Copper is lethal to representative species of mammals through a variety of routes: single oral doses of 6 to 637 mg Cu/kg BW in humans and 200 mg/kg BW in cattle or diets with more than 80 mg Cu/kg ration (about 5.1 to 10.7 mg Cu/kg BW daily) fed to sheep or more than 238 mg/kg ration (more than 133 mg/kg BW daily) fed to rats. Adverse sublethal effects of copper to sensitive mammals occur:

- In human infants at drinking water concentrations greater than 3 mg/L
- In cattle at more than 4.2 mg/kg BW by way of drinking water or more than 20 mg/kg BW via diet
- In sheep given daily oral doses of 7.5 to 15.0 mg/kg BW or fed diets containing more than 37.3 mg/kg ration
- In rats given more than 7.9 mg/kg BW daily by way of diet (equivalent to more than 100 mg Cu/kg DW ration)
- In pigs at more than 14.5 mg/kg BW daily via diet.

Numerous and disparate copper criteria are proposed for protecting the health of agricultural crops, aquatic life, terrestrial invertebrates, poultry, laboratory white rats, and humans ([Table 3.8](#)); however, no copper criteria are now available for protection of avian and mammalian wildlife, and this needs to be rectified. Several of the proposed criteria do not adequately protect sensitive species of plants and animals and need to be reexamined. Other research areas that merit additional effort include biomarkers of early copper stress; copper interactions with interrelated trace elements in cases of deficiency and excess; copper status effects on disease resistance, cancer, mutagenicity, and birth defects; mechanisms of copper tolerance or acclimatization; and chemical speciation of copper, including measurement of flux rates of ionic copper from metallic copper.

CHAPTER 4

Lead

4.1 INTRODUCTION

Lead (Pb) has been known for centuries to be a cumulative metabolic poison; however, acute exposure is lessening. Of greater concern is the possibility that continuous exposure to low concentrations of the metal as a consequence of widespread environmental contamination may result in adverse health effects (Nriagu 1978b). Environmental pollution from lead is now so high that body burdens in the general human population are closer than the burdens of any other toxic chemical to those that produce clinical poisoning (Hejtmancik et al. 1982). Further, lead is a mutagen and teratogen when absorbed in excessive amounts, has carcinogenic or cocarcinogenic properties, impairs reproduction and liver and thyroid functions, and interferes with resistance to infectious diseases (U.S. Environmental Protection Agency [USEPA] 1979). In the United States, about 9% of the children aged 1 to 5 years have blood lead levels $>100 \mu\text{g/L}$, high enough to produce adverse health effects (Ronis et al. 1998c). Among non-Hispanic black children in this age group, about 21% had blood lead levels $>100 \mu\text{g/L}$ and 4.2% had $>200 \mu\text{g/L}$. In some undeveloped Asiatic and eastern European countries blood lead concentrations $>1000 \mu\text{g/L}$ occur in children living near lead smelters (Ronis et al. 1998c).

Ecological and toxicological aspects of lead and its compounds in the environment have been extensively reviewed (Wetmore 1919; Bellrose 1959; Aronson 1971; Barth et al. 1973; National Research Council of Canada [NRCC] 1973; Holl and Hampp 1975; Boggess 1977; Rolfe and Reinbold 1977; Forbes and Sanderson 1978; Nriagu 1978a, 1978b; USEPA 1979, 1980, 1985; Levander 1979; Tsuchiya 1979; Branica and Konrad 1980; Jenkins 1980; National Academy of Sciences [NAS] 1980; Eisler 1981, 1988; Harrison and Laxen 1981; Demayo et al. 1982; Mudge 1983; De Michele 1984; Feierabend and Myers 1984; Walsh and Tilson 1984; Lumeij 1984; Feierabend and Russell 1986; U.S. Fish and Wildlife Service [USFWS] 1986a; Kania and Nash 1986; Lansdown and Yule 1986; McDonald 1986; Sanderson and Bellrose 1986; Pain 1987; Albert and Badillo 1991; U.S. Public Health Service [USPHS] 1993; Blus 1994). There is agreement by all authorities on five points. First, lead is ubiquitous and is a characteristic trace constituent in rocks, soils, water, plants, animals, and air. Second, more than 4 million metric tons of lead are produced worldwide each year, mostly for the manufacture of storage batteries, gasoline additives, pigments, alloys, and ammunition. The widespread broadcasting of lead through anthropogenic activities, especially during the past 40 years, has resulted in an increase in lead residues throughout the environment — an increase that has dislocated the equilibrium of the biogeochemical cycle of lead. Third, lead is neither essential nor beneficial to living organisms; all existing data show that its metabolic effects are adverse. Fourth, lead is toxic in most of its chemical forms and can be incorporated into the body by inhalation, ingestion, dermal absorption, and placental transfer to the fetus. Fifth, lead is an accumulative metabolic poison that affects behavior, as well as the

hematopoietic, vascular, nervous, renal, and reproductive systems. In humans, lead causes stillbirths, miscarriages, inhibited development of fetuses, decreased male fertility, and abnormal sperm. Severe damage to the central nervous system from exposure to large amounts of lead may result in stupor, convulsions, coma, and death. Children who survive lead poisoning are often permanently retarded or have permanent neurological handicaps. At subclinical injury levels, lead causes slight, but irreversible, damage to brain development in growing children.

Natural resources are also affected by environmental lead contamination, and some wildlife species numbers may be reduced as a result. For example, waterfowl deaths resulting from the ingestion of spent lead shot pellets from shotgun shells were discovered more than 100 years ago in Italy and in the United States; since then, lead poisoning of waterfowl has occurred in 20 countries (Pain et al. 1995). In North America alone, approximately 3000 tons of lead shot are expended annually into lakes, marshes, and estuaries by several million waterfowl hunters (USFWS 1986, 1987). Spent pellets are eaten by waterfowl and other birds, because they mistake them for seeds or for pieces of grit. These pellets may be retained in the gizzard for weeks, where they are reduced chemically and mechanically, form soluble toxic salts, and cause characteristic signs of lead intoxication — especially lethargy and emaciation (Street 1983). At least 2% of all North American waterfowl — or about 2 million ducks and geese (Lumeij 1985) — die each year as a direct result of ingesting lead shot (Bellrose 1951). These deaths contribute to the decline of some species, such as the canvasback, *Aythya valisineria* (Dieter 1979), pintail, *Anas acuta* (White and Stendell 1977), northern pintail, *Anas acuta* (Mateo et al. 1997b), black duck, *Anas rubripes* (Pain and Rattner 1988), common pochard, *Aythya ferina* (Mateo et al. 1997b), spectacled eiders, *Somateria fischeri* (Flint et al. 1997), graylag goose, *Anser anser* (Mateo et al. 1998), and mute swan, *Cygnus olor* (O'Halloran et al. 1988; Blus 1994). Up to seven times more waterfowl died from lead toxicosis as a result of ingesting spent pellets than from wounding by hunters (Zwank et al. 1985). In addition, lead-poisoned waterfowl show delayed mortality from lead-induced starvation, are readily captured by predators, are susceptible to disease, and reproduce poorly (Dieter 1979). Susceptibility is markedly influenced by species, by the number and size of shot ingested, and by the types of foods eaten (White and Stendell 1977). Swans are among the more vulnerable waterfowl. In England, lead poisoning through the ingestion of discarded lead fishing sinkers was the major cause of death in the mute swan (Birkhead 1983). For all species of swans in England, about half died as a direct result of lead poisoning (Demayo et al. 1982). In Washington State, 30% of the endangered trumpeter swans (*Cygnus buccinator*) found dead had died of lead poisoning from ingestion of lead shot (Kendall and Driver 1982; Blus 1994; Lagerquist et al. 1994). Fatal lead poisoning of swans through ingestion of shotgun pellets, fishing sinkers, and lead-contaminated sediments is reported in several geographic locations (Koh and Harper 1988; Sears 1988; Spray and Milne 1988; Blus et al. 1989, 1991; Degernes 1991; Lesher 1991; Beyer et al. 1998a). Lead toxicosis from ingested fishing sinkers was the most common cause of death in adult breeding loons (*Gavia immer*) in New England, and may be an important factor limiting loon populations (Pokras and Chafel 1992).

Lead poisoning mortality has occurred in over 30 species of birds other than waterfowl (Pain et al. 1997). Lead toxicosis caused by ingestion of spent shot and other lead objects was reported for the whooping crane, *Grus americana* (Snyder et al. 1992), sandhill crane, *Grus canadensis* (Windingstad et al. 1984), mourning dove, *Zenaidura macroura* (Locke and Bagley 1967), and wild turkey, *Meleagris gallopavo* (Stone and Butkas 1978). Secondary poisoning has been documented in at least six species of raptors that ate food containing lead shot (especially hunter-wounded animals): golden eagle, *Aquila chrysaetos* (Bezzel and Funfstuck 1995), Andean condor, *Vultur gryphus* (Locke et al. 1969), bald eagle, *Haliaeetus leucocephalus* (Pattee and Hennes 1983), honey buzzard, *Pernis apivorus* (Lumeij et al. 1985); king vulture, *Sarcorhampus papa* (Decker et al. 1979), and California condor *Gymnogyps californianus* (Janssen et al. 1986).

The availability of lead-based paints, discarded oil filters, used crankcase oil, lead storage batteries, or pastures contaminated by industrial lead operations make lead one of the most common

causes of accidental poisoning in domestic animals (Demayo et al. 1982). Cattle and horses in the vicinity of a lead smelter in California developed signs of lead poisoning, and many died between 1880, when the smelter opened, and 1971, when the smelter closed (Burrows 1981). Of the mules used in the early mining of lead, all died during their first year of service (Burrows 1981). Lead toxicosis has been reported in buffalos and cattle in India after they ate green fodder near a factory that recycled lead from old batteries (Kwatra et al. 1986). Total milk yield declined sharply, and stillbirths and abortions increased significantly in cattle that ingested lead-contaminated hay; the field from which the hay had been cut had a history as a site for clay pigeon shoots and contained an estimated 3.6 tons of lead shot pellets (Frape and Pringle 1984). In sheep grazing in areas near lead mines, the frequency of abortions was high, and the learning behavior of the lambs was impaired (Demayo et al. 1982). Many species of zoo animals, including monkeys, fruit-eating bats, and parrots, have been fatally poisoned from ingestion of flaking lead-based paint on the walls and bars of their cages (NRC 1973). Ingestion of lead-based paint chips was one cause of epizootic mortality of fledgling Laysan albatross, *Diomedea immutabilis*, at Midway Atoll in 1983 (Sileo and Fefer 1987). At present, there is no known dietary requirement for lead in domestic animals, nor has it been shown unequivocally that lead plays any beneficial role (NRCC 1973). On the contrary, lead demonstrably and adversely affects weight, survival, behavior, litter size, and skeletal development (Tsuchiya 1979), and induces teratogenic and carcinogenic responses in some species of experimental animals (NRCC 1973; USEPA 1980).

Lead is not essential for plants, and excessive amounts can cause growth inhibition, as well as reduced photosynthesis, mitosis, and water absorption (Demayo et al. 1982). The decline of some European spruce forests has been attributed to excessive concentrations of lead in the atmosphere (Backhaus and Backhaus 1986). Lead is toxic to all phyla of aquatic biota, though effects are modified significantly by various biological and abiotic variables (Wong et al. 1978). Wastes from lead mining activities have severely reduced or eliminated populations of fish and aquatic invertebrates, either directly through lethal toxicity or indirectly through toxicity to prey species (Demayo et al. 1982). Health advisories warning anglers against eating lead-contaminated fish have been posted in Missouri (Schmitt and Finger 1987). The significant increases in lead concentration shown by marine corals between 1954 and 1980 were representative of the increases noted in other biota as a direct result of increased global lead availability during that period (Dodge and Gilbert 1984).

4.2 SOURCES AND USES

Lead is a comparatively rare metal, with an average abundance in the earth's crust of 16 mg/kg (EPA 1980); it is also a major constituent of more than 200 identified minerals, of which only three are sufficiently abundant to form mineral deposits (USEPA 1980): galena (PbS), angleside ($PbSO_4$), and cerusite ($PbCO_3$). Galena, the primary form of lead in the natural state, is often associated with sphalerite (ZnS), pyrite (FeS_2), chalcopyrite ($CuFeS_2$), and other sulfur salts (May and McKinney 1981). Most (88%) of the domestic primary lead production originates from stratabound deposits in southeastern Missouri, another 8% from Idaho's Coeur d'Alene district, and the rest from deposits in Colorado and Utah. Primary lead is smelted and refined at plants in Texas, Montana, Nebraska, Missouri, and Idaho. Scrap or secondary lead accounted for about half the domestic consumption in 1978; by 1980, more lead was produced from secondary sources than from domestic ores (May and McKinney 1981). In 1989, nine mines in southeastern Missouri produced 89% of the total domestic output of lead ores and concentrates; other mines in Idaho, Alaska, and Montana contributed 10.4% of the domestic output; the remainder was a by-product from the mining of other commodities in Arizona, California, Colorado, Idaho, Illinois, Nevada, New Mexico, Tennessee, and Utah (USPHS 1993).

About 4 million tons of lead are refined annually worldwide (Table 4.1). Domestic lead consumption is 1.3 million tons annually, of which about half is used in storage battery manufacture

Modified from Harrison, R.M. and D.P.H. Laxen. 1981. *Lead Pollution. Causes and Control.* Chapman and Hall, NY. 168 pp.; Demayo, A., M.C. Taylor, K.W. Taylor, and P.V. Hodson. 1982. Toxic effects of lead and lead compounds on human health, aquatic life, wildlife plants, and livestock. *CRC Crit. Rev. Environ. Control* 12:257-305.

and, until recently, about 20% in the manufacture of gasoline antiknock additives such as tetramethyllead (TML) and tetraethyllead (TEL) (Table 4.2). Domestic use in 1990 was 1.28 million tons, most of which was used in the manufacture of lead-acid storage batteries (80%), as well as ammunition and metal alloys (12.4%), and the rest in ceramics, ballast, oxides, and gasoline additives (USPHS 1993). New uses of lead that seem environmentally innocuous include protection shielding against radiation exposure in computers, televisions, and certain medical instruments; in lead alloy solders; in super conductors; to manufacture certain ceramics and precision glass products; and in energy generation (USPHS 1993). Lead enters the atmosphere mainly through smelter emissions, primarily as PbSO₄ and PbO-PbSO₄, and through vehicle emissions, which include unburned lead, TEL, TML, and various lead halides, sulfates, phosphates, and oxides (Harrison and Laxen 1981). The primary method of lead disposal is recycling, estimated at 50,000 tons annually in the United States (USPHS 1993). Domestically, 70 to 75% of the consumed lead is considered to be recyclable, mostly from lead-acid storage batteries. Municipal and hazardous waste landfills receive about 25,000 tons of lead wastes annually, usually from ammunition and ordnance (USPHS 1993).

Lead and its compounds have been known to humans for about 7000 years, and lead poisoning has occurred for at least 2500 years (Barth et al. 1973). In Egypt, between 5000 and 7000 BCE, lead was used for glazing pottery, solder, ornaments, net sinkers, anchors, caulking, coins, weights, aqueducts, piping, and cooking utensils (Nriagu 1978a). The biocidal properties of lead were familiar to the ancient Egyptians, and they sometimes used lead salts for homicidal purposes (De Michele 1984). Lead encephalopathy (inflammation of the brain) has been recognized since 400 BCE among workers in the lead trades; initial symptoms are dullness, irritability, ataxia, headaches, memory loss, and restlessness. These symptoms often progressed to delirium, mania, coma, convulsions, and sometimes death. The same general effects were described in young children and infants, among which mortality was sometimes 40% (USEPA 1980). Extensive use of lead by

the Romans, circa 500, in pipes for water transport, in cosmetics, and as a wine sweetener (Harrison and Laxen 1981), is estimated to have increased environmental lead levels to about five times the existing background levels (Eisenreich et al. 1986). The decline of the Roman Empire may have been hastened by endemic lead poisoning — a theory supported by residue data showing high lead concentrations in bones and remains of Roman aristocrats (Nriagu 1978a) — perhaps through ingestion of excessive amounts of wine laced with lead (De Michele 1984). After the fall of the Romans, the use of lead declined sharply. In the 14th century, gunpowder was introduced into Europe and was the impetus for the development of a weapon that fired a malleable metal pellet: a lead shot (USEPA 1979). Otherwise, the metal's resistance to corrosion led to its use as lead sheets applied as roofing for cathedrals and as protective encasement of underground pillars.

In 1721, the first lead mine was established in the New World by English settlers at Falling Creek, Virginia, primarily to supply bullets and shot (USEPA 1979). By 1750, European and British lead smelting operations were flourishing (Nriagu 1978a). In 1763, lead deposits in southeastern Missouri were permanently opened (USEPA 1979). The 18th century's Industrial Revolution produced an estimated tenfold increase in existing lead background levels (Eisenreich et al. 1986). In the late 1700s, symptoms of acute lead poisoning recorded among industrial workers were called "Mill Reek" or "Devonshire Colic" (NRCC 1973). Lead poisoning in Mexico was documented in 1878 among users of lead salts for glazing ceramics, a practice that persists today (Albert and Badillo 1991). Lead poisoning was frequently recorded among U.S. lead miners in 1870 through 1900, especially in Utah, Colorado, and New Mexico. By 1880, the United States had surpassed Germany and Spain in the mining and refining of lead, and has continued as the leader in the output of refined lead (USEPA 1979). Air pollution from combustion of leaded gasoline containing TEL rose in the 1920s (NRCC 1973). In the mid-1940s, atmospheric lead concentrations increased sharply due to massive increases in lead emissions from automobiles. Since then, increased lead emissions to the atmosphere have matched trends in gasoline lead content and consumption (Eisenreich et al. 1986; Smith et al. 1987). In 1957, the United States was overtaken by Australia and the U.S.S.R. in domestic mine production of lead; however, in 1967, the opening of the "New Lead Belt" in Missouri revived mining in the United States, and subsequently lead was produced at the annual rate of 450,000 to 550,000 metric tons (USEPA 1979). In 1975, the United States was again the leading lead producer from mine sources, accounting for 16% of the world total; at that time, about 70% of the world lead production came from the U.S., the U.S.S.R., Australia, Canada, Peru, Mexico, China, Yugoslavia, and Bulgaria (Tsuchiya 1979.). In 1986, world mine production of lead was 2,352,000 tons, of which U.S. mine production was 353,000 tons, or 15% of the world total, and production in Missouri was 308,000 tons, or 87% of the U.S. total (personal communication, R. L. Amistadi, Doe Run Company, St. Louis, Missouri). In 1987, the leading lead producers of

the world produced 2,110,000 metric tons: the U.S.S.R. produced 24% of the total, Australia 23%, Canada 20%, the U.S. 15%, Mexico 9%, and Peru 9% (Albert and Badillo 1991).

Human exposure to lead sources is highly variable. In Mexico, for example, lead exposure is comparatively elevated in workers who manufacture or use lead-glazed pottery, urban populations exposed to high air lead concentrations due to the continued use of lead fuel additives, workers in industries that manufacture ballast and pigments, consumers who routinely eat canned foods such as hot peppers (2.4 mg Pb/kg) and fruit products (2.1 mg Pb/kg), and for the general population living in the vicinity of smelters, refineries, and other industries that emit lead (Albert and Badillo 1991). In the United States, consumption of leaded gasoline in automobiles was completely phased out in 1980; however, leaded gasoline is still available at airport pumps for propelled aircraft and this, as well as leaky underground fuel storage tanks, comprise potential sources of human exposure (Mulroy and Ou 1998).

4.3 CHEMICAL PROPERTIES

Elemental lead is a bluish-gray, soft metal of atomic weight 207.19 and atomic number 82; it melts at 327.5°C, boils at 1749°C, and has a density of 11.34 g/cm³ at 25°C. Metallic lead is sparingly soluble in hard, basic waters to 30 µg/L, and up to 500 µg/L in soft, acidic waters. Lead has four stable isotopes: Pb-204 (1.5%), Pb-206 (23.6%), Pb-207 (22.6%), and Pb-208 (52.3%). Of its 24 radioactive isotopes, two (Pb-210, Tb 1/2 of 22 years; Pb-212, Tb 1/2 of 10 hours) have been used in tracer experiments. Lead occurs in four valence states: elemental (Pb⁰), monovalent (Pb⁺), divalent (Pb⁺²), and tetravalent (Pb⁺⁴); all forms are environmentally important, except possibly Pb⁺. In nature, lead occurs mainly as Pb⁺²; it is oxidized to Pb⁺⁴ only under strong oxidizing conditions, and few simple compounds of Pb⁺⁴ other than PbO₂ are stable. Some lead salts are comparatively soluble in water (lead acetate, 443 g/L; lead nitrate, 565 g/L; lead chloride, 9.9 g/L), whereas others are only sparingly soluble (lead sulfate, 42.5 mg/L; lead oxide, 17 mg/L; lead sulfide, 0.86 mg/L); solubility is greatest at elevated temperatures in the range 0 to 40°C. Of the organoleads, tetraethyllead (TEL) and tetramethyllead (TML) are the most stable and the most important because of their widespread use as antiknock fuel additives. Both are clear, colorless, volatile liquids, highly soluble in many organic solvents; however, solubility in water is only 0.18 mg/L for TEL, and 18.0 mg/L for TML. Boiling points are 199°C for TEL and 110°C for TML. Both undergo photochemical degradation in the atmosphere to elemental lead and free organic radicals, although the fate of automotive organoleads has yet to be fully evaluated. Additional information on the general chemistry of lead and its compounds was reviewed by NRCC (1973), Boggess (1977), Nriagu (1978a), USEPA (1979, 1980), Tsuchiya (1979), Harrison and Laxen (1981), and Demayo et al. (1982).

Lead chemistry is complex. In water, for example, lead is most soluble and bioavailable under conditions of low pH, low organic content, low concentrations of suspended sediments, and low concentrations of the salts of calcium, iron, manganese, zinc, and cadmium. Accordingly, solubility of lead is low in water, except in areas of local point source discharges (Harrison and Laxen 1981; Scoullos 1986). Lead and its compounds tend to concentrate in the water surface microlayer (i.e., the upper 0.3 mm), especially when surface organic materials are present in thin films (Demayo et al. 1982). Organolead compounds are generally of anthropogenic origin and are found mostly in the aquatic environment as contaminants. However, some organolead complexes form naturally, and their rate of formation may be affected by man-made organoleads (Nriagu 1978a). In surface waters, lead exists in three forms: dissolved labile (e.g., Pb⁺², PbOH⁺, PbCO₃), dissolved bound (e.g., colloids or strong complexes), or as a particulate (Benes et al. 1985). The labile forms represent a significant part of the Pb input from washout of atmospheric deposits, whereas particulate and bound forms were common in urban runoff and ore-mining effluents (Benes et al. 1985). The solubility of lead compounds in water is pH dependent, and ranges from about 10 g Pb/L at pH 5.5, to less than 1 µg Pb/L at pH 9.0 (USEPA 1980); little detectable lead remains in solution at pH >8.0.

(Prause et al. 1985). At pH 6.5 and water alkalinity of 25 mg CaCO₃/L, elemental Pb⁺² is soluble to 330 µg/L; however, Pb⁺² under the same conditions is soluble to 1000 µg/L (Demayo et al. 1982). In acidic waters, the common forms of dissolved lead are salts of PbSO₄ and PbCl₄, ionic lead, cationic forms of lead hydroxide, and (to a lesser extent) the ordinary hydroxide Pb(OH)₂. In alkaline waters, common species include the anionic forms of lead carbonate and hydroxide, and the hydroxide species present in acidic waters (NRCC 1973). Unfortunately, the little direct information available about the speciation of lead in natural aqueous solutions has seriously limited our understanding of lead transport and removal mechanisms (Nriagu 1978a).

Most lead entering natural waters is precipitated to the sediment bed as carbonates or hydroxides (May and McKinney 1981). Lead is readily precipitated by many common anions; desorption and replacement by other cations is extremely slow (Boggess 1977). In some acidic lakes, the deposition of particulate lead correlated strongly with the deposition of aluminum and carbon, especially during periods of increasing pH (White and Driscoll 1985). Precipitation of sparingly soluble lead compounds is not a primary factor controlling the concentration of dissolved lead in stream waters. Migration and speciation of lead was strongly affected by water flow rate, with increasing flow rate resulting in increased concentrations of particulate and labile lead and a decrease in bound forms. At low stream flow, lead was rapidly removed from the water column by sedimentation (Benes et al. 1985).

In the sediments, lead is mobilized and released when the pH decreases suddenly or ionic composition changes (Demayo et al. 1982). However, there was no significant release of lead from dredge spoils suspended in estuarine waters of different salinities for 4 weeks (Prause et al. 1985). Some Pb⁺² in sediments may be transformed to tetraalkyllead compounds, including TML, through chemical and microbial processes. There is also the possibility of methylation of ionic lead *in vivo* by fish and other aquatic biota, but the mechanisms are unclear (May and McKinney 1981). Methylation of lead in sediments was positively related to increasing temperatures, reduced pH, and microbial activity, but seemed to be independent of lead concentration (Demayo et al. 1982). In general, the concentration of tetraalkylleads in sediments is low, representing less than 10% of total lead (Chau et al. 1980).

Degradation of tetraethyllead in soils not contaminated with gasoline is complete in 14 days (Mulroy and Ou 1998). In subsoils contaminated with lead gasoline, however, 4 to 17% of the applied TEL was still present after 77 days. The retardation of TEL degradation in leaded gasoline-contaminated soils is attributed to the presence of gasoline hydrocarbons. As long as gasoline hydrocarbons remain in the soil, TEL may also remain, most likely in the gasoline hydrocarbon phase (Mulroy and Ou 1998).

4.4 MODE OF ACTION

Lead modifies the function and structure of kidney, bone, the central nervous system, and the hematopoietic system and produces adverse biochemical, histopathological, neuropsychological, fetotoxic, teratogenic, and reproductive effects (Boggess 1977; Nriagu 1978b; De Michele 1984; Eisler 1988; Hsu et al. 1998). The mechanism underlying lead-induced growth suppression is thought to involve disruption of pituitary growth hormone during puberty (Ronis et al. 1998a). Inorganic lead absorbed into the mammalian body enters the bloodstream initially and attaches to the red blood cell. There is a further rapid distribution of the lead between blood extracellular fluid and other storage sites that is so rapid that only about half the freshly absorbed lead remains in the blood after a few minutes. The storage sites for lead are uncertain, although they are probably in soft tissues as well as bone; the half-time residence life (T_b 1/2) of inorganic lead is estimated to be 20 days in blood, 28 days in whole body, and 600 to 3000 days in bone (Harrison and Laxen 1981). Lead levels in bone exert an influence on plasma lead levels. There is concern that previously accumulated lead stores in bone may constitute an internal source of exposure, particularly during

periods of increased bone mineral loss, such as pregnancy or lactation (Hernandez-Avila 1998). Inorganic lead in the environment can be biologically methylated to produce alkyllead compounds (Walsh and Tilson 1984). Bile is an important route of excretion; ingested lead probably proceeds sequentially from gut, to blood, to bone and soft tissue, and by way of the bile to small intestine and fecal excretion (De Michele 1984).

Tetraalkyllead mode of action differs from that of inorganic lead. Although initial entry is still by way of the bloodstream, the lead is evenly distributed between blood plasma and the red blood cells. Tetraalkylleads are lost rapidly from the bloodstream, although some reappear in 5 to 10 hours associated exclusively with the red blood cells, probably as trialkyllead, though a fraction may be converted to inorganic lead. The organoleads concentrate in liver, and it is there that tetraalkyllead is probably converted to trialkyllead. Otherwise, the lead is widely dispersed throughout the body with $T_{1/2}$ values of 200 to 350 days (Harrison and Laxen 1981). Tetraethyllead, by virtue of its high solubility in lipids, is rapidly accumulated in non-bony tissues, particularly the brain, where the onset of signs of poisoning is rapid (Nriagu 1978b). Short-term repeated exposures of rats (*Rattus* spp.) to TEL results in a neurotoxic syndrome consisting of altered reactivity to noxious stimulation through disruption of forebrain-area function (Hong et al. 1983). In marine systems, unstable TEL is rapidly accumulated by marine organisms, probably through controlled diffusion processes. Once assimilated, this compound can be dealkylated into an ionized chemical species and react at the molecular level within the cells (Gnassia-Barelli and Romeo 1993). Several fish species metabolize tetraalkylleads to trialkyllead compounds by way of their mixed function oxidase system (Wong et al. 1981). The trialkyllead derivatives are considered responsible for the toxicity of the parent compound (Walsh and Tilson 1984). Trialkylleads and dialkylleads rapidly traverse biological membranes in bird eggs and accumulate in the yolk and developing embryo (Forsyth et al. 1985). At present, the organolead mode of action is poorly understood, but organolead compounds are known to inhibit amino acid transport, uncouple oxidative phosphorylation, and inhibit cerebral glucose metabolism (Hong et al. 1983).

Biochemically, lead exerts deleterious effects on hematopoiesis through derangement of hemoglobin synthesis, resulting in a shortened life span of circulating erythrocytes, often resulting in anemia. Two essential enzymes in heme formation that are extremely sensitive to lead are delta aminolevulinic acid dehydratase (ALAD), which catalyzes the dehydration of delta amino levulinic acid (ALA) to form porphobilinogen (PBG), and ferrochelatase (= heme synthetase), which catalyzes the insertion of Fe^{+2} into protoporphyrin IX (PP). This second reaction requires the presence of glutathione and ascorbic acid. Some of the intermediates in heme follow sequentially: ALA, PBG, uroporphyrinogen III, coproporphyrinogen III, protoporphyrinogen IX, and PP. It is now well established that ALAD and ferrochelatase are the most sensitive biochemical indicators of lead exposure, the net result being lowered ALAD activity and elevated PP activity (Barth et al. 1973; Nriagu 1978b; USEPA 1979, 1980; Tsuchiya 1979; Harrison and Laxen 1981; Hoffman et al. 1981; De Michele 1984; Schmitt et al. 1984, 1993; Lumeij 1985; Scheuhammer 1989; USPHS 1993). An increase in glutathione content observed in lead-exposed fish may be due to an increase in glutathione synthesis rather than to a decrease in use of the tripeptide or to its sequestration by lead (Thomas and Juedes 1992).

Inhibition of blood ALAD activity after exposure to lead has been documented in many species of freshwater and marine teleosts (Hodson 1976; Hodson et al. 1977, 1980; Johansson-Sjöbeck and Larsson 1979; Krajnovic-Ozretic and Ozretic 1980; Demayo et al. 1982; Schmitt et al. 1984, 1993; Haux et al. 1986), in the freshwater cladoceran, *Daphnia magna* (Berglind et al. 1985), in ducks, quail, doves, swallows, raptors, and songbirds (Finley et al. 1976.; Dieter and Finley 1978; Dieter 1979; Hoffman et al. 1981; Franson and Custer 1982; Kendall et al. 1982; Kendall and Scanlon 1982; Eastin et al. 1983; Franson et al. 1983; Hoffman et al. 1985a, 1985b; Beyer et al. 1988; Scheuhammer 1989), and in humans, sheep, mice, rats, rabbits, and calves (Barth et al. 1973; Boggess 1977; Nriagu 1978b; Tsuchiya 1979; Heitmancik et al. 1982; Hayashi 1983; Peter and Strunc 1983; Schlick et al. 1983; Gietzen and Wooley 1984; Zmudzki et al. 1984). Lead-induced ALAD inhibition has been recorded not only in blood, but also in brain, spleen, liver, kidney, and

bone marrow (Johansson-Sjöbeck and Larsson 1979; Hoffman et al. 1981, 1985a, 1985b; Schlick et al. 1983; Friend 1985). Time for ALAD recovery to normal levels is dose dependent, organ specific, and usually directly correlated with blood lead concentrations (Finley et al. 1976; Hodson et al. 1977; Dieter 1979; Hayashi 1983; Friend 1985). ALAD activity levels in lead-stressed teleosts were normal 3 to 11.7 weeks postadministration (Hodson et al. 1977; Johansson-Sjöbeck and Larsson 1979; Krajnovic-Ozretic and Ozretic 1980; Demayo et al. 1982); this range was 2 to 14 weeks in birds (Dieter and Finley 1978; Kendall et al. 1982; Kendall and Scanlon 1982; Friend 1985), and 3 to 12 weeks in mammals (Barth et al. 1973; Schlick et al. 1983). The physiological significance of depressed blood ALAD activity levels, except perhaps as an early indicator of lead exposure, is debatable. Aside from a few instances of moderate anemia in workers at lead smelters, other abnormalities noted were not regarded as serious (Barth et al. 1973 Lead-induced depression in ALAD activity in mallard (*Anas platyrhynchos*) ducklings and ring-necked pheasant (*Phasianus colchicus*) chicks was not associated with signs of overt toxicity (Eastin et al. 1983); a similar case is made for lead-stressed domestic chickens (*Gallus* sp.) showing 98% reduction in ALAD activity (Franson and Custer 1982), and for American kestrel (*Falco sparverius*) showing an 80% reduction (Franson et al. 1983). Birds may be more sensitive than mammals to lead-induced depressions in blood ALAD activity (Dieter et al. 1976). In ducks, for example, inhibition of ALAD would be more harmful than a comparable depression in mammals, for three reasons (Dieter et al. 1976). First, metabolic activity is greater in nucleated duck erythrocytes than in human erythrocytes. Second, ducks require porphyrin synthesis not only for hemoglobin production (as in humans), but also for production of respiratory heme-containing enzymes. Finally, the half-life of erythrocytes is shorter in ducks than in humans: 40 days vs. 120 days.

Elevated blood protoporphyrin IX activity resulting from lead inhibition of heme synthetase has been documented for humans and small mammals (Peter and Strunc 1983) and for many species of birds (Anders et al. 1982; Carlson and Nielsen 1985; Friend 1985; Franson et al. 1986; Beyer et al. 1988); recovery to normal levels occurs in a lead-free environment in 2 to 7 weeks. Franson et al. (1986) endorsed the blood protoporphyrin IX technique instead of ALAD as a means of measuring lead stress because of its comparative simplicity and lower cost.

Other chemical changes that have been observed as a result of lead exposure include:

- Increased serum creatinine and serum alanine aminotransferase in birds, suggestive of kidney and liver alterations (Hoffman et al. 1981)
- Changes in potassium, chloride, glucose metabolism (Haux and Larsson 1982) and calcium binding proteins (Behra 1993) in rainbow trout, *Oncorhynchus mykiss*
- A decrease in brain acetylcholinesterase activity in rats (Gietzen and Wooley 1984).

In kidney, lead tends to accumulate in the proximal convoluted tubule cells of the renal cortex, producing morphological changes such as interstitial fibrosis, edema, and acid-fast intranuclear inclusion bodies, as well as biochemical changes (Locke et al. 1966; Boggess 1977; Nriagu 1978b; USEPA 1980; De Michele 1984). Renal intranuclear inclusion bodies occurred in 83% of mallards experimentally poisoned by dietary lead acetate or lead shot (Beyer et al. 1988); similar results have been reported in other species of birds (Clemens et al. 1975; Anders et al. 1982) and in primates, cattle, and bats (Zook et al. 1972; Osweiler and Van Gelder 1978; Colle et al. 1980; Tachon et al. 1983).

In the cladoceran *Daphnia magna*, about 90% of the total body lead burden is adsorbed to the exoskeleton (Berglind et al. 1985). In animals with a vertebral column, total amounts of lead tend to increase with age. By far the most lead is bound to the skeleton, especially in areas of active bone formation (Barth et al. 1973; Tsuchiya 1979; USEPA 1980; Hejtmancik et al. 1982; Mykkonen et al. 1982; Peter and Strunc 1983; De Michele 1984; Eisler 1984; Berglind et al. 1985; Marcus 1985). The retention of lead stored in bone pools poses a number of difficulties for the usual multicompartmental loss-rate models. Some lead in bones of high medullary content, such as the

femur and sternum, have relatively long retention times, i.e., Tb 1/2 of >20 years in humans, whereas lead stored in bones of low medullary content have Tb 1/2 values of 20 to 200 days, similar to the values for lead in soft tissues and blood (Tsuchiya 1979; Marcus 1985). In birds, medullary bone undergoes sequences of bone formation and destruction associated with the storage and liberation of calcium during eggshell formation, indicating that sex and physiological condition primarily influence lead kinetics in avian bone (Finley and Dieter 1978). Marcus (1985) endorsed the use of diffusion models based on the exchange of lead between blood in canaliculi and the crystalline bone of the osteon to account for retention and bioavailability. More research is needed on the role of bone in lead kinetics.

Lead damages nerve cells and ganglia, and alters cell structure and enzyme function. Axonal degenerative changes, especially in neuronal cell bodies, were recorded in lead-poisoned freshwater snails (*Viviparous ater*), leading to altered protein synthesis (Fantin et al. 1985). Mallards dosed orally with lead shot developed demyelinating lesions in vagal, branchial, and sciatic nerves, and showed vascular damage in the cerebellum; lesions were similar to those in lead-intoxicated guinea pigs (*Cavia* sp.), rats, and guinea hens, *Gallus* sp. (Hunter and Wobeser 1980). Crop stasis in birds, which is characterized by paralysis of the alimentary tract, impaction of food in the gizzard and proventriculus, and regurgitation of crop fluid, has been produced by lead shot or lead acetate solutions. Lead induces crop dysfunction by acting either directly on the smooth muscle or on associated nerve plexuses of crop tissue, depending on the route of administration (Clemens et al. 1975; Boyer et al. 1985; Boyer and Di Stefano 1985). Mammals, including humans, undergo similar alimentary distress following intakes of lead (Boyer et al. 1985).

Effects of lead on the nervous system are both structural and functional, involving the cerebellum, spinal cord, and motor and sensory nerves; the result may be deterioration of intellectual, sensory, neuromuscular, and psychological functions (Nriagu 1978b). The pathogenesis of lead-induced injury to the nervous system is poorly understood, but may be mediated through vascular damage, the direct action of lead on neurons, or alterations in porphyrin metabolism (Hunter and Wobeser 1980). Retarded brain growth in prenatal guinea pigs has been recorded at subclinical levels of lead (i.e., at concentrations producing no elevation in blood lead and no change in body weight), and this effect is potentiated at temperatures of 42°C (Edwards and Beatson 1984). Lead may cause a transient disturbance in the blood-brain barrier during early postnatal growth of rats. This effect is associated with the presence of hemorrhagic lesions, suggesting focal damage to the vessels as an important event in the pathogenesis of lead encephalopathy to suckling rats (Sundstrom et al. 1985). Brain histopathology has been recorded in lead-poisoned chickens (Narbaitz et al. 1985) and cattle (Osweiler and Van Gelder 1978). Brain lead concentrations are usually among the lowest in body organs, but the brain is one of the main sites of action. During chronic lead poisoning, distribution of lead in the brain is positively related to both dose and duration of exposure; preferential accumulation is in the hippocampus area. Significant amounts of lead persisted in rat brain tissue up to 4 weeks after the withdrawal of lead treatment (Collins et al. 1982). The role of organolead compounds in hippocampal function is largely unknown (Czech and Hoium 1984).

Absorption and retention of lead from the gastrointestinal tract, the major pathway of intake, varies widely because of the age, sex, and diet of the organism. Diet is the major modifier of lead absorption and of toxic effects in many species of domestic and laboratory animals, waterfowl, and aquatic organisms. In fact, the lack of certain major minerals in the diet often affected toxicity and storage of lead in tissue more than did doubling the dosages of lead in the diet (Levander 1979). Dietary deficiencies in calcium, zinc, iron, Vitamin E, copper, thiamin, phosphorus, magnesium, fat, protein, minerals, and ascorbic acid increased lead absorption and its toxic effects (Longcore et al. 1974b; Forbes and Sanderson 1978; Levander 1979; Sleet and Soares 1979; Colle et al. 1980; USEPA 1980; Hodson et al. 1980; De Michele 1984; Stone and Fox 1984; Zmudzki et al. 1983, 1984; Carlson and Nielsen 1985; Gilmartin et al. 1985). Toxic effects of lead-stressed fauna also were exacerbated when animals were fed diets containing excess cadmium, lactose, ethylenediaminetetraacetic acid,

zinc, fat, protein, sodium citrate, ascorbate, amino acids, Vitamin D, copper, mercury, fiber content, and nitrilotriacetic acid (Clemens et al. 1975; Forbes and Sanderson 1978; Nriagu 1978b; Levander 1979; USEPA 1980; Krajnovic-Ozretic and Ozretic 1980; Burrows and Borchard 1982; Hamir et al. 1982; Zmudzki et al. 1983, 1984; De Michele 1984; Carlson and Nielson 1985). Protection against various toxic effects of ingested lead was provided by measured dietary supplements of calcium, iron, zinc, ascorbic acid, Vitamin E, and thiamin (Krajnovic-Ozretic and Ozretic 1980; Gilmartin et al. 1985; Ghazaly 1991). Many other conditions affect lead absorption, including size of lead particle (USEPA 1980; Hamir et al. 1982), type of lead compound ingested (USEPA 1980), presence of other compounds that act synergistically (Barth et al. 1973) or antagonistically (Luoma and Bryan 1978), and dosage (Finley and Dieter 1978). For example, smaller lead particles, <180 µm in diameter, were absorbed from the intestinal tract up to seven times more rapidly than larger particles of 180 to 250 µm (USEPA 1980). However, when large pieces of lead are ingested, such as lead shot, they may lodge in the gastrointestinal tract, dissolve slowly, and cause lead poisoning (Nriagu 1978b). Also, lead phthalates were absorbed more rapidly than carbonates, acetates, sulfides, and naphthanates, in that order (USEPA 1980). It is evident that all of these variables, as well as diet, need to be considered in risk assessment of lead.

4.5 CONCENTRATIONS IN FIELD COLLECTIONS

4.5.1 General

Lead concentrations were usually highest in ecosystems nearest lead mining, smelting, and refining activities; lead storage battery recycling plants; areas of high vehicular traffic; urban and industrialized areas; sewage and spoil disposal areas; dredging sites; and areas of heavy hunting pressure. In general, lead does not biomagnify in food chains. Older organisms usually contain the greatest body burdens, and lead accumulations are greatest in bony tissues. It seems that resources that are now at high risk (i.e., increased mortality, reduced growth, or impaired reproduction) from lead include the following:

- Migratory waterfowl that congregate at heavily-hunted areas
- Raptors that eat hunter-wounded game
- Domestic livestock near smelters, refineries, and recycling plants
- Wildlife that forage extensively near heavily traveled roads
- Aquatic life in proximity to mining activities, lead arsenate pesticides, metal finishing industries, lead alkyl production, and lead aerosol fallout
- Crops and invertebrates growing or living in lead-contaminated soils.

Data on background concentrations in nonbiological and living resources are cited extensively in Bernhard and Zattera (1975), Nriagu (1978a, 1978b), Wong et al. (1978), Branica and Konrad (1980), Jenkins (1980), Eisler (1981, 1988), Harrison and Laxen (1981), and Demayo et al. (1982).

4.5.2 Nonbiological Samples

Average lead concentrations in nonbiological materials worldwide were much higher in sediments (47,000 µg/kg), soils (16,000), and sediment interstitial waters (36) than in atmospheric and other hydrospheric compartments ([Table 4.3](#)). Most of the lead discharged into surface waters is rapidly incorporated into suspended and bottom sediments, and most will ultimately be found in marine sediments (Harrison and Laxen 1981). Sediments now constitute the largest global reservoir of lead; sediment interstitial waters and soils constitute secondary reservoirs ([Table 4.3](#)).

Table 4.3 Amounts of Lead in Global Reservoirs

Reservoir	Concentration ($\mu\text{g/kg}$)	Total Lead in Pool (millions of metric tons)
Atmosphere	0.0035	0.018

Modified from Nriagu, J.O. (ed.). 1978a. *The Biogeochemistry of Lead in the Environment. Part A. Ecological Cycles*. Elsevier/North Holland Biomedical Press, Amsterdam. 422 pp.

Lead concentrations were elevated in certain nonbiological materials as a result of nonhunting human activities and natural processes (Table 4.4). In sediments, lead concentrations ranged from 3 mg/kg in carbonate marls off the Florida coast to more than 11,000 mg/kg at Sorfjord, Norway, the site of massive discharges of lead-containing industrial and domestic wastes (Nriagu 1978a). Lead contaminates sediments from sources as diverse as steelworks, shipyards, crude oil refineries, cement and ceramic factories, lead storage battery recycling plants, and heavy traffic (Scoullos 1986). Mining activities are also important. High concentrations of lead were measured in sediments (up to 2200 mg/kg) and detritus (up to 7000 mg/kg) of the Big River in southeastern Missouri (Czarneski 1985). The Big River drains what was once the largest lead-mining district in the world; commercial mining was extensive between the early 1700s and 1972. During this period more than 200 metric tons of tailings accumulated within the Big River watershed as a result of seepage from tailings ponds, from erosion of tailings piles on the banks, and through accidental discharges (Niethammer et al. 1985).

In soils, lead concentrates in organic-rich surface horizons (NRCC 1973). In one instance, only 17 mg of soluble Pb/kg was found in soils 3 days after the addition of 2784 mg of lead (as lead nitrate)/kg (NRCC 1973). The estimated residence time of lead in soils is about 20 years; complete turnover in topsoil is expected every few decades (Nriagu 1978a). In forest litter, however, the mean residence time of lead is lengthy; estimates range from 220 years (Turner et al. 1985) to more than 500 years (Friedland and Johnson 1985).

Lead may leach from loamy soils of clay target shooting sites, where soils contain about 50,000 mg Pb/kg (about 40% Pb as particulate Pb shot in the most contaminated areas); leachates at 100 mm depth contained up to 3.4 mg Pb/L vs. little or no lead in leachates collected from soil containing background concentrations of lead (Rooney and McLaren 1999).

Lead deposited on roadways is removed in drainage water, and later accumulated in roadside soils (Harrison et al. 1985). Amounts of lead in roadside soils increase as a direct result of the combustion of gasoline containing organolead additives. In general, the amounts of lead were greatest along roads with the highest density of vehicular traffic, and amounts decreased rapidly with increasing distance from the roadway (Harrison and Dyer 1974; Boggess 1977; Chmiel and Harrison 1981; Way and Schroder 1982; Table 4.4). Elevated levels of lead in soils were also

recorded from the vicinity of storage battery reclamation plants, smelting activities, and mining and milling operations (Boggess 1977; Burrows 1981; Kisselberth et al. 1984). Fly ash from coal burned in homes or privately hauled from power plants, which contains 100 to 450 mg Pb/kg and is frequently used to reclaim land for the growth of forage and pasture crops and as an alkaline amendment in the reclamation of strip mined areas (Nriagu 1978a), is considered another source of soil lead. Two additional sources of lead in soils are municipal sewage sludge and lead-arsenate pesticides (Nriagu 1978a). Sewage sludge, which contains up to 100 mg Pb/kg and is applied as a fertilizer and soil conditioner at the rate of 50 million tons annually, may increase topsoil levels by as much as 25 mg Pb/kg. Lead arsenate, a pesticide used to reduce bird hazards near airport runways by controlling earthworm abundance, and also to control pests in fruit orchards, represents another local source of lead contamination to soils.

^b 1, USEPA 1980; 2, NRCC 1973; 3, Eisenreich et al. 1986; 4, Turner et al. 1985; 5, Burrows 1981; 6, Krishnayya and Bedi 1986; 7, Beyer et al. 1985; 8, Edwards and Clay 1977; 9, Demayo et al. 1982; 10, Friedland and Johnson 1985; 11, Fayed and Abd-El-Shafy 1985; 12, Haux et al. 1986; 13, Scoullos 1986; 14, Adams 1975; 15, Harrison and Laxen 1981; 16, Nriagu 1978a; 17, Di Giulio and Scanlon 1985; 18, Wiener et al. 1984; 19, Czarneski 1985.

Lead reaches the aquatic environment through industrial and municipal discharges, in atmospheric deposition, from weathering processes in areas of natural lead mineralization, and in highway runoff (USEPA 1980; Harrison and Laxen 1981; Birdsall et al. 1986). Industrial lead input to aquatic environments is estimated at 10 times that introduced by natural weathering processes (Scoullos 1986); sewage and aerosols are major sources (Harrison and Laxen 1981). Snowmobile exhausts are considered a major source of lead in some locations; concentrations up to 135 µg Pb/L have been recorded in surface waters at the time of ice breakup (Adams 1975). On the other hand, lead content in water (and sediments) of a fly ash settling pond at a coal-fired power plant did not increase as a result of plant operations (White et al. 1986). Isotopic lead ratios ($^{207}\text{Pb}/^{206}\text{Pb}$) and Pb/Ca atomic ratios can demonstrate anthropogenic perturbations of the lead cycle in present-day food webs. As judged by these ratios, lead in teeth of contemporary California sea otters (*Enhydra lutis*) from Alaska have increased by two- to 15-fold over their preindustrial counterparts that died about 2000 years ago. Lead in preindustrial otters derived from natural deposits, while lead in contemporary animals was primarily from Asia and western Canada and was dominated by lead aerosols or industrial waste lead deposits (Smith et al. 1990, 1992).

Anthropogenic activities leading to increased air lead levels include primary and secondary lead smelting, the burning of gasoline containing lead antiknock agents, coal combustion, storage battery manufacture, and pigment production (NRCC 1973). It is generally agreed that combustion of leaded gasoline is the primary source of atmospheric lead. Atmospheric lead is usually attached to aerosols <0.2 µm in diameter, is efficiently scavenged by precipitation, has a short atmospheric residence time that is usually measured in days but may range up to 14 weeks depending on meteorological conditions, and may be transported long distances (i.e., hundreds or thousands of kilometers) from emitting sources (NRCC 1973; Harrison and Laxen 1981; Harrison et al. 1985; Eisenreich et al. 1986). Along roadways, more than 90% of lead emissions are dispersed by the atmosphere away from the immediate vicinity of the road; air lead levels stabilize at low levels about 30 m from the road as a result of rapid settling of particles >5 µm in diameter, and from the downwind traverse of particles entrained in the turbulent atmosphere (Boggess 1977; Harrison et al. 1985). Since 1970, the lead content in gasoline has decreased; profiles of lead in dated sediment cores and lead in atmospheric aerosols suggest that the environment is responding to the decreasing

use of leaded gasoline, and that atmospheric lead concentrations and fluxes will continue to decrease substantially if the use of lead in gasoline is further decreased (Eisenreich et al. 1986). Atmospheric deposition of lead to the Great lakes in 1983 was conservatively estimated at 891 tons, with an upper limit of 1252 tons; these values are considerably lower than those from the early 1970s and may be due, in part, to the decrease in the lead content of gasoline (Gatz et al. 1989).

4.5.3 Fungi, Mosses, Lichens

Concentrations of lead were highest in specimens collected near metal smelters, lead mines, industrial areas, and urban locations ([Table 4.5](#)). Lead concentrations were 9 to 13 times greater in a lichen (*Parmelia baltimorensis*) collected in Washington, D.C., in 1970 than in the same lichen collected 34 years earlier (Jenkins 1980).

4.5.4 Terrestrial Plants

Elevated lead contents were recorded in various species of plants from the vicinity of metal smelters, roadsides, soils heavily contaminated with lead, natural ore deposits, and lead recycling factories ([Table 4.5](#)). Bioavailability of lead in soils to plants is limited but is enhanced by reduced soil pH, reduced content of organic matter and inorganic colloids, reduced iron oxide and phosphorus content, and increased amounts of lead in soils (NRCC 1973; Boggess 1977). Lead, when available, becomes associated with plants by way of active transport through roots and by absorption of lead that adheres to foliage (Boggess 1977). Lead concentrations were always higher in the older parts of plants than in shoots or flowers (Bunzl and Kracke 1984; [Table 4.5](#)).

Damage to plants with elevated lead contents is usually negligible but varies widely among species. Atmospheric lead may have contributed to the decline of European spruce forests. The mean lead content of needles and litter was significantly higher where tree decline was most pronounced than in areas where forests were unaffected (Backhaus and Backhaus 1986). Lead can have deleterious effects on plant growth processes at reported lead levels in urban areas and may similarly affect plants in rural areas in the future (Rolle and Reinbold 1977). A reduction in yield of corn or soybeans is expected in low-binding capacity soils with lead levels greater than 200 mg/kg (Rolle and Reinbold 1977). Hay grown near roadsides may be toxic to horses and cattle (Rolle and Reinbold 1977). In extreme cases, reforestation has been initiated in areas where forage is so heavily contaminated with lead that it has become necessary to slaughter domestic livestock because the amounts of lead in their livers and kidneys is unacceptably high (Edwards and Clay 1977). Typical area reforestation includes removal of contaminated forage by cutting, bailing, and burying native grasses; burning stubble and litter; and adding agricultural lime at the rate of 2244 kg/ha (2000 pounds/acre) to all soils within 1525 m (5000 feet) of sites where lead levels exceed 175 mg/kg (Edwards and Clay 1977).

4.5.5 Terrestrial Invertebrates

In earthworms, lead levels were highest in those closest to highways and in areas with high volumes of traffic (Goldsmith and Scanlon 1977; [Table 4.5](#)). Various species of insects and soil invertebrates from roadsides, from areas receiving sewage sludge, and from metal smelter environs also contain high amounts of lead ([Table 4.5](#)). Amounts of lead in whole body were higher in earthworms, millipedes, and woodlice collected from soil and plant litter near highways than away from highways; soil and litter seem to be major reservoirs of lead in roadside communities (Beyer and Moore 1980). In contrast, lead concentrations in the eastern tent caterpillar (*Malacosoma americanum*) were lower than those reported for roadside soil and litter invertebrates, and were about 76% of that in leaves of its host, the black cherry *Prunus serotina* (Beyer and Moore 1980).

The use of terrestrial invertebrates as sentinel organisms has been suggested for monitoring lead. The spider *Araneus umbricatus*, for example, contained lead body burdens that correlated with that in a lichen (*Lecanora conizaeoides*) that is used to monitor atmospheric lead (Clausen 1984). Similarly, the woodlouse (*Porcellio scaber*) seems to reflect lead concentrations in adjacent soil or leaf litter (Hopkin et al. 1986).

4.5.6 Aquatic Biota

Nationwide, there has been a significant decline in lead concentrations of whole freshwater fish from 1976/77 to 1984, continuing a decrease that became evident in 1978/79 (Schmitt and Brombaugh 1990). Nationwide monitoring of freshwater fishes conducted periodically by the U.S. Fish and Wildlife Service (National Biocontaminant Monitoring Program) showed that whole-body lead burdens were highest for Atlantic coast streams, the Great Lakes drainage, the Mississippi River system, the Columbia River system, and in certain Hawaiian streams (May and McKinney 1981).

- Major sources of lead in Atlantic coast streams included wastes from metal-finishing industries, brass manufacturing, lead alkyl production, primary and secondary lead smelting, coal combustion, and manufacture of lead oxide.
- For the Great Lakes, especially for the Lake St. Clair collection site, industrial sources and urban lead aerosol fallout from the Detroit area were major sources.
- In the Mississippi River system, naturally occurring deposits of lead ores and effluents from zinc producers and industrial dischargers were prevalent.
- The Columbia River system was characterized by lead inputs from natural geologic deposits, industrial effluents, and the mining and smelting of lead.
- Hawaiian streams received most of their lead from urban runoff, vehicle sources, and agricultural and residential use of lead arsenate (May and McKinney 1981).

Fish collected from 1979 to 1981 in the Big River, Missouri, near a ruptured tailings pond dam where lead concentrations in tailings approached 4000 mg/kg, contained greatly elevated whole-body lead burdens of 9 to 18 mg/kg fresh weight (Schmitt et al. 1984). Increased blood lead concentrations in longear sunfish (*Lepomis megalotis*) from this area were associated with decreased blood ALAD activity and altered mechanical and biochemical properties of bone (Dwyer et al. 1988). By comparison, the highest lead concentration recorded to date in the National Biocontaminant Monitoring Program is 6.7 mg/kg fresh weight in whole Mozambique tilapia (*Tilapia mosambica*) from Honolulu in 1979 (Lowe et al. 1985). Catostomids from contaminated portions of the Big River contained elevated blood lead levels, depressed blood ALAD activity levels, and lead concentrations in edible tissues exceeding 0.3 mg/kg fresh weight — a level considered hazardous to human health (Schmitt et al. 1984). The Missouri Department of Health later issued an advisory against eating catostomids caught in a 65-km section of the Big River (Czarneski 1985). Whitefish, *Coregonus* spp., from lead-contaminated Swedish lakes, showed depressed blood ALAD and blood chemistry derangement when compared to fish from a reference lake, suggesting that lead affects natural populations of fish in a manner similar to that observed in laboratory studies (Haux et al. 1986).

In general, freshwater algae, invertebrates, and fish had comparatively elevated lead concentrations when collected near industrialized areas, ponds with high numbers of lead shot, urban areas, lead mines, tailings ponds (Table 4.5), areas of historic mining activities (Schmitt et al. 1993), and near highways (Baekken 1994). For marine biota, lead residues were generally highest where lead concentrations were high in the water: near bridges, near industrial disposal areas, near sewage and disposal areas, near dredging sites, and at mining sites (Table 4.5). Lead concentrations in soft parts of American oysters (*Crassostrea virginica*) were higher in smaller oysters than in larger ones, much lower than the lead burden of the surrounding sediments, and strongly correlated with the

iron content of the geochemical environment (Jiann and Presley 1997). However, soft parts of larger bivalve molluscs from Greenland had higher lead burdens than did smaller bivalves (Dietz et al. 1996). Lead concentrations in tissues of Arctic char (*Salvelinus alpinus*) from Austria were positively correlated with increasing water temperature, increasing age, and decreasing water alkalinity. Enhanced lead accumulation during the summer was a consequence of increasing metabolic rate (Kock et al. 1995a, 1995b). The ability of parasitic acanthocephalans to accumulate high concentrations of lead may prove to be a useful indicator of lead contamination in the aquatic environment; however, the underlying mechanism of accumulation requires additional research (Sures et al. 1994).

Among aquatic biota, lead concentrations were usually highest in algae and benthic organisms, and lowest in upper trophic level predators. No significant biomagnification of lead occurs in aquatic food chains (Bogges 1977; Rolfe and Reinbold 1977; Branica and Konrad 1980; Demayo et al. 1982; Flegal 1985; Henny et al. 1991; Dietz et al. 1996; [Table 4.5](#)). Lead concentrations in cartilaginous and bony fishes (and also birds and mammals) were usually highest in areas of high human and vehicular density, and near lead mines and ore concentration plants. Lead concentrations in aquatic (and terrestrial) vertebrates tend to increase with increasing age of the organism, and to localize in hard tissues such as bone and teeth (Eisler 1981, 1984). In stream sediments, lead was highest in urban streams and lowest in the rural streams, reflecting lead inputs from storm runoff; species diversity was greater in the rural streams, due partly to lowered contaminant loadings, including lead (Rolfe and Reinbold 1977).

The significance of organolead residues in aquatic life is unknown and merits additional research. In Ontario, Canada, about 16% of all fish sampled contained tetraalkyllead compounds, although none were recorded in water, vegetation, or sediments from the collection sites (Chau et al. 1980). Tetramethyllead reportedly was produced from biological and chemical methylation of several inorganic and organic lead compounds in the aquatic environment, and has been detected at low concentrations in marine mussels, lobsters, and bony fishes (Wong et al. 1981).

4.5.7 Amphibians and Reptiles

Tadpoles of bullfrogs (*Rana catesbeiana*) and green frogs (*R. clamitans*) from drainages along highways with different daily average traffic volumes (4272 to 108,800 vehicles per day) contained elevated amounts of lead (up to 270 mg/kg dry weight), which were positively correlated with lead in sediments and with average daily traffic volume. Lead in tadpoles living near highways may contribute to the lead levels reported in wildlife that eat tadpoles. Diets with amounts of lead similar to those in tadpoles collected near heavily traveled highways have caused adverse physiological and reproductive effects in some species of birds and mammals (Birdsall et al. 1986). Elevated lead concentrations were also recorded in various species of amphibians and reptiles collected near lead smelters and mines ([Table 4.5](#)).

4.5.8 Birds

In general, lead concentrations were highest in birds from urban locations (perhaps reflecting greater exposure to automotive and industrial contamination) and in birds near lead mining and smelting facilities. Lead residues are also greatest in older birds (especially in bone, because of accumulation over time), in sexually mature females, and in waterfowl that have ingested lead shot pellets and other lead objects ([Table 4.5](#)). In eastern Canada, elevated lead concentrations in wing bones of ducks are attributed to waterfowl hunting, nonferrous metal mining and smelting, and urban and industrial development. Ingestion of spent lead shot pellets from waterfowl hunting is the primary source of elevated lead exposure for wild ducks in eastern Canada; however, proximity to metal mining sites, especially silver, gold, copper, and zinc mines was also important (Scheuhammer and Dickson 1996).

Continued deposition of lead shot by hunters into wetlands habitats exposes birds to lead. Lead shot is a substantial localized source of contamination, especially in prime waterfowl habitat (Bellrose 1951, 1959; NRCC 1973; White and Stendell 1977; Stendell et al. 1979; Wobeser 1981; Clausen et al. 1982; Longcore et al. 1982; Mudge 1983; Driver and Kendall 1984; Hall and Fisher 1985; Castrale 1989; Pain 1991; Best et al. 1992; Harper and Hindmarsh 1990; Kingsford et al. 1994; Wheeler 1995; Mateo et al. 1998). It is estimated that several million hunters deposit more than 6000 metric tons of lead shot annually into lakes, marshes, and estuaries. This represents about 6440 pellets per bird bagged. Shot densities as great as 330,000 to 860,000 pellets/ha (up to 2,124,000/acre) have been estimated in some locations (Wobeser 1981; Whitehead and Tschirner 1991; Best et al. 1992), and more than 2.6 million shot/ha were estimated for the Ebro Delta, Spain in 1992/93 (Mateo et al. 1997b), although concentrations of 34,000 to 140,000/ha are more common (Longcore et al. 1982; Driver and Kendall 1984). For example, lead shot in bottom sediments from Merrymeeting Bay, Maine, a prime waterfowl staging area, averaged 99,932 shot/ha (274,000/acre), and ranged from 59,541 to 140,324/ha; shot were significantly more numerous in silt than in sand sediments. In general, shot sink more rapidly in soft than in firm substrates, and there is only slight carryover of shot from one season to the next in areas with silt or peat bottoms (Wobeser 1981). In agricultural soils, normal tillage practices may reduce lead shot availability by as much as 73% (Castrale 1989). In some locations, however, lead exposure and lead poisoning in waterfowl will continue to occur despite the conversion to steel shot for waterfowl hunting (Rocke et al. 1997).

Waterfowl and other birds ingest spent shot during feeding and retain them as grit in the gizzard; the pellets are eroded and soluble lead is absorbed from the digestive tract. In many species, the ingestion of a single pellet is often fatal. Most deaths, however, go unnoticed and unrecorded. Species such as the mallard and pintail that feed in shallow water by sifting through bottom mud are more likely to encounter shot than are species that feed on submerged vegetation or at the surface (Wobeser 1981). Several techniques are used to determine the presence of ingested shot in gizzards of birds; these include fluoroscopy of intact gizzards, X-ray of gizzard contents (the most reliable), and microscopic visual examination (Pain and Eon 1993). Shot ingestion in waterfowl is higher where shot densities in sediments are high and grit is absent (Pain 1990), and higher during spring than in autumn for diving ducks (Havera et al. 1992). Incidence of ingested shot in five species of waterfowl harvested in Yucatan, Mexico, in 1986 to 1988 was 10.3% (Thompson et al. 1989). Ingested lead shot frequency was 8.1% in American black ducks (*Anas rubripes*) sampled in Maine during the hunting seasons of 1976 through 1980 (Longcore et al. 1982). Gizzards of black ducks from Prince Edward Island, Canada, examined between 1988 and 1991 had a 7.1% frequency of ingested shot (Daury et al. 1994), and those from Wallace Bay, Nova Scotia, in 1987 had a 13% frequency of ingested shot (Schwab and Daury 1989). In Dartmouth, Nova Scotia, in 1988, 96% of overwintering black ducks had elevated blood lead concentrations (>0.1 mg Pb/L), and 76% had detrimental concentrations in excess of 0.2 mg/L (Daury et al. 1993). In dry seasons, species that probe for food deep in the sediment are especially susceptible (Hall and Fisher 1985; Harper and Hindmarsh 1990). In England, ingested pellets occurred in 3.2% of the total waterfowl in 16 species examined. Incidences of shot were relatively high (7.1% to 11.8%) in four species (Mudge 1983): greylag goose (*Anser anser*), gadwall (*Anas strepera*), pochard (*Aythya ferina*), and tufted duck (*Aythya fuligula*). A very high incidence (>22 to 100%) of shot ingestion was recorded in the gizzards of various species of hunter-shot waterfowl in Japan (Ochiai et al. 1993a), the Netherlands, Greece, France, Spain, and Italy (Lumeij and Scholten 1989; Pain and Handrinos 1990; Mateo et al. 1998). At least 8000 mallards in Britain die each winter of lead toxicosis from ingestion of spent shot (Mudge 1983). It is estimated that about 2.4 million ducks die worldwide of lead shot poisoning each year, and this estimate does not include population losses resulting from the sublethal effects of lead (Wobeser 1981). Among larger species of waterfowl, outbreaks of lead poisoning have been documented in Canada geese (*Branta canadensis*), whistling swans (*Cygnus columbianus*), trumpeter swans, and mute swans (Eskildsen and Grandjean 1984). Lead-poisoned waterfowl tend to seek seclusion and often die in areas of heavy cover. These

carcasses are rapidly removed by predators and scavengers (Wheeler 1995) and may result in secondary lead poisoning, especially among raptors such as the bald eagle (Feierabend and Myers 1984; Reichel et al. 1984). Of 293 bald eagles found dead nationwide between 1978 and 1981, 17 (5.8%) probably died of lead poisoning after ingesting hunter-killed or hunter-crippled waterfowl containing lead pellets (Reichel et al. 1984). Unlike the emaciated state of birds with chronic lead poisoning, bald eagles acutely poisoned by lead may be in good body condition if high concentrations of lead are rapidly absorbed (Langelier et al. 1991; Gill and Langelier 1994).

Raptors are susceptible to lead poisoning wherever lead shot is used for hunting. As raptor populations are often small and reproduction rates low, their populations are particularly vulnerable to adult mortality (Pain and Amiard-Triquet 1993). Lead exposure, especially poisoning, was a major factor affecting the California condor population during 1982–86. The probable source of lead was bullet fragments in carrion on which condors were feeding (Wiemeyer et al. 1988). Of 162 golden eagles (*Aquila chrysaetos*) sampled in California in 1985/86, 5.6% had elevated blood lead concentrations (>0.6 mg Pb/kg), and 2.5% had >1.0 mg Pb/kg blood. Lead was probably ingested from feeding on deer carcasses and offal from hunter-killed deer (Pattee et al. 1990).

Elevated tissue lead concentrations in field collections of birds were associated with a variety of adverse effects. Lead concentrations in livers of the Canada goose (*Branta canadensis*) and goldeneye (*Bucephala clangula*) found dead near mining and smelting activities in northern Idaho ranged from 8 to 38 mg Pb/kg FW; these levels exceeded the lower lethal limit of 5 mg Pb/kg FW liver in experimental birds (Blus et al. 1995). At the Ebro Delta in Spain in 1991/92, as many as 27% of the mallards had tissue lead concentrations sufficiently elevated to qualify as clinically lead-poisoned: >1.5 mg Pb/kg FW liver, >3 mg Pb/kg FW kidney (Guitart et al. 1994). In Poland, livers of dead and sick nestlings of sparrows (*Passer spp.*) had >2 mg Pb/kg DW, and healthy birds <2 mg Pb/kg DW (Pinowski et al. 1993). Toxic lead concentrations (up to 70 mg/kg FW liver) in chicks of the Laysan albatross (*Diomedea immutabilis*) in Hawaii were associated with proximity to buildings and the presence of lead paint chips in the proventriculus (Work and Smith 1996). Elevated blood lead concentrations were associated with ingested shot in gizzards of diving ducks (Havera et al. 1992), black ducks (Daury et al. 1993), and Canada geese (De Stefano et al. 1991, 1992, 1995), and with reduced blood ALAD activity in mallards (Tirelli et al. 1996). Blood lead concentrations in Canada geese from the eastern prairie population in 1986 to 1988 were below levels of recent lead exposure in areas where lead shot had never been used. In areas where lead shot was still in use, as many as 10% of the geese had blood lead levels >0.18 mg/L. The use of steel shot is substantially reducing the effect of lead poisoning in this population and other populations of geese and ducks (De Stefano et al. 1991, 1995).

Lead poisoning through the ingestion of anglers' lead weights was the major cause of death in the mute swan (*Cygnus olor*) in England. Between 1983 and 1985, lead poisoning was most common in areas where the largest number of lead weights were found and accounted for at least 76% — and perhaps up to 94% — of the local swan deaths (Sears 1988, 1989). In Ireland, about 60% of all mute swans found dead from 1984 to 1986 died from lead poisoning; lead sources included spent gunshot from clay pigeon shooting sites in northern Ireland and lost or discarded anglers' weights elsewhere (O'Halloran et al. 1988). Ingestion of lead artifacts (shotgun pellets, fishing sinkers) accounted for about 20% of the known mortality of trumpeter swans (*Cygnus buccinator*) in Idaho, Wyoming, and Montana, where the population has been declining for several decades. In Washington, the incidence of lead-induced mortality was higher and accounted for nearly 50% of the known mortalities (Blus et al. 1989). In Minnesota, lead poisoning of trumpeter swans from ingestion of shot was responsible for 23% of the documented deaths in 1987, and 54% in 1988/89. The increased mortality was attributed to drought conditions that lowered water levels and allowed swans to reach previously inaccessible lake bottoms containing spent lead shot (Degernes 1991). The treatment protocol for lead-poisoned trumpeter swans (blood Pb >0.4 mg/L) included supportive therapy (rehydration fluids, force feeding, injection of vitamins, iron salts, and 5-fluorocystine),

chelation therapy (calcium EDTA), and lead removal from the gizzard using gastric lavage; treatment was successful in about 53% of the cases (Degernes et al. 1990).

Ingestion of spent shot was associated with mortality of black swans (*Cygnus atratus*) in South Australia (Koh and Harper 1988), and up to 47% of all whooper swans (*Cygnus cygnus*) in Scotland in 1980 to 1986 (Spray and Milne 1988). Sediment ingestion by swans and other waterfowl is sometimes the main route of exposure to lead (Beyer et al. 1997). Sediment — not shot or diet — was the primary source of lead ingested by tundra swans (*Cygnus columbianus*) from the Coeur d'Alene River Basin in Idaho, as judged by fecal analysis. Sediment ingestion by tundra swans is associated with ingestion of wild rice (Beyer et al. 1998a). Dead tundra swans found near a lead mining complex in Idaho were attributed to ingestion of sediments that contained up to 8700 mg Pb/kg and plants that contained up to 400 mg Pb/kg (Blus et al. 1991). Chelation therapy using sodium calcium edetate was successful in treating the clinical signs of lead poisoning (i.e., those with blood Pb concentrations >0.4 mg/L) in mute swans in 49% of the cases (Sears et al. 1989). Subcutaneous injections of 0.25 mL/kg BW of a 25% w/v solution of sodium calcium edetate were given 1 to 3 times daily for at least 7 days. About 22% of treated swans survived for at least 2 years. However, results indicate that lead-poisoned swans, despite treatment, have a 59% reduction in survival when compared with untreated swans living in flocks (Sears et al. 1989).

Lead concentrations in feathers reflected population increases or declines of common terns (*Sterna hirundo*) from Long Island, New York. Lead in feathers of adult common terns decreased significantly from 5.6 mg/kg DW in 1978 to 1.0 mg/kg DW in 1985, were stable until 1988, and then increased (to 3.0 mg/kg DW) through 1992 (Burger et al. 1994). Lead declines in feathers coincided with environmental decreases in lead from the phasing out of leaded gasoline in vehicles. Source of the increased lead from 1989 to 1994 is unclear, but may result from increased dredging in the New York area in the early 1990s or from increased amounts of lead paint removed from bridges during repainting operations in the late 1980s and early 1990s (Burger et al. 1994). There was a positive correlation between lead concentrations in maternal feathers of common terns and their eggs (Burger and Gochfeld 1991). Lead concentrations in feathers of pigeons (*Columba livia*) from the Czech Republic were unaffected by season of collection, sex, area of collection, or diet; however, concentrations were lowest in nestlings and increased with increasing age (Janiga et al. 1990).

The relation between embedded shot and lead toxicosis is unclear. The incidence of embedded shot in various species of waterfowl ranged from 11% to 43% in adults, and 2% to 11% in immatures (Perry and Artmann 1979; Perry and Geissler 1980). Many birds that were struck by shotgun pellets but survived may have died prematurely or been eaten by predators. In one study, the bodies of 23% of adult Atlantic brant (*Branta bernicla hrota*) that died from starvation in New Jersey in 1977 contained embedded lead shot (Kirby et al. 1983). The effects on survival and fecundity of receiving and carrying relatively high frequencies of embedded shot might be significant, and during years of low adult numbers might have substantial population consequences (Kirby et al. 1983).

Lead in seeds and invertebrates within rights-of-way of major highways probably is not a hazard to adult ground-foraging songbirds, as judged from experiments with the European starling (*Sturnus vulgaris*). However, the effects of lead on survival of fledglings are unknown, although lead causes reductions in blood hemoglobin, hematocrit, ALAD activity, and brain weight (Grue et al. 1986). In another study, lead concentrations in feather, carcass, and stomach contents of adult and nestling barn swallows (*Hirundo rustica*) were greater near a major U.S. highway than in a rural area; however, the number of eggs and nestlings, the body weight of nestlings at 17 days of age, and body weights of adults were similar in the two colonies, suggesting that contamination of roadsides with lead from automobile emissions is not a major hazard to birds that feed on flying invertebrates (Grue et al. 1984).

Signs of lead poisoning, i.e., depressed blood ALAD activity or elevated blood lead levels, were reported for birds near a metal smelter (Beyer et al. 1985; Henny et al. 1991), in 17% of canvasbacks (*Aythya valisineria*) from Chesapeake Bay in 1974 (Dieter et al. 1976), and in three species of

waders from the Dutch Wadden Sea living in an urban postnuptial molting area (Goede and de Voogt 1985). In some species and locales, such as mallards from California national wildlife refuges, males had significantly higher blood lead concentrations than did females (Mauser et al. 1990). Reduced body mass of 10% was documented in overwintering canvasbacks that had lead shot in their gizzards when compared to birds with no lead shot in gizzards (Hohman et al. 1990). The decline in submerged aquatic vegetation in Chesapeake Bay and the later shift in diet of some waterfowl species of Chesapeake Bay from the vegetation (lead content 2.2 to 18.9 mg/kg dry weight) to the softshell clam *Mya arenaria* (1.3 to 7.6 mg Pb/kg dry weight), or to other bivalve molluscs (0.8 to 20.4 mg Pb/kg dry weight), probably did not increase dietary lead burdens in these species (Di Giulio and Scanlon 1985).

The significance of trace amounts of organolead residues in birds is unknown. Trialkyllead seems to concentrate in avian kidney, but contributes less than 5% of the total amount of lead in kidneys (Johnson et al. 1982).

4.5.9 Mammals

The highest body burdens of lead reported in mammals were near urban areas of dense vehicular traffic, near metal mines and smelters, adjacent to petrochemical refinery industries, or near plants that reclaimed storage batteries. Concentrations were higher in older organisms, especially in bone and hematopoietic tissues (Table 4.5; Goldsmith and Scanlon 1977; Way and Schroder 1982; Blus and Henny 1990; Hariono et al. 1993; Thies and Gregory 1994; Medvedev 1995). A similar pattern of lead occurrence and distribution was evident for human populations (Barth et al. 1973; Heinze et al. 1998). In Italy, tissue lead concentrations in mice correlated positively with vehicular traffic densities. Mice from the highest traffic flow areas also had genetic damage as judged by an increased frequency of micronucleated erythrocytes and abnormal sperm cells (Ieradi et al. 1996).

Diet provides the major pathway for lead exposure, and amounts in bone are indicative of estimated lead exposure and metabolism (Chmiel and Harrison 1981; Ma et al. 1991). Amounts of whole-body lead and feeding habits of roadside rodents were correlated: body burdens were highest in insectivores such as shrews, intermediate in herbivores, and lowest in granivores (Boggess 1977; Getz et al. 1977c). Food chain biomagnification of lead, although uncommon in terrestrial communities, may be important for carnivorous marine mammals, such as the California sea lion (*Zalophus californianus*); accumulations were highest in hard tissues, such as bone and teeth, and lowest in soft tissues, such as fat and muscle (Braham 1973). A similar pattern was observed in the harbor seal, *Phoca vitulina* (Roberts et al. 1976).

The most sensitive index of lead intoxication in populations of deer mice was the formation of acid-fast-staining intranuclear inclusion bodies within proximal convoluted tubule cells of kidney; secondary indicators included decreased body weight, renal edema, reticulocytosis, increased urinary ALA excretion, and decreased hematocrit (Mierau and Favara 1975). Mierau and Favara (1975) concluded that lead pollution from automobile exhausts has had little impact on deer mice, and that severe lead poisoning is unlikely at traffic densities below 200,000 vehicles per day. Others, however, believe that lead emissions from automotive exhausts may pose unnecessary risks to various species of bats, rodents, and mule deer (*Odocoileus hemionus*). Estimated doses of lead ingested by the little brown bat (*Myotis lucifugus*) and highway populations of shrews and voles equaled or exceeded dosages that have caused death or reproductive impairment in domestic animals; further, mean lead concentrations in bats and shrews near highways exceed those reported for small rodents with lead-induced renal abnormalities collected from abandoned lead-mining sites (Clark 1979). Mule deer from the Rocky Mountain National Park, Colorado, that graze on (heavily contaminated) roadside forage must consume 1.4% of their daily intake from roadsides before harmful amounts of lead (3 mg Pb/day) are obtained (Harrison and Dyer 1984); however, this value needs to be verified.

Cows (*Bos bovis*) adjacent to a lead battery reclamation plant showed signs of lead toxicosis, including muscle tremors, blindness, dribbling urine, and drooling. Mice trapped within 400 m of the plant had acid-fast-staining intranuclear inclusions in renal tubular epithelial cells — a useful diagnostic indicator of lead poisoning. A faulty air pollution control system at the plant caused deposition of particulate lead on the cornfield used for cattle forage and was the probable source of the lead toxicosis in the animals (Kisseberth et al. 1984). Industrial airborne lead pollution is responsible for contamination of cattle and horses (*Equus caballus*) within 1000 m of the source, resulting in elevated blood lead levels in both species, stillbirths and abortions in cattle, and some deaths in horses (Edwards and Clay 1977).

Proximity to the smokestacks of metal smelters is positively associated with increased levels of lead in the hair (manes) of horses and in tissues of small mammals, and is consistent with the results of soil and vegetation analyses (USEPA 1972). Lead concentrations were comparatively high in the hair of older or chronically impaired horses (USEPA 1972). However, tissues of white-tailed deer (*Odocoileus virginianus*) collected near a zinc smelter did not contain elevated levels of lead (Sileo and Beyer 1985). Among small mammals near a metal smelter, blood ALAD activity was reduced in the white-footed mouse but normal in others, e.g., the short-tailed shrew (Beyer et al. 1985). The interaction effects of lead components in smelter emissions with other components, such as zinc, cadmium, and arsenic, are unresolved (USEPA 1972) and warrant additional research.

Taxonomic Group, Organism, Tissue, and Other Variables	Concentration ^a	Reference ^b
Blood	0.1 FW	46
Skin	0.1 FW	46
South African clawed frog, <i>Xenopus laevis</i>		
Fed worms from lead-contaminated soils		
Bone	24 FW	47
Skin	3 FW	47
Muscle	1 FW	47
Kidney	15 FW	47
Liver	7 FW	47
Fed uncontaminated worms		
Bone	5 FW	47
Skin	0.8 FW	47
Muscle	0.6 FW	47
Kidney	3 FW	47
Liver	1 FW	47
BIRDS		
Sharp-shinned hawk, <i>Accipiter striatus</i> ; eastern United States; 1991–93; liver	0.07 (0.03–0.14) FW	101
Wood duck, <i>Aix sponsa</i> ; Northern Idaho; lead-contaminated area vs. reference site; maximum values		
Blood	8.0 FW vs. 0.6 FW	86
Diet	610.0 FW vs. 0.6 FW	86
Liver	14.0 FW vs. <0.06 FW	86
Intestinal digesta	32.0 DW vs. 8.4 DW	102
Mallard, <i>Anas platyrhynchos</i>		
Virginia; 1986; lead poisoned from ingested skeet shot; liver Ebro Delta, Spain; 1991–92; from lead shot areas containing 60,000–544,750 shot pellets/ha	21 FW	103
Bone	42 (8–211) FW	104
Brain	1 (0.1–117) FW	104
Kidney	1 (<0.05–30) FW	104
Liver	0.8 (0.06–22) FW	104
Pancreas	3 (1–14) FW	104
Spleen	1 (0.1–2) FW	104
California; August 1987; National Wildlife Refuges; blood		
69% (background)	<0.2 FW	105
12% (elevated)	0.2–0.5 FW	105
19% (toxic)	>0.5 FW	105
France; 1987–90; 12.8% contained ingested lead shot; blood		
22% of birds containing shot	>0.4 FW	191
Italy; Autumn 1990; blood	0.46 (0.1–1.2) FW	106
American black duck, <i>Anas rubripes</i> ; wintering in Tennessee; 1986–88; blood		
All birds		
88%	<0.2 FW	107
12%	>0.2 FW	107
Adults, 14.4%	>0.2 FW	107
Juveniles, 8.2%	>0.2 FW	107
White-fronted geese, <i>Anser albifrons</i> ; Japan; died from ingestion of spent lead shot; liver	6.9–67.7 FW	190

4.6 LETHAL AND SUBLETHAL EFFECTS

4.6.1 General

Lead adversely affects survival, growth, reproduction, development, and metabolism of most species under controlled conditions, but its effects are substantially modified by numerous physical, chemical, and biological variables. In general, organolead compounds are more toxic than inorganic lead compounds; food chain biomagnification of lead is negligible; and the younger, immature organisms are most susceptible. Uptake of lead by terrestrial plants is limited by the low bioavailability of lead from soils; adverse effects seem to occur only at total concentrations of several hundred mg Pb/kg soil.

In aquatic environments, waterborne lead was the most toxic form. Adverse effects were noted on daphnid reproduction at 1.0 µg Pb⁺²/L, on rainbow trout survival at 3.5 µg tetraethyllead/L, and on growth of marine algae at 5.1 µg Pb⁺²/L. High bioconcentration factors were recorded for filter-feeding bivalve molluscs and freshwater algae at 5.0 µg Pb⁺²/L.

Ingestion of spent lead shot by migratory waterfowl and other birds is a significant cause of mortality in these species, as well as in raptors that eat the waterfowl killed or wounded by hunters. Forms of lead other than shot are unlikely to cause clinical signs of lead poisoning in birds, except for certain alkyllead compounds that bioconcentrate in aquatic food items. Among sensitive species of birds, survival was reduced at doses of 75 to 150 mg Pb⁺²/kg BW or 28 mg alkyllead/kg BW; reproduction was impaired at dietary levels of 50 mg Pb⁺²/kg; and signs of poisoning were evident at doses as low as 2.8 mg alkyllead/kg BW.

The veterinary medical literature on lead toxicosis is abundant for domestic livestock and small laboratory animals but notably lacking for feral mammals. Among sensitive species of mammals, survival was reduced at acute oral doses as low as 5 mg/kg BW in the rat, at chronic oral doses of 0.3 mg/kg BW in the dog, and at dietary levels of 1.7 mg Pb/kg BW in the horse. Sublethal effects were documented in monkeys given doses as low as 0.1 mg Pb/kg BW daily (impaired learning 2 years postadministration) or fed diets containing 0.5 mg Pb/kg (abnormal social behavior). Reduction in ALAD activity was recorded in blood of rabbits given 0.005 mg Pb/kg BW, and in mice given 0.05 mg Pb/kg BW. Tissue residues increased in mice given 0.03 mg Pb/kg BW, and in sheep given 0.05 mg Pb/kg BW.

4.6.2 Terrestrial Plants and Invertebrates

Fruits and vegetables acquire lead by surface deposition from rainfall, dust, and soil, and by biological uptake through the root system (USEPA 1980). Foliar absorption of lead and transport to the root could account for a significant portion of the lead in root tissues; however, this transport process varies widely among species. Dollard (1986) showed that this pathway accounted for 35% of the root lead content in the radish (*Raphanus sativus*), but for <3% in carrots (*Daucus carota*) and beans (*Phaseolus vulgaris*). Corn (*Zea mays*) contained 30 mg Pb/kg dry weight when grown in soils containing lead concentrations of 924 mg/kg, but only 17 mg/kg when grown in soils containing 786 mg Pb/kg. Sadiq (1985) concluded that contamination of soils with up to 800 mg Pb/kg probably does not elevate concentrations of lead in corn plants. Within any plant species, however, there are lead-resistant and lead-sensitive breeds; some genetically fixed resistant species grow in soils containing up to 10,000 mg Pb/kg (Holl and Hampp 1975).

Plants readily accumulate lead from soils of low pH or low organic content; however, uptake is significantly reduced after the application of lime or phosphate, which converts lead to hydroxides, carbonates, or phosphates of relatively low solubility (Demayo et al. 1982). Lead persists for lengthy periods in forest litter; the estimated Tb 1/2 is 220 years (Turner et al. 1985). High levels of lead persisted for at least 6 years in litter, soil, amphibians, and mammals after zinc smelting was discontinued in Palmerton, Pennsylvania (Storm et al. 1994). Lead seems to be tightly bound by

most soils, and substantial amounts must accumulate before it affects the growth of higher plants (Boggess 1977). Although lead is preferentially bound in soils by organics and oxides, interaction kinetics of lead with other metals are complex and largely unknown (Bjerre and Schierup 1985). For example, uptake of lead from soils by oat seeds (*Avina sativa*) was inhibited by cadmium salts and reduced in loamy or organic soils; further, lead in soils interfered with manganese uptake and also increased the availability of cadmium and other heavy metals (Bjerre and Schierup 1985).

Lead inhibits plant growth, reduces photosynthesis, and reduces mitosis and water absorption (Demayo et al. 1982). Inhibition of photosynthesis is attributed to the blocking of protein sulfhydryl groups and to changes in phosphate levels in living cells (Holl and Hampp 1975). For two species of roadside weeds (*Cassia* spp.), pollen germination was reduced by 90% and seed germination by 87% at lead levels of about 500 mg/kg dry weight in soil and about 300 mg/kg dry weight in foliage (Krishnayya and Bedi 1986). Normal germination rates were recorded at lead levels of 46 mg/kg in soil and 22 mg/kg dry weight in foliage; however, some adverse effects were evident at lead levels of 12 to 312 mg/kg in soil, and 55 to 97 mg/kg dry weight in foliage (Krishnayya and Bedi 1986). Tetraethyllead from automobile exhaust fumes is known to react in the light to produce the highly phytotoxic triethyllead cation (Backhaus and Backhaus 1986), which can freely permeate the plasma membranes of plant cells (Stournaras et al. 1984). Growth of cultures of soybean (*Glycine max*) cells exposed to 207 µg Pb/L (as triethyllead salts) was inhibited before the cells died (Stournaras et al. 1984). There is no evidence for biomagnification of lead in the food chain of vegetation, to cattle, to dung, to the dung beetle (Robel et al. 1981), nor is there convincing evidence that any terrestrial vegetation is important in food chain biomagnification of lead (USEPA 1980). Concentrations of lead in soil litter ranged from 3200 mg/kg in locations near a zinc smelter in Palmerton, Pennsylvania, to 150 mg/kg at sites 105 km distant; relative concentrations of cadmium, zinc, and copper were similar (Beyer et al. 1984). In woodlice (*Porcellio scaber*) fed litter from these locales for 8 weeks, survival decreased as metal content in the litter increased, but the major cause of death was zinc poisoning and not lead poisoning (Beyer et al. 1984). Woodlouse (*Oniscus asellus*) hepatopancreas that were collected 3 km downwind of a metal smelter contained large amounts of zinc, copper, cadmium and lead. Centipedes (*Lithobius variegatus*) that ate woodlice hepatopancreas did not assimilate lead even though the food contained concentrations that were many times greater than normally encountered (Hopkin and Martin 1984). However, survival and reproduction were reduced in woodlice (*P. scaber*) fed soil litter treated with 12,800 mg Pb/kg, as lead oxide, for 64 weeks, or two generations (Beyer and Anderson 1985). This amount of lead is similar to the amounts reportedly associated with reductions in natural populations of decomposers, such as fungi, earthworms, and arthropods. The poisoning of decomposers may disrupt nutrient cycling, reduce the number of invertebrates available to other wildlife for food, and contribute to food chain contamination (Beyer and Anderson 1985). The effects of lead on soil microbial populations is unknown (Boggess 1977).

Herbivorous land snails (*Helix* spp.) are important in lead cycling through contaminated ecosystems (Dallinger and Wieser 1984; Beeby 1985). *Helix pomatia* fed lettuce enriched with lead (about 1000 mg Pb/kg dry weight lettuce) for 32 days contained 1301 mg Pb/kg dry weight in the mid-gut gland (vs. 52 in controls), and much lower amounts (<30 mg/kg) in other tissues. After the snail had fed on uncontaminated lettuce for 50 days, lead remained elevated at 1203 mg/kg in the mid-gut gland, which contained more than 90% of the total body burden (Dallinger and Wieser 1984).

4.6.3 Aquatic Biota

In general, the responses of aquatic species to lead insult differed markedly (Table 4.6). Among sensitive species, however, several trends were evident:

1. Dissolved waterborne lead was the most toxic form
2. Organic lead compounds were more toxic than inorganic forms

3. Adverse effects on daphnid reproduction were evident at 1.0 µg Pb⁺²/L
4. High bioconcentrations were measured in oysters at 1.0 µg Pb⁺²/L and in freshwater algae at 5.0 µg Pb⁺²/L
5. Tetramethyllead was acutely toxic to rainbow trout at 3.5 µg/L
6. Growth inhibition of a marine alga was reported at 5.1 µg Pb⁺²/L
7. For all species, effects were most pronounced at elevated water temperatures and reduced pH, in comparatively soft waters, in younger life stages, and after long exposures ([Table 4.6](#))

Lead is toxic to all phyla of aquatic biota, but its toxic action is modified by species and physiological state, and by physical and chemical variables. Wong et al. (1978) stated that only soluble waterborne lead is toxic to aquatic biota, and that free cationic forms are more toxic than complexed forms. The biocidal properties of soluble lead are also modified significantly by water hardness: as hardness increases, lead becomes less bioavailable because of precipitation increases (NRCC 1973). In salmonids, for example, the toxicity and fate of lead are influenced by the calcium status of the organism, and this relationship may account for the reduced effects of lead in hard or estuarine waters. In coho salmon (*Oncorhynchus kisutch*), an increase in waterborne or dietary calcium reduced uptake and retention of lead in skin and skeleton (Varanasi and Gmur 1978).

Organolead compounds are, in general, more toxic than inorganic lead compounds to aquatic organisms. Ethyl derivatives were more toxic than methyl derivatives, and toxicity increased with increasing degree of alkylation, tetraalkylead being the most toxic (Chau et al. 1980; Babich and Borenfreund 1990). Tetraethyllead was about 10 times more effective than tetramethyllead in reducing oxygen consumption by coastal marine bacteria, and was 1.5 to 4 times more toxic than tetramethyllead to marine teleosts (Marchetti 1978). Tetramethyllead chloride was 20 times as toxic as Pb(NO₃)₂ to freshwater algae, and twice as toxic as trimethyllead acetate (Wong et al. 1978). In seawater, the release of tetraalkylead compounds is more likely than accumulation to result in acutely toxic effects; however, alkyllead compounds degrade rapidly to trialkyllead chlorides, which are only 0.1 to 0.01 as toxic as TEL compounds (Haddock and Taylor 1980). Alkyllead compounds are accumulated more readily by freshwater teleosts than are inorganic lead compounds. The BCF values for tetramethyllead and rainbow trout, for example, ranged from 124 in lipids after exposure for 1 day, to 934 after 7 days (Demayo et al. 1982). Depuration of tetramethyllead is rapid. The estimated Tb 1/2 values range from 30 hours for intestinal lipids to 45 hours for skin and cephalic fat deposits (Wong et al. 1981). Some microorganisms in lake sediments transform certain inorganic and organic lead compounds into the more toxic tetramethyllead, but the pathways are not well understood (Wong et al. 1978).

Lethal solutions of lead (as well as of many other heavy metals) cause increased mucus formation in fishes. The excess coagulates over the entire body and is particularly prominent over the gills, interfering with respiratory function and resulting in death by anoxia (Aronson 1971; NRCC 1973). Increasing waterborne concentrations of lead over 10 µg/L are expected to provide increasingly severe long-term effects on fish and fisheries (Demayo et al. 1982; Ruby et al. 1993). Fish that are continuously exposed to toxic concentrations of waterborne lead show various signs of lead poisoning: spinal curvature, usually as lordosis; anemia; darkening of the dorsal tail region, producing a black-tail effect due to selective destruction of chromatophores but not of melanophores; degeneration of the caudal fin; destruction of spinal neurons; ALAD inhibition in erythrocytes, spleen, liver, and renal tissues; reduced ability to swim against a current; destruction of the respiratory epithelium; basophilic stippling of erythrocytes; elevated lead concentrations in blood, bone, gill, liver, and kidney; muscular atrophy; paralysis; renal pathology; growth inhibition; retardation of sexual maturity; altered blood and lipid chemistry; testicular and ovarian histopathology; and death (Aronson 1971; NRCC 1973; Adams 1975; Davies et al. 1976; Holcombe et al. 1976; Hodson et al. 1977, 1980, 1982; Johansson-Sjöbeck and Larsson 1979; Reichert et al. 1979; Ozoh 1980; Demayo et al. 1982; Kumar and Pant 1984; Rai and Qayyum 1984; Hodson and Spry 1985; Haux et al. 1986; Thomas and Huedes 1992; Tulasi et al. 1992; Ruby et al. 1993; Conner

and Fowler 1994). The prevalence of signs is closely correlated with duration of exposure to lead and to its uptake (Hodson et al. 1982). Toxic effects of lead uptake in fishes are increased under conditions favoring their rapid growth. Hodson et al. (1982) have shown that the rate of intoxication by lead (as judged by uptake rates into tissues and incidence and prevalence of black tail) did not increase with fish size, but rather with growth rate.

Rooted aquatic plants, such as wild rice (*Zizania aquatica*), can accumulate up to 67 mg Pb/kg dry weight when cultured in tanks contaminated with high concentrations of powdered lead (equivalent to 7400 kg Pb/ha); however, this level is not considered hazardous to waterfowl feeding on wild rice (Behan et al. 1979). Lead content in plants collected from heavily hunted areas near refuges did not differ from those collected in the protected areas (Behan et al. 1979), which suggests that lead bioavailability to rooted aquatics is substantially lower from shot than from powdered lead.

In another study with rooted macrophytes, *Navicula* sp. and *Elodea canadensis* rapidly accumulated lead from solutions containing 1.0 mg Pb⁺²/L, i.e., 70 mg Pb/kg dry weight per minute; the process was overwhelmingly passive (Everard and Denny 1985). Depuration was rapid; 90% of the lead sorbed during the first hour by shoots of *Elodea* was released within 14 days after transfer to clean water, though 10% seemed to be irreversibly bound (Everard and Denny 1985).

Certain emergent aquatic plants, especially hydrilla (*Hydrilla verticillata*) and duckweed (*Lemna obscura*), removed 97 to 98% of all soluble lead from solution in the vicinity of a lead battery site in Tampa, Florida, suggesting that phytoremediation may be feasible as the basis of a lead removal technology (Gallardo et al. 1999).

High accumulations of lead from ambient seawater by marine plants is well documented; concentration factors vary from 13,000 to 82,000 for algae from Raritan Bay, New Jersey (Seeliger and Edwards 1977), and from 1200 to 26,000 for algae from Sorfjorden, Norway (Melhuus et al. 1978). Studies on the kinetics of lead uptake and retention in two species of marine algae (*Phaeodactylum tricornutum*, *Platymonas subcordiformes*) showed that both species accumulated lead from the medium at ambient concentrations of 20 µg/L and higher (Schulz-Baldes and Lewin 1976). In the first phase, usually completed within minutes after addition of lead, cells of *Phaeodactylum* became saturated when the lead reached a remarkable 11,640 mg/kg dry weight. In the second phase, the lead content of *Platymonas* continued to rise slowly, but that of *Phaeodactylum* declined after 2 or 3 days. In both species the content of bound lead increased with increasing exposure time, suggesting that during prolonged exposure lead is initially adsorbed to the cell surface, then translocated into the cell wall, the plasma membrane, and eventually the cytoplasm (Schulz-Baldes and Lewin 1976).

Sediments are not only sinks for lead but may also act as a source of lead to aquatic biota after contamination from the original source has subsided (Knowlton et al. 1983). The uptake of lead from artificially contaminated pond sediments was recorded in roots and foliage of submersed aquatic macrophytes (*Potamogeton foliosus*, *Najas guadalupensis*) and in the exoskeleton of crayfish (*Orconectes nais*). Accumulation of lead in crayfish primarily was through adsorption; most was lost through molting, though some internal uptake and elimination occurred without molting (Knowlton et al. 1983). Crustacean molts represent 15% of the lead body burden and are probably more significant than fecal pellets in lead cycling processes (Fowler 1977). Uptake of lead from sediments containing 7 mg Pb/kg DW is reported for the stone loach (*Noenacheilus barbatulus*) (Douben and Koeman 1989), but this needs verification.

Median BCF values in aquatic biota exposed to various concentrations of Pb⁺² for 14 to 140 days varied from about 42 in fish to 2570 in mussels; intermediate values were 536 for oysters, 500 for insects, 725 for algae, and 1700 for snails (USEPA 1985). There are several notable exceptions to this array: significantly higher values have been reported in crustacean hepatopancreas (Heyraud and Cherry 1979), in various species of freshwater invertebrates (Spehar et al. 1978), in fish bone (Demayo et al. 1982) and liver (Haux and Larsson 1982), and in whole oysters (Zaroogian et al. 1979). In oysters, for example, BCF values varied from 3450 to 6600 after exposure to solutions

containing 1.0 to 3.3 µg Pb⁺²/L for 140 days, but oysters and their progeny were apparently unaffected at whole-body burdens (less shell) up to 11.4 mg Pb/kg dry weight (Zaroogian et al. 1979). Many species of aquatic biota contain lead in amounts >1000 mg/kg fresh weight (>10,000 mg/kg dry weight), including some marine seaweeds, freshwater macrophytes and algae, annelids, crustaceans, echinoderms, molluscs, and teleosts (Wong et al. 1978). Presumably, the lead was sorbed passively, and little, if any, was incorporated biologically. Variations in lead concentrations in aquatic biota probably reflect the ability of individual species to adsorb waterborne lead, and may be a direct function of the ratio of surface to body weight (Demayo et al. 1982). The residence time of lead in aquatic biota seems to be related to the route of administration: Tb 1/2 values were 9 days by waterborne routes and 40 days by diet (Vighi 1981).

Although lead is concentrated by biota from water, there is no convincing evidence that it is transferred through food chains (Wong et al. 1978; USEPA 1979; Branica and Konrad 1980; Settle and Patterson 1980). Lead concentrations tended to decrease markedly with increasing trophic level in both detritus-based and grazing aquatic food chains (Wong et al. 1978). In the marine food chain of seawater (<0.08 µg Pb/L), to a brown alga (*Egregia laevigata*), to the red abalone (*Haliotis rufescens*), lead concentrations in the alga and abalone were both <0.04 mg Pb/kg fresh weight after 6 months, indicating negligible biomagnification (Stewart and Schulz-Baldes 1976). When seawater contained 1000 µg Pb/L, young abalones that fed on *Egregia* for 6 months contained up to 21 mg Pb/kg fresh weight, but neither growth nor activity was affected; lead selectively accumulated in the digestive gland (38 mg/kg) and was lowest in muscle (<1 mg/kg) — the part normally consumed by humans (Stewart and Schulz-Baldes 1976). In the freshwater food chain of an alga (*Selenastrum capricornutum*), to a daphnid (*Daphnia magna*), to the guppy (*Poecilia reticulata*), lead accumulation progressively decreased from the alga to the guppy. Thus, in organisms held for 28 days in solutions containing 5 µg Pb/L, lead content was 460 mg/kg dry weight in the alga, 23 mg/kg in the grazing daphnids, and 4 to 16 mg/kg in the guppies that fed on the daphnids (Vighi 1981). Concentrations of lead in the freshwater snail, *Lymnaea peregra*, collected near an abandoned lead mine were positively correlated with the lead content in its diet. The digestive glands contained up to 5600 mg/kg dry weight (Everard and Denny 1984). The gut contents of eels (*Anguilla anguilla*) grazing on contaminated snails contained up to 4350 mg Pb/kg, but the lead was rapidly released; feces from both snails and eels return the lead to the ecosystem as particulates and detritus (Everard and Denny 1984).

As discussed earlier, lead clearly inhibits the formation of heme at several points, adversely affects blood chemistry, and accumulates in hematopoietic organs of aquatic organisms. In addition, it:

- Interferes with chlorophyll formation in plants by inhibiting the conversion of coproporphyrinogen to protoporphyrinogen by competing with iron
- Inhibits allantoise formation in annelids
- Inhibits alpha-glycerophosphate dehydrogenase activity in trout
- Increases glutamic oxalacetate transaminase activity in *Daphnia*
- Affects neural and hormonal systems that control activity and metabolic rates in fish
- Interacts with polar sites of glycoproteins in epidermal mucus of fish
- May inhibit Vitamin C and tryptophan metabolism (Wong et al. 1978).

Fish may be more resistant to lead than mammals. For example, isolated liver hepatocytes of channel catfish were about 40 times more resistant to lead than rat liver hepatocytes as judged by ALAD inhibition (Conner and Fowler 1994).

Some populations of freshwater isopods are tolerant to lead. Inasmuch as nontolerant isopods from an unpolluted site can be made tolerant by exposure to low levels, it is suggested that naturally occurring tolerance may be achieved by acclimatization (Fraser 1980). Research is needed on lead transformation mechanisms, on toxic forms of lead and interaction effects with other compounds, and on effects of lead-contaminated sediments on benthos (Wong et al. 1978).

Table 4.6 Lethal and Sublethal Effects of Lead^a to Selected Species of Aquatic Organisms

Ecosystem, Taxonomic Group, Species, Dose, and Other Variables	Effect ^b	Reference ^c
FRESHWATER		
Algae and macrophytes		
Alga, <i>Selenastrum capricornutum</i>		
5 µg/L for 28 days	BCF of 92,000	1
50 µg/L for 28 days	BCF of 26,000	1
Alga, <i>Chlamydomonas reinhardtii</i>		
207 µg/L for 3 h	BCF of 26; some inhibition of photosynthesis	2
1000 µg/L for 3 h	BCF of 20; 50% inhibition of photosynthesis	2
4140 µg/L for 24 h	Lethal	2
Alga, <i>Microcystis aeruginosa</i>		
450 µg/L for 8 days	Immobilization	3
Invertebrates		
Chironomid, <i>Chironomus riparius</i> ; 5 generations exposed from egg to fourth instar to 0, 5, 50, or 500 µg Pb/L		
Daphnid, <i>Daphnia magna</i>		
1 µg/L for 19 days	Reproductive impairment, 10%	4
10 µg/L for 19 days	Reproductive impairment, 50%	4
30 µg/L for 21 days	Reproductive impairment, 16%	3, 5
Water hardness (mg CaCO ₃ /L)		
52, 9–16.7 µg/L, lifetime exposure	MATC	3
102, 78–181 µg/L, lifetime exposure	MATC	3
151, 85–193 µg/L, lifetime exposure	MATC	3
54, 612 µg/L for 96 h	LC50	3
110, 952 µg/L for 96 h	LC50	3
152, 1.91 mg/L for 96 h	LC50	3
45, 300 µg/L for 21 days	LC50	6, 7
45, 450 µg/L for 48 h	50% immobilized	3, 7
Snail, <i>Lymnaea palustris</i>		
12–54 µg/L, lifetime exposure	MATC	3
Snail, <i>Lymnaea palustris</i>		
3.8 µg/L, lifetime exposure	No deaths	8
19 µg/L, lifetime exposure	Significant mortality	8
36 µg/L, lifetime exposure	50% reduction in biomass	8
48 µg/L, lifetime exposure	100% reduction in biomass	8
54 µg/L lifetime exposure	Hatching success reduced; survivors dead by age 80 days	8
Protozoan, <i>Entosiphon sulcatum</i>		
20 µg/L for 72 h	Immobilization	3
Amphipod, <i>Gammarus pseudolimnaeus</i>		
28.4 µg/L for 60 days	LC50	5
124.0 µg/L for 96 h	LC50	9
Aquatic invertebrates		
32 µg/L for 28 days	BCF 1000–9000	5
Protozoan, <i>Uronema</i> sp.		
70 µg/L for 20 h	Immobilization	3
Midge, <i>Tanytarsus dissimilis</i>		
258 µg/L for 10 days	LC50	3
Isopod, <i>Asellus meridianus</i>		
Nontolerant strain		
280 µg/L for 48 h	LC50	5
From lead-contaminated river		
3500 µg/L for 48 h	LC50	5

Table 4.6 (continued) Lethal and Sublethal Effects of Lead^a to Selected Species of Aquatic Organisms

Ecosystem, Taxonomic Group, Species, Dose, and Other Variables	Effect ^b	Reference ^c
Daphnid, <i>Daphnia hyalina</i> 600 µg/L for 48 h	LC50	6
Snail, <i>Viviparus ater</i> 1.0 mg/L for 7 days 117.0 mg/L for 96 h	Neuronal cytolysis LC50	10 10
Chironomid, <i>Chironomus tentans</i> ; larvae 2.7 mg/L for 48 h	LC50	31
Aquatic insects, 5 species 3.5–64.0 mg/L for 7–14 days	LC50	5
Isopod, <i>Asellus aquaticus</i> Nontolerant strain Pretreated for 5 days to 100 mg Pb/L then exposed to 794.0 mg/L for 48 h	LC50	11
No pretreatment 330.0 mg/L for 48 h	LC50	11
Fishes		
Bluegill, <i>Lepomis macrochirus</i> Isolated fin cells; various organolead compounds; exposed for 24 h 0.9 µg/L 2.3 µg/L 6.2 µg/L 62.0 µg/L	LC50 for triethyllead LC50 for trimethyllead LC50 for dimethyllead LC50 for diethyllead	43 43 43 43
Water hardness 41 mg CaCO ₃ , 70–120 µg Pb/L for lifetime exposure	MATC	16
Rainbow trout, <i>Oncorhynchus mykiss</i> Tetramethyl lead Weight 1 gram, 3.5 µg/L for 72 h Weight 1 gram, 3.5 µg/L for 7 days Weight 1 gram, 3.5 µg/L for 14 days Weight 20 grams, 24 µg/L for 8–14 days	LC50 BCF of 726 for whole trout LC50 Some deaths at day 8; BCF of 17,300 for intestinal lipids at day 10 and 12,540 at day 14	12 12 12 12
Pb ⁺² 10 µg/L for 30 days 10 µg/L for 12 days; sexually-maturing males exposed during spermatogenesis 13 µg/L for 4 weeks 13 µg/L for 32 weeks 14 µg/L for 14 days 75 µg/L for 30 days 300 µg/L for 30 days plus 7 weeks post exposure	ALAD depression, 21% Decreased number of spermatocytes; increase in spermatogonial cysts Erythrocyte ALAD inhibition Anemia; reduced blood ALAD activity Reduced stamina ALAD depression, 74% ALAD depression, 86%; anemia; basophilic stippling of erythrocytes	13 32 6 3 3 13 13
Eyed eggs 10.0 mg total Pb/L for 56 h 20.0 total Pb/L for 20 h	LC50 LC50	14 14
Water hardness (mg CaCO ₃ /L) 28		
4.0–7.6 µg total Pb/L, lifetime exposure beginning with pre-hatch fry 4.1–7.6 µg dissolved Pb/L, lifetime exposure 7.2 µg total Pb/L for 19 months 7.2–14.6 µg total Pb/L, lifetime exposure	MATC MATC No harmful effects MATC	5 15 6 15

Table 4.6 (continued) Lethal and Sublethal Effects of Lead^a to Selected Species of Aquatic Organisms

Ecosystem, Taxonomic Group, Species, Dose, and Other Variables	Effect ^b	Reference ^c
7.6–14.6 µg total Pb/L, lifetime exposure beginning with post-hatch fry	MATC	5
14.6 µg total Pb/L for 19 months	Vertebral deformities; caudal fin erosion	6
1.2 mg dissolved Pb/L for 96 h	LC50	5
35		
71–146 µg total Pb/L, lifetime exposure	MATC	3
353		
18–32 µg dissolved Pb/L, lifetime exposure	MATC	15
18.2 µg total Pb/L for 19 months	No adverse effects	6
31 µg total Pb/L for 19 months	Vertebral deformities; caudal fin erosion	6
120–360 µg dissolved Pb/L, lifetime exposure	MATC	15
1.0 mg Pb/L for 6–16 days	None dead in 6 days; 50% dead in 11 days; all dead in 16 days; no osmoregulatory effect, even at lethal exposure	33
1.4 mg dissolved Pb/L for 96 h	LC50	15
506.5 mg total Pb/L for 96 h	LC50	15
Brown trout, <i>Salmo trutta</i>		
Yolk-sac fry exposed to 2.5, 5.2, or 10.4 µg Pb/L for 30 days at pH 4.5 in soft or hard water	All dead at 2 high dose levels and >90% dead at 2.5 µg/L in soft water; no deaths in any hard water group	45
Yolk-sac fry exposed to 10 µg Pb/L	Adverse effects on growth and development in groups hatched and maintained in soft, acid water	46
Zebrafish, <i>Brachydanio rerio</i>		
Embryos exposed for 16 days		
<20 µg/L	Normal hatch	41
<30 µg/L	Survival normal	41
480 µg/L	Lethal	41
Eggs exposed to 50 µg total Pb/L for 24 h	Pigmentation patterns of fry irreversibly altered	17
Eggs exposed to 72 µg total Pb/L for 24 h	Hatching inhibited	17
Common carp, <i>Cyprinus carpio</i> ; recently-fertilized eggs exposed to 25–186 µg/L at pH 7.5 or 5.6	At pH 7.5, lead increased heart rate and decreased body movements. At pH 5.6 there was a dose-dependent reduction in survival and increase in spinal cord deformities	42
Lake trout, <i>Salvelinus namaycush</i>		
Water hardness 33 mg CaCO ₃ /L, 48–83 µg total Pb/L, lifetime exposure	MATC	16
Brook trout, <i>Salvelinus fontinalis</i>		
Water hardness 44 mg CaCO ₃ /L		
39–84 µg dissolved Pb/L for 3 generations	MATC	5, 18
58–119 µg total Pb/L for 3 generations	MATC	3, 5, 18
119 µg total Pb/L for 3 generations	First generation: BCF of 571 for liver and 1806 for kidney. Second generation: BCF of 420 for liver, 1504 for kidney; severe spinal deformities in 34%. Third generation: spinal deformities in 21%, reduction in body weight	18
134 µg total Pb/L for 21 days	Growth reduction	6
235 µg Pb/L for 2 generation deformities	All with spinal	18
3.4 mg dissolved Pb/L for 96 h	LC50	18
4.1 mg total Pb/L for 96 h	LC50	18
Channel catfish, <i>Ictalurus punctatus</i>		
Water hardness 36 mg CaCO ₃ , 75–136 µg Pb/L, lifetime exposure	MATC	16
White sucker, <i>Catostomus commersoni</i>		
Water hardness 34 mg CaCO ₃ , 119–253 µg Pb/L, lifetime exposure	MATC	5

Table 4.6 (continued) Lethal and Sublethal Effects of Lead^a to Selected Species of Aquatic Organisms

Ecosystem, Taxonomic Group, Species, Dose, and Other Variables	Effect ^b	Reference ^c
Rosy barb, <i>Barbus conchonius</i> 126 µg/L for 8 weeks 378 µg/L for 96 h	No deaths; altered blood chemistry LC50	40 40
Cyprinid, <i>Puntius conchonius</i> 127 µg Pb/L for 4 months 379 µg Pb/L for 96 h	Gonadal pathology LC50	19 19
Goldfish, <i>Carassius auratus</i> 200 µg Pb/L for 4–5 days	ALAD inhibition	6
Northern pike, <i>Esox lucius</i> Water hardness 34 mg CaCO ₃ /L, 253–483 µg Pb/L for lifetime exposure	MATC	5
Air-breathing catfish, <i>Clarias lazera</i> 270 µg/L for 240 h 1.72 mg/L for 96 h	Whole body content of 6.8 mg Pb/kg FW LC50	31 31
Threespine stickleback, <i>Gasterosteus aculeatus</i> 300 µg Pb/L for 96 h	LC100	6
European eel, <i>Anguilla anguilla</i> Juveniles held in 300 µg/L for 30 days	Increase in number of white blood cell lymphocytes and blood plasma lactate levels; most blood chemistry variables were normal	39
Mozambique tilapia, <i>Oreochromis niloticus</i> 330 µg/L for 240 h 2.15 mg/L for 96 h 18, 24, or 33 mg Pb L as lead acetate for up to 21 days	Whole body concentration of 14.9 mg Pb/kg FW LC5 Dose-dependent decrease in plasma glucose and cholesterol	31 31 34
Smallmouth bass, <i>Micropterus dolomieu</i> Water hardness 152 mg CaCO ₃ /L Fingerlings exposed to 405 µg Pb/L for 90 days Swim-up fry exposed to 2.8 mg Pb/L for 96 h Fingerlings held in 29.0 mg Pb/L for 96 h Eggs and sac-fry held in >15.9 mg Pb/L for 96 h	No effect on growth behavior, blood chemistry LC50 LC50 LC50	20 20 20 20
Fathead minnow, <i>Pimephales promelas</i> Juveniles exposed for 4 weeks to 0.0, 0.5, or 1.0 mg Pb/L as lead acetate 1.0 mg/L for 28 days Water hardness (mg CaCO ₃ /L) 20; 6.5 mg Pb/L for 96 h 360; 460.0 mg Pb/L for 96 h	Brain serotonin and norepinephrine levels higher and feeding success inhibited in lead-exposed groups Altered brain neurotransmitter rhythms LC50 LC50	35 36 7 7
Climbing perch, <i>Anabas testudineus</i> 1.25–20 mg Pb/L for 30 days 5 mg/L for 30 days 60 mg/L for 96 h	Dose-dependent (up to 5 mg/L) accumulations in blood and ovary, decrease in gonadosomatic index and number of ova No deaths. Reduction in liver and ovary total lipids, phospholipids, and cholesterol; increases in free fatty acid levels and lipase activity LC50	37, 38 38 37
Amphibians		
Toad, <i>Bufo arenarum</i> Newly-fertilized eggs held in 120 µg/L–32 mg Pb/L as lead nitrate for 72 h 120 µg/L 250 µg/L	Normal development 25% arrested development	49 49

Table 4.6 (continued) Lethal and Sublethal Effects of Lead^a to Selected Species of Aquatic Organisms

Ecosystem, Taxonomic Group, Species, Dose, and Other Variables	Effect ^b	Reference ^c
470–950 µg/L	LC50 (48 h); high frequency of malformations in survivors	49
2–4 mg/L 8–32 mg/L	Survivors had arrested development LC100 (48 h)	49 49
Larvae exposed for 120 h to lead or lead and zinc mixtures		
8 mg Pb/L	LC60	50
8 mg Pb/L + 4 mg Zn/L	LC65	50
8 mg Pb/L + 8 mg Zn/L	LC15	50
8 mg Pb/L + 16 mg Zn/L	LC5	50
American toad, <i>Bufo americanus</i> ; tadpoles held in lead-enriched waters (0, 500, 750, or 1000 µg Pb/L) for 144 h then given choice of lead-containing solutions (0, 500, 750, or 1000 µg/L) in fluvorium	No deaths. Toads did not prefer or avoid lead-containing solutions	48
Jefferson salamander, <i>Ambystoma jeffersonianum</i> ; embryos (4-days postfertilization) exposed for 21 days to 130–800 µg Pb/L at pH 4.5 and 5.5	At low pH, lead aids development and protects against arrested growth in a dose-dependent manner; normal hatch and development at pH 5.5 and 800 µg Pb/L	47
Green frog, <i>Rana clamitans</i> ; tadpoles Exposed to 500–1000 µg Pb/L as lead nitrate for 144 h then tested in preference/avoidance apparatus	No significant preference or avoidance of lead by controls or lead-exposed tadpoles and no effects on locomotor activity	52
Exposed to 750 µg/L as lead nitrate for 120–144 h	Sublethal exposure to lead adversely affected learning and memory as judged by increased response times and fewer avoidances in associating illumination with shock	53
750–1000 µg/L	Altered feeding behavior and erratic locomotor activity	48
Bullfrog, <i>Rana catesbeiana</i> ; tadpoles exposed to 500–1000 µg Pb/L as lead nitrate for 144 h	No effect on preference or avoidance responses to plumes of lead-contaminated water or on spontaneous locomotor activity. Lead-exposed tadpoles had significantly greater variability in activity than did controls	51
Reptiles		
Slider turtle, <i>Trachemys scripta</i> Hatchlings, aged 6 months, given single intramuscular injection of 50 or 100 mg Pb/kg BW as lead acetate	No significant effect on growth, survival, or behavior	55
Hatchlings, age 3 weeks, given single intramuscular injection of 250, 1000, or 2500 mg Pb/kg BW and observed for 6 months	Dose-dependent decrease in survival; dose-dependent impaired behavior (righting response) in survivors; normal growth in survivors after 4 months. At 120 days, all dead in high dose group, 75% dead in medium dose group; 17% dead in low dose group, and 8% dead in controls	55
MARINE		
Algae and macrophytes		
Diatom, <i>Skeletonema costatum</i>		
0.05 µg Pb/L for 12 days	No effect on growth	21
5.1 µg Pb/L for 12 days	50% growth inhibition	3
10.0 µg Pb/L for 12 days	100% growth inhibition	21
Alga, <i>Phaeodactylum tricornutum</i> Pb ⁺²		
20 µg Pb/L for <1 h	BCF 582,000	22
>5.0 mg Pb/L for 96 h	LC50	23

Table 4.6 (continued) Lethal and Sublethal Effects of Lead^a to Selected Species of Aquatic Organisms

Ecosystem, Taxonomic Group, Species, Dose, and Other Variables	Effect ^b	Reference ^c
Tetramethyl Pb 1.3 mg Pb/L for 96 h	LC50	23
Trimethyl Pb 800 µg Pb/L for 96 h	LC50	23
Triethyl Pb 100 µg Pb/L for 96 h	LC50	23
Tetraethyl Pb 100 µg Pb/L for 96 h	LC50	23
Phytoplankton, mixed populations 21 µg Pb/L for 4 days	Reduced biomass	3
Alga, <i>Dunaliella tertiolecta</i>		
Tetraethyl Pb 150 µg/L for 96 h	Growth inhibition	3
Tetramethyl Pb 1.65 mg/L for 96 h	Growth inhibition	3
Invertebrates		
American oyster, <i>Crassostrea virginica</i> , soft parts		
1.0 µg/L for 140 days	BCF of 6600	24
3.3 µg/L for 140 days	BCF of 3454	24
Common mussel, <i>Mytilus edulis</i>		
Pb ⁺²		
10 µg/L for 63 days	BCF of 12,580 for kidney and 1580 for soft parts	25
476 µg/L for 96 h	LC50, larvae	3
500 µg/L for 150 days	BCF of 25,670 for soft parts	26
>500 mg/L for 96 h	LC50, adults	23
Triethyl lead		
1.1 mg/L for 96 h	LC50; BCF 10	23
Trimethyl lead		
500 µg/L for 96 h	LC50; BCF 23	23
Tetramethyl lead		
270 µg/L for 96 h	LC50; BCF 170	23
Tetraethyl lead		
100 µg/L for 96 h	LC50; BCF 120	23
Softshell clam, <i>Mya arenaria</i> ; soft parts		
14 µg/L for 42 days	BCF of 158 at 0–10°C	27
14 µg/L for 14 days	BCF of 351 at 16–22°C	27
70 µg/L for 42 days	BCF of 180 at 0–10°C	27
70 µg/L for 7 days	BCF of 237 at 16–22°C	27
Mysid, <i>Mysidopsis bahia</i>		
17–37 µg/L for lifetime	MATC	3
Sandworm, <i>Neanthes arenaceodentata</i>		
20 µg/L for 23 days	Inhibited reproduction at 1.5% salinity	28
3.1 mg/L for 28 days	Inhibited reproduction at 2.0% salinity	28
7.7 mg/L for 96 h	LC50 at 20°C	28
10.7 mg/L for 96 h	LC50 at 15°C	28
Shrimp, <i>Crangon crangon</i>		
Pb ⁺²		
375 mg/L for 96 h	LC50	23
Trimethyl lead		
8.8 mg/L for 96 h	LC50; BCF 1	23
Triethyl lead		
5.8 mg/L for 96 h	LC50; BCF 2	23
Tetramethyl lead		
110 µg/L for 96 h	LC50; BCF 20	23

Table 4.6 (continued) Lethal and Sublethal Effects of Lead^a to Selected Species of Aquatic Organisms

Ecosystem, Taxonomic Group, Species, Dose, and Other Variables	Effect ^b	Reference ^c
Tetraethyl lead 20 µg/L for 96 h	LC50; BCF 650	23
American lobster, <i>Homarus americanus</i> 50 µg/L for 30 days	Reduced ALAD activity; biochemical alterations in antennal gland; BCF 2760 for antennal gland, and 58 for gill	3, 29
Protozoan, <i>Cristigera</i> sp. 150 µg/L for 12 h	Reduced growth	3
Amphipod, <i>Ampelisca abdita</i> 547 µg/L for 96 h	LC50	3
Dungeness crab, <i>Cancer magister</i> 575 µg/L for 96 h	LC50	37
Sea urchin, <i>Anthocidaris crassispina</i> (embryos) 1.1 mg/L for 48 h	Development normal	30
2.2 mg/L for 48 h	Development inhibited	30
Fish		
Plaice, <i>Pleuronectes platessa</i>		
Tetramethyl lead 50 µg/L for 96 h	LC50; BCF 60	23
Tetraethyl lead 230 µg/L for 96 h	LC50; BCF 130	23
Triethyl lead 1.7 mg/L for 96 h	LC50; BCF 2	23
Trimethyl lead 24.6 mg/L for 96 h	LC50; BCF 1	23
Diethyl lead 75.0 mg/L for 96 h	LC50	23
Pb ⁺² 180.0 mg/L for 96 h	LC50	23
Dimethyl lead 300.0 mg/L for 96 h	LC50	23
Mummichog, <i>Fundulus heteroclitus</i> 315 µg/L for 96 h	LC50	3
Atlantic croaker, <i>Micropogonias undulatus</i> ; juveniles; oral ingestion of lead chloride equivalent to 12 mg Pb/kg BW daily for up to 6 weeks	Significant increases in the glutathione contents of liver and intestine during first week that plateaued; significant increases in brain and kidney glutathione after 6 weeks. Maximum residues, in mg Pb/kg FW, were 50 in intestine, 20 in kidney, 2 in liver, and <1 in brain	44

^a As total lead, unless indicated otherwise.^b BCF = bioconcentration factor; MATC = maximum acceptable toxicant concentration. Lower value in each MATC pair indicates highest concentration tested producing no measurable effect on growth, survival, reproduction, and metabolic upset during chronic exposure; higher value indicates lowest concentration tested producing a measurable effect.^c 1, Vighi 1981; 2, Irmer et al. 1986; 3, EPA 1985; 4, Berglind et al. 1985; 5, Demayo et al. 1982; 6, Wong et al. 1978; 7, NRCC 1973; 8, Borgmann et al. 1978; 9, Spehar et al. 1978; 10, Fantin et al. 1985; 11, Fraser 1980; 12, Wong et al. 1981; 13, Johansson-Sjöbeck and Larsson 1979; 14, Rombaugh 1985; 15, Davies et al. 1976; 16, EPA 1980; 17, Ozoh 1980; 18, Holcombe et al. 1976; 19, Kumar and Pant 1984; 20, Coughlan et al. 1986; 21, Rivkin 1979; 22, Schulz-Baldes and Lewin 1976; 23, Maddock and Taylor 1980; 24, Zarogian et al. 1979; 25, Schulz-Baldes 1974; 26, Schulz-Baldes 1972; 27, Eisler 1977; 28, Reish and Gerlinger 1984; 29, Gould and Grieg 1983; 30, Kobayashi 1971; 31, Oladimeji and Offem 1989; 32, Ruby et al. 1993; 33, Sola et al. 1994; 34, Ruparelia et al. 1989; 35, Weber et al. 1991; 36, Spieler et al. 1995; 37, Tulasi et al. 1989; 38, Tulasi et al. 1992; 39, Santos and Hall 1990; 40, Gill et al. 1991; 41, Dave and Xiu 1991; 42, Stouthart et al. 1994; 43, Babich and Borenfreund 1990; 44, Thomas and Juedes 1992; 45, Sayer et al. 1989; 46, Sayer et al. 1991; 47, Horne and Dunsen 1995; 48, Steele et al. 1991; 49, Perez-Coll et al. 1988; 50, Herkovits and Perez-Coll 1991; 51, Steele et al. 1989; 52, Taylor et al. 1990; 53, Strickler-Shaw and Taylor 1990; 54, Janssens de Bisthoven et al. 1998; 55, Burger et al. 1998.

4.6.4 Amphibians and Reptiles

Lead poisoning in adult leopard frogs (*Rana pipiens*) is indicated by a series of signs: sloughing of integument; sluggishness; decreased muscle tone; decreases in red blood cells, white blood cells, neutrophils, and monocytes; erosion of the gastric mucosa; and (before death) excitement, salivation, and muscular twitching. The 30-day LC50 value for adult *R. pipiens* was 105 mg Pb/L, but some deaths and elevated liver residues were noted at water concentrations as low as 25 mg/L (Kaplan et al. 1967). Toad (*Bufo arenarum*) eggs are comparatively sensitive to ionic lead, with LC50 (48 h) values of 0.47 to 0.9 mg/L, and a high incidence of malformations in survivors (Perez-Coll et al. 1988). Zinc seems to confer a degree of protection against lead toxicosis in toad eggs (Herkovits and Perez-Coll 1991). In soft water (99 mg CaCO₃/L), some marbled salamanders (*Ambystoma opacum*) exposed to 1.4 mg Pb/L died in 8 days (USEPA 1985). At about 1.0 mg/L, lead blocked synaptic transmission by competitive inhibition of calcium in the bullfrog, *Rana catesbeiana* (Kober and Cooper 1976). At 0.5 mg Pb/L, tadpoles of *Rana utricularia* required additional time to metamorphose; and at 1.5 mg Pb/L, thyroid histopathology was recorded and the delay in metamorphosis was more pronounced (Yeung 1978). Tadpoles of the bullfrog and the green frog (*Rana clamitans*) do not avoid lead concentrations shown to produce behavioral deficiencies, i.e., >0.5 mg Pb/L (Steele et al. 1991). Lead interferes with the normal development of newly fertilized eggs of a toad (*Bufo arenarum*) at concentrations of 250 µg Pb/L and higher (Perez-Coll et al. 1988).

No data were available on toxic or sublethal effects of lead to reptiles under controlled conditions.

4.6.5 Birds

Lead poisoning resulting from the ingestion of lead shotgun pellets has been recognized as a cause of waterfowl deaths since the late 1800s (Wetmore 1919; Bellrose 1959). More than a million ducks — especially mallards — and geese die annually from lead shot poisoning (Clemens et al. 1975; Lumeij et al. 1989; Roscoe et al. 1989; Sanderson 1989; Whitehead and Tschartner 1991; Murase et al. 1993). The principal cause is the ingestion of spent shot by migrating birds feeding in heavily hunted areas. The pellets are retrieved from the marshy bottoms of shallow and deep water by waterfowl in search of food and grit. Shot retained in the gizzard is solubilized by a combination of the powerful muscular grinding action and the low pH (2.0 to 3.5) of gizzard contents. The released lead is available for absorption, producing weakened birds whose reproductive abilities are reduced and that may starve or fall prey to predators (Clemens et al. 1975). There does not appear to be a no-effect level for lead in waterfowl, and the activities of certain enzymes are inhibited at blood lead concentrations of <50 µg/L (Pain 1996). Ionic lead was 10 to 100 times more effective in reducing avian blood ALAD activity than were ionic copper, cadmium, and inorganic or methyl mercury (Scheuhammer 1987a). Absorbed lead causes a variety of effects leading to death, including damage to the nervous system, muscular paralysis, inhibition of heme synthesis, immunotoxic effects, and damage to kidneys and liver (Mudge 1983; Eisler 1988; Rocke and Samuel 1991). Lead poisoning in waterfowl is a debilitating disease in which death follows exposure in an average of 2 to 3 weeks (Friend 1985). During this time, affected birds lose mobility, tend to avoid other birds, and become increasingly susceptible to predation and other causes of mortality. Accordingly, acute large-scale die-offs of lead-poisoned waterfowl are uncommon (Friend 1985).

The relationship between incidence of lead shot in waterfowl gizzards and biological effects varies widely and is probably a function of shot availability caused by differences in shooting intensity, size of pellets, availability of grit, firmness of soil and sediments, and depth of surface water (Street 1983). Also, lead accumulations and the frequency of avian lead toxicosis following

ingestion of lead shot are modified by the age and sex of the bird, geographic location, habitat, and time of year (Finley and Dieter 1978; Mudge 1983; Srebocan and Rattner 1988). There is a growing body of evidence linking waterfowl poisoning with ingestion of lead-contaminated sediments, especially in certain areas of Idaho impacted by mining wastes (Chupp and Dalke 1965; Blus et al. 1991; Beyer et al. 1998a; Heinz et al. 1999). In the common bobwhite (*Colinus virginianus*), tissue lead accumulation can occur from ingestion of lead-contaminated sediments, although there were no signs of overt lead toxicity (Connor et al. 1994).

The effect of diet on vulnerability to lead makes interpretation of published information on experimental lead poisoning in waterfowl extremely difficult (Chasko et al. 1984). For example, many mallards on a diet of corn die within 10 to 14 days after ingesting a single lead shot, whereas similar birds on a balanced commercial duck ration appear outwardly normal after ingesting as many as 32 pellets of the same size (Wobeser 1981). Also, multiple nutritional deficiencies may have additional effects in potentiating the toxicity of lead in mallards (Carlson and Nielsen 1985). Under conditions of reduced dietary calcium availability, such as can occur in acid-impacted environments, birds risk increased uptake of lead (and other metals) and may accumulate toxic concentrations more rapidly (Scheuhammer 1996). Enhanced accumulation of lead was accompanied by an increased synthesis of metallothioneins and a greater inhibition of ALAD activity (Scheuhammer 1996).

Birds of prey may ingest lead in the form of shot from dead or crippled game animals, or as biologically incorporated lead from lead-poisoned waterfowl, small roadside mammals, and invertebrates (Stendell 1980; Pattee 1984; Franson 1996). Lead poisoning in carnivorous birds has been reported in various species of eagles, condors, hawks, harriers, owls, vultures, and falcons, and most — if not all — cases seem to result from ingestion of lead shot in food items (Custer et al. 1984; Wiemeyer et al. 1988; Nelson et al. 1989; Craig et al. 1990; Pain and Amiard-Triquet 1993; Pain et al. 1993a, 1993b, 1995). Some raptors ingest many shot in a short time. For example, the stomach of a bald eagle suspected of dying from lead poisoning contained 75 shot (Jacobson et al. 1977). Results of experimental lead shot poisoning of bald eagles ([Table 4.7](#)) confirmed results of nationwide monitoring showing that 5.4% of all dead eagles found in 1974/1975 died of lead poisoning, as evidenced by liver lead levels of 23 to 38 mg/kg fresh weight (Pattee et al. 1981). Ingestion of food containing biologically incorporated lead, while contributing to the lead burden of carnivorous birds, is unlikely in itself to cause clinical lead poisoning (Custer et al. 1984). A similar case is made for lead residues in soil and biota following field applications of lead arsenate (Stendell et al. 1989), for powdered lead (Franson et al. 1983), and forms of lead other than shot ([Table 4.7](#)). The strong indication is that the form in which lead is ingested is crucial.

Signs of lead poisoning in birds have been extensively documented (Bellrose 1951, 1959; Jordan and Bellrose 1951; Clemens et al. 1975; Forbes and Sanderson 1978; Hunter and Wobeser 1980; Pattee et al. 1981; Wobeser 1981; Franson and Custer 1982; Johnson et al. 1982; Eastin et al. 1983; Kendall and Scanlon 1983; Street 1983; Di Giulio and Scanlon 1984; Fimreite 1984; Gjerstad and Hanssen 1984; Hudson et al. 1984; Anderson and Havera 1985; Burger and Gochfeld 1985; Carlson and Nielsen 1985; Friend 1985; Hoffman et al. 1985a; Lumeij 1985; Beyer et al. 1988, 1998c; Scheuhammer and Wilson 1990; Lawler et al. 1991; Murase et al. 1993; Ochiai et al. 1993b; Franson 1996; Pain 1996). Outwardly, lead-poisoned birds show the following signs:

- Loss of appetite
- Lethargy
- Weakness
- Emaciation
- Tremors
- Drooped wings
- Green liquid feces
- Impaired locomotion, balance, and depth perception

Internally, lead-poisoned birds show:

- Microscopic lesions of the proventricular epithelium, pectoral muscles, brain, proximal tubular epithelium of the kidney, and bone medullary osteocytes
- An enlarged bile-filled gall bladder
- Anemia
- Elevated protoporphyrin IX levels in blood
- Decreased ALAD activity levels in blood, brain, and liver
- Reduced brain weight
- Abnormal skeletal development
- Cephalic edema
- Esophageal impaction

Postmortem examination of lead-poisoned birds may show:

- Edematous lungs
- Serous fluid in the pleural cavity
- Bile regurgitation
- Abnormal gizzard lining
- An unusually pale, emaciated, and dehydrated carcass
- Elevated lead levels in liver (>2 mg/kg fresh weight, >10 mg/kg dry weight), kidney (>6 mg/kg dry weight), and blood (> 0.2 mg/L)

Beyer et al. (1998c) aver that the most reliable indicators of lead poisoning in waterfowl include impactions of the upper alimentary tract, submandibular edema, myocardial necrosis, biliary discoloration of the liver, and hepatic lead concentrations of at least 38 mg/kg DW or 10 mg/kg FW.

Toxic and sublethal effects of lead and its compounds on birds held under controlled conditions vary widely with species, with age and sex, and with form and dose of administered lead (Table 4.7). Several generalizations are possible: decreased blood ALAD and increased protoporphyrin IX activity levels are useful early indicators of lead exposure; lead shot and certain organolead compounds are the most toxic forms of lead; nestlings are more sensitive than older stages; and tissue lead concentrations and pathology both increase in birds given multiple doses over extended periods (Scheuhammer 1987a, 1987b; Table 4.7). Blood lead concentrations of lead-poisoned waterfowl may be reduced with initiation of disodium calcium ethylenediamine tetraacetate therapy; however, ALAD levels remained depressed (Murase et al. 1993).

Trialkyllead salts are 10 to 100 times more toxic to birds than are inorganic lead salts; they tend to accumulate in lipophilic soft tissues in the yolk and developing embryo, and have high potential as neurotoxicants (Forsyth et al. 1985). Accordingly, more research is needed on alkyllead toxicokinetics. Some alkyllead compounds have been implicated in bird kills. In autumn 1979, about 2400 birds of many species were found dead or disabled on the Mersey estuary, England, an important waterfowl and marsh bird wintering area; smaller kills were observed in 1980 and 1981 (Bull et al. 1983). Affected birds contained elevated lead concentrations in liver (>7.5 mg/kg fresh weight), mostly as organolead. Bull et al. (1983) suggested that trialkyllead compounds were discharged from a petrochemical factory producing alkylleads into the estuary, where they were accumulated (up to 1.0 mg/kg fresh weight) by clams (*Macoma balthica*) and other invertebrates on which the birds could feed. Birds dosed experimentally with trialkyllead compounds died with the same behavioral and internal signs found in Mersey casualties; tissue levels of trialkyllead were similar in the two groups (Osborn et al. 1983). Sublethal effects that might influence survival in the wild were found in both sublethally dosed and apparently healthy wild birds when tissue levels of trialkyllead compounds were matched in the two groups. It was concluded that trialkyllead compounds were the main cause of the observed mortalities and that many apparently healthy birds were still at risk (Osborn et al. 1983).

Nestlings of altricial species (those confined to the nest for some time after hatch) may be considerably more sensitive to lead exposure than adults, and also more sensitive than hatchlings of many precocial species (Hoffman et al. 1985a). Hatchlings of precocial species, including chickens, Japanese quail (*Coturnix coturnix*), mallards, and pheasants, are relatively tolerant to moderate lead exposure, i.e., there was no effect on growth at dietary levels of 500 mg Pb/kg, or survival at 2000 mg Pb/kg (Hoffman et al. 1985a, 1985b).

Some species of domestic birds are comparatively resistant to lead toxicosis. For example, blood lead levels of 3.2 to 3.8 mg/L in lead-stressed cockerels (*Gallus* sp.) were much higher than residues considered diagnostic for lead poisoning in most domestic mammals (except swine, which tolerated up to 143 mg Pb/L blood) (Franson and Custer 1982). Captive wild ducks dosed with No. 4 lead shot in summer or winter were more sensitive than their domesticated counterparts, as judged by lower survival, and increased weight loss following lead shot administration and may be related to increased stress and unnatural diet (Rattner et al. 1989). Fatal lead poisoning (50% mortality) is documented for a captive colony of Gentoo penguins (*Pygoscelis papua*) in a zoo in Omaha, Nebraska. The source of lead was ankle weights worn by divers who cleaned the pool; the weights contained 1- to 2-mm lead pellets that were expelled through faulty seams and ingested by the penguins (Brown et al. 1996).

Table 4.7 Lethal and Sublethal Effects of Lead to Selected Species of Birds

Species, Route of Administration, Dose, and Other Variables	Effects	Reference ^a
<i>Northern pintail, Anas acuta</i>		
Single oral dose of 2 No. 5 pellets	No difference from control group in band recovery rate from hunter kills	1
<i>Mallard, Anas platyrhynchos</i>		
Single oral dose of 1 No. 4 shot	Some deaths. Residues (mg/kg fresh weight) >3 in brain, >10 in clotted heart blood, >6 in kidney, and up to 20 in liver	2
Single oral dose of 1 No. 4 shot (0.2 g)	Blood lead concentrations, in mg/L, increased from <0.1 at start to 0.1 after 24 h, 3.2 at 7 days, to 6.8 at 14 days. There were some deaths at day 21 and survivors had 0.6 mg Pb/kg blood FW. All dosed birds had immunosuppressive effects, as seen by lowered hemagglutination titers to sheep red blood cells	42
Intubated with 1 or 2 No. 4 commercial lead pellets; blood taken at 4, 8, and 24 h after death	In dead birds, blood lead declined from 6.0 mg Pb/kg FW 4 h after death, to 5.5 at 8 h, to 3.4 at 24 h; survivors had 10.5–13.9 mg Pb/kg FW during this interval	41
Single oral dose 1 No. 6 shot	Mortality 9% in 20 days	3
1 No. 4 shot	Mortality 19% in 20 days	3
2 No. 6 shot	Mortality 23% in 20 days	3
4 No. 6 shot	Mortality 36% in 20 days	3
6 No. 6 shot	Mortality 50% in 20 days	3
8 No. 6 shot	Mortality 100% in 20 days	3
Single oral dose of 1 No. 4 shot (205 mg), equal to 151 mg/kg body weight (BW)	Some deaths; blood ALAD activity depressed 30% after 3 months, 15% after 4 months	4
Single oral dose of 1 No. 4 lead shot (200 mg)	Residues (mg/kg dry weight femur) 488 in laying hen, 114 in nonlaying hen, and 9 in drake	5
Single oral dose of 1 shot (200 mg)	After 30 days, residues (mg/kg fresh weight) 1.0 in blood, 2.5 in liver, and 0.5 in brain. Decrease in ALAD activity in blood and cerebellum	6
Single oral dose of shot	Dosed birds recaptured in significantly greater numbers than controls	7

Table 4.7 (continued) Lethal and Sublethal Effects of Lead to Selected Species of Birds

Species, Route of Administration, Dose, and Other Variables	Effects	Reference^a
Single oral dose of tetraethyllead	LD50 of 107 mg/kg BW. Signs of intoxication included excessive drinking, regurgitation, hypoactivity, muscular incoordination, fluffed feathers, eyelid drooping, tremors, and loss of appetite. Regurgitation within 7 min, other signs as soon as 20 min, and death usually between 1 and 4 days posttreatment. Remission took up to 8 days	34
Fed diets containing 25 mg Pb/kg, as lead nitrate, for 12 weeks	No deaths; no pathology; no significant accumulations of lead in liver, kidney, or bone; no changes in hemoglobin or hematocrit; decrease in blood ALAD activity, and increase in blood lead levels — both returned to normal diet within 3 weeks on lead-free diet	8
Females fed diets for 12 weeks containing 80 mg Pb/kg ration (as lead acetate) alone or in combination with 8 mg Hg/kg (as methylmercury chloride), or 80 mg Cd/kg ration (as cadmium chloride), or a mixture of Pb, Hg, and Cd	Renal corpuscles of ducks fed Pb, Hg, or Cd alone or in two-way combinations had minor ultrastructural changes when compared to controls. The diet containing all three metals caused marked ultrastructural changes in kidney	40
Fed diets containing 100 mg Pb ⁺² /kg	Elevated levels in bone (9.6 mg/kg fresh weight vs. 0.7 in controls) and egg (1.3 vs. 0.9 in controls)	9
Fed diets containing metallic lead for 42 days 100 mg/kg diet	Elevated lead levels (mg/kg dry weight) in kidney (23), liver (7), and bone (5)	10
10 mg/kg diet	Residues (mg/kg dry weight) of 4 in kidney (vs. <0.5 in controls), 0.7 in liver (vs. <0.5 in controls), and 0.8 in bone (vs. 0.9 in controls)	10
Adult males, age 16 weeks, fed pelleted commercial duck diet for 10 weeks; diet formulated to contain 24% lead-contaminated sediment (3400 mg Pb/kg DW sediment = 816 mg Pb/kg DW total diet)	1 of 10 died vs. none in controls; survivors had atrophied breast muscles, green staining of feathers around the vent, viscous bile; green staining of the gizzard lining, and renal intranuclear inclusion bodies. Blood had 6.1 mg Pb/kg FW, liver had 2.8 mg Pb/kg FW, and feces had 1660 mg Pb/kg DW	61
Adult males, age 7 months, fed ground corn diet for 15 weeks; diet contained 24% lead-contaminated sediment (4000 mg Pb/kg DW sediment = 960 mg Pb/kg total diet)	80% dead (4 of 5); livers had 38 mg Pb/kg DW	61
As above, except mallards were fed a nutritionally balanced commercial duck diet containing 24% lead-contaminated sediments (4000 mg Pb/kg DW sediment)	No deaths; livers had 13 mg Pb/kg DW	61
Held in 1.6 ha enclosures on hunted or nonhunted wetlands; California; 1986–89; lead shot pellet density in enclosures were 15,750, 173,200, or >2 million/ha	Blood lead concentrations increased, and survival reduced with increasing shot density	39
Ducks, Anas spp.		
Single oral dose of 2 shot (254 mg) or 5 shot (635 mg)	Weight loss, emaciation, elevated lead concentrations in bone, some deaths. American black duck, <i>Anas rubripes</i> , more sensitive than mallards	11
Birds		
Dietary route, 11 species, diagnosed as lead poisoned	All had inclusions in proximal convoluted tubules of kidney; liver lead residues ranged from 3.1 to 15 mg/kg fresh weight	12

Table 4.7 (continued) Lethal and Sublethal Effects of Lead to Selected Species of Birds

Species, Route of Administration, Dose, and Other Variables	Effects	Reference^a
Lethal dietary administration of lead acetate, 6 species	Before death, birds were emaciated and showed increases in blood protoporphyrin and decreases in ALAD; renal intranuclear inclusion bodies were present in 83% of all birds that died from lead poisoning. Median lead concentrations (mg/kg fresh weight) ranged in the liver from 20 in male red-winged blackbirds (<i>Agelaius phoeniceus</i>) to 111 in female northern bobwhites (<i>Colinus virginianus</i>), and in the kidney from 22 mg/kg in the blackbird to 190 in the bobwhite	13
<i>Canada goose, Branta canadensis</i>		
Oral dose of 4 to 5 No. 4 shot	Lethal	43
<i>Red-tailed hawk, Buteo jamaicensis</i>		
Exposed daily via oral gavage to sublethal concentrations of 0.82 mg Pb/kg BW (given as 1.5 mg lead acetate /kg BW daily) for up to 11 weeks	Alterations in the heme biosynthetic pathway noted after 7 days. Erythrocyte ALAD activity was depressed and did not recover until 5 weeks after termination of lead treatments	45
Fed 0.82 or 1.64 mg Pb/kg BW daily as lead acetate for 3 weeks	No effect on gastric contractions or egestion of pellets of undigested materials	44
Fed 6.56 mg Pb/kg BW daily for 3 weeks as lead acetate	No effect on frequency or timing of pellet egestion	44
<i>Common bobwhite, Colinus virginianus</i>		
Fed diet for 21 days in which sediments (4.5 g Pb/kg DW) from a lake in northern Idaho contaminated with mining wastes was added to ground poultry ration at 8% dry matter intake, equivalent to about 550 mg Pb/kg DW ration	No effect on food intake or growth. Blood and tissue lead levels elevated, but no overt signs of lead toxicity. Lead concentrations (controls vs. dosed birds) were 0.6 vs. 1.3 mg/kg FW in blood, <0.1 vs. 7 mg/kg DW in liver, and <0.1 vs. 30 mg/kg DW in kidney	46
<i>Rock dove, Columba livia</i>		
Intragastric administration of 6.25 mg Pb (as lead acetate)/kg BW, daily for 64 weeks	Anemia, elevation in erythrocyte porphyrin, kidney pathology; residues (mg/kg fresh weight) of 603 in kidney, 501 in bone, 8 in liver, 2 in brain, 4.4 in blood, 0.8 in sciatic nerve, and 0.1 in crop	14
Intubation of 6.25 mg Pb (as lead acetate)/kg BW, chronic exposure	Interfered with four-step learning sequence; elevated blood lead levels remained for 5 weeks after lead exposure	15
<i>Japanese quail, Coturnix japonica</i>		
Single oral dose of tetraethyllead	LD50 of 24.6 mg/kg BW	38
Fed diets containing different forms of lead for 5 days		
5000 mg metallic Pb/kg	No effect on survival or food consumption	16
5000 mg Pb (as lead nitrate)/kg	No overt signs of toxicity	16
5000 mg Pb (as lead subacetate C ₄ H ₁₀ O ₈ Pb ₃)/kg	No overt signs of toxicity	16
2761 mg Pb(as lead arsenate)/kg	LD50	16
<i>Prairie falcon, Falco mexicanus</i>		
Fed shotgun-killed pheasants and ducks	Death, preceded by vomiting, ataxia, blindness, and convulsions. Lead shot recovered from stomach; residues (mg/kg dry weight) of 57 in liver and 78 in kidney	17

Table 4.7 (continued) Lethal and Sublethal Effects of Lead to Selected Species of Birds

Species, Route of Administration, Dose, and Other Variables	Effects	Reference^a
American kestrel, <i>Falco sparverius</i>		
Fed mallard homogenate containing 16 to 87 (biologically incorporated) mg Pb/kg fresh weight (FW) for 60 days	Residues of 0.4 mg/kg fresh weight in liver and 7.6 mg/kg dry weight in bone	18
Oral administration of 1 No. 9 shot daily for 60 days	Residues (mg/kg FW) of 0.4 in liver and 28.7 in bone	18
Fed control diet with 0.4 mg Pb ⁺² /kg FW	Residues of 0.1 mg/kg fresh weight in liver and 4.2 mg/ kg dry weight in bone	18
Fed pine voles (<i>Microtus pinetorum</i>) containing 38 mg Pb/kg whole-body FW (from apple orchards treated with lead arsenate) for 60 days vs. controls fed uncontaminated laboratory mice (<i>Mus musculus</i>)	At end of study kestrels had 1 mg Pb/kg FW liver vs. 0.06 in controls, and 0.7 mg/kg FW bone vs. 0.27 in controls	47
Fed diets containing 50 mg metallic Pb powder/kg for at least 5 months	Blood ALAD reduced 80%; liver residues of 1.3 to 2.4 mg/kg dry weight; no effects on blood chemistry	19
As above, except diet contained 10 mg/kg	No measurable effects	19
Fed diets containing metallic Pb powder for 6 months		
50 mg Pb/kg diet	No adverse effects on survival, egg laying, fertility, or eggshell thickness. Elevated residues (mg/kg dry weight) in humerus (13), tibia (62), and liver (2)	20
10 mg Pb/kg diet	Elevated lead in bone (4 to 9 mg/kg dry weight vs. <0.8 in controls) and in liver (3 vs. <0.5 in controls)	20
Nestlings dosed orally with metallic lead powder daily for 10 days		
625 mg/kg BW	Mortality (40% in 6 days); reduced growth; reduced kidney and liver weight; abnormal skeletal development; ALAD depression in all tissues examined; elevated burdens (mg/kg fresh weight) in kidney (15), liver (6), and brain (3)	21
125 mg/kg BW	Reduced growth, reduced brain weight, abnormal skeletal development, ALAD depressions in hematopoietic tissues, elevated burdens (mg/kg fresh weight) in kidney (7), and liver (4)	21
25 mg/kg BW	ALAD depression in all tissues examined; burdens (mg/kg fresh weight) elevated in kidney (3) and in liver 1.4)	21
Fed 60 days with cockerels (<i>Gallus</i> sp.) containing up to 448 mg (biologically incorporated) Pb/kg dry weight	No effect on survival, growth, hemoglobin, hematocrit, and erythrocyte number. Elevated burdens in kidney, liver, femur, brain, and blood	22
Chicken, <i>Gallus</i> sp.		
Fed diets containing 1.85 g Pb/kg, as lead acetate, for 4 weeks	No deaths or severe clinical hematological effects; growth rate suppressed 47%, blood lead residues 3.2 to 8.3 mg/L	23
Bald eagle, <i>Haliaeetus leucocephalus</i>		
Oral administration of 10 No. 4 shot (2000 mg)		
Eagles dying 10 to 133 days posttreatment	Residue levels (mg/kg dry weight) 0.9 in muscle, 1.4 in brain, 6 in kidney, 10 in tibia, 10.3 in humerus, 10.4 in femur, and 16.6 in liver. Loss in body weight 16% to 23% at death	24

Table 4.7 (continued) Lethal and Sublethal Effects of Lead to Selected Species of Birds

Species, Route of Administration, Dose, and Other Variables	Effects	Reference^a
Eagle sacrificed at day 133 posttreatment (bird went blind)	Residue levels (mg/kg dry weight) <0.1 in muscle, 2.1 in brain, 3.2 in kidney, 3.4 in liver, and 12.2 to 13.8 in bone	24
Controls	Residue levels (mg/kg dry weight) <0.1 muscle, 0.1 in brain, 0.4 in liver, 0.5 in kidney, and 4.5 to 6.6 in bone	24
<i>Willow ptarmigan, Lagopus lagopus</i>		
Single oral dose		
1 No. 6 shot (100 mg)	Weight loss of 12% in 15 days; residues of 3.3 mg/kg fresh weight in liver, 56 mg/kg dry weight in tibia	25, 26
3 No. 6 shot (300 mg)	Some deaths between days 8 and 15 posttreatment, reduced food intake, weight loss, lethargy, diarrhea; residues of 7.3 mg/kg fresh weight liver, 139 DW tibia	25, 26
6 No. 6 shot (600 mg)	If shot retained in gizzard, death resulted; residues (mg/kg) 72 fresh weight in liver, 154 dry weight in tibia	25, 26
Controls	Residues (mg/kg) 0.1 fresh weight in liver, 5 dry weight in tibia	25, 26
<i>Raptors, 4 spp.</i>		
Fed rock doves (<i>Columba livia</i>) and brown hares (<i>Lepus europaeus</i>) with lead shot for 3 weeks to 6 months	Death preceded by weight loss, convulsions, and inability to fly. Residues (mg/kg dry weight) at death ranged from 57 to 175 in liver, and 34 to 221 in kidney	27
<i>Herring gull, Larus argentatus</i>		
Chicks aged 2 days given intraperitoneal (ip) injection of 0.1 or 0.2 mg Pb/kg BW as lead nitrate and killed after 45 days	Dose-dependent increases in all tissues measured. Largest changes were in bone with controls at 0.8 mg/kg DW, the 0.1 mg/kg at 54 and the high-dose group at 131 mg/kg DW; for liver, these values were 0.05, 7, and 22, respectively; for blood, 0.01, 0.07, and 0.2; for kidney, 0.1, 7, and 41; for brain, 0.01, 0.3, and 1.6; and for muscle 0.01, 0.07, and 0.17 mg/kg DW, respectively	48
Chicks age 1 day given single ip injection of 100 or 200 mg Pb/kg BW as lead nitrate	Dose-dependent decrease in growth rate for at least 40 days postinjection; wing and tarsus bone development inhibited at end of 46-day study	50
Chicks age 1 day given single ip injection of 100 mg Pb/kg BW as lead nitrate at ages 1, 2, 4 or 6 days	Chicks were most sensitive at age 6 days than earlier stages judged by behavioral effects including balance and thermoregulation	51
Chicks, age 2 days, given a single ip injection of 0, 100, or 200 mg Pb/kg BW as lead nitrate and observed for 45 days	Control birds performed better than lead-injected gulls in begging behavior, balance and righting response, depth perception and thermoregulation behavior	49
<i>Zebra finch, Poephila guttata</i>		
Given drinking water with 10 mg Pb/L for 51 days; diets were either low in calcium (0.3% Ca) or adequate in calcium (3% Ca)	Birds given low calcium diets accumulated up to 4 times more lead in tissues than finches on high calcium diets. Lead concentrations in mg/kg DW for low Ca vs. high Ca diets were 2.4 vs. 0.6 in liver, 4.9 vs. 1.5 in kidney, and 48 vs. 8 in bone	52

Table 4.7 (continued) Lethal and Sublethal Effects of Lead to Selected Species of Birds

Species, Route of Administration, Dose, and Other Variables	Effects	Reference^a
Common tern, <i>Sterna hirundo</i>		
Single injection of 200 mg Pb ⁺²	Adverse effects on behavior (locomotion, balance, righting response, feeding tasks, behavioral thermoregulation); most apparent within 5 days postinjection	28
Chicks injected ip with 200–1200 mg Pb/kg BW as lead nitrate		
All birds	Dose-dependent changes in locomotion, survival, and righting response	53
100 mg/kg BW	Adverse effects	53
200 mg/kg BW	After 21 days, reduced growth rate, impaired motor coordination of head and neck, and reduced ability to manipulate fish prey	54
1000 mg/kg BW	LD50 at day 17 postinjection	53
1200 mg/kg BW	LD100 at day 17 postinjection	53
Ringed turtle-dove, <i>Streptopelia risoria</i>		
Single ip injection of 2.5 mg Pb/kg BW	No effect on hepatic ALAD activity; renal ALAD decreased with increasing lead deposition in kidney	55
Single oral dose of 2 pellets (220 mg)	Blood lead (mg/L) 4.69 at 24 h, and 0.14 at 14 days (vs. control values of 0.004 to 0.012 mg/L); blood ALAD depressed from 24 h through 14 days	29
Single oral dose of 4 shot (440 mg)	Mortality 71% at 6°C in 7 days; nil at 21°C in 9 days — but some with seizures and kidney histopathology. No spermatozoa in seminiferous tubules. Lead residues elevated in bone, liver, and brain in both groups, but more elevated in cold-stressed group	30, 31
Single oral dose of 4 shot (440 mg)	Testicular damage in adults held at 6°C or 21°C; mortality higher in cold-stressed group	32
Single oral dose of 4 shot (488 mg)	Some deaths. Intranuclear inclusion bodies in cells of kidney proximal convoluted tubules	12
Single oral dose of 75 mg Pb/kg BW, as lead acetate	Some deaths; kidney damage	12
Intubation with 75 mg Pb (as lead acetate)/kg BW daily for 7 days	Residues, (mg/kg dry weight) 457 in kidney, 29 in liver, and 12.4 in brain; seizures; depressed blood ALAD activity; blood lead concentration 311 µg/L	33
Controls	Concentrations (mg/kg DW) 8.2 in kidney, 3.0 in brain, 1.2 in liver; blood lead concentration 18 µg/L	33
Drinking water with 100 µg Pb ⁺² /L for 2 weeks before pairing, and throughout a breeding cycle	Reduction in testes weight and spermatozoa number. No effect on egg production or fertility. Bone lead levels higher than controls especially in females. Significantly higher lead concentrations in bone, liver, and feather in progeny of lead-treated parents than in controls	34
European starling, <i>Sturnus vulgaris</i>		
Oral administration (capsule) of triethylPb chloride at 2000 µg daily (28 mg/kg BW) for 11 days or until death	Mortality 100% by day 6. Dying birds showed decreased respiration, squatting, fluffed feathers, and abnormal head posture. Mean residues (mg/kg fresh weight) were 6.0 in bone, 7.3 in brain, 19.9 in kidney, 20.0 in muscle, and 40.2 in liver	35
As above, but dose was 200 µg daily (2.8 mg/kg BW)	No deaths, reduced food consumption. All tissue residues <2.0 mg/kg fresh weight (vs. <0.1 in controls)	35

Table 4.7 (continued) Lethal and Sublethal Effects of Lead to Selected Species of Birds

Species, Route of Administration, Dose, and Other Variables	Effects	Reference ^a
Oral administration of trimethylPb chloride capsule of 2000 µg daily (28 mg/kg BW) for 11 days or death	All dead by day 6. Signs included impaired balance, tremors, fluffed feathers, uncoordinated feeding movements, weight loss, inability to fly. Residues (mg/kg FW) averaged 4.3 in bone, 11.0 in muscle, 16.7 in brain, 30.2 in kidney, and 82.4 in liver	35
As above, but dose was 200 µg daily (2.8 mg/kg BW)	No deaths, survivors hyperactive. Average tissue residues (mg/kg fresh weight) 0.4 in bone, 3.1 in muscle, 3.5 in brain, 3.7 in liver, and 5.4 in kidney	35
Starlings from pristine area in Poland were exposed in cages for 8 days near a zinc smelter	Tissue lead concentrations were 3 to 12 times higher after 8 days; stomach content lead levels increased from 2 mg/kg DW to 532, and feces increased from 0.4 to 154 mg Pb/kg DW	56
Mourning dove, Zenaida macroura		
Single oral dose of 0, 1, 2, or 4 No. 8 shot and observed for 28 days	Dose-dependent weight loss, but survivors regained weight with passing of shot. Blood ALAD levels in all dosed groups declined 95–99% within 24 h and remained depressed; mortality was not dose-related	57
As above	Blood lead concentrations rose from 0.06 mg Pb/L prior to dosing to more than 6 mg Pb/L 5 to 9 days after dosing	58
Single oral dose 1 No. 8 shot (72 mg)	Mortality 24% in 4 weeks; normal courtship and reproductive activities, but egg hatching significantly reduced; lead residues elevated in kidney, liver, and bone	36
1 No. 8 shot and held at 5 or 22°C and fed commercial pelleted ration or mixed seed	Tissue lead residues were higher in Pb-dosed birds. Doves on the pelleted diet retained shot longer and eroded more lead than did doves on the mixed seed diet. Temperature had no measurable effect on lead residues	59
Force-fed 1 No. 8 shot vs. force-fed millet seed. All doves were fitted with a radiotransmitter, released, and movements recorded for 21 days	Survival was about 60% for controls and 40% for lead-treated group, but this was not statistically significant	60
2 No. 8 shot (144 mg)	Mortality 60% in 4 weeks	36
4 No. 8 shot (288 mg)	Mortality 52% in 4 weeks	36
Single oral dose of 4 No. 8 shot	Residues (mg/kg dry weight) 345 to 639 in kidney and 58 to 215 in liver (vs. <12 in controls)	37
4 days posttreatment	Residues (mg/kg dry weight) 1279 to 1901 in kidney and 179 to 267 in liver	37
8 days posttreatment

4.6.6 Mammals

Three stages of recognizable lead poisoning, or plumbism, have been reported in humans (NRCC 1973): (1) mild or severe dysfunction of the alimentary tract as shown by loss of appetite, constipation, abdominal cramps, headaches, general weakness, and fatigue; (2) atrophy of forearm extensor muscles, or paralysis of these muscles and more striking atrophy; and (3) lead encephalopathy, which occurs frequently in lead-poisoned infants and young children, but only rarely in industrial workers. In general, people with hepatitis, anemia, and nervous disorders were more susceptible to lead poisoning (Barth et al. 1973). The transfer of lead across the human placenta and its potential threat to the fetus have been recognized for more than 100 years; women occupationally exposed to lead show a comparatively high abortion rate (Tachon et al. 1983). Sensitivity of the brain to the toxic effects of lead is considerably greater in the fetus than in the infant or young child (USEPA 1980). Lead is not considered carcinogenic to humans (Tsuchiya 1979), but reports of chromosomal aberrations in human blood lymphocytes (Barth et al. 1973) suggest that lead is a probable mutagen.

Signs of plumbism in domestic and laboratory animals, which are similar to those in humans, have been well documented (Barth et al. 1973; NRCC 1973; Mierau and Favara 1975; Davies et al. 1976; Roberts et al. 1976; Forbes and Sanderson 1978; Nriagu 1978b; Osweiler and Van Gelder 1978; Tsuchiya 1979; Ward and Brooks 1979; USEPA 1980; Mahaffey et al. 1980; Hamir 1981; Harrison and Laxen 1981; Burrows and Borchard 1982; Demayo et al. 1982; Hamir et al. 1982; Mykkanen et al. 1982; Tachon et al. 1983; Gietzen and Wooley 1984; Berglind et al. 1985; Ma 1996; [Table 4.8](#)). There is general agreement on several details: significant differences occur between species in response to lead insult; effects of lead are more pronounced with organolead than inorganic lead compounds; younger developmental stages are the most sensitive; and the effects are exacerbated by elevated temperatures, and by diets deficient in minerals, fats, and proteins. Tetramethyllead, for example, is about seven times more toxic than tetraethyllead to animals, and both compounds showed toxic effects earlier than did inorganic lead compounds. In severe cases, death is usually preceded by impairment of normal functions of the central nervous system, the gastrointestinal tract, and the muscular and hematopoietic systems. Signs include vomiting, lassitude, loss of appetite, uncoordinated body movements, convulsions, stupor, and coma. In nonfatal cases, signs may include depression, anorexia, colic, disturbed sleep patterns, diarrhea, anemia, visual impairment, blindness, susceptibility to bacterial infections, excessive salivation, eye blinking, renal malfunction, peripheral nerve diseases affecting the motor nerves of the extremities, reduced growth, reduced life span, abnormal social behavior, and learning impairment. Lead crosses the placenta and is passed in milk, producing early intoxication of the fetus during pregnancy and the newborn during lactation. High lead doses in mammals induce abortion, reduce or terminate pregnancy, or can result in stillbirths or an increase in skeletal malformations. These signs, together with lead levels in blood and tissues and histopathological examination, are used to diagnose lead poisoning. The best overall predictors of the risk of clinical lead effects in mammals are the blood lead concentrations and the erythrocyte protoporphyrin values, because they correlate with most toxicity endpoints of either neurological, renal, hematopoietic, or musculoskeletal nature (Ma 1996).

Lead adversely affected the survival of sensitive mammals tested at different concentrations ([Table 4.8](#)): 5 to 108 mg Pb/kg BW in rats (acute oral), 0.32 mg Pb/kg BW daily in dogs (chronic oral), and 1.7 mg Pb/kg diet in horses (chronic dietary). Adverse sublethal effects ([Table 4.8](#)) were noted in monkeys given 0.1 mg Pb/kg BW daily (impaired learning 2 years postadministration) or fed diets containing 0.5 mg Pb/kg (abnormal social behavior); in rabbits given 0.005 mg Pb/kg BW (reduced blood ALAD activity) or 0.03 mg Pb/kg BW (elevated blood lead levels); in mice at 0.05 mg Pb/kg BW (reduced ALAD activity); or in sheep at 0.05 mg Pb/kg BW (tissue accumulations).

Although lead is undeniably toxic at high levels of exposure, the implications of lower levels of exposure are poorly defined (Nriagu 1978b). Behavioral effects such as hyperactivity, distractibility, and decreased learning ability, as well as certain peripheral neuropathies, have been ascribed to subclinical lead exposure (Hejtmancik et al. 1982). Impaired learning ability of lead-stressed animals showing no obvious signs of lead intoxication has been documented for rats (Cory-Slechta

et al. 1981, 1983, 1985; Angell and Weiss 1982; Nation et al. 1982; Geist et al. 1985; Massaro et al. 1986), sheep (Nriagu 1978b; USEPA 1980), and primates (Rice 1985), although variability was great in all studies. Some learning deficits may be reversible and may not persist beyond a period of rehabilitation (Geist et al. 1985), and some may be induced only at relatively high exposure levels (Hastings et al. 1984). Abnormal social behavior (usually aggression) has been reported in baboons and monkeys (Hopkins 1970; Nriagu 1978b), although mice showed inhibited development of isolation-induced aggression (Ogilvie and Martin 1982). Altered parent-child relationships were suggested when suckling rats were used as surrogates. In that study, pregnant rats fed diets containing powdered lead nursed for longer periods than normal, and their offspring were slower to explore their environment (Barrett and Livesey 1983). Lead-exposed pups, with blood lead levels as low as 200 µg/L (considered elevated but within the “normal” range) at weaning, showed an altered dam-pup interaction that resulted in the dam spending longer periods in the nest than usual. Retarded development of lead-treated pups may account for the longer bouts of nesting by lead-stressed dams, and the delay in age at which pups explore and learn. Barrett and Livesey (1983) concluded that maternal behavior was related to delays in pup development, and that the functional isolation of pups from their environment may be the antecedent to altered behavior later in maturity. No data are currently available on effects of lead-induced altered parent-offspring relationships, impaired learning ability, or abnormal social behavior for any population of free-ranging wildlife.

Ingestion of lead-containing paint from bars or walls is a significant cause of death among captive wild animals (including many species of apes, monkeys, bears, ferrets, pinnipeds, foxes, panthers, bats, raccoons, and armadillos) and is probably underreported (Hopkins 1970; Zook et al. 1972; Fowler 1975; Forbes and Sanderson 1978; Sill et al. 1996). A similar situation exists for domestic animals — including dogs, cats, goats, horses, swine, cattle, and sheep (Dollahite et al. 1978; Forbes and Sanderson 1978; Osweiler and Van Gelder 1978; Hamir 1981). Passage of laws regulating the amount of lead in paint has decreased the frequency of lead poisoning, but many animals are still at risk from this source. Lead also occurs in used motor oils, gasoline, batteries, shot, putty, golf balls, linoleum, and printers’ ink — all of which are considered sources of lead poisoning to domestic animals (Dollahite et al. 1978).

Although the use of lead arsenate as an insecticide in orchards is diminishing, residues of lead still remain in the upper soil surface and will continue to be bioavailable almost indefinitely (Gilmartin et al. 1985).

Naturally occurring radiolead-210, which has a half-life of 22 years, is a significant contributor to the natural radiation dose in man. Comparatively high levels have been reported in certain grasses and lichens, and their consumers, such as reindeer, caribou, and ptarmigan, as well as in lanternfishes (Nriagu 1978b). The implications of this finding to wildlife health are unknown.

Treatment of lead-poisoned animals usually involves the removal of ingested lead objects and treatment with antibiotics. For example, a captive bottlenose dolphin (*Tursiops truncatus*) that had 40 lead-containing air pellets in its second stomach, as determined by radiography, was treated with 250 mg penicillamine/kg BW given orally 3 times daily for 5 days after the pellets had been removed from the stomach using an endoscope (Shlosberg et al. 1997). Anemia in chimpanzees (*Pan troglodytes*) is sometimes associated with lead toxicity (Young et al. 1994). In one case, a 19-year-old female chimpanzee with a history of excessive menstrual bleeding had a blood serum level of 1.03 mg Pb/L. The animal was successfully treated using oral chelation therapy: 2,3-dimercaptosuccinic acid at 10 mg/kg BW *per os* for 5 days, then 10 mg/kg BW for 2 weeks (Young et al. 1994).

Table 4.8 Lethal and Sublethal Effects of Lead to Selected Species of Mammals

Species, Dose, and Other Variables	Effects	Ref. ^a
Wood mouse, <i>Apodemus sylvaticus</i>		
Laboratory colony given drinking water containing 200 mg Pb/L as lead nitrate for 30 days; experimental vs. controls Femur	116.0 FW vs. 4.3 FW	33

Table 4.8 (continued) Lethal and Sublethal Effects of Lead to Selected Species of Mammals

Species, Dose, and Other Variables	Effects	Ref.^a
Kidney	13.9 FW vs. 3.5 FW	33
Liver	6.3 FW vs. 4.6 FW	33
Cattle, cows, <i>Bos spp.</i>		
Tissue lead (mg/kg FW) 0.81 in blood, 26.4 in liver, 50.3 in kidney, and 400 in rumen contents	Clinical Pb toxicosis observed	1
Calves given 2.7 mg Pb/kg body weight (BW), as lead acetate, for 20 days; milk diet	Death	2
Calves given 3.0 to 3.5 mg Pb/kg BW daily for 3 months; grain and hay diet	No effect	2
Calves given 5 mg Pb/kg BW, as Pb acetate, for 7 days; grain and hay diet	Appeared normal	3
Calves given 5 mg Pb/kg BW, as Pb acetate, for 7 days; milk diet	Signs of lead poisoning; some deaths	3, 4
Calves given 5 mg Pb/kg BW daily for 10 to 20 days	Blindness, 16% mortality	4
Calves given forage with 5 to 6 mg Pb/kg	Fatal in 2 months	1
Calves given 5 to 6 mg Pb/kg BW daily for 3 years	Chronic toxicity	2
Adults given 6 mg Pb/kg BW daily for 3 years	No deaths	5
Calves given 6 to 7 mg Pb/kg BW daily for 2 months	Fatal	2
Fed 6 to 7 mg Pb (as Pb acetate)/kg BW daily	Intoxication within 8 weeks; most dead at day 105	6
Consumed vegetation (17 to 20 mg Pb/kg fresh weight) near Pb battery recycling plant	Some deaths, mostly younger animals; neurological signs. Lead levels, in mg/kg fresh weight, were 13.8 to 35.8 in blood, 6.9 to 96.5 in feces, 97 in liver, and 138 in kidney. Histopathology of liver and kidney	7
Calves given 20 mg Pb/kg BW daily	Fatal in 8 to 22 days	2
Accidentally exposed for 10 days to toxic levels of Pb, as lead shot, through corn silage. Silage storage area received shot from a nearby trap shooting range. Silage contained 32 mg Pb/kg	1.5% dead (2/70), 27% with signs of poisoning (kidney pathology, hemorrhaging). Tissue lead concentrations of 16 mg/kg FW in liver, >32 in kidney, and up to 0.8 in blood	6
Calves, single oral dose of 220–400 mg Pb/kg BW, as lead acetate	LD50	2
Total dose of 50 to 100 grams	Toxic	6
Dog, <i>Canis familiaris</i>		
Fed 0.32 mg Pb/kg BW daily	Chronic toxic level	4
Fed 3 mg Pb/kg BW daily, as lead carbonate	Anorexia and convulsions at 180 days	8
Fed low calcium/phosphorus diet containing 100 mg Pb/kg, equivalent to about 3.5 mg Pb/kg BW	At 12 weeks, anemia, weight loss, and renal necrosis. Tissue lead levels (mg/kg fresh weight) 1.2 in brain, 1.7 in blood, 15.7 in spleen, 23.4 in liver, 32.2 in kidney, and 735 in bone	9
Total dose of 10–25 grams	Toxic	6
Goat, <i>Capra sp.</i>		
Total dose of 20–25 grams	Toxic	6
Guinea pig, <i>Cavia cobaya</i>		
Single intraperitoneal injection of 25 mg/kg BW, as lead acetate	Reduced brain weight of newborn pigs. Effects synergized when dams were exposed to elevated (42°C) temperatures for 24 h: 88% with microencephaly vs. 5% in group given 25 mg/kg without hyperthermia	10
Bank vole, <i>Clethrionomys glareolus</i>		
Females given diets containing 2, 60, 380, or 780 mg Pb/kg ration after giving birth to litters. Lead residues in whole young voles were determined for up to age 20 days	At day 20, whole body residues, in mg Pb/kg DW, were 13 in controls, 32 in the 60 mg/kg group 124 in the 380 mg/kg group, and 293 in the 780 mg/kg group. Growth rate was reduced in the 380 and 780 mg/kg groups and survival reduced in the 780 mg/kg group	34

Table 4.8 (continued) Lethal and Sublethal Effects of Lead to Selected Species of Mammals

Species, Dose, and Other Variables	Effects	Ref.^a
Horse, <i>Equus caballus</i>		
Tissue lead levels, in mg/kg fresh weight, of 0.39 in blood, 18 in liver, and 16 in kidney	Signs of clinical lead toxicosis observed	1
Ate forage containing 1.7 mg Pb/kg	Fatal in several months	1
Consumed 2.4 mg Pb/kg BW daily	Lethal	4
Fed 6.25 mg Pb/kg BW daily for 105 days, as lead acetate	No deaths; blood lead levels of 350–380 µg/L at day 105	6
Fed hay collected near Idaho smelter containing 423 mg Pb/kg, equivalent to about 4 mg Pb/kg BW daily	All dead in 84–100 days. Total ingested ranged from 136–154 grams	11
Fed 9.8 mg Pb/kg BW daily for 105 days, as lead acetate	No deaths; blood lead levels of 530–650 µg/L at day 105	6
Fed noncontaminated hay plus 10 mg Pg/kg BW daily, as lead acetate	All dead in 113 to 304 days. Total ingested ranged from 190–544 grams	11
Total dose of 500 to 700 grams	Toxic	6
Cat, <i>Felis domesticus</i>		
Fed pine voles (<i>Pitymys pinetorum</i>) from orchard sprayed with lead arsenate. Concentrations (mg Pb/kg dry weight) were 60.3 in whole voles, 5.7 in cat diet containing voles, and 3.2 in control cat diet	After 86 days, tissue residues elevated in cat kidney (1.3 mg Pb/kg dry weight vs. 0.2 for controls), liver (0.5 vs. 0.1), and bone (5.0 vs. 0.9)	12
Rabbit, <i>Lepus sp.</i>		
Given 0.9, 0.03, 0.06, 0.15, 0.3, or 3 mg Pb/kg BW for 6 days	Blood levels (µg Pb/L) increased from 170 (control) to 910 (0.03), 530 (0.06), 1430 (0.15), 1930 (0.3), and 5160 (3.0)	13
Exposed to 2.46 µg Pb/m ³ air for life >5 µg Pg/kg BW daily	No effect Reduced blood ALAD activity	13 13
Mouse, <i>Mus sp.</i>		
0.05 to 0.1 mg Pb/kg BW daily	Irreversible inhibition of ALAD activity in bone marrow and red blood cells	14
Tissue concentrations of 0.78 mg/kg femur bone marrow, 3.7 mg/L blood, 15.8 mg/kg brain, or 43 mg/kg liver	Inhibition of ALAD activity 50% within 10 min	14
1.5 mg Pb/kg BW daily, as tetraethyllead chloride	Reduction in success of implanted ova	8
2.2 mg/kg BW or 3 mg/kg BW daily, as tetraethyllead	Frequency of pregnancy reduced when dose given 3 to 5 days after mating	8
Pregnant females given single intrauterine injection of 20 mg Pb/kg BW on day 8 of gestation	Smaller litters, increased fetal deaths	15
800 mg Pb/L, as lead acetate, in drinking water for 11 weeks	Decrease in litter size, decreased survival of pups, and decreased birth weight	16
1000 mg Pb/L in drinking water for 9 months	No effect on survival or fertility	4
Sheep, <i>Ovis aries</i>		
Lambs fed 50 µg Pb/kg daily (about 3 mg)	Tissue accumulations	5
Lambs exposed to low levels (350 µg Pb/L blood) <i>in utero</i>	Impaired visual discrimination and learning behavior	17
1.0 mg Pb/kg BW daily, as lead acetate, for 3 months	Of 10 ewes, 3 aborted, 6 delivered normally, and 1 died; placental transfer of lead established	5
Pregnant ewes given 3 mg Pb/kg BW daily	No effect	4
4.2 mg Pb/kg BW in diet for 4 weeks before gestation, and throughout gestation and lactation	Lambs showed impaired learning	18
Fed 5 mg Pb/kg BW first 45 days of pregnancy	Bore normal full-term lambs	9
Given 5 mg Pb/kg BW daily for one year	No adverse effects	5
Pregnant ewes given 5.7 mg Pb/kg BW daily	Fatal	4

Table 4.8 (continued) Lethal and Sublethal Effects of Lead to Selected Species of Mammals

Species, Dose, and Other Variables	Effects	Ref.^a
Nonpregnant ewes given 6 mg Pb/kg BW daily 8 mg Pb/kg BW daily for 220 days	Toxic threshold Mortality	4 5
Fed 9 mg Pb/kg BW throughout pregnancy	Aborted and died	9
Fed diet containing 138 mg/kg DW for 124 days	Elevated residues in bone (22 mg/kg vs. 2.6 in controls) and kidney (8.3 vs. 1.0)	4
Lambs fed diets containing 400 mg Pb/kg, but deficient in calcium and sulfate	Dead within 5 weeks	4
Lambs fed diets containing 400 mg Pb/kg, diet adequate in minerals	Some weight loss in 10 months, but normal otherwise	4
Single oral dose of 600 mg Pb/kg BW	Fatal	9
Total dose of 20–25 grams	Toxic	6
Primates, various species		
Cynomolgus monkey, <i>Macaca iris</i>		
Intramuscular injection of 1.0 mg Pb/kg BW daily during pregnancy or lactation	Fetus exposed to lead via placenta or maternal milk	19
1.5 mg Pb/L in drinking water as lead acetate, for 9 months (equivalent to 0.5 mg Pb/kg BW daily), or 6 mg/L (2 mg/kg BW), or 15 mg/L (5 mg/kg BW)	Increasing blood lead levels from 3rd month, according to dose; kidney pathology. Effects more severe in those on low calcium diets	20
Intramuscular injection of 5 mg Pb ⁺² /kg BW daily during pregnancy or lactation	Abortions and death in pregnant monkeys; cerebral pathology in newborns	19
Cynomolgus monkey, <i>Macaca fascicularis</i>		
Dosed orally from birth to age 200 days with 100 µg lead (as Pb acetate)/kg BW, 5 times weekly, milk substitute diet	Blood level of 254 µg Pb/L; declined to 131 µg/L over next 100–150 days. At age 3 years, impaired ability to perform motor discrimination reversal tasks	21
As above, except dose is 50 µg Pb/kg BW	Blood lead 154 µg/L (vs. 35 µg/L in controls), declining to 109 µg/L at day 150 postadministration. At age 3 years, group showed impaired color discrimination. No overt signs of toxicity, normal blood chemistry (except lead), normal growth and development skills	21
Rhesus monkey, <i>Macaca mulatta</i>		
Infants given 0.5 mg Pg/kg diet for 4 weeks	Hyperactivity, insomnia, abnormal social behavior	18
Adults given 20 mg Pb/L in drinking water for 4 weeks	No effect	18
Baboon, <i>Papio anubis</i>		
Intratracheal injection of Pb carbonate at doses of 50–135 mg Pb/kg BW for 29 to 362 days	73% dead (11/15) with total dose of 1250–7800 mg lead. Before death, some animals lost weight, became increasingly aggressive, had hepatic centrilobular necrosis, were uncoordinated and weak, and had convulsions; the blood had up to 62 mg Pb/L	22
Single injection of 105 mg Pb/kg BW	Blood lead concentrations rose from 117 µg/L at start to 3100 µg/L at day 4 postinjection; blood lead remained >1000 µg/L for at least 24 days	22
Laboratory white rat, <i>Rattus spp.</i>		
Exposed to 10 µg Pb/m ³ air for one year	Elevated tissue residues in blood, soft tissues, and bone	13
Exposed to 21.5 µg Pb/m ³ air for one year	Blood lead increased, but stabilized after 4 months; lead levels remained elevated in bone, kidney, and liver after 6 months	13
1.5 mg Pb/L in drinking water for several days	Disturbed sleep patterns	18
Weanling females given 0.0, 0.5, 5, 25, 50, or 250 mg lead (as Pb acetate)/L drinking water for 6 to 7 weeks, then mated and exposed continuously through gestation and lactation	At 25 mg/L and higher, growth retardation and delayed vaginal opening observed; some maternal deaths occurred and were associated with blood lead concentrations	23

Table 4.8 (continued) Lethal and Sublethal Effects of Lead to Selected Species of Mammals

Species, Dose, and Other Variables	Effects	Ref.^a
Single intravenous injection (mg Pb/kg BW in parentheses)	>200 µg/L. Some pup malformations and deaths in all groups. The 5 mg/L group had elevated blood lead levels	
Tetramethyllead (80)	LD50	24
Tetraethyllead (10)	LD50	24
Trimethyllead (20 to 25)	LD50	24
Triethyllead (8)	LD50	24
Single oral dose (mg Pb/kg BW)		
Tetramethyllead (108)	LD50	24
Tetraethyllead (12)	LD50	24
Single intraperitoneal injection (mg Pb/kg BW)		
Tetramethyllead (70–100)	LD50	24
Tetraethyllead (10)	LD50	24
Trimethyllead (17)	LD50	24
Triethyllead (5)	LD50	24
5 mg Pb/L drinking water, lifetime exposure	Lowered survival and reduced longevity	4
Single intraperitoneal injection of 7 mg Pb/kg BW, as tetraethyllead	Depressed food intake, hyperactivity	25
Mature males given weekly intraperitoneal injections of 20 or 50 mg Pb/kg BW as lead acetate for 6 weeks vs. 20 or 50 mg sodium acetate/kg BW as controls	Dose-dependent increases in blood and sperm lead concentrations. Serum testosterone levels reduced in lead-exposed rats, possibly from generation of reactive oxygen species, and resulting in premature acrosome reaction and reduced sperm oocyte-penetrating capability	39
Male weanlings exposed to age 50 days to drinking water with 25 mg Pb/L, as lead acetate	At day 86: behavioral deficits; blood concentrations of 150–200 µg Pb/L; brain lead levels (µg/kg) 70 in treated group vs. 28 in controls	26
25 mg Pb/kg diet for 3 weeks	Increased locomotor activity	18
21-day-old rats exposed to 50, 100, or 500 mg Pb/L drinking water, as Pb acetate, for 335 days	Impaired behavior during first 4 months at 50 mg/L, but not thereafter. At 100 mg Pb/L and higher, behavior was impaired for at least 100 days postadministration. Brain and blood lead levels reflected exposure concentration and duration	27
Neonatal rats given 50 mg Pb/kg BW intragastrically as lead acetate, on days 6–18 postpartum	Impaired transfer of maze learning acquired during food deprivation	28
100 mg/kg BW daily, as lead nitrate	Some deaths of progeny in 3 weeks	8
Lead acetate in drinking water at 100 and 300 mg Pb/L from age 21 to 55 days	Impaired motor skills	29
Lead acetate in drinking water of pregnant females at 150 to 500 mg Pb/L from gestational day 5 until pups were weaned. Pups continued to be exposed to lead acetate in drinking water until killed between age 21 and 85 days	Dose-response decrease in birth weight and length in all lead-exposed litters. Pups had dose-dependent delay in sexual maturity (male prostate weight, female vaginal opening). Decrease in neonatal sex steroid levels and suppression of plasma testosterone levels in males and estradiol in females during puberty	36,37
200 mg/kg BW daily	50% of progeny dead in 3 weeks	8
500 mg Pb/L, as lead acetate, in drinking water ad libitum from (a) gestational day 5 through birth, (b) during pregnancy and lactation, (c) during lactation only, (d) from birth through adulthood, or (e) from gestational day 5 through adulthood	Significant adverse effects included: delayed vaginal opening and disrupted estrus cycling in female pups from groups (d) and (e); decreased birth weights in groups (a) and (b); lowered testosterone levels in male pups from (e); decreased body weight in all lead-treated groups up to weaning; reduced growth rates in group (c); males had reduced growth rates in groups (b), (d), and (e)	38

Table 4.8 (continued) Lethal and Sublethal Effects of Lead to Selected Species of Mammals

Species, Dose, and Other Variables	Effects	Ref.^a
4000 mg Pb/L in drinking water for 130 days	Serum testosterone levels depressed, Leydig cell lesions; no effect at lower concentration tested (2000 mg/L)	30
Nursing rats given diets containing zero, 2000, 4000, or 10,000 mg Pb/kg as metallic lead powder	Lead-treated rats showed dose-related response to noise stimuli. Blood levels (µg/L) in pups were 40 for controls, 250 for the 2000 mg/kg group, 360 for the 4000 mg/kg group, and 550 for the 10,000 mg/kg group	31
Cotton rat, <i>Sigmodon hispidus</i>		
Exposed to 0, 10, 100, or 1000 mg Pb/L in drinking water, as lead acetate, for 7 or 13 weeks	Altered immune function in high-dose group; spleen mass reduced in the 100 mg/kg group. All treated groups had altered blood chemistry, adverse effects on reproductive organs, and histopathology. In general, effects were more pronounced at higher doses and longer exposures	35
Swine, <i>Sus sp.</i>		
Oral doses of 64 mg Pb/kg BW, as lead acetate, 6 times weekly for 13 weeks	No deaths, reduced blood ALAD activity, blood lead concentration (a remarkable) 143 mg/L	32
As above, except doses administered intraperitoneally	All died	32
Total dose of 10–25 grams	Toxic	6

4.7 RECOMMENDATIONS

Proposed lead criteria for the protection of natural resources and human health are numerous and disparate (Table 4.9). Some of the criteria do not provide adequate protection. Criteria for aquatic life protection, for example, range from 1.3 to 7.7 µg total waterborne Pb/L (Table 4.9; USEPA 1985); however, within this range, high accumulations and adverse effects on growth and reproduction were recorded among sensitive species. Moreover, certain organolead compounds were lethal to some species of aquatic biota within this range, but no criteria have been formulated yet for this highly toxic group of chemicals. Nor have any criteria been proposed for lead in tissues of aquatic biota connoting elevated or hazardous levels to the organism. It is noteworthy that health effects to man through ingestion of lead-contaminated seafood (and probably other fishery products) are considered negligible (Friberg 1988). Total lead concentrations observed in highly polluted areas in the 1970s were usually about one-tenth those showing effects on marine organisms (Branica and Konrad 1980).

Organolead compounds are more toxic than ionic forms. Since methylation of ionic lead *in vivo* or in stored tissues is possible, and since some liver enzyme systems are capable of converting tetraethyllead to the more toxic triethyllead species, it would appear that the recommended Canadian

permissible concentration limit of 10 mg Pb/kg fresh weight in fishery products should be reevaluated downward (Sirota and Uthe 1977). Downward evaluation has also been recommended for the standard of 2 mg/kg in the U.K., where new guidelines have been recommended for total lead and for tetraalkylead compounds in fishery products (Wong et al. 1981). Increasing use of organolead compounds as wood preservatives, as biocides, and as catalysts in the manufacture of plastics, polyurethanes, and polyvinyl chlorides (Walsh and Tilson 1984) may adversely affect survival, sensory responsiveness, and behavioral reactivity in aquatic organisms (Chau et al. 1980; Maddock and Taylor 1980; Wong et al. 1981; Demayo et al. 1982) and avian wildlife (Bull et al. 1983; Osborn et al. 1983; Forsyth et al. 1985). It seems that additional research is needed on organolead toxicokinetics, with special reference to fishery and wildlife resources.

The evidence implicating ingestion of spent lead shot as a major cause of mortality in waterfowl and other birds is overwhelming. Moreover, forms of inorganic lead — besides lead shot or other ingestible-sized lead objects — are rarely known to produce subclinical signs of lead toxicosis in avian populations. Accordingly, in the advent of the lead shot phaseout in 1986, steel shot nontoxic zones were established for the protection of bald eagles and waterfowl in 44 states. Possession of shotshells containing lead shot by hunters of waterfowl in a steel shot zone became a violation of federal regulations (USFWS 1986, 1986a, 1987). By 1991/1992, all uses of lead shot for hunting waterfowl and coots were eliminated nationwide, including in Alaska. The conversion to a nontoxic shot zone was deferred in some cases until — but not beyond — the 1991/1992 hunting season in states that demonstrated, through monitoring, compliance with the following criteria: minimum of 100 birds sampled; less than 5% of birds examined having one or more lead shot in the gizzard; and less than 5% of the birds collected having >2 mg Pb/kg fresh weight in liver, or with >0.2 mg Pb/L in blood, or with blood protoporphyrin concentrations >0.4 mg/L. In addition, the occurrence of three or more individual specimens confirmed as lead-poisoned during the monitoring year disqualified the area for deferral (USFWS 1986, 1986a, 1987). States may elect to forego monitoring and convert to nontoxic shot zones on a countywide or statewide scheduled or accelerated basis (USFWS 1986, 1987). Steel shot is the only shot currently approved by the U.S. Fish and Wildlife Service as nontoxic (Sanderson et al. 1992). Alternatives to steel shot are under investigation and include bismuth/tin, tungsten/tin, and tungsten/polymer shot (Sanderson et al. 1992; Scheuhammer and Dickson 1996). Despite the ban on lead shot in the state of Washington since 1986, mortality of swans from lead poisoning continues to occur as a result of ingestion of previously deposited lead pellets. More aggressive enforcement of steel shot regulations in Washington may help reduce or eliminate the illegal use of lead shot. This, and continued settling of lead shot deeper into bottom sediments should eventually result in reduced lead poisoning mortality of swans from ingestion of lead shot (Lagerquist et al. 1994).

In addition to the United States, the use of lead shot is now banned — sometimes voluntarily, sometimes by legislation — locally or nationally in hunting waterfowl in Australia, Canada, Italy, Mexico, Denmark, Finland, the Netherlands, Norway, Sweden, Switzerland, Germany, Japan, and the United Kingdom (Lumeij et al. 1989; Lumeij and Scholten 1989; Langelier 1991; Thomas and Owen 1995; Tirelli et al. 1996; Mateo et al. 1997; Pain et al. 1997). In 1995, the British Department of the Environment recommended that lead-free shot be used when shooting over or within 300 m of a wetland if there is a possibility that the shot would be deposited in it (Thomas and Owen 1995). Beginning in 1997, all migratory game bird hunting in Canada required the use of nontoxic shot (Scheuhammer and Dickson 1996). Legislation has been introduced — and signed by 54 countries — to protect African–Eurasian migratory birds by phasing out the use of lead shot for hunting in wetlands by the year 2000 (Pain et al. 1997). To fully protect raptors, upland game birds, and waterfowl, many researchers now recommend a global ban on the use of lead shot in hunting (Langelier 1991; Pain et al. 1993a; Pain and Amiard-Triquet 1993; Thomas and Owen 1995; Mateo et al. 1997) and in trap and skeet shooting (Roscoe et al. 1989). Continued monitoring of lead residues for waterfowl, in addition to gizzard examination for shot, should also include blood and soft tissues as indicators of short-term exposure, and bone as an indicator of longer

exposure; monitoring is recommended until lead shot is no longer widespread in the wetland environment (Havera et al. 1992).

In Louisiana, deep tillage is a management option for reducing the availability of lead shot to foraging waterfowl. Agricultural deep tillage with a vegetable plow can result in the redistribution of artificially seeded lead shot from the top 10 cm of soil to lower strata. In control sites, 92% of the shot was recovered above 10 cm vs. tillage wherein 97% of the shot was recovered below 10 cm and 75% below 20 cm (Peters and Afton 1993). In wetlands areas lacking naturally available grit and with high shot densities in soils and sediments, the provision of grit 2 to 3 mm in diameter is recommended for the reduction of lead ingestion by waterbirds (Pain 1990). Increasing water depth of wetlands during the hunting season to inhibit foraging by waterfowl in lead shot affected areas is proposed by Whitehead and Tscherner (1991). In Spain, it is recommended that hunter-killed large animals that are currently abandoned in the field should be removed or buried, thus removing the main source of metallic lead for raptors and scavengers (Mateo et al. 1997b).

Lead poisoning of swans in England is due mainly to ingestion of discarded lead weights used in angling. The use of lead weights for this purpose has been sharply curtailed through legislation since 1987, and there has been a substantial reduction in lead poisoning in the swans of the Thames River (Sears 1988, 1989; Thomas and Owen 1995). To protect swans, loons, and other large waterfowl in the United States, replacement of lead fishing weights with nontoxic substitutes is recommended.

The level of human exposure in lead-using industries has been reduced considerably in recent years; associated with this observation is the reduction in lead content of gasolines, the removal of lead-based paints for interior household use, and the reduction in lead content of outside paints (Table 4.9; Boggess 1977; Heinze et al. 1998). These actions will undoubtedly prove beneficial in reducing the elevated lead concentrations now observed in communities of flora and fauna along heavily traveled roads, and in providing additional protection to captive zoo animals and others held in enclosures with lead-painted bars and walls. The decreased use of leaded gasoline has resulted in a significant decline in lead concentrations in streams (Smith et al. 1987) and in whole-body burdens of lead in starlings collected nationwide, among which the decline was most pronounced in birds from urban areas (White et al. 1977). Continued nationwide monitoring of lead in fish and wildlife is necessary to determine if this is a continuing downward trend, and also to identify areas of high or potential lead contamination.

Data for lead effects on mammalian wildlife are scarce. Shore (1995) indicates that lead residues in soils could successfully predict lead concentrations in kidneys and livers of wood mice and field voles; however, this could not be demonstrated for shrews. In view of the large interspecies differences in lead responses reported for domestic livestock and laboratory populations of small animals (Table 4.9), more research is needed to determine if lead criteria for these groups are applicable to sensitive species of mammalian wildlife.

One of the more insidious effects documented for lead in warm-blooded organisms is neurobehavioral deficits (including learning impairments) at dose levels producing no overt signs of toxicity, i.e., apparently normal growth and developmental skills, and sometimes, nonelevated blood lead levels (USEPA 1980, 1985; Rice 1985). Behavioral deficits have been reported for young rats when blood lead levels exceeded 0.1 mg/L, in children with blood lead concentrations of 0.4 to 0.5 mg/L (USEPA 1980; Rice 1985), and in birds when lead was administered early in development (Burger and Gochfeld 1985). Behavioral impairment was recorded in 3-year-old monkeys that received 50 or 100 µg Pb/kg BW from birth to age 200 days. Blood lead levels immediately after exposure and at time of testing were 0.15 to 0.25 mg/L (age 200 days), and 0.11 to 0.13 mg/L (age 3 years). This is the first report of behavioral impairment in a primate species at blood lead concentrations that are considered to be well within the bounds of safety for children (Rice 1985). This subject appears to constitute a high-priority research need for wildlife species of concern.

c One-hour average, not to be exceeded more than once every 3 years.

d Equals 1.8 to 2.5 g/gallon.

e Equals 0.5 g/gallon.

f Average 8-hour period.

g Blood lead levels, usually expressed as µg/deciliter, have been converted to µg/L, for uniformity, in the present work.

4.8 SUMMARY

Lead (Pb) and its compounds have been known to man for about 7000 years, and lead poisoning has been recognized for at least 2500 years. All credible evidence indicates that lead is neither essential nor beneficial to living organisms, and that all measured effects are adverse — including those on survival, growth, reproduction, development, behavior, learning, and metabolism. Various living resources are at increased risk from lead:

- Migratory waterfowl that frequent hunted areas and ingest shot
- Avian predators that eat game wounded by hunters
- Domestic livestock near smelters, refineries, and lead battery recycling plants
- Captive zoo animals and domestic livestock held in enclosures coated with lead-based paints
- Wildlife that forage extensively near heavily traveled roads
- Aquatic life in proximity to mining activities, areas where lead arsenate pesticides are used, metal finishing industries, organolead industries, and areas of lead aerosol fallout
- Crops and invertebrates growing or living in lead-contaminated soils

Adverse effects on aquatic biota reported at waterborne lead concentrations of 1.0 to 5.1 µg/L included reduced survival, impaired reproduction, reduced growth, and high bioconcentration from the medium. Among sensitive species of birds, survival was reduced at doses of 50 to 75 mg Pb⁺²/kg body weight (BW) or 28 mg organolead/kg BW; reproduction was impaired at dietary levels of 50 mg Pb/kg; and signs of poisoning were evident at doses as low as 2.8 mg organolead/kg BW. In general, forms of lead other than shot (or ingestible lead objects), or routes of administration other than ingestion, are unlikely to cause clinical signs of lead poisoning in birds. A notable exception to this generalization is the recent evidence linking waterfowl poisoning with ingestion of lead-contaminated sediments. Data for toxic and sublethal effects of lead on mammalian wildlife are missing. For sensitive species of domestic and laboratory animals, survival was reduced at acute oral lead doses of 5 mg/kg BW (rat), at chronic oral doses of 5 mg/kg BW (dog), and at dietary levels of 1.7 mg/kg BW (horse). Sublethal effects were documented in monkeys exposed to doses as low as 0.1 mg Pb/kg BW daily (impaired learning at 2 years postadministration) or fed diets containing 0.5 mg Pb/kg (abnormal social behavior). Signs of lead exposure were recorded in rabbits given 0.005 mg Pb/kg BW and in mice given 0.05 mg Pb/kg BW. Tissue lead levels were elevated in mice given doses of 0.03 mg Pb/kg BW, and in sheep given 0.05 mg Pb/kg BW. In general, organolead compounds were more toxic than inorganic lead compounds; food chain biomagnification of lead was negligible; and younger organisms were most susceptible. More research seems merited on organolead toxicokinetics (including effects on behavior and learning) and on mammalian wildlife sensitivity to lead and its compounds.

Legislation limiting the content of lead in paints, reducing the lead content in gasoline, and eliminating the use of lead shot nationwide (lead shot phaseout program/schedule started in 1986 and was fully implemented by 1991) in waterfowl hunting areas has substantially reduced environmental burdens of lead and may directly benefit sensitive fishery and wildlife resources. Continued nationwide monitoring of lead in living resources is necessary in order to correlate reduced emission sources with reduced tissue lead concentrations.

CHAPTER 5

Mercury

5.1 INTRODUCTION

The element mercury (Hg) and its compounds have no known normal metabolic function. Their presence in the cells of living organisms represents contamination from natural and anthropogenic sources. All such contamination must be regarded as undesirable and potentially hazardous (National Academy of Sciences [NAS] 1978). The most important ore of mercury, cinnabar (mercuric sulfide), has been mined continuously since 415 BCE (Clarkson and Marsh 1982). In the period before the industrial revolution, mercury was used extensively in gold extraction and in the manufacture of felt hats and mirrors; in the 1800s, it was used in the chloralkali industry, in the manufacture of electrical instruments, and as a medical antiseptic; and since 1900, it has been used in pharmaceuticals, in agricultural fungicides, in the pulp and paper industry as a slimicide, and in the production of plastics (Clarkson and Marsh 1982). World use of mercury is estimated at 10,000 to 15,000 metric tons annually (Boudou and Ribeyre 1983), of which the United States accounts for about 18% (Clarkson and Marsh 1982).

Long-range atmospheric transport of mercury since 1940 has resulted in elevated mercury loadings in remote Canadian lakes up to 1400 km from the closest industrial centers (Lucotte et al. 1995). Since 1985, annual mercury accumulation rates in flooded Florida Everglades soils averaged 53 µg/m², which is about 4.9 times greater than rates observed around the turn of the century. The increase is attributed to increased global and regional deposition and is similar to increases reported for lakes in Sweden and the northern United States (Rood et al. 1995). In 1967, the Swedish medical board banned the sale of fish that contained high concentrations of organomercury salts, originating from about 40 lakes and rivers (Das et al. 1982). More than 10,000 Swedish lakes are closed to fishing because of excessive mercury loadings (Lindqvist et al. 1991). In 1970, after the discovery of high levels of mercury in fish from Lake St. Clair, Canada, restrictions on fishing and the sale of fish were imposed in many areas of the United States and Canada (Das et al. 1982). Since 1970, a total of 26 of the 48 states in the conterminous United States have reported mercury pollution in their waters as a direct result of human activities. These states have banned sport or commercial fishing in mercury-contaminated waters, or have issued health warnings about the consequences of eating mercury-contaminated fish or seafood from selected water courses, or have placed restrictions on fish consumption from certain streams, lakes, or rivers polluted with mercury (NAS 1978; Becker and Bigham 1995). In 1989, the state of Florida, for example, due to excessive mercury in edible tissues of various species, issued, an advisory prohibiting consumption of predatory fishes, such as largemouth bass (*Micropterus salmoides*), bowfin (*Amia calva*), and gar (*Lepisosteus* spp.) in southern Florida, and the entire Everglades watershed has been closed to hunting of alligators (Kannan et al. 1998). In general, the number of mercury-contaminated fish

and wildlife habitats has progressively increased — almost all as a direct result of anthropogenic activities (Boudou and Ribeyre 1983).

Poisoning of game birds and other wildlife in Sweden, apparently by seeds treated with organomercurials, was noticed in 1960 (Das et al. 1982). Massive kills of the grey heron (*Ardea cinerea*) in the Netherlands during 1976 were attributed to a combination of low temperatures, undernourishment, and high body burdens of mercury (Van der Molen et al. 1982). Mercury contamination has resulted in the closure of pheasant and partridge hunting areas in Alberta, Canada (Mullins et al. 1977). Mercury contamination is the most serious environmental threat to fishery and wildlife resources in the southeastern United States, with fish consumption advisories issued in the 10 states comprising this region (Facemire et al. 1995). Declining numbers of wading birds in southern Florida are attributed to mercury contamination of their food supply (Sundolf et al. 1994). In March 1989, the Florida Department of Health and Rehabilitative Services issued a health advisory recommending limited consumption of largemouth bass (*Micropterus salmoides*) and other species caught from the Everglades region of south Florida due to elevated methylmercury concentrations (2 to 3 mg/kg FW) in fish muscle (Fleming et al. 1995). The entire Everglades watershed was closed to the hunting of alligators due to excessive mercury in edible tissues of alligators (Roelke et al. 1991; Sundolf et al. 1994).

The first cases of fatal mercury poisoning in humans were reported for two men in a European chemical laboratory in 1865 (Das et al. 1982). The first documented human poisoning from an agricultural exposure to methylmercury occurred in 1940 (Das et al. 1982). As summarized by Elhassani (1983), exposure of humans to mercury compounds may result from dermal application (e.g., 1600 infants in Argentina showed symptoms of Hg poisoning after a laundry treated their diapers with a mercury disinfectant), from diet (i.e., ingestion of mercury-contaminated fish, pork, seafoods, or grains), and from contact by respiratory routes (e.g., occupational exposure of mercury fungicide applicators in Nicaragua). Sporadic incidences of human poisonings have occurred in the United States, the former Soviet Union, and Canada; and major epidemics have been reported in Japan, Pakistan, Guatemala, Ghana, Yugoslavia, and Iraq (Clarkson and Marsh 1982; Das et al. 1982; Elhassani 1983; Greener and Kochen 1983). In 1972, for example, there were 6530 hospital admissions within 18 months (459 hospital deaths) among Iraqi farmers who ate bread made from seed wheat treated with a methylmercury fungicide. A water-soluble red dye was washed off the wheat, with the assumption that the mercury would be equally soluble. Before the wheat was consumed by humans, it was fed (without apparent effect) to chickens and other livestock for only a few days; it was not realized that a lengthy latency period was involved (Das et al. 1982; Elhassani 1983). There is no effective antidote to the effects of methylmercury on the central nervous system (Elhassani 1983).

Most authorities on mercury ecotoxicology agree on six points:

- Mercury and its compounds have no known biological function, and its presence in living organisms is undesirable and potentially hazardous
- Forms of mercury with relatively low toxicity can be transformed into forms with very high toxicity through biological and other processes
- Methylmercury can be bioconcentrated in organisms and biomagnified through food chains, returning mercury directly to man and other upper trophic level consumers in concentrated form
- Mercury is a mutagen, teratogen, and carcinogen, and causes embryocidal, cytochemical, and histopathological effects
- High body burdens of mercury normally encountered in some species of fish and wildlife from remote locations emphasize the complexity of natural mercury cycles and human impacts on these cycles
- Anthropogenic use of mercury should be curtailed, because the difference between tolerable natural background levels of mercury and harmful effects in the environment is exceptionally small

These, and other aspects of mercury and its compounds in the environment as a result of anthropogenic or natural processes, have been the subject of many reviews, including those by Montague and Montague (1971), D'Itri (1972), Friberg and Vostal (1972), Jernelov et al. (1972, 1975), Keckes and Miettinen (1972), Buhler (1973), Holden (1973), D'Itri and D'Itri (1977), Eisler (1978, 1981, 1987), National Academy of Sciences [NAS] (1978), Birge et al. (1979), Magos and Webb (1979), Nriagu (1979), U.S. Environmental Protection Agency [USEPA] (1980, 1985), Jenkins (1980), Clarkson and Marsh (1982), Das et al. (1982), Boudou and Ribeyre (1983), Elhassani (1983), Clarkson et al. (1984), Robinson and Touvinen (1984), Wren (1986), Scheuhammer (1987), Lindqvist (1991), Lindqvist et al. (1991), Zillioux et al. (1993), U.S. Public Health Service [USPHS] (1994), Hamasaki et al. (1995), Porcella et al. (1995), Heinz (1996), Thompson (1996), Wiener and Spry (1996), and Wolfe et al. (1998).

5.2 SOURCES OF ENVIRONMENTAL MERCURY

The atmosphere plays an important role in the mobilization of mercury with 25 to 30% of the total atmospheric mercury burden of anthropogenic origin (NAS 1978). The global anthropogenic atmospheric emission of mercury is estimated at 900 to 6200 tons annually, of which the United States contributed 300 metric tons in 1990 with 31% from combustion of fossil fuels by power plants (Chu and Porcella 1995). Atmospheric deposition is generally acknowledged as the major source of mercury for watersheds. In northern Minnesota watersheds, for example, atmospheric deposition was the primary source of mercury, and geologic and point source contributions were not significant. Transport from soils and organic materials may also be important, but the mercury from these sources probably originates from precipitation and direct atmospheric sorption by watershed components (Swain and Helwig 1989; Sorensen et al. 1990). In Sweden, increased mercury concentrations in lakes are attributed to increased atmospheric emissions and deposition of mercury, and to acid rain (Hakanson et al. 1990). Airborne particulates may contribute to the high mercury levels found in some marine dolphins and whales (Rawson et al. 1995). A total of 60 to 80 metric tons of mercury is deposited from the atmosphere into the Arctic each year, the main sources of which are Eurasia and North America from combustion of fossil fuels to produce electricity and heat (Pacyna and Keeler 1995). However, elevated mercury concentrations in fish muscle (0.5 to 2.5 mg/kg FW) from remote Arctic lakes over extended periods (1975 to 1993) are sometimes due to natural sources of mercury (Stephens 1995). Atmospheric deposition of mercury into the Great Lakes from sources as much as 2500 km distant are documented at annual deposition rates of 15 µg Hg/m² (Glass et al. 1991). In south Florida, 80 to 90% of the annual mercury deposition occurs during the summer wet season (Guentzel et al. 1995). Dry deposition processes are important for the flux of inorganic mercury and methylmercury to Swedish forested ecosystems; for methylmercury, the most important deposition route is from the air to a relatively stable form in litter (Munthe et al. 1995).

In the Florida Everglades, 61% of the mercury is due to atmospheric deposition from anthropogenic sources, especially municipal solid waste combustion facilities (15%), medical waste incinerators (14%), paint manufacturing and application (11%), electric utility industries (11%) and private residences (2%) through combustion of fossil fuels, and electrical apparatus including fluorescent, metal halide, and mercury vapor lights (6%). All other anthropogenic sources combined — including sugarcane processing, the dental industry, open burning, and sewage sludge disposal — account for about 3% of the total mercury emitted to the environment. Virtually all of the mercury in the Florida Everglades from natural sources (39%) is attributed to release from the soil through natural processes, including microbial transformations of inorganic and organic mercury to methylmercury (Sundolf et al. 1994).

As a direct result of human activities, mercury levels in river sediments have increased fourfold since precultural times, and twofold to fivefold in sediment cores from lakes and estuaries (Das et al. 1982). Analysis of sediment cores of North American mid-continental lakes show that mercury deposition rates have increased by a factor of 3.7 since 1850 at a rate of about 2% annually (Rolphus and Fitzgerald 1995). During the past 100 years, more than 500,000 metric tons of mercury entered the atmosphere, hydrosphere, and surface soils, with eventual deposition in subsurface soils and sediments (Das et al. 1982). Several activities that contribute significantly to the global input of mercury include the combustion of fossil fuels; mining and reprocessing of gold, copper, and lead; operation of chloralkali plants; runoff from abandoned cinnabar mines; wastes from nuclear reactors, pharmaceutical plants, and military ordnance facilities; incineration of municipal solid wastes and medical wastes; and disposal of batteries and fluorescent lamps (NAS 1978; Das et al. 1982; Gonzalez 1991; Lodenius 1991; Facemire et al. 1995; Gustafsson 1995). In one case, more than 5.5 million kg of metallic mercury was released into the Carson River Drainage Basin in Nevada during historic mining operations (now closed) in which mercury was used to amalgamate gold and silver ore (Gustin et al. 1995). Mercury concentrations in sample tailings were as high as 1570 mg/kg. The air directly over the site contained 1.0 to 7.1 ng Hg/m³, and was as high as 240 ng/m³ in October 1993. The estimated range of mercury flux to the atmosphere from the site was 37 to 500 ng/m² hourly (Gustin et al. 1995).

Mercury contamination of more than 500,000 miners, adjacent Indian populations, and numerous populations of fish and wildlife is one consequence of the gold rush that took place in the early 1980s in the Amazon region of Brazil. Metallic mercury was used to agglutinate the fine gold particles through amalgamation. During this process, large amounts of mercury were lost to the river and soil; additional mercury was lost as vapor to the atmosphere during combustion of the amalgamated gold to release the gold (Barbossa et al. 1995). Elemental mercury used in seals of three trickling filters in municipal wastewater treatment plants — each seal contained several hundred kg of mercury — leaked repeatedly, discharging 157 grams of mercury and 0.4 grams of methylmercury daily; the use of mercury seals for this purpose should be discontinued (Gilmour and Bloom 1995). Also discontinued in 1967 by Finland was the use of phenyl mercury compounds as slimicides in the pulp industry (Lodenius 1991).

Major producers of mercury include the former Soviet Union, Spain, Yugoslavia, and Italy (USPHS 1994). In the United States, mercury consumption rose from 1305 metric tons in 1959 to 2359 tons in 1969 ([Table 5.1](#)). The major use of mercury has been as a cathode in the electrolytic

Table 5.1 Industrial and Other Uses of Mercury in the United States in 1959 and in 1969 (All values are in metric tons)

Use	1959		1969	
	Tons	Percent	Tons	Percent
Chloralkali process	201	15.5	716	30.4
Electrical apparatus	308	23.6	644	27.3

Modified from Montague, K. and P. Montague. 1971. *Mercury*. Sierra Club, NY. 158 pp.

preparation of chlorine and caustic alkali (Nriagu 1979). In 1968 this use accounted for about 33% of the total U.S. demand for mercury (USEPA 1980). In regard to mercury consumption in the United States, electrical apparatus accounted for about 27%; industrial and control instruments, such as switches, thermometers, and barometers, and general laboratory appliances, 14%; antifouling and mildew-proofing paints, 12%; mercury formulations to control fungal diseases of seeds, bulbs, and vegetables, 5%; and dental amalgams, pulp and paper manufacturers, pharmaceuticals, metallurgy and mining, and catalysts, 9% (USEPA 1980). Mercury, however, is no longer registered for use in antifouling paints, nor for the control of fungal diseases of bulbs (USEPA 1980). Accurate data on recent mercury consumption in the United States were difficult to obtain. In 1987, the United States imported 636 metric tons; this fell to 329 tons in 1988, and 131 tons in 1989 (USPHS 1994). Domestic production of mercury produced as a by-product was 207 metric tons in 1990, 180 tons in 1991, and 160 tons in 1992; during this same period we imported 15 tons in 1990, 56 tons in 1991, and 100 tons in 1992 (USPHS 1994).

Mercury from natural sources enters the biosphere directly as a gas, in lava (from terrestrial and oceanic volcanic activity), in solution, or in particulate form. Cinnabar (HgS), for example, is a common mineral in hot spring deposits and a major natural source of mercury (Das et al. 1982). The global cycle of mercury involves degassing of the element from the earth's crust and evaporation from natural bodies of water, atmospheric transport (mainly in the form of mercury vapor), and deposition of mercury back onto land and water. Oceanic effluxes of mercury are tied to equatorial upwelling and phytoplankton activity and may significantly affect the global cycling of this metal. If volatilization of mercury is proportional to primary production in the world's oceans, oceanic phytoplankton activity represents about 36% of the yearly mercury flow to the atmosphere, or about 2400 tons per year (Kim and Fitzgerald 1986). Mercury finds its way into sediments, particularly oceanic sediments, where the retention time can be lengthy (Table 5.2), and where it may continue to contaminate aquatic organisms (Lindsay and Dimmick 1983). Estimates of the quantities of mercury entering the atmosphere from degassing of the surface of the planet vary widely, but a commonly quoted figure is 30,000 tons annually (Clarkson et al. 1984). In aquatic ecosystems, removal of the source of anthropogenic mercury results in a slow decrease in the mercury content of sediments and biota (NAS 1978). The rate of loss depends, in part, on the initial degree of contamination, the chemical form of mercury, physical and chemical conditions of the system, and the hydraulic turnover time (NAS 1978).

Terrestrial plants function as conduits for the transport of elemental mercury from the geosphere to the atmosphere (Leonard et al. 1998a). Estimated mercury emissions from plants in the Carson River Drainage Basin of Nevada over the growing season (0.5 mg Hg/m^2) add to the soil mercury

Table 5.2 Amount of Mercury in Some Global Reservoirs and Residence Time

Reservoir	Hg Content (metric tons)	Residence Time
Atmosphere	850	6 to 90 days
Soils	21,000,000	1000 years
Freshwater	200	—
Freshwater biota (living)	4	—
Ocean water	4,150,000,000	2000 years
Oceanic biota (living)	3	—
Ocean sediments	330,000,000,000	>1 million years

Data from National Academy of Sciences (NAS). 1978. *An Assessment of Mercury in the Environment*. Natl. Acad. Sci., Washington, D.C. 185 pp. Clarkson, T.W., R. Hamada, and L. Amin-Zaki. 1984. Mercury. Pages 285-309 in J.O. Nriagu (ed.). *Changing Metal Cycles and Human Health*. Springer-Verlag, Berlin.

emissions (8.5 mg Hg/m²) for a total landscape emission in that area of 9 mg Hg/m². In one species (tall whitetop, *Lepidium latifolium*), as much as 70% of the mercury taken up by the roots during the growing season was emitted to the atmosphere (Leonard et al. 1998a). Factors known to increase the flux of elemental mercury from terrestrial plants growing in soils with high (34 to 54 mg Hg/kg soil DW) levels of mercury include increasing air temperature in the range 20 to 40°C, increasing irradiance, increasing soil mercury concentrations, and increasing leaf area (Leonard et al. 1998b).

5.3 CHEMICAL AND BIOCHEMICAL PROPERTIES

Mercury, a silver-white metal that is liquid at room temperature and is highly volatile, can exist in three oxidation states: elemental mercury (Hg⁰), mercurous ion (Hg₂²⁺), and mercuric ion (Hg²⁺). It can be part of both inorganic and organic compounds (USEPA 1980; Clarkson et al. 1984; Table 5.3). All mercury compounds interfere with thiol metabolism, causing inhibition or inactivation of proteins containing thiol ligands and ultimately leading to mitotic disturbances (Das et al. 1982; Elhassani 1983). The mercuric species is the most toxic inorganic chemical form, but all three forms of inorganic mercury may have a common molecular mechanism of damage in which Hg²⁺ is the toxic species (Clarkson and Marsh 1982; Figure 5.1).

Chemical speciation is probably the most important variable influencing ecotoxicology of mercury, but mercury speciation is difficult, especially in natural environments (Boudou and Ribeyre 1983). Mercury compounds in an aqueous solution are chemically complex. Depending on pH, alkalinity, redox, and other variables, a wide variety of chemical species can be formed, each having different electrical charges and solubilities. For example, HgCl₂ in solution can speciate into Hg(OH)₂, Hg²⁺, HgCl⁺, Hg(OH)⁻, HgCl₃⁻, and HgCl₄²⁻; anionic forms predominate in saline environments (Boudou and Ribeyre 1983). In the aquatic environment, under naturally occurring conditions of pH and temperature, mercury may also become methylated by biological or chemical processes, or both (Beijer and Jernelov 1979; USEPA 1980; Ramamoorthy and Blumhagen 1984; Zillioux et al. 1993; Figure 5.1), although abiological methylation is limited (Callister and Winfrey 1986). Methylmercury is the most hazardous mercury species due to its high stability, its lipid solubility, and its possession of ionic properties that lead to a high ability to penetrate membranes in living organisms (Beijer and Jernelov 1979; Hamasaki et al. 1995). In general, essentially all mercury in freshwater fish tissues is in the form of methylmercury; however, methylmercury accounts for less than 1% of the total mercury pool in a lake (Regnell 1990).

Table 5.3 Some Properties of Mercury and Its Compounds^a

Property	Elemental Mercury	Mercurous Chloride	Mercuric Chloride	Methylmercury Chloride
Empirical formula	Hg	Hg ₂ Cl ₂	HgCl ₂	CH ₃ HgCl

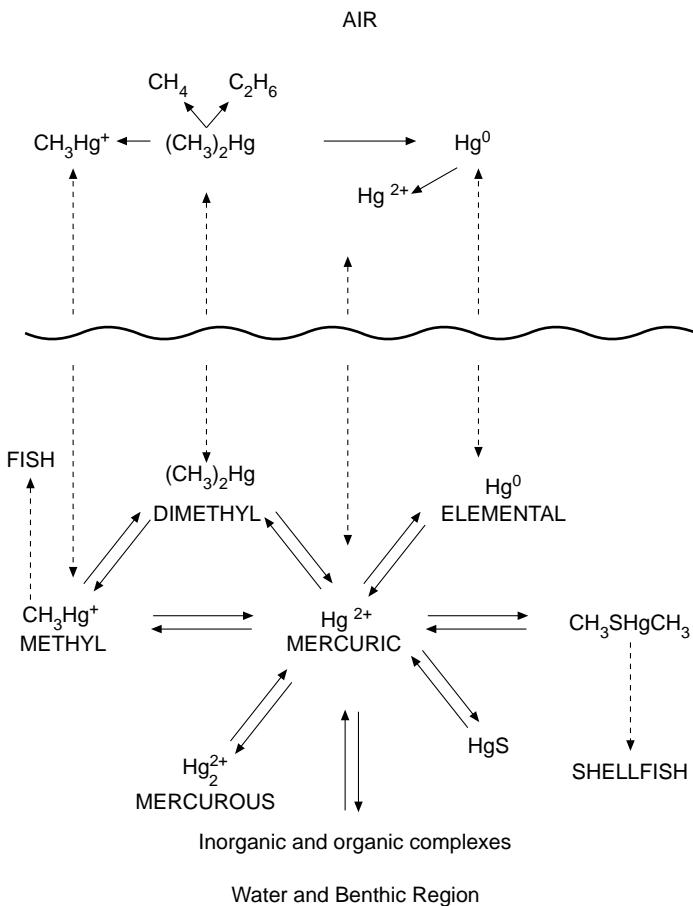

Figure 5.1 Major transformations of mercury in the environment. (Modified from Beijer, K. and A. Jernelov. 1979. Methylolation of mercury in natural waters. Pages 201-210 in J. O. Nriagu (ed.). *The Biogeochemistry of Mercury in the Environment*. Elsevier/North-Holland Biomedical Press, NY).

All mercury discharged into rivers, bays, or estuaries as elemental (metallic) mercury, inorganic divalent mercury, phenylmercury, or alkoxyalkyl mercury can be converted into methylmercury compounds by natural processes (Jernelov 1969). The mercury methylation in ecosystems depends on mercury loadings, microbial activity, nutrient content, pH and redox condition, suspended sediment load, sedimentation rates, and other variables (NAS 1978; Compeau and Bartha 1984; Berman and Bartha 1986; Callister and Winfrey 1986; Jackson 1986). Net methylmercury production was about 10 times higher in reduced sediments than in oxidized sediments (Regnell 1990). The finding that certain microorganisms are able to convert inorganic and organic forms of mercury into the highly toxic methylmercury or dimethylmercury has made it clear that any form of mercury is highly hazardous to the environment (USEPA 1980, 1985). The synthesis of methylmercury by bacteria from inorganic mercury compounds present in the water or in the sediments is the major source of this molecule in aquatic environments (Boudou and Ribeyre 1983). This process can occur under both aerobic and anaerobic conditions (Beijer and Jernelov 1979; Clarkson et al. 1984), but seems to favor anaerobic conditions (Olson and Cooper 1976; Callister and Winfrey 1986). Transformation of inorganic mercury to an organic form by bacteria alters its biochemical reactivity and hence its fate (Windom and Kendall 1979; [Figure 5.1](#)). Methylmercury is decomposed by bacteria in two phases. First, hydrolytic enzymes cleave the C-Hg bond, releasing the methyl group.

Second, a reductase enzyme converts the ionic mercury to the elemental form, which is then free to diffuse from the aquatic environment into the vapor phase. These demethylating microbes appear to be widespread in the environment; they have been isolated from water, sediments, and soils and from the gastrointestinal tract of mammals, including humans (Clarkson et.al. 1984). Some strains of microorganisms contain mercuric reductase, which transforms inorganic mercury to elemental mercury, and organomercurial lyase, which degrades organomercurials to elemental mercury (Baldi et al. 1991).

Humic substances can reduce inorganic divalent mercury (Hg^{2+}) to elemental mercury (Hg^0). In aquatic environments, Hg^0 was highest under anoxic conditions, in the absence of chloride, and at pH 4.5 (Allard and Arsenie 1991). Under these conditions, about 25% of 400 μg Hg^{2+}/L was reduced to Hg^0 in 50 h. Production of Hg^0 was reduced in the presence of europium ions and by methylated carboxyl groups in the humic substances (Allard and Arsenie 1991). Mercury is efficiently transferred through wetlands and forests in a more reactive form relative to other land-use patterns, resulting in an increased uptake by organisms inhabiting these rivers or downstream impoundments and drainage lakes (Hurley et al. 1995). The behavior and accumulation of mercury in forest soils of Guyana, South America, is related to the penetration of humic substances and the progressive adsorption onto iron oxy-hydroxides in the mineral horizons; flooding of these soils may lead to a release of 20% of the mercury initially present (Roulet and Lucotte 1995).

Methylmercury is produced by methylation of inorganic mercury present in both freshwater and saltwater sediments, and it accumulates in aquatic food chains in which the top-level predators usually contain the highest concentrations (Clarkson and Marsh 1982). The percent of total mercury accounted for by methylmercury generally increases with higher trophic levels, confirming that methylmercury is more efficiently transferred to higher trophic levels than inorganic mercury compounds (Becker and Bigham 1995). Organomercury compounds other than methylmercury decompose rapidly in the environment and behave much like inorganic mercury compounds (Beijer and Jernelov 1979). In organisms near the top of the food chain, such as carnivorous fishes, almost all mercury accumulated is in the methylated form, primarily as a result of the consumption of prey containing methylmercury; methylation also occurs at the organism level by way of mucus, intestinal bacteria, and enzymatic processes, but these pathways are not as important as diet (Huckabee et al. 1979; Boudou and Ribeyre 1983). In tissues of marine flounders, inorganic mercury compounds are strongly bound to metallothioneins and high-molecular-weight ligands; however, methylmercury has a low affinity for metallothioneins and is strongly lipophilic (Bargigiani et al. 1989).

The biological cycle of mercury is delicately balanced, and small changes in input rates, geophysical conditions, and the chemical form of mercury may result in increased methylation rates in sensitive systems (NAS 1978). For example, the acidification of natural bodies of freshwater is statistically associated with elevated concentrations of methylmercury in the edible tissues of predatory fishes (Clarkson et al. 1984). Acidification has a stronger effect on the supply of methylmercury to the ecosystem than on specific rates of uptake by the biota (Bloom et al. 1991). In chemically sensitive waterways, such as poorly buffered lakes, the combined effects of acid precipitation and increased emissions of mercury to the atmosphere (with subsequent deposition) pose a serious threat to the biota if optimal biomethylation conditions are met (NAS 1978). In remote lakes of the Adirondack mountain region in upstate New York, fish contain elevated mercury concentrations in muscle; mercury loadings in fish were directly associated with decreasing water column pH and increasing concentrations of dissolved organic carbon (DOC), although high DOC concentrations may complex methylmercury, diminishing its bioavailability (Driscoll et al. 1995). At high concentrations of monomeric aluminum, the complexation of methylmercury with DOC decreases, enhancing the bioavailability of methylmercury (Driscoll et al. 1995).

Mercury binds strongly with sulphydryl groups and has many potential target sites during embryogenesis. Phenylmercury and methylmercury compounds are among the strongest known inhibitors of cell division (Birge et al. 1979). In mammalian hepatocytes, the L-alanine carrier

contains a sulphydryl group that is essential for its activity and is inhibited by mercurials (Sellinger et al. 1991). In the little skate (*Raja erinacea*), HgCl_2 inhibits Na^+ -dependent alanine uptake and Na^+/K^+ -ATPase activity, and increases K^+ permeability. Inhibition of Na^+ -dependent alanine in skate hepatocytes by HgCl_2 is attributed to three different concentration-dependent mechanisms: (1) direct interaction with the transporters; (2) dissipation of the Na^+ gradient; and (3) loss of membrane integrity (Sellinger et al. 1991). Organomercury compounds, especially methylmercury, cross placental barriers and can enter mammals by way of the respiratory tract, gastrointestinal tract, skin, or mucus membranes (Elhassani 1983). When compared with inorganic mercury compounds, organomercurials are more completely absorbed, are more soluble in organic solvents and lipids, pass more readily through biological membranes, and are slower to be excreted (Clarkson and Marsh 1982; Elhassani 1983; Greener and Kochen 1983). Biological membranes, including those at the blood-brain interface and placenta, tend to discriminate against ionic and inorganic mercury but allow relatively easy passage of methylmercury and dissolved mercury vapor (Greener and Kochen 1983). As judged by membrane model studies, it appears that electrically neutral mercurials are responsible for most of the diffusion transport of mercury, although this movement is modified significantly by pH and mercury speciation. It seems, however, that the liposolubility of methylmercury is not the entire reason for its toxicity and does not play a major role in its transport. This hypothesis needs to be examined further in studies with living membranes (Boudou et al. 1983).

Mercury point sources and rates of particle scavenging are key factors in atmospheric transport rates to sites of methylation and subsequent entry into the marine food chain (Rolphus and Fitzgerald 1995). Airborne soot particles transport mercury into the marine environment either as nuclei for raindrop formation or by direct deposition on water (Rawson et al. 1995). In early 1990, both dimethylmercury and monomethylmercury were found in the subthermocline waters of the equatorial Pacific Ocean; the formation of these alkylmercury species in the low oxygen zone suggests that Hg^{2+} is the most likely substrate (Mason and Fitzgerald 1991; Figure 5.1).

Mercury-antagonistic and mercury-protectant drugs and compounds now include 2,3-dimercaptopropanol, polythiol resins, selenium salts, thiamin, Vitamin E, metallothionein-like proteins, and sulphydryl agents (Magos and Webb 1979; Elhassani 1983; Siegel et al. 1991; USPHS 1994; Caurent et al. 1996). Thiols ($\text{R}-\text{SH}$), which compete with mercury for protein binding sites, are the most important antagonists of inorganic mercury salts and have been used extensively in attempts to counteract mercury poisoning in humans (Das et al. 1982). Thiamin was the most effective of the Group VIB derivatives (which includes sulfur, selenium, and tellurium) in protecting against organomercury poisoning in higher animals (Siegel et al. 1991). The protective action of selenium (Se) against adverse or lethal effects induced by inorganic or organic mercury salts is documented for algae, aquatic invertebrates, fish, birds, and mammals (Magos and Webb 1979; Heisinger 1979; Chang et al. 1981; Lawrence and Holoka 1981; Das et al. 1982; Gotsis 1982; Eisler 1985; Satoh et al. 1985; Goede and Wolterbeek 1994; Paulsson and Lundbergh 1989; USPHS 1994; Caurent et al. 1996; Kim et al. 1996). For example, selenium, as sodium selenite, that was introduced into a nonacidified mercury-contaminated lake in Sweden to concentrations of 3 to 5 $\mu\text{g Se/L}$ (from 0.4 $\mu\text{g Se/L}$) and sustained at this level for 3 years resulted in declines of 50 to 85% in mercury concentrations in fish muscle (Paulsson and Lundbergh 1989). The mercury-protective effect of selenium is attributed to competition by selenium for mercury-binding sites associated with toxicity, formation of a Hg-Se complex that diverts mercury from sensitive targets, and prevention of oxidative damage by increasing the amount of selenium available to the selenium-dependent enzyme glutathione peroxidase (USPHS 1994). In seabirds, an equivalent molar ratio of 1:1 between total mercury and selenium was found in livers of individual seabirds which contained more than 100 mg Hg/kg DW ; this relation was unclear in other individuals which had relatively low mercury levels (Kim et al. 1996). The selenium-protective mechanism in birds is explained by a strong binding between mercury and selenium, possibly by the formation of a selenocysteamine methylmercury complex ($\text{CH}_3\text{HgSeCH}_2\text{CH}_2\text{NH}_3^+$), mercury binding to selenocysteine residues ($\text{CH}_3\text{HgSeCH}_2\text{CH}(\text{NH}_3)(\text{COO})\text{H}_2\text{O}$), the formation of

insoluble mercuric selenide (HgSe), or binding of mercury to SeH residues of selenoproteins, notably metallothioneins with thiols replaced by SeH (Goede and Wolterbeek 1994). However, high selenium concentrations in tissues of marine wading birds do not have their origin in elevated levels of mercury. The Se:Hg ratio in marine wading birds from the Wadden Sea is 32:1 and greatly exceeds the 1:1 ratio found when selenium is accumulated to detoxify mercury (Goede and Wolterbeek 1994). In marine mammals and humans, selenium and mercury concentrations are closely related, almost linearly in a 1:1 molar ratio (Eisler 1985). The molar ratio between mercury and selenium in marine mammals suggests that the major mechanism of detoxification is through the formation of a complex Hg-Se which leads to mercury demethylation (Caurent et al. 1996). The site of this process is the liver, in which mercury appeared mainly as inorganic, whereas in the muscle the percent of organic to total mercury was much higher. Detoxification is limited in lactating female whales, and sometimes in all the individuals of one school (Caurent et al. 1996). Selenium does not, however, protect against mercury-induced birth defects, such as cleft palate in mice (USPHS 1994). It is clear that more research is needed on mercury protectants.

Techniques for analysis of different mercury species in biological samples and abiotic materials include atomic absorption, cold vapor atomic fluorescence spectrometry, gas–liquid chromatography with electron capture detection, and inductively coupled plasma mass spectrometry (Lansens et al. 1991; Schintu et al. 1992; Porcella et al. 1995). Methylmercury concentrations in marine biological tissues are detected at concentrations as low as 10 $\mu\text{g Hg/kg}$ tissue using graphite furnace sample preparation techniques and atomic absorption spectrometry (Schintu et al. 1992).

5.4 MERCURY IN MINAMATA, JAPAN

One of the earliest and most extensively documented cases of mercury poisoning occurred in the 1950s at Minamata Bay in southwestern Kyushu, Japan (Fujiki 1963, 1980; Irukayama 1967; Matida and Kumada 1969; Kojima and Fujita 1973; NAS 1978; Elhassani 1983; Nishimura and Kumagai 1983; Doi et al. 1984; Davies 1991). The source of the mercury was waste discharged from an acetaldehyde plant that used inorganic mercury as a catalyst. Between 1932 and 1968, Minamata Bay received at least 260 tons of mercury and perhaps as much as 600 tons. A severe neurological disorder was recognized in late 1953 and had reached epidemic proportions by 1956. The mortality rate for acutely affected patients in 1957 was 32.8%. Infants born between 1955 and 1958 and diagnosed with mercury poisoning had a mental retardation rate of 29.1%, excluding congenital cases. By the end of 1960, 111 cases of poisoning were reported, and by August 1965, 41 of the 111 had died. By 1982, there were 1800 verified human victims of mercury poisoning in a total regional population of 200,000. Symptoms evidenced by human victims included sensory impairment, constriction of visual fields, hearing loss, ataxia, and speech disturbances. Congenital cases were accompanied by disturbance of physical and mental development; about 6% of babies born in Minamata had cerebral palsy (vs. 0.5% elsewhere).

In 1987, afflicted humans displayed symptoms of peripheral neuropathy (70.1%), ataxia (22.9%), constriction of the visual field (17.4%), tremor of the digits (10.2%), and dysarthria (9.2%); another 12.1% had no symptoms (Davies 1991). Nearly all patients complained of fatigue, numbness of parts of the body, and muscle cramps. Over 20,000 people are now thought to have been affected; symptoms were mainly neurological and resulted in death, chronic disability, and congenital abnormalities. As of June 1989, 1757 patients were officially diagnosed with Minamata disease, of which 765 had died and their families awarded compensation. Another 7621 people were disapproved for compensation. Another group of 918 (94 dead) were under investigation. A group of 2347 (320 dead) were awaiting official examination, and a final group of 1876 patients received health costs compensation only (Davies 1991). It is alleged that a large proportion of the population residing near Minamata Bay, especially the older population, is still incapacitated to varying degrees by the disease and that the more chronic effects are still becoming apparent (Davies 1991).

Minamata disease resulted from the discharge of methylmercury from chemical factories into Minamata Bay. Once diluted and diffused in the water, it was concentrated to a high level in fish and filter-feeding shellfish by several routes, including bioconcentration and food chain biomagnification. When these fish and shellfish were consumed by humans, methylmercury gradually accumulated to exceed a threshold value, causing intoxication. Spontaneously poisoned cats, dogs, rats, waterfowl, and pigs behaved erratically and died; flying crows and grebes suddenly fell into the sea and drowned; and large numbers of dead fish were seen floating on the sea surface (Doi et al. 1984). In laboratory studies, cats and rats fed shellfish from the bay developed the same signs as those seen in animals affected spontaneously. Abnormal mercury content — i.e., more than 30 mg/kg fresh weight — was measured in fish, shellfish, and muds from the bay, and in organs of necropsied humans and cats that had succumbed to the disease. Total mercury concentrations in tissues of fish from Minamata Bay with signs of methylmercury poisoning were about 15 mg/kg FW in liver and 8 to 24 mg/kg FW in muscle (Wiener and Spry 1996). Mercury contamination of fish and sediments was still evident in 1981, although discharges from the acetaldehyde plant ceased in 1971 (Doi et al. 1984). Plans are under way to reopen Minamata Bay for fishing in the future; however, as of June 1989 certain species of fish were still likely to have concentrations of mercury unsafe for human consumption (Davies 1991).

There is a strong relationship between the food of birds from Minamata and the mercury content in feathers; the content is highest in fish-eating seabirds and lowest in herbivorous waterfowl (Doi et al. 1984; [Table 5.4](#)). This same relationship held in birds collected from China and Korea,

although concentrations were significantly lower (Doi et al. 1984). There are close correlations between mercury contents of zooplankton and suspended particulate matter, and of sediments and fish muscle, suggesting a pathway from sediment to fish by way of suspended matter and zooplankton. The conversion from inorganic mercury to methylmercury is believed to have occurred primarily in zooplankton (Nishimura and Kumagai 1983).

Tokuyama Bay, Japan, received 6.6 metric tons of mercury wastes between 1952 and 1975 in wastewater from two chloralkali plants, although sediment analysis suggests that as much as 380 tons of mercury were released (Nakanishi et al. 1989). Unlike Minamata Bay, however, there were no human sicknesses reported, and the hair of residents contained 0 to 5 mg Hg/kg FW vs. 15 to 100 mg Hg/kg FW in Minamata residents. In 1970, a maximum concentration of 3.3 mg total Hg/kg FW was reported in tissues of *Squilla*, a crustacean. In 1973, a health safety limit was set of 0.4 mg total Hg/kg FW in edible fish and shellfish tissues with a maximum of 0.3 mg methylmercury/kg FW permitted; at least five species of fish had more than 0.4 mg total Hg/kg FW, and fishing was prohibited. Contaminated sediments (>15 mg total Hg/kg) were removed by dredging and reclamation between 1974 and 1977. By 1979, the mercury content of all fish, except one species, was less than 0.4 mg total Hg/kg FW; fishing was prohibited. By 1983, all fish and shellfish contained less than 0.4 mg Hg/kg FW and fishing was allowed (Nakanishi et al. 1989).

In aquatic environments where point sources of industrial contamination have been identified, the elimination of mercury discharges has usually improved environmental quality. Such improvement has been reported for Minamata Bay (Table 5.4); for sediments in Saguenay Fjord, Quebec,

when chloralkali wastes were limited; for fish residues in Canada's Lake St. Clair after two chloralkali plants were closed; and in various sections of Europe and North America when industrial discharges were eliminated (Barber et al. 1984).

5.5 CONCENTRATIONS IN FIELD COLLECTIONS

5.5.1 General

Mercury burdens in sediments and other nonbiological materials are estimated to have increased up to five times prehuman levels, primarily as a result of anthropogenic activities (NAS 1978). The residence time of mercury is comparatively short (about 11 days) in the atmosphere, but is much longer (at least 1000 years) in oceanic waters, soils, and sediments (Clarkson 1984). An elevated concentration of mercury (i.e., >1.0 mg/kg FW), usually as methylmercury, in any biological sample is often associated with proximity to human use of mercury. The elimination of mercury point-source discharges has usually been successful in improving environmental quality. However, elevated levels of mercury in biota may persist in contaminated areas long after the source of pollution has been discontinued (Rada et al. 1986). For example, mercury remains elevated in resident biota of Lahontan Reservoir, Nevada, which received about 7500 tons of mercury as a result of gold and silver mining operations from 1865 to 1895 (Cooper 1983). It is noteworthy that some groups of organisms with consistently elevated mercury residues may have acquired these concentrations as a result of natural processes, rather than from anthropogenic activities. These groups include older specimens of long-lived predatory fishes, marine mammals (especially pinnipeds), and organisms living near natural mercury-ore-cinnabar deposits.

5.5.2 Nonbiological

Mercury burdens have increased two to five times precultural levels in freshwater and estuarine sediments and freshwater lakes and rivers, but estimated increases in oceanic waters and terrestrial soils have been negligible (NAS 1978). Significant mercury enrichment in sediments of Newark Bay, New Jersey, may represent a hazard to aquatic life (Gillis et al. 1993). Total mercury concentrations in uncontaminated natural waters (presumably unfiltered) now range from about 0.001 to 0.050 µg/L ([Table 5.5](#)). In sediments that were anthropogenically contaminated with mercury, concentrations were significantly elevated (usually >20.0 mg/kg) when compared with uncontaminated sediments (usually <1.0 mg/kg). The residence time of mercury in nonbiological materials is variable and depends on a number of physicochemical conditions. Estimated half-time residence values for mercury are 11 days in the atmosphere, 1000 years in terrestrial soils, 2100 to 3200 years in ocean waters, and >250 million years in oceanic sediments (NAS 1978, as quoted in Boudou and Ribeyre 1983); the estimate was 1 month to 5 years for water from the contaminated Saguenay River in Quebec (Smith and Loring 1981). Methylmercury accounts for a comparatively small fraction of the total mercury found in sediments, surface waters, and sediment interstitial waters of Poplar Creek, Tennessee, which was initially contaminated with mercury in the 1950s and 1960s. Mercury measurements in Poplar Creek in 1993/94 showed that methylmercury accounted for 0.01% of the total mercury in sediments, 0.1% in surface waters, and 0.3% in sediment interstitial waters (Campbell et al. 1998). In Florida, methylmercury in sediments from uncontaminated southern estuaries in 1995 accounted for 0.77% of the total mercury and was not correlated with total mercury or organic content of sediments (Kannan et al. 1998).

Much of the mercury that enters freshwater lakes is deposited in bottom sediments (Rada et al. 1993). Sedimentary pools of mercury in these lakes greatly exceed the inventories of mercury in

^a 1, Nishimura et al. 1983; 2, Fitzgerald 1979; 3, Smith and Loring 1981; 4, Skei 1978; 5, Suckcharoen and Lodenius 1980; 6, Martin and Hartman 1984; 7, Bycroft et al. 1982; 8, Kiorboe et al. 1983; 9, Paasivirta et al. 1983; 10, Chu and Porcella 1995; 11, Wilken and Hintelmann 1991; 12, Hamasaki et al. 1995; 13, Rada et al. 1989; 14, Meuleman et al. 1995; 15, Campbell et al. 1998.

water, seston, and fish, and the release of mercury from the sediments would significantly increase bioavailability and uptake. The dry weight mercury concentrations of sediments seem to underrepresent the significance of the shallow water sediments as a reservoir of potentially available mercury when compared to the mass per volume of wet sediment, which more accurately portrayed the depth distribution of mercury in Wisconsin seepage lakes (Rada et al. 1993). The increase in the mercury content of recent lake sediments in Wisconsin is attributed to increased atmospheric deposition of mercury, suggesting that the high mercury burdens measured in gamefish in certain Wisconsin lakes originated from atmospheric sources (Rada et al. 1989). Levels of mercury in sediments may be reflected by an increased mercury content in epibenthic marine fauna. For example, mercury concentrations in sediments near the Hyperion sewer outfall in Los Angeles, which ranged up to 820 µg/kg and decreased with increasing distance from the outfall, were reflected in the mercury content of crabs, scallops, and whelks. Concentrations of mercury were highest in organisms collected nearest the discharge, and lowest in those collected tens of kilometers away (Klein and Goldberg 1970).

Uptake from the soil is probably a significant route for the entrance of mercury into vegetation in terrestrial ecosystems. In Italy, elevated mercury concentrations in soils near extensive cinnabar deposits and mining activities were reflected in elevated mercury concentrations in plants grown on those soils (Ferrara et al. 1991). Mercury concentrations in tissues of different species of vascular plants growing on flood plain soils at Waynesboro, Virginia, were directly related to soil mercury concentrations that ranged between <0.2 and 31 mg Hg/kg DW soil (Cocking et al. 1995). In a study conducted in Fulton County, Illinois, it was shown that repeated applications of sewage sludge to land will significantly increase the concentration of mercury in surface soils (Granato et al. 1995). However, 80 to 100% of the mercury remained in the top 15 cm and was not bioavailable to terrestrial vegetation. The authors concluded that models developed by the EPA overpredict the uptake rates of mercury from sludge-amended soils into grains and animal forage, and need to be modified (Granato et al. 1995).

Creation of reservoirs by enlargement of riverine lakes and flooding of adjacent lands has led to a marked rise in rates of methylmercury production by microorganisms in sediments. This process has resulted mainly from increased microbial activity via increased use of organic materials under conditions of reduced oxygen (Jackson 1988). Increased net methylation in flooded humus and peat soils, especially in anoxic conditions, was determined experimentally and judged to be the main reason for increased methylmercury concentrations in reservoirs (Porvari and Verta 1995). Enlargement of northern Manitoba lakes to form hydroelectric reservoirs caused a rise in the mercury content of native fishes owing to stimulation of mercury methylating bacteria by submerged

terrestrial organic matter (Jackson 1991). Increased organic substrates beyond a critical amount mitigated this effect via promotion of mercury demethylation and production of mercury-binding agents such as sulfides. Variability in mercury concentrations between fish species was high and was due to differences in habitat preference, metabolic rate, age, growth rate, size, biomass, diet, and excretory pathways (Jackson 1991). Elevated mercury levels in fish flesh found after impoundment of a reservoir are predicted to decline as the reservoir ages (Anderson et al. 1995). In Labrador, Canada, omnivorous species of fishes reached background levels in 16 to 20 years; however, mercury in piscivorous species remained elevated 21 years after impoundment (Anderson et al. 1995).

High concentrations of methylmercury in subthermocline low-oxygen seawater were significantly and positively correlated with median daytime depth (<200 m to >300 m) of eight species of pelagic fishes; mean total mercury concentrations in whole fishes ranged between 57 and 377 µg/kg DW. The enhanced mercury accumulations in the marine mesopelagic compartment is attributable to diet and ultimately to water chemistry that controls mercury speciation and uptake at the base of the food chain (Monteiro et al. 1996).

5.5.3 Biological

Information on mercury residues in field collections of living organisms is especially abundant ([Table 5.6](#)). Elevated concentrations of mercury occur in aquatic biota from areas receiving high atmospheric depositions of mercury, or when mercury concentrations in the diet or water are elevated (Sorensen et al. 1990; Wiener et al. 1990a; Fjeld and Rognerud 1993). Mercury levels are comparatively elevated in fish-eating fishes, birds, and mammals (Langlois et al. 1995). In general, mercury concentrations in biota were usually less than 1.0 mg/kg FW tissue in organisms collected from locations not directly affected by man's use of the element. However, they exceed 1.0 mg/kg, and are sometimes markedly higher, in animals and vegetation from the vicinity of chloralkali plants; agricultural users of mercury; smelters; mining operations; pulp and paper mills; factories producing mercury-containing paints, fertilizers, and insecticides; sewer outfalls; sludge disposal areas; and other anthropogenic point sources of mercury (Schmitt and Brumbaugh 1990; [Table 5.6](#)). In some Minnesota lakes, mercury concentrations in fish are high enough to be potentially hazardous when ingested by mink, otters, loons, and raptors (Swain and Helwig 1989).

Certain species of macrophytes strongly influence mercury cycling. For example, *Spartina alterniflora* — a dominant salt marsh plant in Georgia estuaries — accounted for almost half the total mercury budget in that ecosystem (Windom et al. 1976). Mangrove vegetation plays a similarly important role in mercury cycling in the Florida Everglades (Tripp and Harriss 1976). These findings suggest that more research is needed on the role of higher plants in the mercury cycle.

Mercury was detectable in the tissues of almost all freshwater fishes examined, with the majority of the mercury (>80–99%) present as methylmercury (Huckabee et al. 1979; Chvojka 1988; Grieb et al. 1990; Southworth et al. 1995). Methylmercury is absorbed more efficiently than inorganic mercury from water, and probably from food, and is retained longer regardless of the uptake pathway (Huckabee et al. 1979; Hill et al. 1996). Three important factors modifying mercury uptake in aquatic organisms are the age of the organism, water pH, and the dissolved organic carbon content. In fish, for example, mercury tends to accumulate in muscle tissues of numerous species of freshwater and marine fishes and to increase with increasing age, weight, or length of the fish (Eisler 1984; Braune 1987b; Phillips et al. 1987; Chvojka 1988; Nicoletto and Hendricks 1988; Cope et al. 1990; Grieb et al. 1990; Sorensen et al. 1990; Wiener et al. 1990a; Leah et al. 1991, 1992; Rask and Metsala 1991; Lange et al. 1993, 1994; Staveland et al. 1993; Mathieson and McLusky 1995; Joiris et al. 1997; Munn and Short 1997; Stafford and Haines 1997). Mercury concentrations in muscle of freshwater teleosts were significantly higher in acidic lakes than in neutral or alkaline lakes (Allard and Stokes 1989; McMurtry et al. 1989; Cope et al. 1990; Grieb et al. 1990; Wiener et al. 1990a, 1990b; Rask and Metsala 1991; Haines et al. 1992; Lange et al. 1993). Highest levels of mercury in fish muscle were from lakes with a pH near 5.0; liming acidic lakes resulted in as much as an

80% decrease in muscle mercury content after 10 years (Andersson et al. 1995). And mercury concentrations in fish muscle were positively correlated with dissolved organic carbon concentration (McMurtry et al. 1989; Sorensen et al. 1990; Wren et al. 1991; Fjeld and Rognerud 1993).

In addition to age, water pH, and dissolved organic carbon, other variables known to modify mercury accumulation rates in aquatic organisms include water temperature, sediment mercury concentrations, lake size, season, diet, chemical speciation of mercury, and sex. Elevated water temperatures were associated with elevated accumulations of mercury. Rates of mercury methylation were positively dependent on water temperature, and mercury demethylation rates were inversely related to water temperature (Bodaly et al. 1993). Elevated mercury concentrations in fish muscle were positively correlated with sediment mercury concentrations (Munn and Short 1997): a similar case is made for benthic marine invertebrates (Becker and Bigham 1995). Mercury concentrations were inversely related to lake size in planktivorous, omnivorous, and piscivorous fishes from remote lakes in northwestern Ontario; lakes ranged in size from 89 to 35,000 surface ha and were far from anthropogenic influences (Bodaly et al. 1993). Mercury levels in muscle of marine flatfishes were higher in the spring than in the autumn (Staveland et al. 1993). In the yellow perch, *Perca flavescens*, seasonal variations in uptake rate of methylmercury and in the proportion of uptake from aqueous and food sources is attributed to seasonal variations in water temperature, body size, diet, and prey availability. Methylmercury uptake was primarily from aqueous sources during the spring and fall and was dominated by food sources in the summer (Post et al. 1996). Food chain transfer of mercury from benthic invertebrates to fishes depended primarily on the consumption rate of benthivorous fishes, and secondarily on the total invertebrate mercury pools (Wong et al. 1997). In the absence of pelagic forage fish, mercury concentrations in muscle of lake trout are likely to be depressed (Futter 1994). Trophic transfer of methylmercury is much more efficient than that of Hg^{2+} (Hill et al. 1996). Sometimes, fish pellets fed to laboratory fish may contain elevated (0.09 mg Hg/kg DW) concentrations of mercury, resulting in elevated blood mercury levels (0.06 mg Hg/L) after 10 weeks, as was the case for the Sacramento blackfish, *Orthodon microlepidotus* (Choi and Cech 1998). Sexually mature female centrarchids had significantly higher concentrations of mercury in muscle tissue than did sexually mature males (Nicoletto and Hendricks 1988), although this has not been reported for other aquatic species. Mercury concentrations in fish muscle were higher in fish from humic lakes (Rask and Metsala 1991), from lakes of low mineralization (Allard and Stokes 1989), and from lakes with low concentrations of dissolved iron (Wren et al. 1991), calcium, alkalinity, chlorophyll *a*, magnesium, phosphorus, and nitrogen (Lange et al. 1993). It is noteworthy that low atmospheric depositions of selenium did not affect mercury concentrations in muscle of brown trout (Fjeld and Rognerud 1993); that mercury and selenium in muscle of marine fishes were not correlated (Chvojka 1988; Chvojka et al. 1990); and that mercury and selenium concentrations in blood of tunas were independent of each other (Kai et al. 1988).

Reservoir construction has often been inferred to be a cause of elevated mercury concentrations in fish. Reservoir conditions facilitating the bioavailability of mercury include upstream flooding and leaching of terrestrial sediments, relatively high pH and conductivity of the water, high bacterial counts in the water, complete thermal mixing, low clay content, and low concentrations of sulfur and iron and magnesium oxides in bottom sediments (Lodenius 1983; Lodenius et al. 1983; Phillips et al. 1987; Allen-Gil et al. 1995). It is hypothesized that increases in mercury levels observed in fish were due to bacterial methylation of naturally occurring mercury in the flooded soils (Bodaly et al. 1984). Methylation and transfer of methylmercury from flooded soils to suspended particulate matter and zooplankton is rapid and involves the bioaccumulation of methylmercury by phytoplankton and the ingestion of suspended soil-derived organic particles by zooplankton (Plourde et al. 1997). Suspended particulate matter and zooplankton are disproportionate contributors to methylmercury contamination of aquatic food chains in Quebec reservoirs (Plourde et al. 1997). In general, mercury levels are higher in fish from younger oligotrophic reservoirs, and lower in fish from older eutrophic reservoirs. In both situations, tissue mercury levels usually decline as the reservoirs age

(Abernathy and Cumbie 1977). Mercury concentrations greater than 0.5 mg/kg (but less than 1.0 mg/kg) FW have been reported in trout from several wilderness lakes in northern Maine (Akielaszak and Haines 1981) and from the Adirondacks region of New York (Sloan and Schofield 1983); these values are considerably higher than might be expected for fish inhabiting remote lakes. These elevated concentrations were usually associated with lakes of low pH, low calcium, low dissolved organic carbon concentrations, and low water hardness and alkalinity.

Nationwide monitoring of whole fish during the period 1969 to 1981 demonstrated that the highest mercury concentrations (0.33 to 1.7 mg/kg FW) were in northern squawfish (*Ptychocheilus oregonensis*) from the Columbia River basin in the Pacific Northwest (Henderson and Shanks 1973; Lowe et al. 1985). Elevated mercury concentrations in this piscivorous species were attributed primarily to the presence of major cinnabar deposits and with Hg use associated with mineral mining in the Columbia River basin. Northern squawfish may have a natural tendency to accumulate high concentrations of mercury in their flesh — as is well known for older specimens of long-lived predatory fishes such as tunas, billfishes, bluefish (*Pomatomus saltatrix*), striped bass (*Morone saxatilis*), northern pike (*Esox lucius*), and many species of sharks — but mercury uptake kinetics in squawfish requires further research (Lowe et al. 1985). Of 159 species of finfish and sharks from the coastal waters of Alaska, Hawaii, and the conterminous United States, mercury concentrations in muscle were usually less than 0.3 mg/kg fresh weight (Hall et al. 1978). Mean mercury concentrations in excess of 0.5 mg/kg FW muscle were recorded in 31 species, including 10 species of sharks and 4 species of billfishes; however, these 31 species accounted for less than 0.65% of the catch intended for human consumption (Hall et al. 1978).

In birds, it is generally acknowledged that mercury concentrations in tissues and feathers are highest in species that eat fish and other birds. Mercury contamination of prey in the diet of nestling wood storks (*Mycteria americana*), an endangered species, may represent a potential concern to the recovery of this species in the southeastern United States (Garibaldi et al. 1998). Increased concentrations of total mercury in livers of diving ducks were associated with lower weights of whole body, liver, and heart, and decreased activities of enzymes related to glutathione metabolism and antioxidant activity (Hoffman et al. 1998). In seabirds, mercury concentrations were highest in tissues and feathers of species that ate fish and benthic invertebrates and lowest in birds that ate mainly pelagic invertebrates (Braune 1987a; Lock et al. 1992; Kim et al. 1996). In seabirds, the relation between tissues and total mercury concentrations is frequently 7:3:1 between feather, liver, and muscle; however, there is much variability and these ratios should be treated with caution. Factors known to affect these ratios include the chemical form of mercury present in liver, the sampling date relative to the stage of the molt sequence, and the types of feathers used for analysis (Thompson et al. 1990). Mercury concentrations in feathers of wading birds collected in Florida between 1987 and 1990 were highest in older birds that consumed large fishes (Beyer et al. 1997). Also, wading birds whose prey base consisted of larger fish had four times more mercury in their livers than did species which consumed smaller fish or crustaceans (Sundlof et al. 1994). Wading birds with minimal to moderate amounts of body fat had two to three times more mercury in liver than did birds with relatively abundant body fat reserves (Sundlof et al. 1994). Essentially all of the mercury in body feathers of all seabirds studied was organic mercury; however, more than 90% of the mercury in liver is inorganic (Thompson and Furness 1989). Mercury residues are usually highest in kidney and liver, but total mercury contents are significantly modified by food preference and availability, and by migratory patterns (NAS 1978; Delbekke et al. 1984). Also, there is an inverse relationship between total mercury and percent methylmercury in tissues of various avian species (Norheim et al. 1982; Karlog and Clausen 1983) — a pattern that seems to hold for all vertebrate organisms for which data are available. Diet and migration are the most important mercury modifiers in birds. For example, the higher levels of mercury in juvenile than in adult wood ducks (*Aix sponsa*) from Tennessee were related to dietary patterns: juveniles preferred insects, whereas adults preferred pondweed tubers; mercury residues were higher in the insects than in the pondweeds (Lindsay and Dimmick 1983). Concentrations of mercury in livers of Antarctic birds reflected mercury body

burdens accumulated during migration, while the birds were overwintering near industrialized areas. Concentrations were highest in species that ate higher trophic levels of prey and were especially pronounced for skuas, *Catharacta* spp.; however, significant inherent interspecies differences were evident (Norheim et al. 1982; Norheim and Kjos-Hanssen 1984).

Bird feathers have been used for some time as indicators of mercury loadings in terrestrial and marine environments. The keratin in bird feathers is not easily degradable, and mercury is probably firmly associated with the disulfide bonds of keratin. Consequently, it has been possible to compare mercury contents of feathers recently sampled with those from museum birds, thereby establishing a time series (Applequist et al. 1984; Thompson et al. 1992; Monteiro and Furness 1995; Odsjö et al. 1997). There is considerable variability in mercury content of seabird feathers. Concentrations in adults were higher than those in chicks and independent of adult age or sex (Thompson et al. 1991), and were lower in spring breeders than in autumn breeders (Monteiro et al. 1995). After the completion of molting, new feathers contained up to 93% of the mercury body burden in gulls (Braune and Gaskin 1987). The most probable source of elevated mercury residues in feathers of the Finnish sparrowhawk (*Accipiter nisus*) was from consumption of avian granivores that had become contaminated as a result of eating seeds treated with organomercury compounds; in 1981, 5.6 tons of methoxyethylmercury compounds were used in Finnish agriculture to protect seeds against fungi (Solonen and Lodenius 1984). Concentrations of mercury in feathers of herring gulls (*Larus argentatus*) from the German North Sea coast were higher in adults than in juveniles and two times higher after 1940 than in earlier years (Thompson et al. 1993). A maximum of 12 mg/kg FW in feathers during the 1940s was recorded, presumed to be due to high discharges of mercury during the Second World War. Concentrations dropped in the 1950s, increased in the 1970s to 10 mg Hg/kg FW, before falling again in the late 1980s. This pattern correlates well with known discharges of mercury into the Elbe and Rhine (Thompson et al. 1993). Captive Swedish eagle-owls (*Bubo bubo*), with low mercury content in feathers (<1.0 mg/kg DW), that were introduced into coastal areas quickly reflected the high (6.5 mg/kg) mercury levels in feathers of wild eagle-owls from that region. Captive birds released into inland territories, where mercury levels were near background, did not accumulate Hg in feathers (Broo and Odsjöe 1981). Mercury levels in feathers of nestling Swedish gyrfalcons (*Falco rusticolus*) showed a better correlation with mercury levels in actual food items than with levels based on adult feathers. Mercury concentrations in feathers were higher in nestlings fed partly with aquatic bird species containing more than 0.07 mg Hg/kg in pectoral muscle than in nestlings fed willow grouse (*Lagopus lagopus*) and ptarmigan (*Lagopus mutus*), both of which contained less than 0.01 mg Hg/kg in pectoral muscle (Lindberg 1984). In some instances there was a substantial time lag, up to 10 years, between the introduction of a pesticide, such as alkylmercury, its subsequent banning, and measurable declines of mercury in feathers of several species of Swedish raptors; this was the case for various species of *Falco*, *Haliaeetus*, *Bubo*, *Buteo*, and *Accipiter* (Wallin 1984). Accordingly, a reduction in mercury content in feathers of free-living birds may be sufficient to establish an improved situation.

Molting is a major excretory pathway for mercury (Honda et al. 1986). Down and feathers were effective excretion routes of mercury in contaminated gull and tern chicks (Becker et al. 1994). Some seabirds demethylate methylmercury in the liver and other tissues, and store mercury as an immobilizable inorganic form in the liver; species with a high degree of demethylation capacity and slow molting pattern had low mercury burdens in feathers (Kim et al. 1996). Egg laying is an important route in reducing the female's mercury burden, especially the first egg because egg mercury levels decline with laying sequence in gulls and terns (Becker 1992; Lewis et al. 1993). In gulls and terns, 90% of the mercury in eggs is in the form of methylmercury (Becker et al. 1993). In kittiwakes (*Rissa tridactyla*), mercury concentrations in feathers and tissues of nestlings decreased with increasing age, suggesting that egg contamination was more important in chicks than consumption of mercury-contaminated food items (Wenzel et al. 1996). Eggs of the common loon (*Gavia immer*) from Wisconsin in 1993 to 1996 had 0.9 mg Hg/kg FW, which is within the range associated with reproductive failure in sensitive avian species (Meyer et al. 1998).

Significant downward trends in mercury liver burdens of raptors in England between 1960 and 1990 (Newton et al. 1993) is a useful indicator of the prohibitions placed on mercury discharges in that region. The full significance of mercury residues in birds, however, is not fully understood. For example, all eggs of the bald eagle (*Haliaeetus leucocephalus*) collected nationwide contained detectable levels of mercury, but the mean was 0.15 mg Hg/kg (fresh weight basis) in eggs from unsuccessful nests vs. 0.11 in eggs from successful nests (Wiemeyer et al. 1984). Many other contaminants — especially organochlorine compounds — were in eagle eggs, and several were present at levels that potentially interfere with eagle reproduction (Wiemeyer et al. 1984). It is not now possible to implicate mercury as a major cause of unsuccessful eagle reproduction. In the Great Lakes, mercury has no apparent effect on reproduction or nesting success of bald eagles (Bowerman et al. 1994). Livers of 30 to 80% of some species of wading birds — such as the great blue heron, *Ardea herodias* — contained mercury concentrations greater than 30 mg Hg/kg FW; these herons appeared normal although concentrations >30 mg Hg/kg FW liver are typically associated with overt neurological signs and reproductive impairment in ducks and pheasants (Sundlof et al. 1994). If reproductive disorders are expected when concentrations in feathers of adult birds approach 9 mg total Hg/kg DW (Beyer et al. 1997), then mercury in southern Florida may be sufficiently high to reduce productivity of wading bird populations (Beyer et al. 1997), but this needs to be verified.

Many factors are known to modify mercury concentrations in tissues of the common loon (*Gavia immer*). Total mercury concentrations were higher in tissues of emaciated loons when compared with apparently healthy birds, and sometimes exceeded 100 mg Hg/kg DW in tissues of loons that were in poor condition (Scheuhammer et al. 1998b). There was a strong positive correlation between total mercury and selenium concentrations in livers and kidneys. As total mercury concentrations increased in liver and kidney of loons, the fraction that was methylmercury decreased. Livers and kidneys with the highest total mercury concentrations had only 5 to 7% of the total as methylmercury. Concentrations of methylmercury were always less than 10 mg/kg DW, regardless of total mercury concentration in liver or kidney. In contrast, methylmercury contributed 80 to 100% of the total mercury in breast muscle, which ranged between 0.7 and 35.0 mg/kg DW (Scheuhammer et al. 1998b). In general, males had higher mercury concentrations in blood and feathers than did their female mates (Scheuhammer et al. 1998a). The possible transfer of mercury to eggs by females during egg laying may account for the sexual discrepancy, in part. Adult loons had higher blood mercury concentrations (up to 13 times higher) than their chicks. Adult and chick blood mercury concentrations were correlated with mercury concentrations in their fish diet (Scheuhammer et al. 1998a). Blood mercury concentrations of loon chicks near Wisconsin lakes increased with decreasing lake pH (Meyer et al. 1998). Blood and feather mercury concentrations from the same individuals were correlated, especially in loons with the highest blood mercury levels (Evers et al. 1998). Common loons had aberrant nesting behavior and low reproductive success when mercury concentrations in prey (small fish and crayfish) exceeded 0.3 mg Hg/kg FW, levels known to occur in fish from many lakes in central Ontario; up to 30% of Ontario lakes exceeded the mercury threshold for loon reproductive impairment (Scheuhammer and Blancher 1994; Scheuhammer et al. 1998a). Populations of the common loon are also declining in the northeastern United States, and this may be due to mercury, in part, as evidenced by the high concentrations in their feathers (9.7 to 20.2 mg Hg/kg DW) — twice that of other species (Burger et al. 1994).

Human intake of total mercury from the diet normally ranges between 7 and 16 µg daily (Schumacher et al. 1994; Richardson et al. 1995). Fish consumption accounts for much of this exposure in the form of methylmercury; 27% of the intake, and 40% of the absorbed dose. Intake of inorganic mercury arises primarily from foods other than fish, and is estimated at 1.8 µg daily with 0.18 µg absorbed daily (Richardson et al. 1995). In certain areas of India, blood mercury concentrations of people who ate fish were three to four times higher than non-fish eaters (Srinivasen and Mahajan 1989). In some countries, mercury in dental amalgams accounts for 2.8 µg daily, equivalent to as much as 36% of the total mercury intake and 42% of the absorbed dose (USPHS

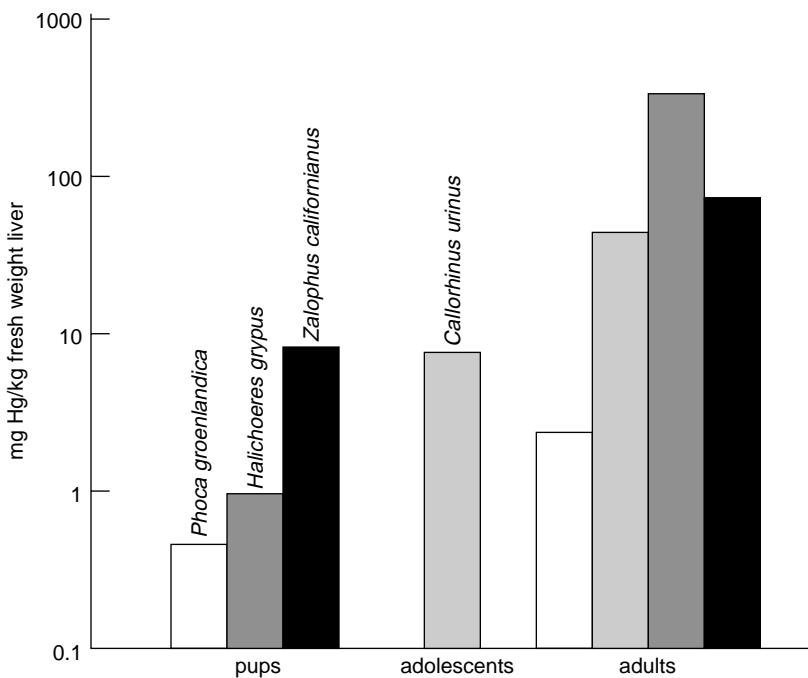

Figure 5.2 Mercury concentrations in livers of four species of pinniped mammals. (From Eisler, R. 1984. Trace metal changes associated with age of marine vertebrates. *Biol. Trace Elem. Res.* 6:165-180. With permission.)

1994; Richardson et al. 1995). Some Canadian aboriginal peoples had grossly elevated blood mercury concentrations of >100 to 660 µg Hg/L, although there was no definitive diagnosis of methylmercury poisoning (Wheatley and Paradis 1995).

Among nonhuman mammals, marine pinnipeds usually contained the highest reported concentrations of mercury in tissues (Table 5.6). The relatively high concentrations appeared to be a result of natural processes rather than anthropogenic activities, however, and probably did not represent a significant risk to pinniped health. Mercury in pinniped muscle was mostly methylmercury in both mothers and pups; pups acquired most of their mercury during gestation (Wagemann et al. 1988). In general, mercury concentrations increased significantly with increasing age of the organism, as shown in the livers of harbor seal (*Phoca groenlandica*), grey seal (*Halichoerus grypus*), California sea lion (*Zalophus californianus*), and northern fur seal (*Callorhinus ursinus*; Figure 5.2) and in various tissues of the Baikal seal (*Phoca sibirica*; Watanabe et al. 1998). The mechanisms to account for this phenomenon in pinnipeds are similar to those reported by Itano et al. (1984a, 1984b, 1984c) for the striped dolphin (*Stenella coeruleoalba*). They showed that tissue concentrations of mercury in striped dolphins increased with increasing age of the animal, reaching a plateau in 20 to 25 years; were highest in liver, although muscle accounted for about 90% of the total body mercury burden; were present in the methylated form in fetal and suckling stages, but the proportion of methylmercury decreased over time with no absolute increase after age 10 years; were excreted slowly by all developmental stages, and slowest in older dolphins (resulting in higher accumulations); and correlated strongly with selenium concentrations in all age groups. It is probable that inorganic mercury and selenium were complexed in a 1:1 molar ratio, in a form biologically unavailable to marine mammals (and probably other mammals), thereby significantly decreasing the risk of mercury toxicosis to individuals with grossly elevated mercury body burdens (Eisler 1984, 1985). The Hg/Se ratio was close to 1.0 in adults of four species of Norwegian seals provided

that tissue mercury concentrations were greater than 15 mg/kg FW (Skaare et al. 1994). Total mercury in livers of pinniped mothers (but not pups) correlated positively with selenium (Wagemann et al. 1988). Large colonies of pinnipeds and, to a lesser extent, marine birds along the western coast of the United States may make mercury available to mussels (*Mytilus californianus*) through fecal elimination of large amounts of mercury, resulting in abnormally high mercury levels in mussels from several west coast sites (Flegal et al. 1981).

Mercury concentrations in mammals are modified by age, sex, sexual condition, diet, season of collection, and other variables. Increasing concentrations of total and organic mercury in muscle and liver were observed with increasing age of fin whales (*Balaenoptera physalus*; Sanpera et al. 1993) and striped dolphins (Andre et al. 1991a), and in livers of white-tailed deer (*Odocoileus virginianus*; Khan and Forester 1995), otters (Mason and Madsen 1992), and the endangered Florida panther (*Felis concolor coryi*; Roelke et al. 1991). However, in harbor porpoises (*Phocoena phocoena*), total mercury — but not methylmercury — increased in tissues with increasing age (Joiris et al. 1991). Pregnant or lactating sperm whales (*Physeter macrocephalus*) had significantly higher mercury concentrations in muscle than nonbreeding females (Cannella and Kitchener 1992). In river otters (*Lutra canadensis*), mercury concentrations in liver and kidney were higher in males than in females (Ropek and Neely 1993). No sexual differences in liver mercury concentrations were evident in white-tailed deer (Khan and Forester 1995) or Danish otters (*Lutra lutra*; Mason and Madsen 1992). Polar bears (*Ursus maritimus*) probably obtain mercury from eating ringed seals (*Phoca hispida*), their main food (Lentfer and Galster 1987). Polar bear cubs had lower concentrations of mercury in hair than did yearlings or adults, and the low concentrations in adult hair in summer is attributed to molting (Born et al. 1991). Florida panthers found dead contained as much as 110 mg total Hg/kg FW liver, a level found lethal to feral cats in Minamata, Japan. Panthers feed primarily on raccoons, which contain as much as 3 mg Hg/kg FW (Roelke et al. 1991), but it is not known if this is the source of the elevated liver mercury in panthers.

Among furbearers in the Wisconsin River drainage system, mercury burdens were higher in fish-eating than in herbivorous species — i.e., river otter > mink (*Mustela vison*) > raccoon (*Procyon lotor*) > red fox (*Vulpes fulva*) > muskrat (*Ondatra zibethicus*) > beaver (*Castor canadensis*) (Sheffy and St. Amant 1982). In general, fur contained the highest mercury levels, followed by liver, kidney, muscle, and brain, in that order (Table 5.6; Sheffy and St. Amant 1982). Mercury levels in piscivorous furbearers collected from the Wisconsin River basin paralleled mercury levels in fish, crayfish, and bottom sediments from that system; levels in all compartments were highest about 30 km downstream from an area that supported 16 pulp and paper mills and a chloralkali plant (Sheffy and St. Amant 1982). Mercury concentrations in tissues of minks and otters trapped from various locations in Ontario between 1983 and 1985 varied as much as sixfold (Table 5.6); mercury levels in fish and crayfish from the study areas followed a similar pattern (Wren et al. 1986). Mink and river otter accumulated about ten times more mercury than did predatory fishes from the same drainage areas, suggesting that these furbearers can serve as sensitive indicators of mercury, even at very low levels of contamination (Kucera 1983). The shorttail shrew, *Blarina brevicauda*, from certain mercury-contaminated sites in Tennessee have extremely high concentrations in kidney (38.8 mg Hg/kg FW) and may be ingesting nephrotoxic levels of mercury through the diet (8.8 mg Hg/kg FW ration; Talmage and Walton 1993).

In the serow (*Capricornis crispus*), a free-ranging bovine ruminant, about 40% of the total mercury body burden was in the fleece at 0.37 mg Hg/kg FW fleece (Honda et al. 1987). Domestic sheep (*Ovis* sp.) allowed to graze for 23 months on grass contaminated with mercury (up to 6.5 mg/kg dry weight) from the atmospheric emissions of a nearby chloralkali site retained about 0.1% of the total mercury taken in by ingestion and inhalation, although residues in flesh were negligible (Edwards and Pumphrey 1982). It was concluded that contamination of grass as a result of atmospheric discharges of inorganic mercury from chloralkali sites causes no hazard, either directly to grazing animals or indirectly to humans who might ultimately consume their flesh.

Table 5.6 Mercury Concentrations in Field Collections of Selected Species of Plants and Animals (Values shown are in mg total Hg/kg fresh weight [FW], or dry weight [DW].)

Taxonomic Group, Organism, Tissue, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
FUNGI, LICHENS, MOSSES, PLANTS		
Mandarin orange, <i>Citrus tachibana</i> ; Japan Sprayed with Hg		
Fruit skin	0.03–0.24 FW	1
Fruit pulp	0.01–0.4 FW	1
Unsprayed		
Skin and pulp	0.01–0.05 FW	1
Fungi, <i>Cortinarius</i> spp.		
Near smelter	9.5–35.0 DW	1
Moss, <i>Dicranum scoparium</i> , whole		
Tennessee		
Exposed to fly ash	1.1 DW	1
Remote areas	0.1 DW	1
Great Smoky Mountains	0.07 DW	1
Hawaii	0.16 DW	1
Iceland	0.03 DW	1
Water hyacinth, <i>Eichhornia crassipes</i> ; from sewage lagoon in Bay St. Louis, Mississippi		
Leaves	70.0 DW	2
Lichen, <i>Hypogymnia physodes</i> , whole; Finland, 1982–83; distance, in km, from chloralkali plant		
0–1	18.0 FW	3

Kidney	3.7 (2.1–6.5) FW	92
Liver	7.9 (2.7–23.3) FW	92

Table 5.6 (continued) Mercury Concentrations in Field Collections of Selected Species of Plants and Animals (Values shown are in mg total Hg/kg fresh weight [FW], or dry weight [DW].)

Taxonomic Group, Organism, Tissue, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
Clear Lake, site of abandoned mercury mine		
1984, liver	6.1 (3.7–9.8) FW	92
1992		
Brain	0.3 FW	175
Muscle	1.1 FW	175
Kidney	2.1 FW	175
Liver	2.7 FW	175
Wood duck, <i>Aix sponsa</i>		
Tennessee, 1972–73		
Juveniles		
Liver	0.4 (0.1–1.1) FW	33
Muscle	0.1 (0.05–0.4) FW	33
Fat	0.1 (0.01–0.4)	33
Adults		
Liver	0.2 (0.1–0.3) FW	33
Muscle	0.08 (0.06–0.11) FW	33
Fat	0.06 (0.01–0.11) FW	33
Blue-winged teal, <i>Anas discors</i>		
Muscle		
Lake St. Clair	0.1–2.3 FW	1
Ontario	3.8–10.4 FW	1
Wisconsin	0.0–0.5 FW	1
Illinois	0.05 FW	1
Antarctic, February–March 1989		
Adelie penguin, <i>Pygoscelis adeliae</i> ; muscle vs. liver	Max. 0.7 DW vs. Max. 2.0 DW	93
Chinstrap penguin, <i>Pygoscelis antarctica</i> ; feces	1.6 DW	93
Gentoo penguin, <i>Pygoscelis papua</i> , liver	34.7 DW	93
Golden eagle, <i>Aquila chrysaetos</i>		
Scotland, 1981–86, unhatched eggs		
Eastern district	ND	94
Western coastal district	0.39 (0.1–0.1.4) DW	94
Western inland district		
25 of 27 eggs	ND	94
2 of 27 eggs	0.21 DW, 0.56 DW	94
Great blue heron, <i>Ardea herodius</i>		
Liver		
Lake St. Clair	97.0 (14.6–175.0) FW	1
New Brunswick	4.5 FW	1
Lake Erie	0.7–4.3 FW	1
Wisconsin	0.5 (0.2–1.1) FW	1
Clear Lake, California; 1993; distance from abandoned mercury mine; 8 km vs. 23 km		
Blood	1.3 FW vs. 1.2 FW	176
Diet	0.9 FW vs. 0.5 FW	176
Feathers	2.2 FW vs. 3.1 FW	176
Kidney	1.1 FW vs. 1.1 FW	176
Liver	1.4 FW vs. 1.3 FW	176
Great white heron, <i>Ardea herodias occidentalis</i> ; Florida, 1987–89; radiotagged and recovered soon after death; liver		
Dead from known acute causes	1.8 (0.6–4.0) FW	95
Dead from chronic multiple causes	9.8 (2.9–59.4) FW	95
Dead birds with signs of kidney disease and gout	>25 FW	95
Birds		
Antarctic		
Liver		
1977–79		
4 spp.	0.5–1.3 FW	34
3 spp.	2.7–2.9 FW	34

Table 5.6 (continued) Mercury Concentrations in Field Collections of Selected Species of Plants and Animals (Values shown are in mg total Hg/kg fresh weight [FW], or dry weight [DW].)

Taxonomic Group, Organism, Tissue, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
1980		
5 spp.	0.5–2.1 FW	35
Belgium, 1970–81		
Liver, 30 spp.		
Aquatic birds	0.11–35.0 FW	36
Terrestrial birds	ND–14.0 FW	36
Hawaiian, 1980		
Egg, 3 spp.	0.12–0.36 FW	37
North America		
Feather		
From areas with mercury-treated seed dressing		
Seed-eating songbirds	1.6 DW	21
Upland game birds	1.9 DW	21
From untreated areas		
Seed-eating songbirds	0.03 DW	21
Upland game birds	0.35 DW	21
Northwestern Ontario, Canada, from a heavily mercury-contaminated freshwater system		
Liver		
Scavengers	57 (13.8–121) FW	38
Fish eaters	39 (1.7–91) FW	38
Omnivores	26 (9.5–53) FW	38
Invertebrate feeders	12 (3.2–28) FW	38
Vegetarians	6 (1.9–28) FW	38
Diving ducks	Max. 175	21
Muscle		
Diving ducks	Max. 23.0 FW	21
Mallard, <i>Anas platyrhynchos</i>	Max. 6.1 FW	21
Eagle-owl, <i>Bubo bubo</i> , Sweden; 1963–76; feather		
Inland populations	3.2 DW	39
Coastal populations	6.5 DW	39
1829–1933	0.3–3.6 FW	1
1964–65	12.8–41.0 FW	1
Cattle egret, <i>Bubulcus ibis</i> ; eggs; Egypt, 1986; declining colony between 1977 and 1984	0.48 (0.28–0.84) DW	96
California, Clear Lake (mercury-contaminated site); feathers		
Western grebe, <i>Aechmophorus occidentalis</i> , adults	9.8 DW	177
Great blue heron, <i>Ardea herodias</i> ; adults	6.1 DW	177
Turkey vulture, <i>Cathartes aura</i> ; adults	1.3 DW	177
Osprey, <i>Pandion haliaetus</i>		
Adults	20.0 DW	177
Juveniles	5.3 DW	177
Juveniles from reference sites	2.3 DW	177
Great skua, <i>Catharacta skua</i>		
Total mercury, adults vs. chicks, feather	7.0 (1.0–32.4) FW vs. 1.3 (0.7–2.4) FW	97
Total mercury vs. inorganic mercury, adults		
Kidney	9.7 DW vs. 5.0 DW	97
Liver	11.6 DW vs. 6.2 DW	97
Muscle	2.3 DW vs. 2.3 DW	97
Diving ducks; California; 1989; livers; Tomales Bay vs. Suisin Bay		
Greater scaup, <i>Aythya marila</i>	19 (5–66) DW vs. 6 (3–11) DW	173
Surf scoter, <i>Melanitta perspicillata</i>	19 (3–35) DW vs. 10 (5–21) DW	173
Ruddy duck, <i>Oxyura jamaicensis</i>	6 (4–9) DW vs. 4 (2–7) DW	173

5.6 LETHAL EFFECTS

5.6.1 General

For all organisms tested, early developmental stages were the most sensitive, and organomercury compounds — especially methylmercury — were more toxic than inorganic forms. Numerous biological and abiotic factors modify the toxicity of mercury compounds, sometimes by an order of magnitude or more, but the mechanisms of action are not clear. Lethal concentrations of total mercury to sensitive, representative organisms varied from 0.1 to 2.0 µg/L of medium for aquatic fauna; from 2.2 to 31.0 mg/kg body weight (acute oral) and 4.0 to 40.0 mg/kg (dietary) for birds; and from 0.1 to 0.5 mg/kg body weight (daily dose) and 1.0 to 5.0 mg/kg (dietary) for mammals.

5.6.2 Aquatic Organisms

Lethal concentrations of mercury salts ranged from less than 0.1 µg Hg/L to more than 200 µg/L for representative sensitive species of marine and freshwater organisms (Table 5.7). The lower concentrations (less than 2.0 µg/L) were usually associated with early developmental stages, long exposures, and flowthrough tests (Table 5.7). Females and larger fish were more resistant to lethal effects of mercury than males and smaller fishes (Diamond et al. 1989). Among metals tested, mercury was the most toxic to aquatic organisms, and organomercury compounds showed the greatest biocidal potential (Eisler 1981; Jayaprakash and Madhyastha 1987). In general, toxicity was higher at elevated temperatures (Armstrong 1979), at reduced salinities in marine organisms (McKenney and Costlow 1981), and in the presence of other metals such as zinc and lead (Parker 1979).

Signs of acute mercury poisoning in fish included flaring of gill covers, increased frequency of respiratory movements, loss of equilibrium, excessive mucus secretion, darkening coloration, and sluggishness (Armstrong 1979; Hilmy et al. 1987). Signs of chronic mercury poisoning included emaciation (due to appetite loss), brain lesions, cataracts, diminished response to change in light intensity, inability to capture food, abnormal motor coordination, and various erratic behaviors (Armstrong 1979; Hawryshyn et al. 1982). Mercury residues in severely poisoned fish that died soon after ranged (in mg/kg fresh weight) from 26 to 68 in liver, 16 to 20 in brain, and 5 to 7 in whole body (Armstrong 1979).

Some fish populations have developed a resistance to methylmercury, but only in the gamete and embryonic stage. For example, eggs of the mummichog (*Fundulus heteroclitus*), an estuarine cyprinodontiform fish, from a mercury-contaminated creek, when compared to a reference site, were more than twice as resistant to methylmercury (LC50 values of 1.7 mg Hg/L vs. 0.7 mg Hg/L) when exposed for 20 min prior to combination with untreated sperm. Eggs from the polluted creek that were subjected to 1 or 2.5 mg $\text{CH}_3\text{HgCl}/\text{L}$ produced embryos with a 5 to 7% malformation frequency vs. 32% malformations at 1.0 mg/L and little survival at 2.5 mg/L in the reference group (Khan and Weis 1987). Genetic polymorphism in mosquitofish (*Gambusia* sp.) at specific enzyme loci are thought to control survival during mercury exposure (Diamond et al. 1989). In one population of mosquitofish during acute exposure to mercury, genotypes at 3 loci were significantly related to survival time, as was heterozygosity, but neither genotype of heterozygosity was related to survival in a different population of mosquitofish during acute mercury exposure (Diamond et al. 1991).

5.6.3 Birds

Signs of mercury poisoning in birds includes muscular incoordination, falling, slowness, fluffed feathers, calmness, withdrawal, hyporeactivity, hypoactivity, and eyelid drooping. In acute oral exposures, signs appeared as early as 20 min postadministration in mallards and 2.5 h in pheasants. Deaths occurred between 4 and 48 h in mallards and 2 and 6 days in pheasants; remission took up to 7 days (Hudson et al. 1984). In studies with coturnix (*Coturnix coturnix coturnix*), Hill (1981)

found that methylmercury was always more toxic than inorganic mercury and that young birds were usually more sensitive than older ones. Furthermore, some birds poisoned by inorganic mercury recovered after treatment was withdrawn, but chicks that were fed methylmercury and later developed toxic signs usually died, even if the treated feed was removed. *Coturnix* subjected to inorganic mercury, regardless of the route of administration, showed a violent neurological dysfunction that ended in death 2 to 6 h posttreatment. The withdrawal syndrome in *coturnix* poisoned by Hg^{2+} was usually preceded by intermittent, nearly undetectable tremors, coupled with aggressiveness toward cohorts; time from onset to remission was usually 3 to 5 days, but sometimes extended to 7 days. *Coturnix* poisoned by methylmercury appeared normal until 2 to 5 days posttreatment; then, ataxia and low body carriage with outstretched neck were often associated with walking. In advanced stages, *coturnix* lost locomotor coordination and did not recover; in mild to moderate clinical signs, recovery usually took at least 1 week (Hill 1981).

Mercury toxicity to birds varies with the form of the element, dose, route of administration, species, sex, age, and physiological condition (Fimreite 1979). For example, in northern bobwhite chicks fed diets containing methylmercury chloride, mortality was significantly lower when the solvent was acetone than when it was another carrier, such as propylene glycol or corn oil (Spann et al. 1986). In addition, organomercury compounds interact with elevated temperatures and pesticides, such as DDE and parathion, to produce additive or more-than-additive toxicity, and with selenium to produce less-than-additive toxicity (Fimreite 1979). Acute oral toxicities of various mercury formulations ranged between 2.2 and about 31.0 mg Hg/kg body weight for most avian species tested ([Table 5.8](#)). Similar data for other routes of administration were 4.0 to 40.0 mg/kg for diet and 8.0 to 15.0 mg/kg body weight for intramuscular injection ([Table 5.8](#)).

Residues of mercury in experimentally poisoned passerine birds usually exceeded 20 mg/kg FW and were similar to concentrations reported in wild birds that died of mercury poisoning (Finley et al. 1979). In one study with the zebra finch (*Poephila guttata*), adults were fed methylmercury in the diet for 76 days at dietary levels of <0.02 (controls), 1, 2.5, or 5 mg Hg/kg DW ration (Scheuhammer 1988). There were no signs of mercury intoxication in any group except the high-dose group, which experienced 25% dead and 40% neurological impairment. Dead birds from the high-dose group had 73 mg Hg/kg FW in liver, 65 in kidney, and 20 in brain; survivors without signs had 30 in liver, 36 in kidney, and 14 in brain; impaired birds had 43 mg Hg/kg FW in liver, 55 in kidney, and 20 in brain (Scheuhammer 1988). Mercury levels in tissues of poisoned wild birds were highest (45 to 126 mg/kg FW) in red-winged blackbirds (*Agelaius phoeniceus*), intermediate in starlings (*Sturnus vulgaris*) and cowbirds (*Molothrus ater*), and lowest (21 to 54) in grackles (*Quiscalus quiscula*). In general, mercury residues were highest in the brain, followed by the liver, kidney, muscle, and carcass. Some avian species are more sensitive than passersines (Solonen and Lodenius 1984; Hamasaki et al. 1995): liver residues (in mg Hg/kg FW) in birds experimentally killed by methylmercury ranged from 17 in red-tailed hawks (*Buteo jamaicensis*) to 70 in jackdaws (*Corvus monedula*); values were intermediate in ring-necked pheasants, kestrels (*Falco tinnunculus*), and magpies (*Pica pica*). Experimentally poisoned grey herons (*Ardea cinerea*) seemed to be unusually resistant to mercury; lethal doses produced residues of 415 to 752 mg Hg/kg dry weight of liver (Van der Molen et al. 1982). However, levels of this magnitude were frequently encountered in livers from grey herons collected during a massive die-off in the Netherlands during a cold spell in 1976; the interaction effects of cold stress, mercury loading, and poor physical condition of the herons are unknown (Van der Molen et al. 1982).

5.6.4 Mammals

Methylmercury affects the central nervous system in humans — especially the sensory, visual, and auditory areas concerned with coordination. The most severe effects lead to widespread brain damage, resulting in mental derangement, coma, and death (Clarkson and Marsh 1982; USPHS 1994). In mule deer (*Odocoileus hemionus hemionus*), after acute oral mercury poisoning was

^b 55 to 80% reduction in egg production; embryonic survival sharply reduced.

induced experimentally, additional signs included belching, bloody diarrhea, piloerection (hair more erect than usual), and loss of appetite (Hudson et al. 1984). The kidney is the probable critical organ in adult mammals due to the rapid degradation of phenylmercurials and methoxyethylmercurials to inorganic mercury compounds and subsequent translocation to the kidney (Suzuki 1979), whereas in the fetus the brain is the principal target (Khera 1979). Most human poisonings were associated with organomercury compounds used in agriculture as fungicides to protect cereal seed grain (Elhassani 1983); judging from anecdotal evidence, many wildlife species may have been similarly afflicted. Organomercury compounds, especially methylmercury, were the most toxic mercury species tested. Among sensitive species of mammals, death occurred at daily organomercury concentrations of 0.1 to 0.5 mg/kg body weight, or 1.0 to 5.0 mg/kg in the diet (Table 5.9). Larger animals such as mule deer and harp seals appear to be more resistant to mercury than smaller mammals such as mink, cats, dogs, pigs, monkeys, and river otters; the reasons for this difference are unknown, but may be related to differences in metabolism and detoxification rates. Tissue residues in fatally poisoned mammals (in mg Hg/kg fresh weight) were 6.0 in brain, 10.0 to 55.6 in liver,

Table 5.9 Lethality of Organomercury Compounds to Selected Mammals

Organism	Dose, Route of Administration, and Other Variables	Effects	Ref. ^a
Domestic dog, <i>Canis familiaris</i>	0.1 to 0.25 mg/kg body weight (BW) during entire pregnancy; oral route	High incidence of stillbirths	1
Domestic cat, <i>Felis domesticus</i>	0.25 mg/kg BW daily for 90 days (total 80–90 mg Hg); dietary route	Mean survival time 78 days. Convulsions starting at day 68; all with signs by day 90. Liver residues of survivors were 40.2 and 18.1 mg/kg FW for total mercury and inorganic mercury, respectively	2
Pig, <i>Sus</i> spp.	0.5 mg/kg BW during pregnancy; oral route	High incidence of stillbirths	1
Rhesus monkey, <i>Macaca mulatta</i>	0.5 mg/kg BW during days 20–30 of pregnancy	Maternally toxic, and abortive	1
Mink, <i>Mustela vison</i>	1.0 mg/kg in diet	Fatal to 100% in about 2 months	3
Mink	1.0 mg/kg diet daily for 4 months; then every other day for 4 months alternating with control diet	High mortality after 4 months when subjected to cold stress; significant placental transfer to the fetus	9
Mink	5.0 mg/kg in diet	All dead in 30 to 37 days. Elevated residues in kidney (37.7 mg/kg fresh weight) and liver (55.6) prior to death	3
River otter, <i>Lutra canadensis</i>	>2.0 mg/kg in diet	Fatal within 7 months	4, 8
Humans, <i>Homo sapiens</i>	Various	Lethal residues in tissues, in mg/kg fresh weight, were >6.0 in brain, >10.0 in liver, and >17.0 in whole body	1
Mule deer, <i>Odocoileus hemionus hemionus</i>	17.88 mg/kg BW; single oral dose	LD50	5
Harp seal, <i>Pagophilus groenlandicus</i>	25.0 mg/kg BW daily; oral route	Dead in 20 to 26 days. Blood Hg levels just before death were 26.8 to 30.3 mg/L	6
Rat, <i>Rattus</i> sp.	27 mg/m ³ air for 1–2 h	Fatal; death by asphyxiation; lung edema; necrosis of alveolar epithelium	7

^a 1, Khera 1979; 2, Eaton et al. 1980; 3, Sheffy and St. Amant 1982; 4, Kucera 1983; 5, Hudson et al. 1984; 6, Ronald et al. 1977; 7, PHS 1994; 8, Ropek and Neely 1993; 9, Wren et al. 1987a.

17.0 in whole body, about 30.0 in blood, and 37.7 in kidney (Table 5.9). Mercury interactions with other compounds should be considered. Adverse effects on growth and survival of mink kits are reported for diets containing 1.0 mg Hg/kg ration as methyl mercury and Aroclor 1254 — a polychlorinated biphenyl — at 1.0 mg/kg ration (Wren et al. 1987b).

5.6.5 Other Groups

Methylmercury compounds at concentrations of 25.0 mg Hg/kg in soil were fatal to all tiger worms (*Eisenia foetida*) in 12 weeks; at 5.0 mg/kg, however, only 21% died in a similar period (Beyer et al. 1985). Inorganic mercury compounds were also toxic to earthworms (*Octochaetus pattoni*); in 60 days, 50% died at soil Hg levels of 0.79 mg/kg, and all died at 5.0 mg/kg (Abbasi and Soni 1983).

5.7 SUBLETHAL EFFECTS

5.7.1 General

Mercury is a known mutagen, teratogen, and carcinogen. At comparatively low concentrations in birds and mammals, it adversely affects reproduction, growth and development, behavior, blood

and serum chemistry, motor coordination, vision, hearing, histology, and metabolism. It has a high potential for bioaccumulation and biomagnification, and is slow to depurate. Organomercury compounds were more effective in producing adverse effects than were inorganic mercury compounds; however, effects were significantly enhanced or ameliorated by numerous biotic and nonbiological modifiers. For sensitive aquatic species, adverse effects were observed at water concentrations of 0.03 to 0.1 µg Hg/L. For sensitive species of birds, harmful levels were 640 µg Hg/kg body weight daily, or 50 to 500 µg Hg/kg in the diet; for sensitive mammals, these levels were 250 µg Hg/kg body weight daily, or 1100 µg Hg/kg diet.

5.7.2 Carcinogenicity, Genotoxicity, and Teratogenicity

Mercury has been assigned a weight-of-evidence classification of D, which indicates that it is not classifiable as to human carcinogenicity (USPHS 1994). Beluga whales (*Delphinapterus leucas*) in the St. Lawrence estuary have a high incidence of cancer (Gauthier et al. 1998). Studies with isolated skin fibroblasts of beluga whales exposed to mercuric chloride or methylmercury induced a significant dose-response increase of micronucleated cells. Concentrations as low as 0.5 mg Hg²⁺/L and 50 µg CH₃Hg⁺/L — comparable to concentrations present in certain whales of this population — significantly induced proliferation (Gauthier et al. 1998).

Mercury is not genotoxic in humans. Dental amalgam has been used for more than 150 years, and it is well established that patients with amalgam dental fillings are chronically exposed to mercury and that the number of amalgam fillings correlates positively with mercury levels in blood and plasma (Loftenius et al. 1998). Amalgam removal, however, did not have a measurable effect on proliferation of peripheral blood lymphocytes, suggesting that mercury contributed by amalgams was not mitogenic to lymphocytes (Loftenius et al. 1998). Mercury does not adversely affect the number or structure of chromosomes in human somatic cells in workers occupationally exposed to mercury compounds by inhalation or accidentally exposed through ingestion (USPHS 1994). In the laboratory, however, mercury compounds often exerted genotoxic effects, especially by binding SH groups and acting as spindle inhibitors, resulting in abnormal chromosome numbers (De Flora et al. 1994). Chromosomal aberrations and sister chromatid exchanges have been produced by mercury compounds in larvae and embryos of amphibians and fishes; various species of bacteria, yeasts, and molds; and cultured somatic cells of fish, insects, echinoderms, and mammals — including somatic cells of rodents, dolphins, cats, and humans (Heagler et al. 1993; De Flora et al. 1994; Kramer and Newman 1994; USPHS 1994; Betti and Nigro 1996).

Toxicant stress to individuals may modify genetic characteristics of mosquitofish populations. Allozyme polymorphisms existing in mosquitofish populations with no history of contaminant stress can be subject to selection and provide the basis for adaptation to anthropogenic stress (Mulvey et al. 1995). For example, metabolic differences in glucosephosphatase isomerase genotypes, or closely related loci, may be expressed in degree of environmental stress or fluctuation (Mulvey et al. 1995). Allozyme genotypes could be responsible for transient genotype effects noted in electrophoretic surveys of mercury-stressed mosquitofish populations (Lee et al. 1992).

Methylmercury induces increased teratogenic and mutagenic effects in killifish (*Fundulus heteroclitus*) embryos after exposure to 50 µg Hg/L for up to 7 days postfertilization (Perry et al. 1988). Chromosomal aberrations were 13% in the treated group vs. 5.1% in controls. Mutagenic effects in killifish embryos occurred at levels below that measured in some marine sediments (Perry et al. 1988). In terms of ability to affect normal development of embryos of the horseshoe crab (*Limulus polyphemus*), mercury — as the acetate or chloride — was the most toxic metal tested, followed in decreasing order by tributyltin chloride, hexavalent chromium, cadmium, copper, lead, and zinc (Itow et al. 1998). Mercury was associated with a high frequency of segment-defective embryos and could be replicated with SH inhibitors, and by compounds inhibiting SH-SS exchange (Itow et al. 1998).

5.7.3 Aquatic Organisms

Sublethal concentrations of mercury are known to adversely affect aquatic organisms through inhibition of reproduction (Dave and Xiu 1991; Kanamadi and Saidapur 1991; Kirubagaran and Joy 1992; Khan and Weis 1993; Punzo 1993), reduction in growth rate (Kanamadi and Saidapur 1991; Punzo 1993), increased frequency of tissue histopathology (Kirubagaran and Joy 1988, 1989; Handy and Penrice 1993; Voccia et al. 1994), impairment in ability to capture prey (Weis and Weis 1995) and olfactory receptor function (Baatrup et al. 1990; Baatrup and Doving 1990), alterations in blood chemistry (Allen 1994) and enzyme activities (Nicholls et al. 1989; Kramer et al. 1992), disruption of thyroid function (Kirubagaran and Joy 1989), chloride secretion (Silva et al. 1992), and other metabolic and biochemical functions (Nicholls et al. 1989; Angelow and Nicholls 1991). In general, the accumulation of mercury by aquatic biota is rapid and depuration is slow (Newman and Doubet 1989; Angelow and Nicholls 1991; Wright et al. 1991; Handy and Penrice 1993; Pelletier and Audet 1995; Geffen et al. 1998). It is emphasized that organomercury compounds, especially methylmercury, were significantly more effective than inorganic mercury compounds in producing adverse effects and accumulations (Baatrup et al. 1990; Wright et al. 1991; Kirubagaran and Joy 1992; Odin et al. 1995).

Reproduction was inhibited among sensitive species of aquatic organisms at water concentrations of 0.03 to 1.6 µg Hg/L. In the planarian (*Dugesia dorotocephala*), asexual fission was suppressed at 0.03 to 0.1 µg organomercury/L (Best et al. 1981); in the slipper limpet (*Crepidula fornicate*), spawning was delayed and fecundity was decreased at 0.25 µg Hg²⁺/L (Thain 1984); in the zebrafish (*Brachydanio rerio*), hatching success was reduced at 0.1 µg Hg²⁺/L and egg deposition was reduced at 0.8 µg/L (Armstrong 1979); fathead minnows (*Pimephales promelas*) exposed to 0.12 µg methylmercury/L for 3 months failed to reproduce (Birge et al. 1979); the leopard frog (*Rana pipiens*) did not metamorphose during exposure to 1.0 µg methylmercury/L for 4 months (USEPA 1980); and in the mysid shrimp (*Mysidopsis bahia*), the abortion rate increased and population size decreased after lifetime (i.e., 28 days) exposure to 1.6 µg/L of mercury as mercuric chloride (Gentile et al. 1983). For sensitive marine invertebrates such as hydroids, protozoans, and mysid shrimp, reproduction was inhibited at concentrations between 1.1 and 2.5 µg Hg²⁺/L; this range was 5 to 71 µg/L for more resistant species of marine invertebrates (Gentile et al. 1983). Impairment of testicular lipid metabolism in catfish (*Clarias batrachus*) at sublethal concentrations of inorganic and organic mercury compounds may account for the mercury-induced inhibition of steroidogenesis and spermatogenesis (Kirubagaran and Joy 1992). Inorganic and organic mercury compounds produce different morphological effects on the micropyle of fish eggs. Reduced insemination success of killifish (*Fundulus heteroclitus*) eggs exposed to methylmercury was due to rupture of cortical vesicles and blockage of the micropyle. However, reduced insemination due to inorganic mercury was due to swelling of the micropylar lip and a decrease in micropyle diameter (Khan and Weis 1993).

Reduced growth of sensitive species of aquatic organisms has been recorded at water concentrations of 0.04 to 1.0 µg Hg/L. The rainbow trout (*Oncorhynchus mykiss*) was the most sensitive species tested; growth reduction was observed after 64 days in 0.04 µg Hg/L as methylmercury, or 0.11 µg Hg/L as phenylmercury (USEPA 1980). In adults of the marine mollusc *Crepidula fornicate*, growth was reduced after 16 weeks in 0.25 µg Hg²⁺/L (Thain 1984). Growth inhibition was recorded in freshwater algae after exposure of 24 h to 10 days to 0.3 to 0.6 µg organomercury/L, in brook trout (*Salvelinus fontinalis*) alevins after exposure for 21 days to 0.79 µg organomercury/L (USEPA 1980), and in the marine alga *Scripsiella faeroense* exposed to 1.0 µg Hg²⁺/L for 24 h (Kayser 1976).

Adverse effects of mercury on aquatic organisms, in addition to those listed on reproduction and growth, have been documented at water concentrations of 0.88 to 5.0 µg/L: enzyme disruption in brook trout (*Salvelinus fontinalis*) embryos immersed for 17 days in solutions containing

0.88 µg/L, as methylmercury (USEPA 1980); an increased incidence of frustule abnormalities and burst thecae in two species of marine algae during exposure to 1.0 µg Hg²⁺/L for 24 h (Kayser 1976; Saboski 1977); arrested development of sea urchin larvae at 3.0 µg Hg²⁺/L for 40 h (USEPA 1980); decreased rate of intestinal transport of glucose, fructose, glycine, and tryptophan in the murrel (*Channa punctatus*) at 3.0 µg Hg²⁺/L for 30 days (Sastry et al. 1982); altered blood chemistry in striped bass (*Morone saxitilis*) at 5.0 µg Hg²⁺/L in 60 days (Dawson 1982); and decreased respiration in striped bass 30 days postexposure after immersion for 30 to 120 days in 5.0 µg Hg²⁺/L (Armstrong 1979; USEPA 1980). In largemouth bass, elevated liver metallothioneins are indicative of elevated muscle mercury concentrations, suggesting that mercury-induced metallothioneins may be useful biomarkers of mercury exposure (Schlenk et al. 1995). In marine molluscs exposed to water concentrations of 6 to 10 µg Hg²⁺/L for 96 h, the feeding of adults ceased, and the swimming rate of larval stages declined (Thain 1984). At 44 µg Hg²⁺/L for 30 days, the freshwater fish *Notopterus notopterus* showed generalized metabolic derangement (Verma and Tonk 1983). In freshwater planarians exposed to 80 to 100 µg/L as methylmercury, behavior was modified and regeneration retarded (Best et al. 1981). And at high sublethal concentrations of methylmercury, rainbow trout were listless and darkly pigmented; appetite was reduced; and digestion was poor (Rodgers and Beamish 1982). Olfactory receptor function in Atlantic salmon is highly vulnerable to brief exposures of sublethal concentrations of mercuric chloride or methylmercury chloride. In both cases, mercury was deposited in the olfactory system along its whole length from receptor cell apices to the brain (Baatrup and Diving 1990). Inorganic mercury inhibited the olfactory response after exposure to 10 µg Hg/L for 10 min, with effects reversible; however, methylmercury-induced inhibition was not reversible (Baatrup et al. 1990).

At lower trophic levels, the efficiency of mercury transfer was low through natural aquatic food chains; however, in animals of higher trophic levels, such as predatory teleosts and fish-eating birds and mammals, the transfer was markedly amplified (Eisler 1978, 1981, 1987). High uptake and accumulation of mercury from the medium by representative species of marine and freshwater teleosts and invertebrates are documented (Kopfler 1974; Eisler 1978, 1981; Birge et al. 1979; Huckabee et al. 1979; USEPA 1980, 1985; Stokes et al. 1981; Rodgers and Beamish 1982; Hirota et al. 1983; Clarkson et al. 1984; McClurg 1984; Niimi and Lowe-Jinde 1984; Ramamoorthy and Blumhagen 1984; Ribeyre and Boudou 1984; Thain 1984; Newman and Doubet 1989; Angelow and Nicholls 1991; Wright et al. 1991; Handy and Penrice 1993). Accumulation patterns were enhanced or significantly modified by numerous biological and abiotic factors (NAS 1978; Eisler 1978, 1981, 1984, 1985; USEPA 1980, 1985; Stokes et al. 1981; Rodgers and Beamish 1982; Clarkson et al. 1984; Ramamoorthy and Blumhagen 1984; Ribeyre and Boudou 1984; Ponce and Bloom 1991; Odin et al. 1995; Choi et al. 1998). In general, the accumulation of mercury was markedly enhanced at elevated water temperatures, reduced water salinity or hardness, reduced water pH, increased age of the organism, and reduced organic matter content of the medium; in the presence of zinc, cadmium, or selenium in solution; after increased duration of exposure; and in the presence of increased nominal concentrations of protein-bound mercury. Uptake patterns were significantly modified by sex, sexual condition, prior history of exposure to mercury salts, the presence of complexing and chelating agents in solution, dietary composition, feeding niche, tissue specificity, and metabolism. However, trends were not consistent between species and it is difficult to generalize. In one example, Ribeyre and Boudou (1984) immersed rainbow trout in solutions containing 0.1 µg Hg/L as methylmercury: after 30 days, bioconcentration factors (BCF) ranged from 28,300 for brain to 238,000 for spleen; values were intermediate for muscle (30,000), whole fish (36,000), blood (102,000), liver (110,000), kidney (137,000), and gill (163,000). These values may have been higher if exposure had extended beyond 30 days. Rodgers and Beamish (1982) showed that whole body mercury residues in rainbow trout subjected to mercury insult continued to increase for the first 66 days before stabilizing. When mercury was presented as inorganic mercuric ion at 0.1 µg/L for 30 days, BCF values were usually lower than in trout exposed to methylmercury: 2300 for muscle; 6800 for brain; 7000 for whole trout; 14,300 for blood; 25,000

for liver; 53,000 for kidney; 68,600 for gill; and 521,000 for spleen (Ribeyre and Boudou 1984). The high BCF values recorded for rainbow trout were probably due to efficient uptake from water, coupled with slow depuration (Rodgers and Beamish 1982).

Total mercury concentrations, in mg/kg FW, in tissues of adult freshwater fishes with signs of methylmercury intoxication ranged from 3 to 42 in brain, 6 to 114 in liver, 5 to 52 in muscle, and 3 to 35 in whole body (Wiener and Spry 1996). Whole body levels up to 100 mg Hg/kg were reportedly not lethal to rainbow trout, although 20 to 30 mg/kg were associated with reduced appetite, loss of equilibrium, and hyperplasia of gill epithelium (Niimi and Lowe-Jinde 1984). However, brook trout showed toxic signs and death at whole body residues of only 5 to 7 mg/kg (Armstrong 1979). In another example, the marine copepod *Acartia clausi*, subjected to 0.05 µg/L of mercury and higher, reached equilibrium with the medium in only 24 h. In that study (Hirota et al. 1983), BCF values for whole *Acartia* after 24-h exposures were 14,360 for inorganic mercuric ion (0.05 µg/L) and, for methylmercury, 179,200 (0.05 µg/L) and 181,000 (0.1 µg/L).

Elimination of accumulated mercury, both organic and inorganic, from aquatic organisms is a complex multicompartmental process, but appears to be largely dependent on its rate of biological assimilation. This rate, in turn, varies widely (20 to 90%) between species, for reasons as yet unexplained (NAS 1978). For example, mercury associated with dietary components that are not assimilated is eliminated rapidly with feces. The rest is absorbed across the gut and incorporated into tissues. This assimilated fraction of mercury is depurated much more slowly, at a rate positively correlated with the organism's metabolism (NAS 1978; Rodgers and Beamish 1982). Route of administration is also important. Bioavailability estimates of methylmercury from orally administered doses to channel catfish (*Ictalurus punctatus*) tend to overestimate the true bioavailability (McCloskey et al. 1998) and indicate that data based on this route of administration need to be reexamined. Time to eliminate 50% of biologically assimilated mercury and its compounds (T_b 1/2) is variable. Among various species of freshwater teleosts, T_b 1/2 values (in days) were 20 for guppies *Poecilia reticulatus*, 23 for goldfish *Carassius auratus*, 100 for northern pike, and 1000 each for mosquitofish *Gambusia affinis*, brook trout, and rainbow trout (Huckabee et al. 1979). A similar range in T_b 1/2 values was recorded for invertebrates and marine fishes: 297 days for the crayfish *Astacus fluviatilis*, 435 days for mussel, 481 days for the clam *Tapes decussatus*, 1030 days for the eel *Anguilla vulgaris*, and 1200 days for the flounder *Pleuronectes flesus* (NAS 1978).

Mercury-tolerant strains of bacteria (Colwell et al. 1976), protozoa (Berk et al. 1978), crustaceans (Green et al. 1976; Weis 1976), and fish (Weis 1984) are reported. Mercury-resistant strains of bacteria are recommended as bioindicators of environmental mercury contamination and as markers of methylmercury in biological samples (Baldi et al. 1991). The mercury-resistant strains of bacteria that have been cultured or discovered may have application in mobilization or fixation of mercury from contaminated aquatic environments to the extent that polluted areas may become innocuous (Colwell et al. 1976). The marine protozoan *Uronema nigricans*, after feeding on mercury-laden bacteria, acquired mercury tolerance within a single generation (Berk et al. 1978). The white shrimp (*Penaeus setiferus*), preexposed for 57 days to 1 µg Hg/L, did not differ from controls during either exposure or subsequent mercury stress experiments (Green et al. 1976). These observations suggest that nonsensitization or adaptation mechanisms are involved. The fiddler crab (*Uca pugilator*) seemed unusually resistant and showed negligible uptake or effects during exposure to 100 µg Hg/L for 2 weeks (Weis 1976). Reasons to account for mercury adaptation of the estuarine cyprinodontiform teleost *Fundulus heteroclitus* to both methylmercury and inorganic mercury are under investigation (Weis 1984).

5.7.4 Birds

Sublethal effects of mercury on birds, administered by a variety of routes, included adverse effects on growth, development, reproduction, blood and tissue chemistry, metabolism, and behavior. Histopathology and bioaccumulation were also noted.

The dietary route of administration is the most extensively studied pathway of avian mercury intake. Domestic chickens fed diets containing as little as 50 µg/kg of mercury, as methylmercury, contained elevated total mercury (2.0 mg/kg fresh weight) residues in liver and kidney after 28 weeks; at 150 µg/kg, residues ranged from 1.3 to 3.7 mg/kg in heart, muscle, brain, kidney, and liver, in that general order. At 450 µg/kg in diets, residues in edible chicken tissues (3.3 to 8.2 mg/kg) were considered hazardous to human consumers, although no overt signs of mercury toxicosis were observed in the chickens (March et al. 1983). High inorganic mercury levels (500 mg/L) in drinking water of chickens decreased growth rate and food and water consumption, and elevated hemoglobin, hematocrit, and erythrocyte content within 3 days (Grissom and Thaxton 1985).

The dietary concentration of 0.5 mg Hg/kg dry weight (equivalent to about 0.1 mg/kg fresh weight) in the form of methylmercury was fed to three generations of mallards (Heinz 1979). Females laid a greater percentage of their eggs outside nest boxes than did controls, and also laid fewer eggs and produced fewer ducklings. Ducklings from parents fed methylmercury were less responsive than controls to tape-recorded maternal calls, but were hyperresponsive to a fright stimulus in avoidance tests (Heinz 1979). Mallard hens fed diets containing 3 mg Hg/kg ration as methylmercury for two reproductive seasons produced eggs with elevated mercury concentrations (5.5 to 7.2 mg Hg/kg FW); hatched ducklings from this group had brain lesions of the cerebellum and reduced survival (Heinz and Locke 1976).

Adult female mallards fed diets containing 1 or 5 mg Hg/kg ration, as methylmercury chloride, produced eggs that contained 1.4 mg Hg/kg FW (1.0 mg/kg ration) or 8.7 mg Hg/kg FW (5 mg Hg/kg diet); breast muscle had 1.0 or 5.3 mg Hg/kg FW; the addition of 5 mg DDE/kg diet did not affect mercury retention in breast muscle or eggs (Heinz 1987). Lesions in the spinal cord were the primary effect in adult female mallards fed diets containing 1.5 or 2.8 mg Hg/kg DW ration as methylmercury (Pass et al. 1975). The tissues and eggs of ducks and other species of birds collected in the wild have sometimes contained levels of mercury equal to, or far exceeding, those associated with reproductive and behavioral deficiencies in domestic mallards (e.g., 9 to 11 mg/kg in feathers; >2.0 mg/kg in other tissues); therefore, it is possible that reproduction and behavior of wild birds have been modified by methylmercury contamination (Heinz 1979). Tissue mercury residues of wild-strain mallards and game-farm mallards were not significantly different after the birds were fed diets containing 0.5 mg Hg/kg as methylmercury for extended periods — indicating that game-farm mallards are suitable substitutes for wild mallards in toxicological evaluations (Heinz 1980).

Interaction effects of mercury with other metals need to be considered. Pekin duck (*Anas platyrhynchos*), age 6 months, fed a diet containing 8 mg Hg/kg ration as methylmercury chloride for 12 weeks, had kidney histopathology; damage effects were exacerbated when diets also contained 80 mg lead acetate/kg, 80 mg cadmium chloride/kg, or both (Rao et al. 1989). Recent studies with mallard adults show significant interaction effects of mercury and selenium. In one 10-week study, mallard adults were fed diets containing 10 mg Hg/kg DW ration as methylmercury chloride, 10 mg Se/kg as seleno-DL-methionine, or a mixture containing 10 mg Hg/kg plus 10 mg Se/kg (Heinz and Hoffman 1998). One of the 12 adult mallards fed the 10 mg Hg/kg diet and 8 others suffered paralysis of the legs; however, none of the 12 males on the mixture diet became sick. Both selenium and mercury diets lowered duckling production through reduced hatching success and survival; the mixture diet was worse than either Hg or Se alone. Controls produced 7.6 ducklings/female, females fed 10 mg Se/kg produced 2.8, females fed 10 mg Hg/kg produced 1.1 young, and the mixture diet resulted in 0.2 ducklings/females. Deformity frequency was 6.1% in control ducklings, 16.4% for the mercury group, 36.2% for the selenium group, and 73.4% for the group fed the methylmercury and selenomethionine mixture. The presence of mercury in the diet enhanced selenium storage; however, Se did not enhance Hg storage (Heinz and Hoffman 1998). In another study with mallard adult males fed diets as outlined in the Heinz and Hoffman (1998) study, the investigators analyzed blood, liver, and brain samples for clinical and biochemical alterations after

10 weeks (Hoffman and Heinz 1998). The 10 mg Hg/kg ration group had decreased hematocrit and hemoglobin, and decreased activities of various enzymes involved in glutathione metabolism. Selenium in combination with methylmercury partially or totally alleviated effects of mercury on various glutathione activities. The ability of seleno-DL-methionine to restore the glutathione status involved in antioxidative defense mechanisms may be important in protecting against the toxic effects of methylmercury (Hoffman and Heinz 1998).

Dietary concentrations of 1.1 mg total Hg/kg have been associated with kidney lesions in juvenile starlings (*Sturnus vulgaris*) and with elevated residues in the liver (6.5 mg/kg dry weight and kidney (36.3 mg/kg), after exposure for 8 weeks (Nicholson and Osborn 1984). In American black ducks (*Anas rubripes*) fed diets containing 3.0 mg Hg/kg as methylmercury for 28 weeks, reproduction was significantly inhibited; tissue residues were elevated in kidney (16.0 mg/kg fresh weight) and liver (23.0 mg/kg); and brain lesions characteristic of mercury poisoning were present (Finley and Stendell 1978). Japanese quail (*Coturnix japonica*) fed diets containing 8 mg Hg/kg of inorganic mercury for 3 weeks had depressed gonad weights; those fed 3 mg/kg inorganic mercury or 1 mg/kg methylmercury for 9 weeks showed alterations in brain and plasma enzyme activities (Hill and Soares 1984). Grossly elevated tissue residues of 400 mg/kg in feathers and 17 to 130 mg/kg in other tissues were measured in gray partridge (*Perdix perdix*) after dietary exposure of 20 to 25 mg total Hg/kg for 4 weeks (McEwen et al. 1973).

Mercury exposure by immersion and oral administration have caused reproductive and behavioral modifications. Brief immersion of mallard eggs in solutions of methylmercury resulted in a significant incidence of skeletal embryonic aberrations at dosages of 1.0 µg Hg/egg, and higher; no increases in embryonic malformations were noted at 0.3 µg Hg/egg (Hoffman and Moore 1979). Reduced reproductive ability was noted in grey pheasants ingesting 640 µg Hg (as organomercury)/kg body weight daily for 30 days (McEwen et al. 1973); similar results were observed in ring-necked pheasants (Spann et al. 1972; Mullins et al. 1977). Behavioral alterations were noted in pigeons (*Columba livia*) given 3000 µg inorganic Hg/kg body daily for 17 days (Leander et al. 1977) or 1000 µg/kg body weight of methylmercury for 5 weeks (Evans et al. 1982). Observed behavioral changes in posture and motor coordination of pigeons were permanent after the brain accumulated >12,000 µg Hg/kg fresh weight, and were similar to the "spastic paralysis" observed in wild crows during the Minamata, Japan, outbreak of the 1950s, although both species survived for years with these signs (Evans et al. 1982).

Tissue concentrations >15,000 µg Hg/kg FW brain and >30,000 to 40,000 µg/kg FW liver or kidney are associated with neurological impairment (Scheuhammer 1988). Mercury residues of 790 to 2000 µg/kg in egg and 5000 to 40,000 µg/kg in feathers are linked to impaired reproduction in various bird species (Spann et al. 1972; NAS 1978; Heinz 1979; Fimreite 1979; Solonen and Lodenius 1984). Residues in eggs of 1300 to 2000 µg Hg/kg fresh weight were associated with reduced hatching success in white-tailed sea-eagles (*Haliaeetus albicilla*), the common loon (*Gavia immer*), and in several seed-eating species (Fimreite 1979). This range was 900 to 3100 µg/kg for ring-necked pheasant (Spann et al. 1972), and 790 to 860 µg/kg for mallards (Heinz 1979). Residues of 5000 to 11,000 µg Hg/kg in feathers of various species of birds have been associated with reduced hatch of eggs and with sterility (NAS 1978). Sterility was observed in the Finnish sparrow hawk (*Accipiter nisus*) at mercury concentrations of 40,000 µg/kg in feathers (Solonen and Lodenius 1984). Chicks of the common tern (*Sterna hirundo*) from a colony in Long Island, New York, with abnormal feather loss, had significantly elevated mercury levels in blood and liver (Gochfeld 1980); however, the linkage of feather loss to mercury contamination requires further examination.

Interaction effects of mercury with other contaminants, such as herbicides and pesticides, could intensify hazards to avian populations (Mullins et al. 1977). For example, a striking parallel exists between levels of Hg and of DDT and its metabolites in birds of prey, suggesting the existence of common ecotoxicological mechanisms (Delbeke et al. 1984; Wiemeyer et al. 1984); additional research is clearly needed.

5.7.5 Mammals

Mercury has no known physiological function (USEPA 1985). In humans and other mammals, it causes teratogenic, mutagenic, and carcinogenic effects; the fetus is the most sensitive life stage (NAS 1978; Chang 1979; Khera 1979; USEPA 1980, 1985; Elhassani 1983; Greener and Kochen 1983; Clarkson et al. 1984). Methylmercury irreversibly destroys the neurons of the central nervous system. Frequently, a substantial latent period intervenes between the cessation of exposure to Hg and the onset of signs and symptoms. This interval is usually measured in weeks or months, but sometimes in years (Clarkson et al. 1984). At high sublethal doses in humans, mercury causes cerebral palsy, gross motor and mental impairment, speech disturbances, blindness, deafness, microcephaly, intestinal disturbances, tremors, and tissue pathology (Chang 1979; USEPA 1980, 1985; Elhassani 1983; Clarkson et al. 1984; USPHS 1994). Pathological and other effects of mercury may vary from organ to organ, depending on factors such as the effective toxic dose in the organ, the compound involved and its metabolism within the organ, the duration of exposure, and the other contaminants to which the animal is concurrently exposed (Chang 1979). Many compounds — especially salts of selenium — protect humans and other animals against mercury toxicity, although their mode of action is not clear (NAS 1978; Chang 1979; USEPA 1980, 1985; Eisler 1985).

Adverse effects of organomercury compounds to selected species of mammals have been recorded at administered doses of 0.25 mg Hg/kg body weight daily, dietary levels of 1.1 mg/kg, and blood Hg levels of 1.2 mg/L ([Table 5.10](#)).

Mercury transfer and biomagnification through mammalian food chains is well documented (Galster 1976; NAS 1978; Eaton et al. 1980; Eisler 1981; Huckabee et al. 1981; Sheffy and St. Amant 1982; Kucera 1983; Clarkson et al. 1984; Wren 1986), but there is considerable variation. Among terrestrial mammals, for example, herbivores such as mule deer, moose (*Alces alces*), caribou (*Rangifer tarandus*), and various species of rabbits usually contained less than 1.0 mg Hg/kg fresh weight in liver and kidney, but carnivores such as the marten (*Martes martes*), polecat (*Mustela putorius*), and red fox (*Vulpes vulpes*) frequently contained more than 30 mg/kg (NAS 1978). The usually higher mercury concentrations in fish-eating furbearers than in herbivorous species seemed to reflect the amounts of fish and other aquatic organisms in the diet. In river otter and mink from the Wisconsin River drainage system, Hg levels paralleled those recorded in fish, crayfish, and bottom sediments at that location. Highest Hg levels in all samples were recorded about 30 km downstream from an area that supported 16 pulp and paper mills and a chloralkali plant. Residues were highest in the fur, followed by the liver, kidney, muscle, and brain (Sheffy and St. Amant 1982).

In marine mammals, more than 90% of the mercury content is inorganic; however, enough methylmercury occurs in selected tissues to result in the accumulation of high tissue concentrations of methylmercury in humans and wildlife consuming such meat (Clarkson et al. 1984). The liver of the ringed seal (*Phoca hispida*) normally contains 27,000 to 187,000 µg Hg/kg fresh weight, and is a traditional and common food of the coastal Inuit people (Eaton et al. 1980). Although levels of Hg in hair (109,000 µg/kg) and blood (37 µg/L) of Inuits were grossly elevated, no symptoms of Hg poisoning were evident in the coastal Inuits. Similar high concentrations have been reported for Alaskan Inuit mothers who, during pregnancy, ate seal oil twice a day, and seal meat or fish from the Yukon–Kuskokwim Coast every day (Galster 1976). Despite the extremely high total Hg content of seal liver, only the small organomercury component was absorbed and appeared in the tissues. Cats fed a diet of seal liver (26,000 µg Hg/kg fresh weight) for 90 days showed no neurologic or histopathologic signs (Eaton et al. 1980). It seems that the toxic potential of seal liver in terms of accumulated tissue levels in cats (up to 862 µg total Hg/L blood, and 7600 µg total Hg/kg hair) is better indicated by the organomercury fraction in seal liver than by the concentration of total Hg (Eaton et al. 1980).

Table 5.10 Sublethal Effects of Organomercury Compounds Administered to Selected Species of Mammals

Organism	Dose, and Other Variables	Effect	Ref. ^a
Cat, <i>Felis domesticus</i>	250 µg/kg BW daily on days 10 to 58 of gestation; oral route	Increased incidence of anomalous fetuses	1
Human, <i>Homo sapiens</i> ; adult	50 µg/day	Risk of paresthesia, 0.3% (burning-prickling sensation of skin)	2
Human, adult	200 µg/day	Risk of paresthesia, 8%	2
Human, adult	1000 µg/day	Risk of paresthesia, 50%	2
Human, adult	50 µg Hg/m ³ air for 8 h	Mercury content, in µg/L, of 100 in urine and 280 in blood	9
Human, adult	100 µg/m ³ air for 8 h	Mercury content, in µg/L, of 250 in urine and 500 in blood	9
Human, whole blood Hg concentration	<10–100 µg/L	Increased tremors	9
	10–20 µg/L	Increased prevalence of abnormal psychomotor scores	9
	>15 µg/L	Disturbances in tests on verbal intelligence and memory	9
Human, urine	0–510 µg/L	Short-term memory loss	9
	5–1000 µg/L	Increased tremor frequency and reaction time	9
	20–450 µg/L	Increased motor and sensory nerve latency	9
	>56 µg/L	Disturbances in tests on verbal intelligence and memory	9
Human, adult	Various	Symptoms of poisoning evident at residues of 1200 µg Hg/L blood, 2000 to 3000 µg/kg whole body, or 3400 µg/kg hair	6
Human, infant	Various	Severe effects at blood levels of 3000 µg Hg/L	8
Monkeys, <i>Macaca fascicularis</i> ; adults; age 7–10 years	Exposed <i>in utero</i> ; maternal doses of 0, 50, 70, or 90 µg methylmercury/kg BW daily resulted in blood mercury levels in treated infants of 1.0–2.5 mg/L; offspring were conditioned and tested for ability to respond to a lit button for an apple juice reward and other tasks	<i>In utero</i> exposure to mercury did not produce significant adverse effects on adult performance, although gender differences may interact with methylmercury on certain behaviors	11
Monkeys, <i>Macaca fascicularis</i> ; female adults	Daily dose of methylmercury chloride in apple juice for 150 days equivalent to daily doses of 0.0, 0.4, 4.0, or 50.0 µg methylmercury/kg BW	All groups seemed normal at day 150; no difference in blood or serum cholinesterase activity	12
Monkeys, <i>Macaca</i> spp.	Various	Visual upset at blood mercury levels of 1200 to 4000 µg/L or brain levels of 6000 to 9000 µg Hg/kg; tremors at blood levels of 2000 to 10,000 µg Hg/L; kidney pathology at brain levels of 1500 µg Hg/kg	6
Rhesus monkey, <i>Macaca mulatta</i>	16 µg/kg body weight (BW) daily on days 20 to 30 of pregnancy	No effect on reproduction	1
Mice, <i>Mus</i> spp.	Various	Residues of 2000 to 5000 µg/kg hair or >10,000 µg/kg brain associated with motor incoordination and decreased swimming ability; no observable effect at <2000 µg/kg hair	6
Mink, <i>Mustela vison</i>	1.0 µg/kg ration as methylmercury	Reproduction normal; growth rate of kits normal	10
Mink	1100 mg/kg in diet	Residues of 7100 to 9300 µg/kg in brain; signs of poisoning	5

Table 5.10 (continued) Sublethal Effects of Organomercury Compounds Administered to Selected Species of Mammals

Organism	Dose, and Other Variables	Effect	Ref. ^a
Harp seal, <i>Pagophilus groenlandicus</i>	250 µg kg BW daily for 90 days in diet	Increased incidence of anomalous fetuses	3, 4
Brown Norway rat, <i>Rattus norvegicus</i>	Adult males gavaged twice weekly for 19 weeks with methylmercury chloride equivalent to 0.8, 8, or 80 µg Hg/kg BW daily	Intratesticular testosterone in high dose group reduced 44% and sperm count 17%. Negative relation between fertility and testicular Hg content. Testicular Hg concentrations, in µg/kg FW, were 1 in controls, 10 in 0.8 µg/kg BW daily group, 107 in 8 µg/kg group, and 1670 in high dose group	13
Laboratory white rat, <i>Rattus</i> sp.	50 µg/m ³ air, 4 h daily for 7 days	Impaired spatial learning; increased locomotor activity	9
Rat	500 µg/kg BW daily; oral route	Reduced fertility	1
Rat	2000 µg/kg in diet (as Pacific blue marlin); gestation through postnatal day 16	Adverse behavioral changes in offspring	6
Rat	13,300 to 50,000 µg/kg BW daily for 5 days; subcutaneous injection	Impaired cutaneous sensitivity and hearing up to one year post-treatment	7

^a 1, Khera 1979; 2, Clarkson et al. 1984; 3, Ronald et al. 1977; 4, Ramprashad and Ronald 1977; 5, Kucera 1983; 6, Suzuki 1979; 7, Wu et al. 1985; 8, Elhassani 1983; 9, USPHS 1994; 10, Wren et al. 1987b; 11, Gilbert et al. 1994; 12, Petruccioli and Turillazzi 1991; 13, Friedmann et al. 1998.

Retention of mercury by mammalian tissues is longer for organomercury compounds (especially methylmercury) than for inorganic mercury compounds (NAS 1978; Clarkson and Marsh 1982; Elhassani 1983; Clarkson et al. 1984). Excretion of all mercury species follows a complex, variable, multicompartmental pattern; the longer-lived chemical mercury species have a biological half-life that ranges from about 1.7 days in human lung to 1.36 years in whole body of various pinnipeds. In humans, increased urinary excretion and blood levels of mercury were observed in volunteers who used phenylmercuric borate solutions or lozenges intended for treatment of throat infections (USPHS 1994).

5.7.6 Other Groups

Seedlings of rice (*Oryza sativa*) grown on mercury-contaminated waste soil from a chloralkali factory for 75 days showed increasing mercury concentrations over time with increasing soil mercury content. At 2.5% waste soil in garden soil, rice seedlings contained 8.0 mg Hg/kg FW; at 10%, 15.2 mg Hg/kg; and at 17.5% waste soil in garden soil, seedlings had 19.1 mg Hg/kg FW (Nanda and Misra 1997). Content of nucleic acids and proteins in rice shoot decreased with increasing mercury concentrations in waste soils and with time, but free amino acid content increased. An increase in the RNA/DNA ratio occurred, indicating an enhanced synthesis of RNA per molecule of DNA (Nanda and Mishra 1997). Seedlings of spruce (*Picea abies*) exposed to solutions containing up to 0.2 mg Hg/L as inorganic mercury or methylmercury showed a dose-dependent inhibition in root growth, especially for methylmercury. Dose-dependent decreases in concentrations of potassium, manganese, and magnesium were evident in roots and root tips, and increases in iron in root tips (Godbold 1991).

Methylmercury compounds have induced abnormal sex chromosomes in the fruit fly (*Drosophila melanogaster*) (NAS 1978; Khera 1979). Earthworms (*Eisenia foetida*) exposed to soil containing methylmercury concentrations of 5.0 mg Hg/kg — typical of soil Hg levels near chloralkali plants — showed a significant reduction in the number of segments regenerated after 12 weeks, and contained

85 mg Hg/kg on a whole-body fresh weight basis. Regeneration was normal at soil Hg levels of 1.0 mg/kg, although body burdens up to 27 mg/kg were recorded. It was concluded that soil contaminated with methylmercury posed a greater hazard to the predators of earthworms than to the earthworms (Beyer et al. 1985). Studies with a different species of earthworm (*Octochaetus pattoni*) and mercuric chloride demonstrated a progressive initial increase in reproduction as soil mercury levels increased from 0.0 to the 60-day lethal level of 5.0 mg/kg (Abbasi and Soni 1983).

5.8 RECOMMENDATIONS

Proposed mercury criteria for the protection of sensitive aquatic organisms, birds, and mammals, as well as human health, are shown in [Table 5.11](#). In almost every instance, these criteria are listed as concentrations of total mercury, with most, if not all, the mercury present as an organomercury species. In some cases the recommended criteria are routinely exceeded, as is the case for brown bears (*Ursus arctos*) in the Slovak Republic (Zilincar et al. 1992), and in Italian seafood products recommended for human consumption (Barghigiani and De Ranieri 1992).

In 1980, the U.S. Environmental Protection Agency's proposed mercury criteria for freshwater aquatic life protection were 0.00057 µg/L (24-h average), not to exceed 0.0017 µg/L at any time. These criteria seemed to afford a high degree of protection to freshwater biota, as judged by survival, bioconcentration, and biomagnification. Literature documented in this paper showed that mercury concentrations in water of 0.1 to 2.0 µg/L were fatal to sensitive aquatic species and that concentrations of 0.03 to 0.1 µg/L were associated with significant sublethal effects. The 1980 proposed freshwater criteria provided safety factors for acute toxicities of 175 to 3508 based on the 24-h average, and 58 to 1176 based on the maximum permissible concentration ([Table 5.11](#)). For

Table 5.11 Proposed Mercury Criteria for Protection of Various Resources and Human Health

Resource and Criterion (units in parentheses)	Mercury Concentration	Reference ^b
AQUATIC LIFE		
Freshwater (µg/L)	Total recoverable mercury less than 0.00057 (24 h average), not to exceed 0.0017 at any time	1
Freshwater (µg/L)	Less than 0.012, 4-day average (not to be exceeded more than once every 3 years; less than 2.4, one-h average (not to be exceeded more than once every 3 years) ^a	2
Freshwater (µg/L)	Less than 0.1	33, 34
	Less than 0.01	34
Freshwater (µg/L)	Less than 10.0 from point source discharge	3
Inland surface waters, India		
Public water supply, Wisconsin	Less than 0.079	42
Warmwater sport fish communities	Less than 0.079	42
Coldwater communities	Less than 0.079	42
Great Lakes communities	Less than 0.079	42
Saltwater (µg/L)	Total recoverable mercury less than 0.025 (24-h average), not to exceed 3.7 at any time	1
Saltwater (µg/L)	Less than 0.025, 4-day average (not to be exceeded more than once every 3 years); less than 2.1, one-h average (not to be exceeded more than once every 3 years) ^a	2

^c Assuming continuous exposure until steady-state balance for methylmercury is achieved. This process will take up to one year in most cases (Clarkson 1990).

^d Derived from lowest observable adverse effect level (LOAEL) of 42 µg Hg/kg BW daily of phenylmercuric acetate for detectable kidney damage in rats after 2 years and an uncertainty factor of 5 (USPHS 1994).

^e Loon (*Gavia immer*) reproduction declined when mercury in prey exceeded 300 µg total Hg/kg FW.

^f No observed adverse effect level with uncertainty factor of 20.

^g Based on food chain biomagnification in aquatic webs.

protection against sublethal effects, these values were 53 to 175 based on the 24-h mean, and 18 to 59 based on the maximum permissible concentration ([Table 5.11](#)). However, more recent freshwater criteria of 0.012 µg/L, not to exceed 2.4 µg/L ([Table 5.11](#); USEPA 1985), dramatically reduces the level of protection afforded aquatic biota: safety factors for acute toxicities are now 8 to 167 based on the 96-h average, and only 0.04 to 0.8 based on the maximum permissible concentration. For protection against sublethal effects, these values were 2 to 8 based on the 4-day average, and only 0.01 to 0.04 based on the maximum permissible concentration, or essentially no significant protection. The proposed saltwater criteria of USEPA (1980) for mercury and marine life were unsatisfactory. Proposed saltwater values of 0.025 µg/L (24-h average), not to exceed 3.7 µg/L at any time ([Table 5.11](#)), provided safety factors of 4 to 80 against acute toxicity (based on a 24-h average), but less than 0.5 based on the maximum permissible level. For protection against sublethal damage effects, the safety factors computed were 1.2 to 4 (based on a 24-h average) and less than 0.03 (based on maximum allowable concentration). The more recent saltwater criteria of 0.025 µg/L, not to exceed 2.1 µg/L ([Table 5.11](#); USEPA 1985), does not appear to offer a substantive increase in protection to marine life, when compared to criteria proposed 5 years earlier (USEPA 1980). It seems that some downward modification is needed in the proposed mercury saltwater criteria if marine and estuarine biota are to be provided even minimal protection.

The significance of elevated mercury residues in tissues of aquatic organisms is not fully understood. Induction of liver metallothioneins and increased translatability of mRNA are biochemical indicators of the response of fish to mercury exposure (Angelow and Nicholls 1991; Schlenk et al. 1995), and more research is recommended on this and other indicators of mercury stress. Concentrations exceeding 1000 µg Hg/kg fresh weight can occur in various tissues of selected species of fish and aquatic mammals eaten by humans, but it would be incorrect to assume that aquatic food chains — especially marine food chains — incorporate mercury exclusively from anthropogenic activities (Barber et al. 1984). Some organisms, however, do contain mercury tissue residues associated with known adverse effects to the organism and its predators. Thus, whole-body residues of 5000 to 7000 µg Hg/kg fresh weight in brook trout eventually proved fatal to that species (USEPA 1980). To protect sensitive species of mammals and birds that regularly consume fish and other aquatic organisms, total mercury concentrations in these food items should probably not exceed 100 µg/kg for avian protection, or 1100 µg/kg for small mammals ([Table 5.11](#)). By comparison, proposed mercury levels in fish and seafood, in µg/kg fresh weight, for human health protection should not exceed 250 for expectant mothers, and 400 to 1000 for adults worldwide ([Table 5.11](#)). In humans, methylmercury concentration in head hair during pregnancy is considered to be the most reliable indicator for predicting the probability of psychomotor retardation in the child. The minimum toxic intake for pregnant humans is estimated to range between 0.6 and 1.1 µg methylmercury/kg body weight daily (Clarkson 1990).

Since long-lived, slow-growing, high-trophic-position aquatic organisms usually contain the highest tissue mercury residues (Eisler 1981), some fisheries managers have proposed a legal maximum limit based on fish length or body weight, or alternatively, constraining the mean mercury concentration of the entire catch to a designated level. In the Australian shark fishery, for example, implementation of a maximum length restriction (to a designated level of 500 µg Hg/kg), would result in retention of less than half of the present catch of seven species (Lyle 1984). Also in Australia, a maximum total length of 92 cm is proposed for the taking of yellowtail kingfish (*Seriola grandis*) and would effectively remove 23% of the total weight of the catch and 9% of the numbers (Chvojka 1988). If the total length of the yellowtail kingfish is reduced to 73 cm, a length that ensures that almost all fish will contain less than 500 µg Hg/kg FW muscle, this would preclude 59% by weight and 30% by numbers (Chvojka 1988). Other strategies to control mercury concentrations in predatory fishes include control of forage fish, overfishing, and various chemical treatments. In lakes with pelagic forage fish, there is less than a 5% probability of finding elevated mercury levels in muscle of lake trout less than 30 cm in total length vs. 45 cm in lakes where pelagic forage fish were absent. In the case of lake trout lakes with no pelagic forage fish, every

effort should be made to avoid their introduction (Futter 1994). Overfishing of top-level predators is recommended as a means of lowering methylmercury levels in certain types of lakes and is attributed to the more rapid growth of the predators and by changes in the dietary intake of methylmercury (Verta 1990). The treatment of lakes with selenium compounds is one of the few known methods of lowering the mercury content of fish muscle to less than 1.0 mg Hg/kg FW (Paulsson and Lundbergh 1989). Treatments that have achieved partial success in reducing mercury content in fish tissues include liming of lakes, wetlands, and drainage areas (Lindqvist et al. 1991). More research is needed on mercury protectants because several are known to cause substantial reductions in tissue mercury concentrations in fishes and plants (Siegel et al. 1991). Thiamine and various group VI derivatives, including sulfur, selenium, and tellurium compounds, protect against organomercury poisoning by their antagonistic effects; thiamine was the most effective of the derivatives against the widest spectrum of organisms and test systems (Siegel et al. 1991).

Among sensitive avian species, adverse effects — predominantly on reproduction — have been reported at mercury concentrations (in µg/kg fresh weight) of 5000 in feather, 900 in egg, 50 to 100 in diet, and daily administered doses of 640 on a body weight basis ([Table 5.11](#)). Although low mercury concentrations (e.g., 50 µg/kg in the diets of domestic chickens) sometimes produced no adverse effects in chickens, the tissue residues of mercury were sufficiently elevated to pose a hazard to human consumers (March et al. 1983). In contrast, in eggs of the bald eagle (with 150 µg Hg/kg and low hatch), other contaminants present — especially organochlorine compounds — probably had a greater effect on hatchability than did mercury (Wiemeyer et al. 1984).

Mammals, such as the domestic cat and the harp seal, showed birth defects, histopathology, and elevated tissue residues at doses of 250 µg Hg/kg body weight daily ([Table 5.11](#)). The mink, at dietary levels of 1100 µg Hg/kg, had signs of mercury poisoning; mercury residues in mink brain at this dietary level ranged from 7100 to 9300 µg/kg (Kucera 1983). Tissue residues in kidney, blood, brain, and hair in excess of 1100 µg Hg/kg in other nonhuman mammals are usually considered presumptive evidence of significant mercury contamination ([Table 5.11](#)). Tissue residues of mercury, as methylmercury, considered harmful to adult inland mammals and birds ranged between 8 mg/kg FW in brain to 15 in muscle to 20 mg/kg FW in liver and kidney (Heinz 1996). In Canadian aboriginal peoples, a 20-year followup study on methylmercury levels has been initiated, with emphasis on age, sex, location, relation between maternal and fetal levels, and a reassessment of potential risk in communities where the highest known methylmercury levels have been found (Wheatley and Paradis 1995). Similar studies are recommended for avian and mammalian wildlife.

More research is needed on mercury removal technology. In the Florida Everglades, for example, using prototype wetlands of 1545 ha, removal of agricultural nutrients from stormwater reduced total mercury and methylmercury concentrations in water by as much as 70% in the first 2 years of operation; moreover, total mercury concentrations in largemouth bass were about 0.1 mg Hg/kg FW muscle throughout the project site vs. 0.5 mg Hg/kg FW in adjacent areas (Miles and Fink 1998).

At this point, it seems that four courses of action are warranted. First, toxic mercurials in agriculture and industry should be replaced by less toxic substitutes. In Sweden, for example, clinical mercury thermometers have been prohibited since January 1992 for import, manufacture, and sales (Gustafsson 1995). Since January 1993, the same prohibition was applied to other measuring instruments and electrical components containing mercury. By the year 2000, Sweden plans to prohibit mercury in all processes and products, including thermometers and sphygmomanometers, and to replace them with available substitutes (Gustafsson 1995). In Quebec hospitals, medical instruments containing mercury are being replaced with mercury-free instruments because of inadequate maintenance and disposal of existing instruments (Guerrier et al. 1995).

Second, controls should be applied at the point of origin to prevent the discharge of potentially harmful mercury wastes. Point sources need to be identified and regulated (Facemire et al. 1995). In Sweden, discharges from point sources in the 1950s and 1960s averaged 20 to 30 metric tons annually. Since the end of the 1960s, the annual emission of mercury in Sweden has been reduced

to about 3.5 tons through better emission control legislation, improved technology, and reduction of polluting industrial production (Lindqvist et al. 1991).

Third, continued periodic monitoring of fishery and wildlife resources is important, especially in areas with potential for reservoir development, in light of the hypothesis that increased flooding increases the availability of mercury to biota. The use of museum collections for mercury analysis is strongly recommended for monitoring purposes. For example, the Environmental Specimen Bank at the Swedish Museum of Natural History constitutes a base for ecotoxicological research and for spatial and trend monitoring of mercury and other contaminants in Swedish fauna (Odsjo et al. 1997).

And finally, additional research is needed on mercury accumulation and detoxification in comparatively pristine ecosystems. Key uncertainties in understanding the process of mercury uptake in aquatic ecosystems, for example, include relations between water chemistry and respiratory uptake, quantitative estimates of intestinal tract methylation and depuration, and degree of seasonal variability in mercury speciation and methylation–demethylation processes (Post et al. 1996).

5.9 SUMMARY

Mercury has been used by man for at least 2300 years, most recently as a fungicide in agriculture, in the manufacture of chlorine and sodium hydroxide, as a slime control agent in the pulp and paper industry, in the production of plastics and electrical apparatus, and in mining and smelting operations. Mercury burdens in some environmental compartments are estimated to have increased up to five times precultural levels, primarily as a result of human activities. The construction of artificial reservoirs, for example, which releases mercury from flooded soils, has contributed to the observed elevation of Hg concentrations in fish tissues from these localities. Elevated levels of Hg in living organisms in Hg-contaminated areas may persist for as long as 100 years after the source of pollution has been discontinued. One major consequence of increased mercury use, coupled with careless waste disposal practices, has been a sharp increase in the number of epidemics of fatal mercury poisonings in humans, wildlife, and aquatic organisms.

Most authorities agree on six points: (1) mercury and its compounds have no known biological function, and the presence of the metal in the cells of living organisms is undesirable and potentially hazardous; (2) forms of mercury with relatively low toxicity can be transformed into forms of very high toxicity, such as methylmercury, through biological and other processes; (3) mercury can be bioconcentrated in organisms and biomagnified through food chains; (4) mercury is a mutagen, teratogen, and carcinogen, and causes embryocidal, cytochemical, and histopathological effects; (5) some species of fish and wildlife contain high concentrations of mercury that are not attributable to human activities; (6) anthropogenic use of mercury should be curtailed, as the difference between tolerable natural background levels of mercury and harmful effects in the environment is exceptionally small.

Concentrations of total mercury lethal to sensitive, representative, nonhuman species range from 0.1 to 2.0 µg/L (ppb) of medium for aquatic organisms; from 2200 to 31,000 µg/kg body weight (acute oral) and 4000 to 40,000 µg/kg (dietary) for birds; and from 100 to 500 µg/kg body weight (daily dose) and 1000 to 5000 µg/kg diet for mammals. Organomercury compounds, especially methylmercury, are always more toxic than inorganic Hg compounds. Numerous biological and abiotic factors modify the toxicity of Hg compounds — sometimes by an order of magnitude or more — but the mechanisms of action are not clear. Significant adverse sublethal effects were observed among selected aquatic species at water concentrations of 0.03 to 0.1 µg Hg/L. For some birds, adverse effects (predominantly on reproduction) have been associated with total mercury concentrations (in µg/kg fresh weight) of 5000 in feather, 900 in egg, and 50 to 100 in diet; and with daily intakes of 640 µg/kg body weight. Sensitive nonhuman mammals showed significant

adverse effects of mercury when daily intakes were 250 µg/kg body weight, when dietary levels were 1100 µg/kg, or when tissue concentrations exceeded 1100 µg/kg.

Mercury criteria proposed by the U.S. Environmental Protection Agency for protection of freshwater aquatic life are 0.012 µg/L medium (4-day average), not to exceed 2.4 µg/L on an hourly average; however, these criteria offer only limited protection to freshwater ecosystems. The saltwater criteria of 0.025 µg Hg/L medium (4-day average), not to exceed 2.1 µg/L hourly, are unsatisfactory for the protection of marine life. For the protection of sensitive species of mammals and birds that regularly consume fish and other aquatic organisms, total Hg concentrations in these prey items should probably not exceed 100 µg/kg fresh weight for birds, and 1100 µg/kg for small mammals. The significance of elevated Hg levels in tissues of fish and wildlife is not fully understood; some species of marine pinnipeds, for example, normally contain high concentrations of Hg in various tissues without apparent adverse effects. Usually, however, concentrations in excess of 1100 µg/kg fresh weight of tissue (liver, kidney, blood, brain, hair) should be considered as presumptive evidence of an environmental mercury problem.

Four courses of action now seem warranted. First, toxic mercurials in agriculture and industry should be replaced by less toxic substitutes. Second, controls should be applied at the point of origin to prevent the discharge of potentially harmful mercury wastes. Third, continued periodic monitoring of mercury in fish and wildlife is needed for identification of potential problem areas, and for evaluation of ongoing mercury curtailment programs. And fourth, additional research is merited on mechanisms of mercury accumulation and detoxification in comparatively pristine ecosystems.

CHAPTER 6

Nickel

6.1 INTRODUCTION

In Europe, nickel (Ni) is listed on European Commission List II (Dangerous Substances Directive) and regulated through the Council of European Communities because of its toxicity, persistence, and affinity for bioaccumulation (Bubb and Lester 1996). In Canada, nickel and its compounds are included in the Priority Substances List under the Canadian Environmental Protection Act (Hughes et al. 1994). The World Health Organization (WHO) classifies nickel compounds in Group 1 (human carcinogens) and metallic nickel in group 2B (possible human carcinogen; U.S. Public Health Service [USPHS] 1993). The U.S. Environmental Protection Agency (USEPA) classifies nickel refinery dust and nickel subsulfide as Group A human carcinogens (USPHS 1993) and nickel oxides and nickel halides as Class W compounds, that is, compounds having moderate retention in the lungs and a clearance rate from the lungs of several weeks (USEPA 1980). Nickel and its compounds are regulated by USEPA's Clean Water Effluent Guideline for many industrial point sources, including the processing of iron, steel, nonferrous metals, and batteries; timber products processing; electroplating; metal finishing; ore and mineral mining; paving and roofing; paint and ink formulating; porcelain enameling; and industries that use, process, or manufacture chemicals, gum and wood, or carbon black (USPHS 1993).

Nickel is ubiquitous in the biosphere. Nickel introduced into the environment from natural or human sources is circulated through the system by chemical and physical processes and through biological transport mechanisms of living organisms (National Academy of Sciences [NAS] 1975; Sevin 1980; WHO 1991). Nickel is essential for the normal growth of many species of microorganisms and plants and several species of vertebrates, including chickens, cows, goats, pigs, rats, and sheep (NAS 1975; USEPA 1980; WHO 1991; USPHS 1993, 1995).

Human activities that contribute to nickel loadings in aquatic and terrestrial ecosystems include mining, smelting, refining, alloy processing, scrap metal reprocessing, fossil fuel combustion, and waste incineration (NAS 1975; WHO 1991; Chau and Kulikovsky-Cordeiro 1995). Nickel mining and smelting in the Sudbury, Ontario, region of Canada is associated with denudation of terrestrial vegetation and subsequent soil erosion (Adamo et al. 1996), and gradual ecological changes, including a decrease in the number and diversity of species and a reduction in community biomass of crustacean zooplankton (WHO 1991). At nickel-contaminated sites, plants accumulate nickel, and growth is retarded in some species at high nickel concentrations (WHO 1991). However, nickel accumulation rates in terrestrial and avian wildlife near nickel refineries are highly variable; Chau and Kulikovsky-Cordeiro (1995) claim similar variability for plants, soils, and interstitial sediment waters.

The chemical and physical forms of nickel and its salts strongly influence bioavailability and toxicity (WHO 1991). In general, nickel compounds have low hazard when administered orally

Table 6.1 Nickel Chronology

Date	Event	Ref. ^a
220 BCE	Nickel alloys made by the Chinese	1
1500s	Toxicity observed in miners of nickel	2
1751	Nickel isolated and identified. The name nickel was derived from "Old Nick," a gremlin to whom miners ascribed their problems	3
Early 1800s	Purified nickel obtained	1
1826	Nickel toxicity in rabbits and dogs demonstrated experimentally. High doses of nickel sulfate given by stomach gavage caused gastritis, convulsions, and death; sublethal doses produced emaciation and conjunctivitis	1, 2, 4
1840s	Commercial nickel electroplating initiated	1
1850s	Commercial exploitation of nickel begins after development of technology to remove copper and other impurities	3
1850–1900	Nickel used therapeutically in human medicine to relieve rheumatism (nickel sulfate) and epilepsy (nickel bromide)	2, 5
1880s	Excess nickel found lethal to animals under controlled conditions	2
1889	Skin dermatitis in humans caused by chemicals used in nickel plating	5
1890	Extraordinary toxicity of nickel carbonyl ($\text{Ni}(\text{CO})_4$) established	1
1893	Excess nickel found lethal to plants	2
1912	Nickel dermatitis documented	1
1915–1960	Nickel applied as fungicide found to enhance plant growth and increase yield	2
1926	Nickel dust caused skin dermatitis, especially in hot industrial environments	5
1932	Increased frequency of lung and nasal cancers reported among English nickel refinery workers exposed to high concentrations of nickel carbonyl	1, 5, 6
1939–1958	Certain forms of nickel found to be carcinogenic to humans	2
1943	Certain forms of nickel found to be carcinogenic to animals	2
1965–1967	Nickel found beneficial to plants	2
1970s	Nickel deficiency leads to adverse effects in microorganisms and plants	2
1980s	Nickel found to be constituent of various essential plant enzymes	2

^a 1, Nriagu 1980b; 2, Hausinger 1993; 3, Sevin 1980; 4, Nielsen 1977; 5, USPHS 1977; 6, Benson et al. 1995.

(NAS 1975; USEPA 1980). In humans and other mammals, however, nickel-inhalable dust, nickel subsulfide, nickel oxide, and especially nickel carbonyl induce acute pneumonitis, central nervous system disorders, skin disorders such as dermatitis, and cancer of the lungs and nasal cavity (Graham et al. 1975; NAS 1975; USPHS 1977; Sevin 1980; Smialowicz et al. 1984; WHO 1991; Benson et al. 1995; Table 6.1). Nickel carbonyl is acutely lethal to humans and animals within 3 to 13 days of exposure; recovery is prolonged in survivors (Sevin 1980). An excess number of deaths from lung cancer and nasal cancer occurs in nickel refinery workers, usually from exposure to airborne nickel compounds (USPHS 1977). At one nickel refinery, workers had a fivefold increase in lung cancer and a 150-fold increase in nasal sinus cancer compared to the general population (Lin and Chou 1990). Pregnant female workers at a Russian nickel hydrometallurgy refining plant, when compared to a reference group, show a marked increase in frequency of spontaneous and threatening abortions and in structural malformations of the heart and musculoskeletal system in live-born infants with nickel-exposed mothers (Chashchin et al. 1994). Nickel is also a common cause of chronic dermatitis in humans as a result of industrial and other exposures, including the use of nickel-containing jewelry, coins, utensils, and various prostheses (NAS 1975; Chashchin et al. 1994). Additional information on ecological and toxicological aspects of nickel in the environment is presented in reviews and annotated bibliographies by Sunderman (1970), Eisler (1973), Eisler and Wapner (1975), NAS (1975), USEPA (1975, 1980, 1985, 1986), International Agency for Research on Cancer [IARC] (1976), Nielsen (1977), USPHS (1977, 1993), Eisler et al. (1978b, 1979), Norseth and Piscator (1979), Brown and Sunderman (1980), Nriagu (1980a), Sevin (1980), National Research Council of Canada [NRCC] (1981), Norseth (1986), Kasprzak (1987), Sigel and Sigel (1988), WHO (1991), Hausinger (1993), Outridge and Scheuhammer (1993), Chau and Kulikovsky-Cordeiro (1995), and Eisler (1998).

6.2 SOURCES AND USES

6.2.1 General

About 250,000 people in the United States are exposed annually to inorganic nickel in the workplace. This group includes workers in the mining, refining, smelting, electroplating, and petroleum industries and workers involved in the manufacture of stainless steel, nickel alloys, jewelry, paint, spark plugs, catalysts, ceramics, disinfectants, varnish, magnets, batteries, ink, dyes, and vacuum tubes (USPHS 1977). Nonoccupational exposure to nickel and its compounds occurs mainly by ingestion of foods and liquids and by contact with nickel-containing products, especially jewelry and coins (Sunderman et al. 1984; WHO 1991). Food processing adds to nickel already present in the diet through leaching from nickel-containing alloys in food-processing equipment made from stainless steel, milling of flour, use of nickel catalysts to hydrogenate fats and oils, and use of nickel-containing fungicides in growing crops (NAS 1975; USEPA 1980). Nickel contamination of the environment occurs locally from emissions of metal mining, smelting, and refining operations; from combustion of fossil fuels; from industrial activities, such as nickel plating and alloy manufacturing; from land disposal of sludges, solids, and slags; and from disposal as effluents (Cain and Pafford 1981; Chau and Kulikovsky-Cordeiro 1995). In Canada in 1988, the mining industry released a total of 11,664 tons of nickel into the air (9.4%), water (0.5%), and on land as sludges or solids (15.4%) and slags (74.7%). The global nickel cycle is unknown, but recent estimates suggest that 26,300 to 28,100 tons are introduced each year into the atmosphere from natural sources and 47,200 to 99,800 tons from human activities; airborne nickel is deposited on land at 50,800 tons and in the ocean at 21,800 tons annually (Chau and Kulikovsky-Cordeiro 1995).

6.2.2 Sources

More than 90% of the world's nickel is obtained from pentlandite ($(\text{FeNi})_9\text{S}_8$), a nickel-sulfitic mineral, mined underground in Canada and the former Soviet Union (Sevin 1980; IARC 1976; WHO 1991). One of the largest sulfitic nickel deposits is in Sudbury, Ontario (USPHS 1993). Nickeliferous sulfide deposits are also found in Manitoba, South Africa, the former Soviet Union, Finland, western Australia, and Minnesota (Norseth and Piscator 1979; USPHS 1993). Most of the rest of the nickel obtained is from nickel minerals such as laterite, a nickel oxide ore mined by open pit techniques in Australia, Cuba, Indonesia, New Caledonia, and the former Soviet Union (Sevin 1980). Lateritic ores are less well defined than sulfitic ores, although the nickel content (1 to 3%) of both ores is similar (USPHS 1993). Important deposits of laterite are located in New Caledonia, Indonesia, Guatemala, the Dominican Republic, the Philippines, Brazil, and especially Cuba, which holds 35% of the known reserves (USPHS 1993). Nickel-rich nodules are found on the ocean floor, and nickel is also present in fossil fuels (Sevin 1980).

Total world mine production of nickel is projected to increase steadily from 7500 metric tons in 1900 to 2 million tons by 2000 (Table 6.2). In 1980, nickel mine production in the United States was 14,500 tons or about 1.8% of the world total (Kasprzak 1987). In 1986, primary nickel production ceased in the United States. Secondary nickel production from scrap became a major source of nickel for industrial applications (USPHS 1993). In 1988, the United States imported 186,000 tons of primary nickel; Canada supplied 58% of the total and Norway 14% (USPHS 1993). In 1990, Canada produced 196,606 metric tons of nickel. About 63% of the total production was exported, mostly (56%) to the United States (Chau and Kulikovsky-Cordeiro 1995).

Natural sources of airborne nickel include soil dust, sea salt, volcanoes, forest fires, and vegetation exudates and account for about 16% of the atmospheric nickel burden (Kasprzak 1987; WHO 1991; Chau and Kulikovsky-Cordeiro 1995). Human sources of atmospheric nickel — which account for about 84% of all atmospheric nickel — include emissions from nickel ore mining, smelting, and refining activities; combustion of fossil fuels for heating, power, and motor vehicles;

Table 6.2 World Mine Production of Nickel

Year	Metric tons
1900	7500
1925	42,700
1950	141,000
1970	694,100
1975	753,000 ^a
1980	784,100
1985	821,000 ^b
2000 (projected)	>2,000,000

^a About 32% from Canada, 18% from New Caledonia, 17% from the former Soviet Union, 10% from Australia, 5% from Cuba, 4% from the Dominican Republic, 3% from the Republic of South Africa, 2% each from Greece, Indonesia, and the United States, and 5% from other countries.

^b Mostly from Canada, the former Soviet Union, Australia, and Cuba in that order. The United States produced 6900 tons in 1985.

Data from NAS 1975; International Agency for Research on Cancer 1976; Duke 1980; Kasprzak 1987; WHO 1991.

incineration of sewage sludges; nickel chemical manufacturing; electroplating; nickel–cadmium battery manufacturing; asbestos mining and milling; and cement manufacturing (NAS 1975; IARC 1976; USEPA 1986; Kasprzak 1987; WHO 1991; USPHS 1993). In Canada in 1975, human activities resulted in the release of about 3000 tons of nickel into the atmosphere, mostly from metallurgical operations (NRCC 1981). Between 1973 and 1981, atmospheric emissions of nickel from stacks of four smelters in the Sudbury Basin, Canada, averaged a total of 495 tons annually (WHO 1991). Industrial nickel dust emissions from a single Canadian stack 381 meters high averaged 228 tons annually (range 53 to 342) between 1973 and 1981. This stack accounted for 396 tons annually (range 53 to 896) between 1982 and 1989 (Chau and Kulikovsky-Cordeiro 1995). Three other emission stacks of Canadian nickel producers emitted an average of 226, 228, and 396 tons of nickel, respectively, each year between 1973 and 1989. Industrial emissions of nickel to the Canadian atmosphere in 1982 were estimated at 846 tons, mostly from nickel production in Ontario (48% of total) and Quebec (14%) and from industrial fuel combustion (17%). Nickel released into the air in Canada from smelting processes is likely in the form of nickel subsulfide (52%), nickel sulfate (20%), and nickel oxide (6%). Fuel combustion is also a major contributor of airborne nickel in Canada, mostly from combustion of petroleum (Chau and Kulikovsky-Cordeiro 1995). In the United States, yearly atmospheric emissions from coal and oil combustion are estimated at 2611 metric tons (WHO 1991).

Chemical and physical degradation of rocks and soils, atmospheric deposition of nickel-containing particulates, and discharges of industrial and municipal wastes release nickel into ambient waters (USEPA 1986; WHO 1991). Nickel enters natural waterways from wastewater because it is poorly removed by treatment processes (Cain and Pafford 1981). The main anthropogenic sources of nickel in water are primary nickel production, metallurgical processes, combustion and incineration of fossil fuels, and chemical and catalyst production (USEPA 1986). The primary human sources of nickel to soils are emissions from smelting and refining operations and disposal of sewage sludge or application of sludge as a fertilizer. Secondary sources include automobile emissions and emissions from electric power utilities (USEPA 1986). Weathering and erosion of geological materials release nickel into soils (Chau and Kulikovsky-Cordeiro 1995), and acid rain may leach nickel from plants into soils as well (WHO 1991).

6.2.3 Uses

Most metallic nickel produced is used to manufacture stainless steel and other nickel alloys with high corrosion and temperature resistance (Norseth and Piscator 1979; Norseth 1980; WHO 1991). These alloys are used in ship building, jet turbines and heat elements, cryogenic installations, magnets, coins, welding rods, electrodes, kitchenware, electronics, and surgical implants. Other nickel compounds are used in electroplating, battery production, inks, varnishes, pigments, catalysts, and ceramics (IARC 1976; Nriagu 1980b; Sevin 1980; Sunderman et al. 1984; USEPA 1986; Kasprzak 1987; USPHS 1993). Some nickel compounds are preferred for use in nickel electroplating (nickel sulfate, nickel ammonium sulfate, nickel chloride, nickel fluoborate, nickel sulfamate), refining (nickel carbonyl), nickel–cadmium batteries (nickel hydroxide, nickel fluoride, nickel nitrate), manufacture of stainless steel and alloy steels (nickel oxide), electronic components (nickel carbonate), mordant in textile industry (nickel acetate), catalysts and laboratory reagents (nickel acetate, nickel hydroxide, nickel nitrate, nickel carbonate, nickel monosulfide, nickelocene), and some, such as nickel subsulfide, are unwanted toxic by-products (IARC 1976).

In 1973, global consumption of nickel was 660,000 tons and that of the United States 235,000 tons (Sevin 1980). End uses of nickel in the United States in 1973 were transportation (21%), chemicals (15%), electrical goods (13%), fabricated metal products (10%), petroleum (9%), construction (9%), machinery (7%), and household appliances (7%; IARC 1976). A similar pattern was evident for 1985 (Table 6.3). In 1988, 40% of all nickel intermediate products consumed was in the production of steel; 21% was in alloys, 17% in electroplating, and 12% in super alloys (USPHS 1993). The pattern for 1985 was similar (Table 6.3). In Canada, nickel is the fourth most important mineral commodity behind copper, zinc, and gold. In 1990, Canada produced 197,000 tons of nickel worth 2.02 billion dollars and was the second largest global producer of that metal (Chau and Kulikovsky-Cordeiro 1995). Most of the nickel used in the United States is imported from Canada and secondarily from Australia and New Caledonia (USPHS 1977).

Table 6.3 Nickel Consumption in the United States by Intermediate Product and End-Use Industry in 1985^a

Index	Consumption (% of total)
Intermediate Product	
Stainless and alloy steels	42
Nonferrous alloys	36
Electroplating	18
Other	4
Total	100
End-use Industry	
Transportation	23
Chemicals	15
Electrical equipment	12
Construction	10
Fabricated metal products	9
Petroleum	8
Household appliances	8
Machinery	8
Other	7
Total	100

^a Nickel consumption in the United States, exclusive of scrap, was 160,000 tons.

Data from Kasprzak, K.S. 1987. Nickel. *Adv. Modern Environ. Toxicol.* 11:145-183; World Health Organization (WHO). 1991. *Nickel. Environ. Health Crit.* 108. 383 pp.

Various nickel salts — including the sulfate, chloride, and bromide — were used in human medicine during the mid- to late-1800s to treat headache, diarrhea, and epilepsy and as an antiseptic. Therapeutic use of nickel compounds was abandoned in the early 1900s after animal studies demonstrated acute and chronic toxicity of these salts (NAS 1975; Nriagu 1980b). Some nickel salts have been incorporated into fungicides to combat plant pathogens, although their use has not been approved by regulatory agencies (NAS 1975).

6.3 CHEMICAL AND BIOLOGICAL PROPERTIES

6.3.1 General

Nickel normally occurs in the 0 and +2 oxidation states, although other oxidation states are reported (NAS 1975; Nriagu 1980b; Higgins 1995). In natural waters Ni^{2+} is the dominant chemical species in the form of $(\text{Ni}(\text{H}_2\text{O})_6)^{2+}$ (WHO 1991; Chau and Kulikovsky-Cordeiro 1995). In alkaline soils, the major components of the soil solution are Ni^{2+} and $\text{Ni}(\text{OH})^+$; in acidic soils, the main solution species are Ni^{2+} , NiSO_4 , and NiHPO_4 (USPHS 1993). Most atmospheric nickel is suspended onto particulate matter (NRCC 1981).

Nickel interacts with numerous inorganic and organic compounds (Schroeder et al. 1974; Nielsen 1980a; USEPA 1980, 1985; USPHS 1993). Some of these interactions are additive or synergistic in producing adverse effects, and some are antagonistic.

Toxic and carcinogenic effects of nickel compounds are associated with nickel-mediated oxidative damage to DNA and proteins and to inhibition of cellular antioxidant defenses (Rodriguez et al. 1996). Most authorities agree that albumin is the main transport protein for nickel in humans and animals and that nickel is also found in nickeloplasmin — a nickel-containing alpha-macroglobulin — and in an ultrafilterable serum fraction similar to a nickel-histidine complex (Norseth and Piscator 1979; Sarkar 1980; Sevin 1980; USEPA 1980; Norseth 1986; Sigel and Sigel 1988; WHO 1991; USPHS 1993). Normal routes of nickel intake for humans and animals are ingestion, inhalation, and absorption through the skin (Mushak 1980; USEPA 1975, 1980, 1986; Sigel and Sigel 1988; WHO 1991; USPHS 1993). Nickel absorption is governed by the quantities inhaled or ingested and by the chemical and physical forms of the nickel. Following oral intake by mammals, nickel was found mainly in the kidneys after short-term or long-term exposure to various soluble nickel compounds; significant levels of nickel were also found in the liver, heart, lung, and fat. Nickel also crosses the placental barrier, as indicated by increases in the levels of nickel in the fetuses of exposed mothers (USPHS 1993). Inhaled nickel carbonyl results in comparatively elevated nickel concentrations in lung, brain, kidney, liver, and adrenals (USEPA 1980). Parenteral administration of nickel salts usually results in high levels in kidneys and elevated concentrations in endocrine glands, liver, and lung (USEPA 1980, 1986; WHO 1991). Nickel concentrations in whole blood, plasma, serum, and urine provide good indices of nickel exposure (Sigel and Sigel 1988).

6.3.2 Physical and Chemical Properties

Nickel was first isolated in 1751, and a relatively pure metal was prepared in 1804. In nature, nickel is found primarily as oxide and sulfide ores (USPHS 1977). It has high electrical and thermal conductivities and is resistant to corrosion at environmental temperatures between -20°C and $+30^\circ\text{C}$ (Chau and Kulikovsky-Cordeiro 1995). Nickel, also known as carbonyl nickel powder or C.I. No. 77775, has a CAS number of 7440-02-0. Metallic nickel is a hard, lustrous, silvery white metal with a specific gravity of 8.9, a melting point of about 1455°C , and a boiling point at about 2732°C . It is insoluble in water and ammonium hydroxide, soluble in dilute nitric acid or aqua regia, and slightly soluble in hydrochloric and sulfuric acid. Nickel has an atomic weight of 58.71. Nickel is

a composite of five stable isotopes: Ni-58 (68.3%), -60 (26.1%), -61 (1.1%), -62 (3.6%), and -64 (0.9%). Seven unstable isotopes have been identified: ^{56}Ni (half-life of 6 days), ^{57}Ni (36 h), ^{59}Ni (80,000 years), ^{63}Ni (92 years), ^{65}Ni (2.5 h), ^{66}Ni (55 h), and ^{67}Ni (50 sec). Radionickel-59 (^{59}Ni) and ^{63}Ni are available commercially. In addition to the 0 and +2 oxidation states, nickel can also exist as -1, +1, +3, and +4 (NAS 1975; IARC 1976; Kasprzak 1987; Nriagu 1980b; WHO 1991; Hausinger 1993; USPHS 1993; Foulds 1995; Higgins 1995).

Nickel enters surface waters from three natural sources: as particulate matter in rainwater, through the dissolution of primary bedrock materials, and from secondary soil phases. In aquatic systems, nickel occurs as soluble salts adsorbed onto or associated with clay particles, organic matter, and other substances. The divalent ion is the dominant form in natural waters at pH values between 5 and 9, occurring as the octahedral, hexahydrate ion $(\text{Ni}(\text{H}_2\text{O})_6)^{2+}$. Nickel chloride hexahydrate and nickel sulfate hexahydrate are extremely soluble in water at 2400 to 2500 g/L. Less soluble nickel compounds in water include nickel nitrate (45 g/L), nickel hydroxide (0.13 g/L), and nickel carbonate (0.09 g/L). Nickel forms strong, soluble complexes with OH^- , SO_4^{2-} , and HCO_3^- ; however, these species are minor compared with hydrated Ni^{2+} in surface water and groundwater. The fate of nickel in fresh water and marine water is affected by the pH, pE, ionic strength, type and concentration of ligands, and the availability of solid surfaces for adsorption. Under anaerobic conditions, typical of deep groundwater, precipitation of nickel sulfide keeps nickel concentrations low (IARC 1976; USEPA 1980; WHO 1991; USPHS 1993; Chau and Kulikovsky-Cordeiro 1995).

In alkaline soils, the major components of the soil solution are Ni^{2+} and $\text{Ni}(\text{OH})^+$; in acidic soils the main solution species are Ni^{2+} , NiSO_4 , and NiHPO_4 (USPHS 1993). Atmospheric nickel exists mostly in the form of fine respirable particles less than 2 μm in diameter (NRCC 1981), usually suspended onto particulate matter (USEPA 1986).

Nickel carbonyl ($\text{Ni}(\text{CO})_4$) is a volatile, colorless liquid readily formed when nickel reacts with carbon monoxide; it boils at 43°C and decomposes at more than 50°C. This compound is unstable in air and is usually not measurable after 30 min (NRCC 1981; Norseth 1986; USPHS 1993). The intact molecule is absorbed by the lung (USEPA 1980) and is insoluble in water but soluble in most organic solvents (WHO 1991).

Analytical methods for detection of nickel in biological materials and water include various spectrometric, photometric, chromatographic, polarographic, and voltammetric procedures (Sunderman et al. 1984; WHO 1991). Detection limits for the most sensitive procedures — depending on sample pretreatment, and extraction and enrichment procedures — were 0.7 to 1.0 ng/L in liquids, 0.01 to 0.2 $\mu\text{g}/\text{m}^3$ in air, 1 to 100 ng/kg in most biological materials, and 12 $\mu\text{g}/\text{kg}$ in hair (WHO 1991; Chau and Kulikovsky-Cordeiro 1995).

6.3.3 Metabolism

In mammalian blood, absorbed nickel is present as free hydrated Ni^{2+} ions, as small complexes, as protein complexes, and as nickel bound to blood cells. The partition of nickel among these four components varies according to the metal-binding properties of serum albumin, which is highly variable between species (NAS 1975; USEPA 1980, 1986; Kasprzak 1987). A proposed transport model involves the removal of nickel from albumin to histidine via a ternary complex composed of albumin, nickel, and L-histidine. The low-molecular-weight L-histidine nickel complex can then cross biological membranes (Sunderman et al. 1984; Kasprzak 1987; USPHS 1993). Once inside the mammalian cell, nickel accumulates in the nucleus and nucleolus (Sunderman et al. 1984), disrupting DNA metabolism and causing crosslinks and strand breaks (Kasprzak 1987; USPHS 1993; Hartwig et al. 1994). The observed redox properties of the nickel–histidine complex are crucial for maximizing the toxicity and carcinogenicity of nickel (Datta et al. 1992, 1994).

The acute toxicity and carcinogenicity of Ni_3S_2 and Ni_3S_2 -derived soluble nickel (Ni^{2+}) in mice depend, in part, on the antioxidant capacity of target organs, which varies among different strains

(Rodriguez et al. 1996). Experimental evidence now supports the conclusion that the nickel-dependent formation of an activated oxygen species — including superoxide ion, hydrogen peroxide, and hydroxy radical — is a primary molecular event in acute nickel toxicity and carcinogenicity (WHO 1991; Hausinger 1993; Tkeshelashvili et al. 1993; Novelli et al. 1995; Stohs and Bagchi 1995; Rodriguez et al. 1996; Zhang et al. 1998). For example, the superoxide radical (O_2^-) is an important intermediate in the toxicity of insoluble nickel compounds such as NiO and NiS (Novelli et al. 1995). One of the keys to the mechanism of nickel-mediated damage is the enhancement of cellular redox processing by nickel. Accumulated nickel in tissues elicits the production of reactive oxygen species, such as the superoxide radical, as the result of phagocytosis of particulate nickel compounds and through the interaction of nickel ions with protein ligands, which promote the activation of the Ni^{2+}/Ni^{3+} redox couple. Thus, NiS and NiO can elicit the formation of O_2^- (Novelli et al. 1995).

The most serious type of nickel toxicity is that caused by the inhalation of nickel carbonyl (Nielsen 1977). The half-time persistence of nickel carbonyl in air is about 30 min (Sevin 1980). Nickel carbonyl can pass across cell membranes without metabolic alteration because of its solubility in lipids, and this ability of nickel carbonyl to penetrate intracellularly may be responsible for its extreme toxicity (NAS 1975). In tissues, nickel carbonyl decomposes to liberate carbon monoxide and Ni^0 , the latter being oxidized to Ni^{2+} by intracellular oxidation systems. The nickel portion is excreted with urine, and the carbon monoxide is bound to hemoglobin and eventually excreted through the lungs (USEPA 1980; Kasprzak 1987). Nickel carbonyl inhibits DNA-dependent RNA synthesis activity, probably by binding to chromatin or DNA and thereby preventing the action of RNA polymerase, causing suppression of messenger-RNA-dependent induction of enzyme synthesis (Sunderman 1968; NAS 1975; USEPA 1980). The lung is the target organ in nickel carbonyl poisoning (USEPA 1980). Acute human exposures result in pathological pulmonary lesions, hemorrhage, edema, deranged alveolar cells, degeneration of bronchial epithelium, and pulmonary fibrosis. The response of pulmonary tissue to nickel carbonyl is rapid: interstitial edema may develop within 1 h of exposure and cause death within 5 days. Animals surviving acute exposures show lung histopathology (USEPA 1980).

Gastrointestinal intake of nickel by humans is high compared to some other trace metals because of contributions of nickel from utensils and from food processing machinery. Average human dietary values range from 300 to 500 μg daily with absorption from the gastrointestinal tract of 1 to 10% (USEPA 1980, 1986; Sigel and Sigel 1988). In humans, nearly 40 times more nickel was absorbed from the gastrointestinal tract when nickel sulfate was given in the drinking water (27%) than when it was given in the diet (0.7%). Uptake was more rapid in starved individuals (WHO 1991; USPHS 1993). Dogs and rats given nickel, nickel sulfate hexahydrate, or nickel chloride in the diet or by gavage rapidly absorbed 1 to 10% of the nickel from the gastrointestinal tract, while unabsorbed nickel was excreted in the feces (USPHS 1993).

During occupational exposure, respiratory absorption of soluble and insoluble nickel compounds is the major route of entry, with gastrointestinal absorption secondary (WHO 1991). Inhalation exposure studies of nickel in humans and test animals show that nickel localizes in the lungs, with much lower levels in liver and kidneys (USPHS 1993). About half the inhaled nickel is deposited on bronchial mucosa and swept upward in mucus to be swallowed; about 25% of the inhaled nickel is deposited in the pulmonary parenchyma (NAS 1975). The relative amount of inhaled nickel absorbed from the pulmonary tract is dependent on the chemical and physical properties of the nickel compound (USEPA 1986). Pulmonary absorption into the blood is greatest for nickel carbonyl vapor; about half the inhaled amount is absorbed (USEPA 1980). Nickel in particulate matter is absorbed from the pulmonary tract to a lesser degree than nickel carbonyl; however, smaller particles are absorbed more readily than larger ones (USEPA 1980). Large nickel particles ($>2 \mu\text{m}$ in diameter) are deposited in the upper respiratory tract; smaller particles tend to enter the lower respiratory tract. In humans, 35% of the inhaled nickel is absorbed into the blood from the respiratory tract; the remainder is either swallowed or expectorated. Soluble nickel compounds

were more readily absorbed from the respiratory tract than insoluble compounds (USPHS 1993). In rodents, the half-time persistence of nickel particles was a function of particle diameter: 7.7 months for particles 0.6 μm in diameter, 11.5 months for particles 1.2 μm in diameter, and 21 months for particles 4.0 μm in diameter (USPHS 1993). In rodents, a higher percentage of insoluble nickel compounds was retained in the lungs for a longer time than soluble nickel compounds, and the lung burden of nickel decreased with increasing particle size. Nickel retention was 6 to 10 times greater in rodents exposed to insoluble nickel subsulfide compared to soluble nickel sulfate. Lung burdens of nickel generally increased with increasing duration of exposure and increasing concentrations of various nickel compounds in the air (USPHS 1993). Animals exposed to nickel carbonyl by inhalation exhale some of the respiratory burden in 2 to 4 h. The remainder is slowly degraded to divalent nickel, which is oxidized, and carbon monoxide, which initially binds to hemoglobin, with nickel eventually excreted in the urine (NAS 1975; Norseth and Piscator 1979; USEPA 1980; Norseth 1986).

Dermal absorption of nickel occurs in animals and humans and is related to nickel-induced hypersensitivity and skin disorders (Samitz and Katz 1976; USEPA 1986). Absorption of nickel sulfate from the skin is reported for guinea pigs, rabbits, rats, and humans (Norseth and Piscator 1979). Nickel ions in contact with the skin surface diffuse through the epidermis and combine with proteins; the body reacts to this conjugated protein (Samitz and Katz 1976; Nielsen 1977). Nickel penetration of the skin is enhanced by sweat, blood and other body fluids, and detergents (Nielsen 1977; USEPA 1980). Absorption is related to the solubility of the compound, following the general relation of nickel carbonyl, soluble nickel compounds, and insoluble nickel compounds, in that order; nickel carbonyl is the most rapidly and completely absorbed nickel compound in mammals (WHO 1991). Anionic species differ markedly in skin penetration: nickelous ions from a chloride solution pass through skin about 50 times faster than do nickelous ions from a sulfate solution (USPHS 1993). Radionickel-57 (^{57}Ni) accumulates in keratinous areas and hair sacs of the shaved skin of guinea pigs and rabbits following dermal exposure. After 4 h, ^{57}Ni was found in the stratum corneum and stratum spinosum; after 24 h, ^{57}Ni was detected in blood and kidneys, with minor amounts in liver (USPHS 1993). As much as 77% of nickel sulfate applied to the occluded skin surface of rabbits and guinea pigs was absorbed within 24 h; sensitivity to nickel did not seem to affect absorption rate (USPHS 1993). In humans, some protection against nickel may be given by introducing a physical barrier between the skin and the metal, including fingernail polish, a polyurethane coating, dexamethasone, or disodium EDTA (Nielsen 1977).

Nickel retention in the body of mammals is low. The half-time residence of soluble forms of nickel is several days, with little evidence for tissue accumulation except in the lung (USEPA 1980, 1986). Radionickel-63 (^{63}Ni) injected into rats and rabbits cleared rapidly; most (75%) of the injected dose was excreted within 24 to 72 h (USEPA 1980). Nickel clears at different rates from various tissues. In mammals, clearance was fastest from serum, followed by kidney, muscle, stomach, and uterus; relatively slow clearance was evident in skin, brain, and especially lung (Kasprzak 1987). The half-time persistence in human lung for insoluble forms of nickel is 330 days (Sevin 1980).

The excretory routes for nickel in mammals depend on the chemical forms of nickel and the mode of nickel intake. Most (>90%) of the nickel that is ingested in food remains unabsorbed within the gastrointestinal tract and is excreted in the feces (NAS 1975; Sevin 1980; USEPA 1986; Kasprzak 1987; Hausinger 1993; USPHS 1993). Urinary excretion is the primary route of clearance for nickel absorbed through the gastrointestinal tract (USEPA 1976, 1986; USPHS 1993). In humans, nickel excretion in feces usually ranges between 300 and 500 μg daily, or about the same as the daily dietary intake; urinary levels are between 2 and 4 $\mu\text{g/L}$ (USEPA 1980, 1986). Dogs fed nickel sulfate in the diet for as long as 2 years excreted most of the nickel in feces and 1 to 3% in the urine (USPHS 1993). Biliary excretion occurs in rats, calves, and rabbits, but the role of bile in human metabolism of nickel is not clear (USEPA 1980). Absorbed nickel is excreted in the urine regardless of the route of exposure. The excretory route of inhaled nickel depends on the

solubility of the nickel compound. Inhalation studies show that rats excrete 70% of the nickel in soluble nickel compounds through the urine within 3 days and 97% in 21 days. Less soluble nickel compounds (nickel oxide, nickel subsulfide) are excreted in urine (50%) and feces (50%); 90% of the initial dose of nickel subsulfide was excreted within 35 days, and 60% of the nickel oxide — which is less soluble and not as rapidly absorbed as nickel subsulfide — was excreted in 90 days (USPHS 1993). The half-time persistence of inhaled nickel oxide is 3 weeks in hamsters (Sevin 1980). In addition to feces, urine, and bile, other body secretions, including sweat, tears, milk, and mucociliary fluids, are potential routes of excretion (WHO 1991). Sweat may constitute a major route of nickel excretion in tropical climates. Nickel concentrations in sweat of healthy humans sauna bathing for brief periods were 52 µg/L in males and 131 µg/L in females (USEPA 1980). Hair deposition of nickel also appears to be an excretory mechanism (as much as 4 mg Ni/kg dry weight [DW] hair in humans), but the relative magnitude of this route, compared to urinary excretion, is unclear (USEPA 1980, 1986). In the case of nickel compounds administered by way of injection, tests with small laboratory animals show that nickel is cleared rapidly from the plasma and excreted mainly in the urine (Norseth and Piscator 1979; USEPA 1980). About 78% of an injected dose of nickel salts was excreted in the urine during the first 3 days after injection in rats and during the first day in rabbits (Norseth 1986). Exhalation via the lungs is the primary route of excretion during the first hours following injection of nickel carbonyl into rats, and afterwards via the urine (Norseth and Piscator 1979).

In microorganisms, nickel binds mainly to the phosphate groups of the cell wall. From this site, an active transport mechanism designed for magnesium transports the nickel (Kasprzak 1987). In microorganisms and higher plants, magnesium is the usual competitor for nickel in the biological ion-exchange reactions. In lichens, fungi, algae, and mosses, the active binding sites are the carboxylic and hydroxycarboxylic groups fixed on the cell walls. Nickel in hyperaccumulating genera of terrestrial plants is complexed with polycarboxylic acids and pectins, although phosphate groups may also participate (Kasprzak 1987). In terrestrial plants, nickel is absorbed through the roots (USEPA 1975).

6.3.4 Interactions

In minerals, nickel competes with iron, cobalt, and magnesium because of similarities in their ionic radius and electronegativity (NRCC 1981). At the cellular level, nickel interferes with enzymatic functions of calcium, iron, magnesium, manganese, and zinc (Kasprzak 1987). Binding of nickel to DNA is inhibited by salts of calcium, copper, magnesium, manganese, and zinc (WHO 1991). In toads (*Bufo arenarum*), ionic nickel interferes with voltage-sensitive ionic potassium channels in short muscle fibers (Bertran and Kotsias 1997). Among animals, plants, and microorganisms, nickel interacts with at least 13 essential elements: calcium, chromium, cobalt, copper, iodine, iron, magnesium, manganese, molybdenum, phosphorus, potassium, sodium, and zinc (Nielsen 1980a). Nickel interacts noncompetitively with all 13 elements and also interacts competitively with calcium, cobalt, copper, iron, and zinc. Quantification of these relationships would help clarify nickel-essential mineral interactions and the circumstances under which these interactions might lead to states of deficiency or toxicity (Nielsen 1980a). Mixtures of metals (arsenic, cadmium, copper, chromium, mercury, lead, zinc) containing nickel salts are more toxic to daphnids and fishes than are predicted on the basis of individual components (Enserink et al. 1991). Additive joint action of chemicals, including nickel, should be considered in the development of ecotoxicologically relevant water-quality criteria (Enserink et al. 1991).

Nickel may be a factor in asbestos carcinogenicity. The presence of chromium and manganese in asbestos fibers may enhance the carcinogenicity of nickel (USEPA 1980), but this relation needs to be verified. Barium–nickel mixtures inhibit calcium uptake in rats, resulting in reduced growth (WHO 1991). Pretreatment of animals with cadmium enhanced the toxicity of nickel to the kidneys and liver (USPHS 1993). Simultaneous exposure to nickel and cadmium — an industrial situation

common in nickel and cadmium battery production — caused a significant increase in beta-2-macroglobulin excretion (Sunderman et al. 1984). Nickel or cadmium alone did not affect calcium kinetics of smooth muscle from bovine mesenteric arteries. However, mixtures of cadmium and nickel at greater than 100 Nm inhibited the calcium function and may explain the vascular tension induced by nickel and other cations (Stockard et al. 1993). Smooth muscle of the ventral aorta of the spiny dogfish (*Squalus acanthias*) contracted significantly on exposure to cadmium or nickel but not to other divalent cations. Cadmium-induced vasoconstriction of shark muscle (but not nickel) was inhibited by atropine (Evans and Walton 1990). Nickel toxicity in soybeans (*Glycine max*) was inhibited by calcium, which limited the binding of nickel to DNA (WHO 1991). Chromium–nickel mixtures were more-than-additive in toxicity to guppies (*Poecilia reticulata*) in 96-h tests (Khangarot and Ray 1990). Rabbits (*Oryctolagus* sp.) exposed by inhalation to both nickel and trivalent chromium had more severe respiratory effects than did rabbits exposed to nickel alone (USPHS 1993). In natural waters, the geochemical behavior of nickel is similar to that of cobalt (USEPA 1980). It is therefore not surprising that nickel–cobalt mixtures in drinking water of rats were additive in toxicity (WHO 1991) and that there is a high correlation between nickel and cobalt concentrations in terrestrial plants (Memon et al. 1980).

Copper–nickel mixtures have a beneficial effect on growth of terrestrial plants but are more-than-additive in toxic action to aquatic plants (NRCC 1981; WHO 1991). Nickel interacts with iron in rat nutrition and metabolism, but the interaction depends on the form and level of the dietary iron (Nielsen 1980b; USEPA 1985). Weanling rats fed diets containing nickel chloride and ferric sulfate had altered hematocrit, hemoglobin level, and alkaline phosphatase activity which did not occur when a mixture of ferric and ferrous sulfates were fed (Nielsen 1980b). In iron-deficient rats, nickel enhanced the absorption of iron administered as ferric sulfate (USPHS 1993), and nickel acted as a biological cofactor in facilitating gastrointestinal absorption of ferric ion when iron was given as ferric sulfate (USPHS 1993). Mice given a lead–nickel mixture in drinking water (57 mg Ni/L to 200 mg Pb/L) for 12 days had increased urinary excretion of delta aminolevulinic acid and increased delta aminolevulinic dehydratase activity in erythrocytes when compared to groups given lead alone or nickel alone (Tomokuni and Ichiba 1990).

Magnesium competes with nickel in isolated cell studies (WHO 1991). Treatment with magnesium reduces nickel toxicity, presumably through inhibition of nickel binding to DNA (USPHS 1993; Hartwig et al. 1994). Manganese also inhibits the binding of nickel to DNA (WHO 1991), and manganese administration reduces the accumulation of nickel in some organs (Murthy and Chandra 1979). Manganese dust inhibits nickel subsulfide-induced carcinogenesis in rats following simultaneous intramuscular injection of the two compounds (USPHS 1993). Also, nickel–manganese mixtures are less-than-additive in producing cytotoxicity of alveolar macrophages in rats (WHO 1991). Nickel compounds enhance the cytotoxicity and genotoxicity of ultraviolet radiation, X-rays, and cytostatic agents such as *cis*-platinum, *trans*-platinum, and mitomycin C (Hartwig et al. 1994). Nickel is less-than-additive in toxicity to aquatic algae in combination with zinc (WHO 1991). Treatment with zinc lessens nickel toxicity, presumably by competing with nickel in binding to DNA and proteins (USEPA 1985; WHO 1991; USPHS 1993; Hartwig et al. 1994). Zinc binding sites of DNA-binding proteins, known as “finger loop domains,” are likely molecular targets for metal toxicity. Ionic nickel has an ionic radius similar to Zn²⁺ and substitution is possible. Such substitution may disrupt nickel-induced gene expression by interfering with site-specific free radical reactions, which can result in DNA cleavage, formation of DNA protein crosslinks, and disturbance of mitosis (WHO 1991).

Nickel also interacts with chelating agents, phosphatases, viruses, vitamins, and polycyclic aromatic hydrocarbons (PAHs). Chelating agents mitigate the toxicity of nickel by stimulating the excretion of nickel (USPHS 1993). Chelators reduced the toxicity of nickel to aquatic plants, presumably by lowering nickel bioavailability (WHO 1991). Lipophilic chelating agents, such as triethylenetetramine and Cyclam (1,4,8,11-tetraazacyclotetradecane) are more effective in reducing toxicity than hydrophilic chelating agents such as EDTA, cyclohexanediamine tetraacetic acid,

diethylenetriamine pentaacetic acid, and hydroxyethylenediamine triacetic acid. The greater efficacy of the lipophilic agents may be due to their ability to bind to nickel both intracellularly and extracellularly, while the hydrophilic agents can only bond extracellularly (USPHS 1993). Nickel irreversibly activates calcineurin, a multifunctional intracellular phosphatase normally activated by calcium and calmodulin (Kasprzak 1987). With nickel present, Newcastle Disease virus suppresses mouse L-cell interferon synthesis, suggesting virus–nickel synergism (USEPA 1980). Nickel interacts with Vitamin C (USEPA 1985) and has a synergistic effect on the carcinogenicities of various PAHs (USEPA 1980). Rats given intratracheal doses of nickel oxide and 20-methylcholanthrene develop squamous cell carcinomas more rapidly than with 20-methylcholanthrene alone. Simultaneous exposure of rats to benzopyrene and nickel subsulfide reduced the latency period of sarcomas by 30% and induced lung histopathology at a higher frequency than either agent alone. Also, tissue retention of PAH carcinogens is prolonged with nickel exposure (USEPA 1980).

6.4 CARCINOGENICITY, MUTAGENICITY, AND TERATOGENICITY

6.4.1 General

Some forms of nickel are carcinogenic to humans and animals (IARC 1976; Smialowicz et al. 1984; USEPA 1986; WHO 1991; Hausinger 1993; USPHS 1993; Hartwig et al. 1994). Carcinogenicity of nickel compounds varies significantly with the chemical form of nickel, route of exposure, animal model used (including intraspecies strain differences), dose, and duration of exposure (USEPA 1980). In tests with small laboratory mammals, induction of carcinomas of the types found in humans has only been accomplished following exposures by the respiratory route (Sunderman 1968). Inhalation studies with nickel subsulfide and nickel oxide show evidence of carcinogenicity in mammals and humans. However, the evidence based on oral or cutaneous exposure to these and other nickel compounds is either negative or inconclusive (NAS 1975; IARC 1976; Norseth 1980; USEPA 1980, 1986; WHO 1991; USPHS 1993). Nickel carbonyl and metallic nickel are carcinogenic in experimental animals, but data regarding their carcinogenicity in humans are inconclusive (USEPA 1975; Norseth 1980; USPHS 1993).

Certain nickel compounds are weakly mutagenic in a variety of test systems, but much of the evidence is inconclusive or negative (USPHS 1977, 1993; USEPA 1986; Kasprzak 1987; WHO 1991; Outridge and Scheuhammer 1993). Mutagenicity — as measured by an increased frequency of sister chromatid exchange, chromosome aberrations, cell transformations, spindle disturbances, and dominant lethal effects — is induced by various nickel compounds at high concentrations in isolated cells of selected mammals including humans; however, these effects have not been observed *in vivo* (Sunderman 1981; USEPA 1986; WHO 1991; USPHS 1993). Nickel mutagenesis is thought to occur through inhibition of DNA synthesis and excision repair, resulting in an increased frequency of crosslinks and strand breaks (USEPA 1986; WHO 1991; USPHS 1993). DNA strand breaks occur in rat cells exposed to 5 to 40 mg Ni/kg medium as nickel carbonate; similar effects occur in hamster cells at 10 to 2000 mg Ni/kg medium as nickel chloride and nickel subsulfide, and in human cells with nickel sulfate (WHO 1991). The ability of a particular nickel compound to cause mutations is considered proportional to its cellular uptake; however, data on nickel bioavailability to cells is scarce (Niebuhr et al. 1980; USPHS 1993).

No teratogenic effects of nickel compounds occur in mammals by way of inhalation or ingestion except from nickel carbonyl (USEPA 1986; Outridge and Scheuhammer 1993). However, injection of low nickel doses results in consistent fetal malformations, particularly when nickel is administered during the organogenic stage of gestation of mammals or during the early development of domestic chick embryos (Outridge and Scheuhammer 1993). Injected doses causing teratogenic effects in rodents were as low as 1.0 to 1.2 mg Ni/kg body weight (BW), although more malformations resulted at higher dosages (2.3 to 4.0 mg/kg BW), which also increased fetal mortality

and toxicity in the dam (Mas et al. 1985; Outridge and Scheuhammer 1993). Possible causes of nickel-induced malformations include direct toxicity from high transplacental nickel levels, reduced availability of alpha-fetoprotein to fetuses, or an increase in maternal glucose levels, which induces hyperglycemia in fetuses (Mas et al. 1985; Outridge and Scheuhammer 1993).

6.4.2 Carcinogenicity

Epidemiological studies conducted some decades ago in England, Canada, Japan, Norway, Germany, Russia, New Caledonia, and West Virginia indicated that humans working in the nickel processing and refining industries — or living within 1 km of processing or refining sites — had a significantly increased risk of developing fatal cancers of the nose, lungs, larynx, and kidneys, and a higher incidence of deaths from nonmalignant respiratory disease (Sunderman 1968, 1981; NAS 1975; IARC 1976; USPHS 1977, 1993; Norseth and Piscator 1979; Norseth 1980; Sevin 1980; USEPA 1980; Kasprzak 1987; WHO 1991). Nasal cancers in nickel refinery workers were similar to those of the general population; however, lung cancers of nickel refinery workers had a higher frequency of squamous cell carcinomas (USPHS 1993). Smoking of tobacco contributed to the development of lung cancers in the nickel-exposed workers. Smoking about 15 cigarettes daily for one year adds about 1930 µg of nickel, as nickel carbonyl, to the human lung; this is equivalent to a carcinogenic dose of nickel for rats (Sunderman 1970, 1981). Symptoms of cancer in humans may occur 5 to 35 years after exposure (Furst and Radding 1980; Kasprzak 1987; USPHS 1993). The incidence of human lung and nasal cancers in occupationally exposed workers is related to nickel concentration and duration of exposure (USEPA 1986). Nickel compounds implicated as carcinogens include insoluble dusts of nickel subsulfide (Ni_3S_2) and nickel oxides (NiO , Ni_2O_3), the vapor of nickel carbonyl ($\text{Ni}(\text{CO})_4$), and soluble aerosols of nickel sulfate (NiSO_4), nickel nitrate (NiNO_3), and nickel chloride (NiCl_2 ; USEPA 1980; USPHS 1977). Soluble nickel compounds, though toxic, have relatively low carcinogenic activities (Ho and Furst 1973). In general, carcinogenicity of nickel compounds is inversely related to its solubility in water, the least soluble being the most active carcinogen (Sunderman 1968; Furst and Radding 1980; USEPA 1980; USPHS 1993). The highest risk to humans of lung and nasal cancers comes from exposure to respirable particles of metallic nickel, nickel sulfides, nickel oxide, and the vapors of nickel carbonyl (NAS 1975; USPHS 1977; Norseth and Piscator 1979; Norseth 1980; Sunderman 1981; Sunderman et al. 1984; USEPA 1986; Kasprzak 1987; WHO 1991; USPHS 1993). Cancers were most frequent when workers were exposed to soluble nickel compounds at concentrations greater than 1.0 mg Ni/m³ air and to exposure to less soluble compounds at greater than 10.0 mg Ni/m³ air (USPHS 1993). Nickel subsulfide appears to be the nickel compound most carcinogenic to humans, as judged by animal studies and epidemiological evidence (Furst and Radding 1980; Outridge and Scheuhammer 1993). The death rate of nickel workers from cancer has declined significantly since the mid-1920s because of improved safety and awareness (USPHS 1977, 1993).

The underlying biochemical mechanisms governing the carcinogenicity of various nickel compounds are imperfectly understood. There is general agreement that intracellular nickel accumulates in the nucleus, especially the nucleolar fraction (NAS 1975; USEPA 1980). Intracellular binding of nickel to nuclear proteins and nuclear RNA and DNA may cause strand breakage and other chromosomal aberrations, diminished RNA synthesis and mitotic activity, and gene expression (USEPA 1980; Kasprzak 1987). A key mechanism of the transformation of tumorous cells involves DNA damage resulting from mutation (Sigel and Sigel 1988) caused by hydroxy radical or other oxidizing species (Datta et al. 1994). Alterations in cytokine (also known as tumor necrosis factor) production is associated with fibrotic lung injury in rats. Inhaled nickel oxide is known to increase cytokine production in rats (Morimoto et al. 1995).

Nickel entering the digestive tract of mammals is likely to be noncarcinogenic. Chronic ingestion studies of various nickel compounds that lasted as long as 2 years using several species of mammals show no evidence of carcinogenesis (Outridge and Scheuhammer 1993). Inhalation is the dosing

route most relevant to human occupational exposure (Sunderman et al. 1984) and probably an important route for wildlife exposure in the case of nickel powder, nickel carbonyl, and nickel subsulfide (IARC 1976).

Inhalation of airborne nickel powder at 15 mg Ni/m³ air causes an increased frequency of lung anaplastic carcinomas and nasal cancers in rodents and guinea pigs, especially when the particles are less than 4 µm in diameter (USPHS 1977; USEPA 1980). Rats exposed to airborne dusts of metallic nickel at 70 mg Ni/m³ air for 5 h daily, 5 days weekly over 6 months had a 40% frequency of lung cancers; the latent period for tumor development was 17 months (Sunderman 1981). A similar case is made for nickel sulfide and nickel oxide (Sunderman 1981). In Canada, however, metallic nickel is considered "unclassifiable with respect to carcinogenicity" due to the limitations of identified studies (Hughes et al. 1994). Inhaled nickel carbonyl is carcinogenic to the lungs of rats, a species generally considered to be peculiarly resistant to pulmonary cancer (Sunderman and Donnelly 1965; NAS 1975; IARC 1976; USEPA 1980; WHO 1991). Pulmonary cancers developed in rats 24 to 27 months after initial exposure to nickel carbonyl, and growth and survival of rats during chronic exposure were markedly reduced (Sunderman and Donnelly 1965). Rats exposed to air containing 250 µg nickel carbonyl/L for only 30 min had a 4% incidence of lung cancer in 2-year survivors vs. 0% in controls; rats exposed to 30 to 60 µg/L air for 30 min, three times weekly for 1 year had a 21% incidence of lung cancer in 2-year survivors (Sunderman 1970; NAS 1975). Inhaled nickel oxides do not seem to be tumorigenic to hamsters at concentrations of 1.2 mg Ni/m³ air during exposure for 12 months (Outridge and Scheuhammer 1993). Hamsters did not develop lung tumors during lifespan inhalation exposure to nickel oxide; however, inhaled nickel oxide enhanced nasal carcinogenesis produced by diethylnitrosamine (USPHS 1977). Inhalation of nickel subsulfide produced malignant lung tumors and nasal cancers in rats in a dose-dependent manner (Ottolenghi et al. 1974; IARC 1976; USPHS 1977, 1993; WHO 1991; Benson et al. 1995; Rodriguez et al. 1996). Rats develop benign and malignant lung tumors (14% frequency vs. 0% in controls) after exposure for 78 weeks (6 h daily, 5 days weekly) to air containing 1.0 mg Ni/m³ (as nickel subsulfide; particles <1.5 µm in diameter) and during a subsequent 30-week observation period (IARC 1976; USPHS 1977; USEPA 1980; NRCC 1981).

Local sarcomas may develop in humans and domestic animals at sites of nickel implants and prostheses made of nickel. Latency of the implant sarcomas varies from 1 to 30 years in humans (mean, 10 years) and from 1 to 11 years in dogs (mean, 5 years). No cases of malignant tumors are reported at sites of dental nickel prostheses (Kasprzak 1987).

Injection site tumors are induced by many nickel compounds that do not cause cancer in animals by other routes of exposure (USPHS 1977). In fact, most of the published literature on nickel carcinogenesis concerns injected or implanted metallic nickel or nickel compounds. However, these data seem to be of limited value in determining carcinogenic exposure levels for avian and terrestrial wildlife (Outridge and Scheuhammer 1993). The applicability of these studies to a recommendation for human workplace exposure is also questionable (USPHS 1977). Nevertheless, injection- or implantation-site sarcomas have been induced by many nickel compounds after one or repeated injections or implantations in rats, mice, hamsters, guinea pigs, rabbits, and cats (NAS 1975; IARC 1976; USPHS 1977, 1993; Norseth and Piscator 1979; USEPA 1980; NRCC 1981; Sunderman 1981; WHO 1991). Nickel compounds known to produce sarcomas or malignant tumors by these routes of administration (implantation, intratracheal, intramuscular, intraperitoneal, subcutaneous, intrarenal, intravenous, intratesticular, intraocular, intraosseus, intrapleural, intracerebral, intrahepatic, intraarticular, intrasubmaxillary, intraadipose, intramedullary) include nickel subsulfide, nickel carbonyl, nickel powder or dust, nickel oxide, nickel hydroxide, nickel acetate, nickel fluoride, nickelocene, nickel sulfate, nickel selenide, nickel carbonate, nickel chromate, nickel arsenide, nickel telluride, nickel antimonide, nickel-iron matte, nickel ammonium sulfate and nickel monosulfide.

Some parenteral routes of administration were less effective than others in producing an increase in the frequency of benign or malignant tumors, including intravenous, submaxillary, and intrahepatic

injection routes (Sunderman 1981). Some nickel compounds are more effective at inducing tumors than others; for example, nickel sulfate and nickel acetate induce tumors in the peritoneal cavity of rats after repeated intraperitoneal injections but nickel chloride does not (WHO 1991). Likewise, some species are more sensitive to tumor induction by injection than others; rats, for example, are more sensitive than hamsters (USPHS 1977). Most nickel compounds administered by way of injection usually produce responses at the site of injection; however, nickel acetate injected intraperitoneally produced pulmonary carcinomas in mice (USEPA 1980). Some carcinogenic nickel compounds produce tumors only when a threshold dose is exceeded (IARC 1976; USPHS 1993), and some strains of animals are more sensitive than others. In one study, three strains of male mice (*Mus* sp.) were given a single intramuscular injection of 0.5, 2.5, 5.0, or 10.0 mg nickel subsulfide per mouse — equivalent to 19, 95, 190, or 380 mg Ni₃S₂/kg BW — and observed for 78 weeks for tumor development (Rodriguez et al. 1996). Nickel subsulfide is a water-insoluble compound suspected to damage cells through oxidative mechanisms. The highest dose injected was lethal (53 to 93% dead) within 7 days. The final incidence of sarcomas in the 5 mg/mouse groups ranged between 40 and 97%, with decreased survival and growth noted in all test groups. In the most sensitive strain tested, there was a dose-dependent increase in tumor frequency, with a significant increase in tumors at the lowest dose tested (Rodriguez et al. 1996).

Carcinogenic properties of nickel are modified by interactions with other chemicals (NAS 1975; USEPA 1985; WHO 1991). Nickel–cadmium battery workers exposed to high levels of both nickel and cadmium have an increased risk of lung cancer when compared to exposure from cadmium alone (WHO 1991). Some nickel compounds interact synergistically with known carcinogens (WHO 1991). Nickel chloride enhances the renal carcinogenicity of N-ethyl-N-hydroxyethyl nitrosamine in rats. Metallic nickel powder enhances lung carcinogenicity of 20-methylcholanthrene when both are administered intratracheally to rats. Nickel subsulfide in combination with benzo(a)pyrene shortens the latency time to local tumor development and produces a disproportionately higher frequency of malignant tumors. Nickel sulfate enhanced dinitrosopiperazine carcinogenicity in rats (WHO 1991), and nickel potentiated the specific effects of cobalt in rabbits by enhancing the formation of lung nodules (Johansson et al. 1991). Some chemicals inhibit nickel-induced carcinogenicity. Carcinogenicity induced by nickel subsulfide is reduced by manganese dust (Sunderman 1981; Sunderman et al. 1984; WHO 1991). Manganese protects male guinea pigs against tumorigenesis induced by nickel subsulfide, possibly due to the stimulating effect of manganese on macrophage response and by displacing nickel from the injection site (Murthy and Chandra 1979). Sodium diethyldithiocarbamate reduced tumor incidence in rats implanted with nickel subsulfide (WHO 1991), and magnesium acetate and calcium acetate inhibit lung adenoma formation in mice treated intraperitoneally with nickel acetate (WHO 1991). Nickel interactions with other suspected carcinogens, such as chromium, merit additional research (Norseth 1980). Nickel and other trace metals in asbestos fibers are responsible, in part, for the pulmonary carcinogenicity found in asbestos workers (Sunderman 1968). Nickel–sulfur mineral complexes may also have carcinogenic potential; a similar case is made for the corresponding arsenides, selenides, and tellurides (USEPA 1980).

6.4.3 Mutagenicity

Nickel salts gave no evidence of mutagenesis in tests with viruses (USPHS 1977), and bacterial mutagenesis tests of nickel compounds have consistently yielded negative or inconclusive results (USPHS 1977; Sunderman 1981; Sunderman et al. 1984; WHO 1991). However, nickel chloride and nickel sulfate were judged to be mutagenic or weakly mutagenic in certain bacterial eukaryotic test systems (USEPA 1985). Nickel subsulfide was positively mutagenic to the protozoan *Paramecium* sp. at 0.5 mg Ni/L (WHO 1991). Ionic Ni²⁺ was mutagenic to *Escherichia coli*; mutagenesis was enhanced by the addition of both hydrogen peroxide and tripeptide glycyl-L-histidine, suggesting

that short-lived oxygen free radicals are generated (Tkeshelashvili et al. 1993). Nickel chloride hexahydrate induced respiratory deficiency in yeast cells, but this may be a cytotoxic effect rather than a gene mutation (USPHS 1977; WHO 1991).

Nickel is weakly mutagenic to plants (USPHS 1977) and insects (WHO 1991). Abnormal cell divisions occur in roots of the broad bean (*Vicia faba*) during exposure to various inorganic nickel salts at nickel concentrations of 0.1 to 1000 mg/L (USPHS 1977). All nickel salts tested produced more abnormal cell divisions than did controls. In beans, nickel nitrate was the most effective inorganic nickel compound tested in producing deformed cells, abnormal arrangement of chromatin, extra micronuclei, and evidence of cell nucleus disturbances; however, nickel salts showed only weak mutagenic action on rootlets of peas (*Pisum* sp.; USPHS 1977). Nickel sulfate induced chromosomal abnormalities in root tip cells of onions, *Allium* sp. (Donghua and Wusheng 1997) and caused sex-linked recessive mutations in the fruit fly (*Drosophila melanogaster*) at 200 to 400 mg Ni/L culture medium (WHO 1991).

Human cells exposed to various nickel compounds have an increased frequency of chromosomal aberrations, although sister chromatid exchange frequency is unaffected. Cells from nickel refinery workers exposed to nickel monosulfide (0.2 mg Ni/m³) or nickel subsulfide (0.5 mg Ni/m³) showed a significant increase in the incidence of chromosomal aberrations (Boysen et al. 1980; WHO 1991; USPHS 1993). No correlation was evident between nickel exposure level and the frequency of aberrations (USPHS 1993).

In Chinese hamster ovary cells, nickel chloride increased the frequency of chromosomal aberrations and sister chromatid exchanges. The cells with aberrations increased from 8% at about 6 µg Ni/L to 21% at about 6 mg Ni/L in a dose-dependent manner (Howard et al. 1991). There is a large difference in the mutagenic potential of soluble and insoluble nickel compounds, which seems to reflect the carcinogenic potential of these forms of nickel (Lee et al. 1993). For example, insoluble particles less than 5 µm in diameter of crystalline nickel subsulfide — a carcinogen — produced a strong dose-dependent mutagenic response in Chinese hamster ovary cells up to 80 times higher than untreated cells. However, soluble nickel sulfate produced no significant increase in mutational response over background in Chinese hamster ovary cells (Lee et al. 1993). A similar response is reported for Syrian hamster embryo cells (USPHS 1993). Interactions of carcinogens and soluble nickel salts need to be considered. Benzo(a)pyrene, for example, showed a comutagenic effect with nickel sulfate in hamster embryo cells (USEPA 1985).

In rats, nickel carbonyl is reported to cause dominant lethal mutations (WHO 1991), but this needs verification. Nickel sulfate, when given subcutaneously at 2.4 mg Ni/kg BW daily for 120 days causes infertility; testicular tissues are adversely affected after the first injection (USEPA 1980). Nickel salts given intraperitoneally to rats at 6 mg Ni/kg BW daily for 14 days did not produce significant chromosomal changes in bone marrow or spermatogonial cells (Mathur et al. 1978).

In mice, nickel chloride produces a dose-dependent increase in abnormal lymphoma cells (WHO 1991). Mice given high concentrations of nickel in drinking water, equivalent to 23 mg Ni/kg BW daily and higher, have an increased incidence of micronuclei in bone marrow (USPHS 1993). However, mice injected once with 50 mg Ni/kg BW as nickel chloride show no evidence of mutagenicity (USPHS 1977).

6.4.4 Teratogenicity

Nickel carbonyl at high doses is a potent animal teratogen (Sunderman et al. 1984). Inhalation exposure to nickel carbonyl caused fetal death and decreased weight gain in rats and hamsters (WHO 1991) and eye malformations in rats (Sevin 1980; Sunderman et al. 1980). Studies on hamsters, rats, mice, birds, frogs, and other species suggest that some individuals are susceptible to reproductive and teratogenic effects when given high doses of nickel by various routes of administration (USPHS 1977; Sunderman et al. 1980; USEPA 1986; WHO 1991; Hausinger 1993). Intravenous injection of nickel sulfate to hamsters at 2 to 25 mg/kg BW on day 8 of gestation

produces developmental abnormalities (USPHS 1977; Norseth and Piscator 1979). Teratogenic malformations — including poor bone ossification, hydronephrosis, and hemorrhaging — occur in rats when nickel is administered during organogenesis, and these malformations are maximal at dose levels toxic for the dam (Mas et al. 1985). A dose of 4 mg/kg BW given intraperitoneally on day 12 or 19 of pregnancy is teratogenic in rats (Mas et al. 1985). Rats exposed continuously for three generations to drinking water containing 5 mg Ni/L produce smaller litters, higher offspring mortality, and fewer males (NAS 1975; USPHS 1977). An increase in the number of runts suggests that transplacental toxicity occurs (USPHS 1977; Norseth and Piscator 1979).

Divalent nickel is a potent teratogen for the South African clawed frog (*Xenopus laevis*). Frog embryos actively absorb Ni²⁺ from the medium and develop ocular, skeletal, craniofacial, cardiac, and intestinal malformations (Sunderman et al. 1990; Hopfer et al. 1991; Hausinger 1993; Luo et al. 1993; Hauptman et al. 1993; Plowman et al. 1994). A Ni²⁺-binding serpin, *pNiXa*, is abundant in clawed frog oocytes and embryos; binding of Ni²⁺ to *pNiXa* may cause embryotoxicity by enhancing oxidative reactions that produce tissue injury and genotoxicity (Beck et al. 1992; Haspel et al. 1993; Sunderman et al. 1996). Another Ni²⁺-binding protein, *pNiXc*, isolated from mature oocytes of the clawed frog, was identified as a monomer of fructose-1,6-biphosphate aldolase A and raises the possibility that aldolase A is a target enzyme for nickel toxicity (Antonijczuk et al. 1995).

Nickel is embryolethal and teratogenic to white leghorn strains of the domestic chicken (*Gallus* sp.), possibly due to the mitosis-inhibiting activity of nickel compounds (Gilani and Marano 1980). Fertilized chicken eggs injected with 0.02 to 0.7 mg Ni/egg as nickel chloride on days 1 through 4 of incubation show a dose-dependent response. All dose levels of nickel tested were teratogenic to chickens. Malformations include poorly developed or missing brain and eyes, everted viscera, short and twisted neck and limbs, hemorrhaging, and a reduction in body size. Toxicity and teratogenicity are highest in embryos injected on day 2 (Gilani and Marano 1980). Mallard (*Anas platyrhynchos*) ducklings from fertile eggs treated at age 72 h with 0.7 µg Ni as nickel mesotetraphenylporphine show a marked decrease in survival. Among survivors, there is a significant increase in the frequency of developmental abnormalities, a reduction in bill size, and a reduction in weight (Hoffman 1979).

Changes in employment practices in North America and Europe have increased the proportion of women among workers in nickel mines and refineries and in nickel-plating industries and have increased the concern regarding possible fetal toxicity associated with exposures of pregnant women to nickel during gestation (Sunderman et al. 1978). One preliminary report (Chashschin et al. 1994) strongly suggests that exposure to nickel of Russian female hydrometallurgy workers causes significantly increased risks for abortion, total defects, cardiovascular defects, and defects of the musculoskeletal system. Nickel was observed to cross the human placenta and produce teratogenesis and embryotoxicity, as judged by studies with isolated human placental tissues (Chen and Lin 1998). Nickel disrupts lipid peroxidative processes in human placental membranes, and this metabolic change may be responsible for the observed decrease in placental viability, altered permeability, and embryotoxicity (Chen and Lin 1998).

Nonteratogenic reproductive effects of nickel include increased resorption of embryos and fetuses, reduced litter size, testicular damage, altered rates of development and growth, and decreased fertility. Nickel compounds can penetrate the mammalian placental barrier and affect the fetus (USEPA 1980; Sunderman et al. 1984; Mas et al. 1985). Intravenous administration of nickel acetate (0.7 to 10.0 mg Ni/kg BW) to pregnant hamsters on day 8 of gestation resulted in dose-dependent increases in the number of resorbed embryos (USEPA 1980). Rats injected intramuscularly with nickel chloride on day 8 of gestation with 12 or 16 mg Ni/kg BW produced significantly fewer live fetuses than did controls (USPHS 1977). Three generations of rats given nickel in their diets at 250 to 1000 mg Ni/kg ration had increased fetal mortality in the first generation and reduced body weights in all generations at 1000 mg/kg (USPHS 1977). Litter sizes were reduced in pregnant rats fed nickel in various forms at 1000 mg Ni/kg ration (USEPA 1980). Rodents exposed to nickel

during gestation show a decline in the frequency of implantation of fertilized eggs, enhanced resorption of fertilized eggs and fetuses, an increased frequency of stillbirths, and growth abnormalities in live-born young (Hausinger 1993). Exposure of eggs and sperm of rainbow trout to 1.0 mg Ni/L as nickel sulfate for 30 min did not affect fertilization or hatchability; however, most exposed zygotes hatched earlier than the controls (NAS 1975). Nickel salts produced testicular damage in rats and mice given oral, subcutaneous, or intratesticular doses of 10 to 25 mg Ni/kg BW; nickel-treated male rats were unable to impregnate females (USPHS 1977). Nickel sulfate at 25 mg Ni/kg BW daily for 120 days via the esophagus selectively damaged the testes of rats (inhibition of spermatogenesis) and resulted in a reduced procreative capacity (USPHS 1977); males were permanently infertile after 120 days on this regimen (NAS 1975).

6.5 CONCENTRATIONS IN FIELD COLLECTIONS

6.5.1 General

Nickel is ubiquitous in the biosphere and is the 24th most abundant element in the earth's crust with a mean concentration of 75 mg/kg (Sevin 1980; Chau and Kulikovsky-Cordeiro 1995). Nickel enters the environment from natural and human sources and is distributed throughout all compartments by means of chemical and physical processes and biological transport by living organisms. Nickel is found in air, soil, water, food, and household objects; ingestion or inhalation of nickel is common, as is dermal exposure (USPHS 1977). In general, nickel concentrations in plants, animals, and abiotic materials are elevated in the vicinity of nickel smelters and refineries, nickel–cadmium battery plants, sewage outfalls, and coal ash disposal basins (NAS 1975; Kasprzak 1987; WHO 1991; USPHS 1993; Chau and Kulikovsky-Cordeiro 1995). A global inventory estimate of nickel shows that living organisms contain about 14 million metric tons of nickel, mostly (98.8%) in terrestrial plants ([Table 6.4](#)), but plants and animals account for only 0.00000031% of the total nickel inventory estimate of 4500 trillion metric tons, the vast majority of the nickel being present in the lithosphere and other abiotic materials ([Table 6.4](#)).

Table 6.4 Inventory of Nickel in Various Global Environmental Compartments

Compartment	Mean Concentration (mg/kg)	Nickel in Compartment (metric tons)
Lithosphere, down to 45 km	75	4,300,000,000,000,000
Sedimentary rocks	48	120,000,000,000,000
Soils, to 100 cm	16	5,300,000,000,000
Oil shale deposits	30	1,400,000,000,000
Dissolved oceanic	0.0006	840,000,000
Nickel ore reserves	>2000	160,000,000
Coal deposits	15	150,000,000
Terrestrial litter	15	33,000,000
Terrestrial plants	6	14,000,000
Suspended oceanic particulates	95	6,600,000
Crude oil	10	2,300,000
Terrestrial animals	2.5	50,000
Swamps and marshes	7	42,000
Lakes and rivers, total	0.001	34,000
Consumers/reducers (biological)	3.5	11,000
Atmosphere	0.3	1500
Oceanic plants	2.5	500
Lakes and rivers, plankton	4	230

Modified from Nriagu, J.O. 1980b. Global cycle and properties of nickel. Pages 1–26 in J.O. Nriagu (ed.). *Nickel in the Environment*. John Wiley, NY.

6.5.2 Abiotic Materials

Nickel concentrations are elevated in air, water, soil, sediment, and other abiotic materials in the vicinity of nickel mining, smelting, and refining activities; in coal fly ash; in sewage sludge; and in wastewater outfalls ([Table 6.5](#)). Maximum concentrations of nickel found in abiotic materials were 15,300 ng/L in air under conditions of extreme occupational exposure, 19.2 µg/L in seawater, 30 µg/L in rain, 240 µg/L in sewage liquids, 300 µg/L in drinking water near a nickel refinery, 500 µg/kg in snow, 183,000 µg/L in fresh water near a nickel refinery, 4430 µg/L in groundwater, 27,200 µg/L in waste water from nickel refineries, 1600 mg/kg in coal fly ash, 2000 mg/kg in ultramafic rocks, 24,000 mg/kg in soils near metal refineries, 53,000 mg/kg in sewage sludge, more than 100,000 mg/kg in lake sediments near a nickel refinery, and 500,000 mg/kg in some meteorites ([Table 6.5](#)).

Nickel in the atmosphere is mainly in the form of particulate aerosols (WHO 1991) resulting from human activities (Sevin 1980). Air concentrations of nickel are elevated near urbanized and industrialized sites and near industries that process or use nickel (USPHS 1993; Chau and Kulikovsky-Cordeiro 1995; Pirrone et al. 1996; [Table 6.5](#)). The greatest contributor to atmospheric nickel loadings is combustion of fossil fuels, in which nickel appears mainly as nickel sulfate, nickel oxide, and complex metal oxides containing nickel (USEPA 1986). Nickel concentrations in the atmosphere of the United States are highest in winter and lowest in summer, demonstrating the significance of oil and coal combustion sources (USPHS 1993; Pirrone et al. 1996). Nickel in the atmosphere is removed through rainfall and dry deposition, locating into soils and sediments; atmospheric removal usually occurs in several days. When nickel is attached to small particles, however, removal can take more than a month (USPHS 1993). Cigarette smoke contributes significantly to human intake of nickel by inhalation; heavy smokers can accumulate as much as 15 µg of nickel daily from this source (USEPA 1980).

Most unpolluted Canadian rivers and lakes sampled between 1981 and 1992 contained 0.1 to 10 µg Ni/L; however, natural waters near industrial sites may contain 50 to 2000 µg Ni/L (Chau and Kulikovsky-Cordeiro 1995). Nickel concentrations in snow from Montreal, Canada, are high compared with ambient air ([Table 6.5](#)); nickel burdens in Montreal snow are positively correlated with those of vanadium, strongly suggesting that combustion of fuel oil is a major source of nickel (USPHS 1993). In drinking water, nickel levels may be elevated due to the corrosion of nickel-containing alloys used in the water distribution system and from nickel-plated faucets (USPHS 1993). Nickel concentrations in uncontaminated surface waters are usually lower with increasing salinity or phosphorus loadings (USPHS 1993). Nickel tends to accumulate in the oceans and leaves the ocean as sea spray aerosols, which release nickel-containing particles into the atmosphere (USEPA 1986).

Sediment nickel concentrations are grossly elevated near the nickel–copper smelter at Sudbury, Ontario, and downstream from steel manufacturing plants. Sediments from nickel-contaminated sites have between 20 and 5000 mg Ni/kg DW; these values are at least 100 times lower at comparable uncontaminated sites (Chau and Kulikovsky-Cordeiro 1995). A decrease in the pH of water caused by acid rain may release some of the nickel in sediments to the water column (NRCC 1981). Transfer of nickel from water column to sediments is greatest when sediment particle size is comparatively small and sediments contain high concentrations of clays or organics (Bubb and Lester 1996).

In soils, nickel exists in several forms, including inorganic crystalline minerals or precipitates, as free ion or chelated metal complexes in soil solution, and in various formulations with inorganic cationic surfaces (USEPA 1986). Soil nickel is preferentially adsorbed onto iron and manganese oxides (USPHS 1993; Chau and Kulikovsky-Cordeiro 1995); however, near Sudbury, Ontario, soil nickel is mostly associated with inorganic sulfides (Adamo et al. 1996). The average residence time of nickel in soils is estimated at 3500 years, as judged by nickel concentrations in soils and estimates of the loss of nickel from continents (Nriagu 1980b). Natural levels of soil nickel are augmented by contamination from anthropogenic activities including atmospheric fallout near nickel-emitting industries, automobile traffic, and treatment of agricultural lands with nickel-containing phosphate

fertilizers or municipal sewage sludge (USEPA 1980; Munch 1993). Soils with less than 3 mg Ni/kg DW are usually too acidic to support normal plant growth (NAS 1975). Nickel availability to plants grown in sludge-amended soils is correlated with soil-solution nickel (USPHS 1993). Sewage-derived fertilizers from industrial areas may contain 1000 mg Ni/kg DW or more (NRCC 1981). In sewage sludge, a large percentage of the nickel exists in a form that is easily released from the solid matrix (USPHS 1993). Water solubility of nickel in soils and its bioavailability to plants are affected by soil pH, with decreases in pH below 6.5 generally mobilizing nickel (USPHS 1993; Chau and Kulikovsky-Cordeiro 1995).

6.5.3 Terrestrial Plants and Invertebrates

Nickel is found in all terrestrial plants, usually at concentrations of less than 10 mg/kg DW (NRCC 1981; Kasprzak 1987). The majority of terrestrial plants are nickel-intolerant species and are restricted to soils of relatively low nickel content; some plants without specific nickel tolerance can accumulate anomalous levels of nickel, but at a cost of reduced metabolism (Rencz and Shilts 1980). Plants grown in nickel-rich soils can accumulate high concentrations of nickel (Sigel and Sigel 1988). Crops grown in soils amended with sewage sludge may contain as much as 1150 mg Ni/kg DW (USEPA 1986). Vegetation near point sources of nickel, such as nickel refineries, have elevated nickel concentrations that decline with increasing distance from the source (WHO 1991; Table 6.6). Fruits and vegetables grown near nickel smelters contain 3 to 10 times more nickel in edible portions than those grown in uncontaminated areas (NRCC 1981). Trees, ferns, and grasses near nickel smelters had elevated concentrations of nickel: as much as 174 mg/kg DW in trees and ferns and 902 mg/kg DW in wavy hairgrass (*Deschampsia flexuosa*; Table 6.6). Nickel concentrations in lichens and other vegetation were elevated when grown on nickeliferous rocks, serpentine soils, near nickel smelters (Jenkins 1980b), near urban and industrial centers (Richardson et al. 1980), and near roadsides treated with superphosphate fertilizers (NAS 1975).

Terrestrial vegetation within 3.5 km of one of the Sudbury, Ontario, smelters had as much as 140 mg Ni/kg DW; concentrations decreased with distance from the smelter, reaching a mean concentration of about 12 mg Ni/kg DW at a distance of 60 km (Chau and Kulikovsky-Cordeiro 1995). Some vegetation near a Sudbury smelter — including lawn grasses, timothy (*Phleum pratense*), and oats (*Avena sativa*) — showed signs of nickel toxicosis. Concentrations in these species ranged between 80 and 150 mg Ni/kg DW. Vegetables — beets (*Beta vulgaris*), radishes (*Raphanus* spp.), cabbages (*Brassica oleracea capitata*), and celery (*Apium graveolans*) — grown in soils about 1 km from a nickel refinery had 40 to 290 mg Ni/kg DW in their top portions. All of these vegetables had reduced yield, stunted growth, and chlorosis and necrosis, which is attributed to the high levels of nickel in local soils (Chau and Kulikovsky-Cordeiro 1995).

Mosses and lichens accumulate nickel readily and at least nine species are used to monitor environmental gradients of nickel (Jenkins 1980a). Maximum concentrations of nickel found in whole lichens and mosses from nickel-contaminated areas range between 420 and 900 mg/kg DW vs. 12 mg/kg DW from reference sites (Jenkins 1980a). Nickel concentrations in herbarium mosses worldwide have increased dramatically during this century. In one case, nickel concentrations in *Brachythecium salebrosum* from Montreal, Canada, rose from 6 mg/kg DW in 1905 to 105 mg/kg DW in 1971 (Richardson et al. 1980).

Nickel-tolerant or accumulator species of plants are likely to be found only on nickel-rich soils (Rencz and Shilts 1980). Hyperaccumulator species usually grow on relatively infertile nickel-rich serpentine soils and contain more than 10,000 mg Ni/kg DW (Jenkins 1980b; NRCC 1981; WHO 1991; Table 6.6). Leaves from some genera of nickel hyperaccumulator plants, including *Alyssum*, *Homalium*, and *Hybanthus*, growing on soils derived from volcanic rocks, which are rich in nickel, accumulate nickel to concentrations of 120,000 mg kg DW (Kasprzak 1987; Table 6.6). Nickel is bound as a citrate complex in hyperaccumulator plants from New Caledonia; however, nickel accumulator plants from other locations do not contain unusually high levels of citrate, and nickel is not present as a citrate complex but as a carboxylic acid complex (Lee et al. 1978).

Terrestrial plants take up nickel from soil primarily via the roots (NRCC 1981; WHO 1991). The nickel uptake rate from soil is dependent on soil type, pH, humidity, organic content, and concentration of extractable nickel (NAS 1975; WHO 1991). For example, at soil pH less than 6.5 nickel uptake is enhanced due to breakdown of iron and manganese oxides that form stable complexes with nickel (Rencz and Shilts 1980). The exact chemical forms of nickel that are most readily accumulated from soil and water are unknown; however, there is growing evidence that complexes of nickel with organic acids are the most favored (Kasprzak 1987). In addition to their uptake from the soils, plants consumed by humans may receive several milligrams of nickel per

kilogram through leaching of nickel-containing alloys in food-processing equipment, milling of flour, and catalytic hydrogenation of fats and oils by use of nickel catalysts (USEPA 1986). Nickel reportedly disrupts nitrogen cycling, and this could have serious ecological consequences for forests near nickel smelters (WHO 1991), although adverse effects of nitrogen disruption by nickel need to be verified.

Data are limited on nickel concentrations in terrestrial invertebrates. Earthworms from uncontaminated soils may contain as much as 38 mg Ni/kg DW, and workers of certain termite species may normally contain as much as 5000 mg Ni/kg DW (Table 6.6). Larvae of the gypsy moth (*Lymantria dispar*) near a nickel smelter had 20.4 mg Ni/kg DW; concentrations in pupae and adults were lower because these stages have higher nickel elimination rates than larvae (Bagatto et al. 1996).

6.5.4 Aquatic Organisms

Nickel concentrations are comparatively elevated in aquatic plants and animals in the vicinity of nickel smelters, nickel–cadmium battery plants, electroplating plants, sewage outfalls, coal ash disposal basins, and heavily populated areas (Kniep et al. 1974; Eisler et al. 1978a; Montgomery et al. 1978; Jenkins 1980a; Eisler 1981; Kasprzak 1987; Chau and Kulikovsky-Cordeiro 1995; Table 6.6). For example, at Sudbury, Ontario, mean nickel concentrations, in mg/kg DW, were 22 for larvae of aquatic insects, 25 for zooplankton, and 290 for aquatic weeds; maximum concentrations reported were 921 mg/kg DW in gut of crayfish (*Cambarus bartoni*) and 52 mg/kg fresh weight (FW) in various fish tissues (Chau and Kulikovsky-Cordeiro 1995; Table 6.6). For all aquatic species collected, nickel concentrations were highly variable between and within species; this variability is attributable, in part, to differential tissue uptake and retention of nickel, depth of collection, age of organism, and metal-tolerant strains (Bryan et al. 1977; Bryan and Hummerstone 1978; Jenkins 1980a; Eisler 1981; Chau and Kulikovsky-Cordeiro 1995; Table 6.6).

The bioaccumulation of nickel under field conditions varies greatly among groups. Bioconcentration factors (BCF, which equals the milligrams of nickel per kilogram fresh weight of the sample divided by the milligrams of nickel per liter in the medium) for aquatic macrophytes range from 6 in pristine areas to 690 near a nickel smelter; for crustaceans these values are 10–39; for molluscs, 2 to 191; and for fishes, 2 to 52 (Sigel and Sigel 1988). Bioconcentration factors of 1700 have been reported for marine plankton, 800 and 40 for soft parts and shell, respectively, of some marine molluscs, and 500 for brown algae, suggesting that some food chain biomagnification may occur (NAS 1975).

Concentrations of nickel in roots of *Spartina* sp. from the vicinity of a discharge from a nickel–cadmium battery plant on the Hudson River, New York, ranged between 30 and 500 mg/kg DW and reflected sediment nickel concentrations in the range of 100 to 7000 mg Ni/kg DW (Kniep et al. 1974). The detritus produced from dead algae and macrophytes is the major food source for fungi and bacteria, and in this way nickel can again enter the food chain (NRCC 1981; Chau and Kulikovsky-Cordeiro 1995). Nickel concentrations in tissues of sharks from British and Atlantic water range between 0.02 and 11.5 mg/kg FW; concentrations were highest in fish-eating, mid-water species such as the blue shark (*Prionace glauca*) andtope shark (*Galeorhinus galeus*) (Vas 1991). Concentrations of nickel in livers of tautogs (*Tautoga onitis*) from New Jersey significantly decreased with increasing body length in both males and females; however, this trend was not observed in bluefish (*Pomatomus saltatrix*) or tilefish (*Lopholatilus chamaeleonticeps*) (Mears and Eisler 1977).

6.5.5 Amphibians

In Maryland, nickel concentrations in tadpoles of northern cricket frogs (*Acrida crepitans*) and gray treefrogs (*Hyla versicolor*) increased with increasing soil nickel concentrations, with maximum nickel concentrations recorded of 7.1 mg/kg DW in gray treefrogs and 10.0 mg/kg DW in northern

cricket frogs (Sparling and Lowe 1996). In study sites 9 to 66 km from Sudbury, Ontario, populations of treefrogs (*Hyla crucifer*) and American toads (*Bufo americanus*) declined. Population abundance of adult treefrogs declined with increasing atmospheric deposition of nickel, and abundance of toad tadpoles declined as nickel concentrations in pond water rose from 3.3 µg Ni/L at more distant sites to 19.5 µg Ni/L at sites near Sudbury (Glooschenko et al. 1992).

6.5.6 Birds

Nickel concentrations in the organs of most avian wildlife species in unpolluted ecosystems range from about 0.1 to 2.0 mg/kg DW and occasionally reach 5.0 mg/kg DW (Eisler 1981; Outridge and Scheuhammer 1993). In nickel-contaminated areas, nickel concentrations were elevated in feathers, eggs, and internal tissues of birds when compared to conspecifics collected at reference sites (Darolova et al. 1989; Outridge and Scheuhammer 1993; [Table 6.6](#)). In contaminated ecosystems, mean nickel concentrations between 31 and 36 mg/kg DW occur in primary feathers of mallards (*Anas platyrhynchos*) collected 20 to 30 km from a nickel smelter, bone of the common tern (*Sterna hirundo*) from Hamilton Harbor, Ontario, and eggshell of the tree swallow (*Tachycineta bicolor*) from the Hackensack River, New Jersey ([Table 6.6](#)).

Waterfowl feeding in areas subjected to extensive nickel pollution — such as smelters and nickel–cadmium battery plants — are at special risk because waterfowl food plants in those areas contain 500 to 690 mg Ni/kg DW (Eastin and O’Shea 1981). Dietary items of the ruffed grouse (*Bonasa umbellus*) near Sudbury, Ontario, had 32 to 95 mg Ni/kg DW, whereas nickel concentrations in grouse body tissues usually contain less than 10% of the dietary level. Nickel concentrations in aspen (*Populus tremula*) from the crop of ruffed grouse near Sudbury ranged from 62 mg/kg DW in May to 136 mg/kg DW in September (Chau and Kulikovsky-Cordeiro 1995), which shows the role of season in dietary nickel composition.

6.5.7 Mammals

Mammalian wildlife from uncontaminated habitats usually contain less than 0.1 to about 5 mg Ni/kg DW in tissues; in nickel-contaminated areas, these same species have 0.5 to about 10 mg Ni/kg DW in tissues (Outridge and Scheuhammer 1993; Chau and Kulikovsky-Cordeiro 1995), with a maximum of 37 mg/kg DW in kidneys of the common shrew (*Sorex araneus*) ([Table 6.6](#)). Nickel accumulations in wildlife vary greatly between species. For example, tissues of mice have higher concentrations of nickel than rats and other rodents, while beavers and minks have higher nickel concentrations in their livers than birds in similar sites near Sudbury (Chau and Kulikovsky-Cordeiro 1995).

The highest concentrations in wildlife tissues from nickel-contaminated locales are associated with tissues exposed to the external environment, such as fur and skin. Nickel concentrations in internal organs are usually similar, regardless of degree of contamination (Outridge and Scheuhammer 1993; [Table 6.6](#)). However, nickel concentrations in bone, reproductive organs, and kidneys in certain herbivorous species of wildlife and livestock are elevated when compared to other internal tissues, especially in the vicinity of nickel smelters and other nickel point sources (Outridge and Scheuhammer 1993; Kalas et al. 1995). Trophic position in the food chain, sex, and reproductive state do not seem to significantly influence the nickel body burdens of mammals (Outridge and Scheuhammer 1993), but age is an important variable, and nickel generally increases in various organs with increasing age of terrestrial and marine mammals. Fetuses of a variety of wildlife and domestic species contain concentrations of nickel significantly lower than those in their mothers or in juveniles, suggesting that placental transfer of nickel is restricted. Nickel concentrations in aquatic macrophytes and lower plants in the vicinity of nickel smelters may approach or exceed dietary levels known to cause adverse effects in young animals. Sensitive species of wildlife ingesting this vegetation for extended periods could experience nickel-related toxicity or risk

alterations in community structure as nickel-sensitive taxa are eliminated or their abundance is reduced (Outridge and Scheuhammer 1993).

Elevated nickel concentrations in Norwegian wildlife are linked to emissions from Russian nickel smelters (Kalas et al. 1995). In Norway, nickel concentrations were elevated in livers and kidneys of moose (*Alces alces*) and caribou (*Rangifer tarandus*) because of atmospheric transport of wastes from nickel-processing plants of nearby Russian towns (Sivertsen et al. 1995). In Russia between 1974 and 1992, three species of voles (*Clethrionomys glareolus*, *Clethrionomys rutilus*, *Lemmus lemmus*) were eliminated from the immediate vicinity of a copper–nickel smelter that discharged 2700 metric tons of nickel annually to the atmosphere, and these species were scarce at a moderately contaminated area 28 km south of the smelter (Kataev et al. 1994). Declines were associated with a decrease of important food plants: lichens for *C. glareolus* and *C. rutilus*, mosses for *L. lemmus*, and seed plants for other species of *Clethrionomys*. Close to the smelter, direct toxic effects of accumulated nickel and other metals also may have reduced population densities (Kataev et al. 1994). Nickel concentrations are also elevated in rodents, shrews, soil, vegetation, and earthworms in the vicinity of roads with high automobile density (Pankakoski et al. 1993). In ruminant mammals, tissue nickel concentrations were higher in winter (WHO 1991), presumably because of increased combustion of fossil fuels.

Nickel is normally present in human tissues, and under conditions of high exposure, these levels may increase significantly (WHO 1991). Nickel enters the human body through the diet, through inhalation, by absorption through the skin, and in medications (NAS 1975). The diet accounts for about 97% of the total intake, and drinking water about 2.5% (Kasprzak 1987). Foods rich in nickel include tea (7.6 mg/kg DW), cereals (6.5), vegetables (2.6), and fish (1.7 mg/kg DW) (IARC 1976; Table 6.6). The daily dietary intake of nickel by humans in the United States ranges between 0.15 and 0.6 mg, almost all of which is excreted in the feces (NAS 1975; Norseth and Piscator 1979; USEPA 1980; NRCC 1981; Sunderman et al. 1984). Minor amounts are also excreted in sweat, urine, and hair (Kasprzak 1987). Residents of the Sudbury, Ontario, area who consume homegrown garden products ingest an average of 1.85 mg of nickel daily, of which 0.6 mg comes from the drinking water (NRCC 1981). Inhalation intake of nickel for residents of New York City is estimated at 2.4 µg daily; for Chicago, a maximum value of 13.8 µg daily is recorded; and 14.8 µg are inhaled daily by smokers of 40 cigarettes (NAS 1975; WHO 1991). Canadians in urban areas inhale 0.06 to 0.6 µg Ni daily; near nickel smelters, this may increase to 15 µg daily (NRCC 1981). In Connecticut, serum nickel levels in newborns were normal (3 µg/L) and similar to those of their mothers (Norseth and Piscator 1979). Nickel concentrations in human serum, however, are modified by disease and stress. Concentrations are usually elevated after strokes, pregnancy, and extensive burns, and are depressed in cases of cirrhosis, hypoalbuminemia, extremes of heat, and uremia (Mushak 1980; USEPA 1980, 1986).

About 727,000 workers were potentially exposed to nickel metal, nickel alloys, or nickel compounds during the period 1980 to 1983 (USPHS 1993). Worker exposure differs from that of the general population in that the major route of exposure for nickel workers is inhalation and for the general population it is dermal contact (Sevin 1980). Nickel workers with lung cancer had elevated concentrations of 1.97 mg/kg DW in their lungs when compared to the general population (0.03 to 0.15 mg/kg DW; USPHS 1977). Plasma concentrations of nickel quickly reflect current exposure history to nickel (USEPA 1980). Mean nickel concentrations in plasma of humans occupationally exposed to nickel have declined by about 50% since 1976, suggesting decreased exposure due to improved safety (Boysen et al. 1980).

6.5.8 Integrated Studies

Beaver ponds downstream from an abandoned copper–nickel ore roast yard near Sudbury, Ontario, were devoid of fish and had reduced macroinvertebrate taxon richness and diversity when compared to upstream ponds. Nickel water concentrations, in µg Ni/L, were 57 in upstream ponds,

82 in downstream ponds, and 1800 at the station directly on the roast pit (Rutherford and Mellow 1994). Beavers (*Castor canadensis*) near nickel smelters had elevated nickel concentrations in livers and kidneys when compared to conspecifics from a reference site; accumulations were attributed to food chain contamination (Hillis and Parker 1993).

Hutchinson et al. (1975) found nickel contamination in the Sudbury, Ontario, region to be the result of aerial transport and terrestrial drainage from mining and smelting activities. Nickel concentrations in soils were elevated as far as 52 km from the source. Erosion of soils following the death of vegetation was widespread and affected an area of more than 820 km². Soils increased in acidity, increasing the solubility of nickel. In aquatic ecosystems, nickel was accumulated from the water column by periphyton, rooted aquatic macrophytes, zooplankton, crayfish, clams, and fishes. However, there was no evidence of food chain biomagnification of nickel in the Sudbury ecosystem (Hutchinson et al. 1975). For example, in the nickel-contaminated Wanapitei River, bioconcentration factors during the summer of 1974 were highest for whole periphyton (19,667), followed by whole pondweeds (11,429), sediments (5333), whole crayfish (929), whole zooplankton (643), muscle of carnivorous fishes (329), soft tissues of clams (262), and muscle of omnivorous fishes (226) (Hutchinson et al. 1975). Higher BCF values are recorded for acid- and metal-tolerant flora (Outridge and Scheuhammer 1993).

There is little convincing evidence for the biomagnification of nickel in the food chain. Most authorities agree that nickel concentrations do not increase with ascending trophic levels of food chains and that predatory animals do not have higher concentrations (Jenkins 1980a; WHO 1991; Outridge and Scheuhammer 1993; Chau and Kulikovsky-Cordeiro 1995). The potential for biomagnification exists because algae and macrophytes have comparatively elevated concentrations of nickel; however, animals seem to be able to regulate the nickel content of their tissues by controlled uptake and increased excretion (Jenkins 1980a; Outridge and Scheuhammer 1993).

Table 6.6 Nickel Concentrations (milligrams of nickel per kilogram fresh weight [FW] or dry weight [DW]) in Field Collections of Representative Plants and Animals

Taxonomic Group, Organism, and Other Variables	Concentration (mg/kg) ^a	Reference ^b
TERRESTRIAL PLANTS		
Red maple, <i>Acer rubrum</i> ; leaf; various distances from nickel smelter		
2 km	98 DW	1
20 km	57 DW	1
40 km	14 DW	1
Onion, <i>Allium cepa</i> ; spring vs. fall		
Leaf	9.4 DW vs. 3.8 DW	1
Root	18.4 DW vs. 10.9 DW	1
Celery, <i>Apium graveolans</i> ; spring vs. fall		
Leaf	36 DW vs. 5 DW	1
Root	32 DW vs. 3 DW	1
Paper birch, <i>Betula papyrifera</i> ; leaf; various distances from nickel smelter; June vs. August		
1.0 km	158 DW vs. 148 DW	1
4.6 km	82 DW vs. 111 DW	1
12.0 km	66 DW vs. 64 DW	1
Coffee, <i>Coffea arabica</i> ; green beans	0.1–0.3 FW	1
Sweet fern, <i>Comptonia peregrina</i> ; leaf; various distances from nickel smelter; August		
1.0 km	174 DW	1
6.5 km	46 DW	1
31.0 km	15 DW	1
Lichen, <i>Complum polyatum</i> ; whole; from serpentine soils	420 DW	1

Table 6.6 (continued) Nickel Concentrations (milligrams of nickel per kilogram fresh weight [FW] or dry weight [DW]) in Field Collections of Representative Plants and Animals

Taxonomic Group, Organism, and Other Variables	Concentration (mg/kg) ^a	Reference ^b
Wavy hairgrass, <i>Deschampsia flexuosa</i> ; leaf; various distances from nickel smelter		
1.7 km	902 DW	1
2.1 km	242 DW	1
7.4 km	160 DW	1
20.4 km	43 DW	1
52.7 km	37 DW	1
Tall fescue, <i>Festuca</i> sp.; shoot; Maryland; various distances from highway		
8 m	(3.8–5.0) DW	1
16 m	(2.5–3.8) DW	1
32 m	(1.3–2.8) DW	1
Forest species; Nagoya University, Japan; leaves		
57 species	2–8 DW	2
3 species	10–16 DW	2
Grasses, various species; near roadside vs. >30 m from roadside	3.8 DW vs. 1.3 DW	3
Hypnum moss, <i>Hypnum cupressiforme</i> ; whole; U.K.; downwind of nickel industrial complex		
<3 km	All dead; no residues measured	1
8 km	193 DW	1
25 km	420 DW	1
Lettuce, <i>Lactuca sativa</i> ; spring vs. fall		
Leaf	28 DW vs. 3 DW	1
Root	15 DW vs. 4 DW	1
Lichens		
Industrial sites; 13 species	2–52 DW	4
Near nickel smelters; 3 species	220–846 DW	4
Rural sites		
Mineralized substrates; 19 species	1–115 DW	4
Nonmineralized substrates; 13 species	1–10 DW	4
Urban sites; 2 species	33–183 DW	4
Macrophytes, 4 species; 1.6 km from nickel smelter (soil had 2679 mg Ni/kg DW)	109–902 DW	5
Mosses, 4 species; isolated areas	0.2–5.0 DW	4
Nickel hyperaccumulator plants		
<i>Allysum</i> spp.; various locations		
Flowers	Max. 5400 DW	1
Fruits	Max. 5800 DW	1
Leaves	2590–9330 DW; Max. 20,400 DW	1, 6
Roots	Max. 3100 DW	1
Seeds	Max. 6100 DW	1
Stems	Max. 13,500 DW	1
<i>Geissosoma prainosa</i> ; New Caledonia; leaves	6720 DW	6
<i>Homalium</i> spp.; New Caledonia; 9 species; leaves		
3 species	3730–9580 DW	6
3 species	446–662 DW	6
3 species	15–75 DW	6
<i>Hybanthus</i> spp.; New Caledonia; 2 species; leaves	6820–14,900 DW	6
<i>Pearsonia metallifera</i> ; Rhodesia; leaves	10,600 DW	6
<i>Planchonella oxyedra</i> ; southeast Asia; leaves	1600 (50–19,600) DW	1
<i>Psychotria douarrei</i> ; New Caledonia; leaf	13,400 DW; Max. 47,000 DW	1, 6
<i>Sebertia acuminata</i> ; New Caledonia		
Latex	112,000 FW; 167–257,000 DW	1, 6
Leaves	10,200–11,700 DW	1, 6
Rice, <i>Oryza sativa</i> ; Japan; polished vs. unpolished grain	0.50–0.65 FW vs. 1.8 FW	1

Common Atlantic slippersnail, <i>Crepidula fornicata</i> ; United Kingdom; shell vs. soft parts	1.6 DW vs. 127.0 FW; 850.0 DW	1, 10
Red abalone, <i>Haliotis rufescens</i> ; California		
Digestive gland	(3–11) DW	1, 10
Foot	(0.2–1.6) DW	1, 10
Gills	(69–112) DW	1, 10
Mantle	(19–57) DW	1, 10
Abalone, <i>Haliotis tuberculata</i> ; soft parts; England	13.6–15.9 DW	14
Marine molluscs; 21 species; soft parts	Max. 3.4 FW	10
Northern quahog, <i>Mercenaria mercenaria</i> ; soft parts		
United Kingdom	2.2 FW; (6.5–19.2) DW	1
United States	1.2 (0.1–2.4) FW	1
Common mussel, <i>Mytilus edulis</i> ; soft parts		
France	0.5 FW; 2.4 DW	1
The Netherlands, 1985–90	0.33–0.52 FW	15
Norway	(6–43) DW	1
United Kingdom	0.4 FW; Max. 53.0 FW; 3.7 (5–12) DW	1
United States	(11–14) DW	1
Mud snail, <i>Nassarius</i> sp.; soft parts; Los Angeles, California	36 DW	1
Common limpet, <i>Patella vulgata</i> ; soft parts		
Israel; near sewage discharge vs. control site	12 DW vs. 5–9 DW	1
Norway	(4–11) DW	1
United Kingdom	7.3 (2.5–24.0) DW	1
Pen shell, <i>Pinna nobilis</i> ; contaminated area		
Byssus gland	200 DW	10
Gonads	74 DW	10
Nervous system	18 DW	10
Soft parts	21 DW	10
Stomach plus intestines and hepatopancreas	170 DW	10
Sea scallop, <i>Placopecten magellanicus</i>		
Long Island, New York; 1974–75; soft parts	(<0.5–3.3) FW	13
North Atlantic coast, 42 stations		
Gonads	0.2–2.5 FW	16
Muscle	<0.3–0.7 FW	16
Viscera	0.3–1.6 FW	16
Vicinity ocean disposal sites; soft parts	4.4 DW	17
Clam, <i>Scrobicularia plana</i>		
Contaminated estuary, soft parts	Max. 11.9 DW	18
United Kingdom; digestive gland		
Camel estuary	10.6 DW	10
Gannel estuary	43.1 DW	10
Tamar estuary	(6.6–25.0) DW	10
Arthropods		
Amphipods; whole; Antarctica	2.2 DW	19
Green crab, <i>Carcinus maenas</i> ; all tissues	6.2–12.3 FW	1
Sand shrimp, <i>Crangon allmani</i> ; Scotland; soft parts; reference site vs. waste dump site	15 DW vs. 92 DW	1

Table 6.6 (continued) Nickel Concentrations (milligrams of nickel per kilogram fresh weight [FW] or dry weight [DW]) in Field Collections of Representative Plants and Animals

Taxonomic Group, Organism, and Other Variables	Concentration (mg/kg) ^a	Reference ^b
Seaskaters (oceanic insects), <i>Halobates</i> spp., <i>Rheumobates</i> sp.; whole; from mangrove swamps	6–18 DW	20
American lobster, <i>Homarus americanus</i> ; serum	0.012 (0.008–0.020) FW	3, 21
Marine crustaceans		
Muscle, 10 species	0.2–0.9 FW	10
Whole, various species	6.5–9.8 FW	10
Aesop shrimp, <i>Pandalus montagui</i> ; soft parts; Scotland; reference site vs. waste dump site	25 DW vs. 70 DW	1
Caribbean spiny lobster, <i>Panulirus argus</i> ; soft parts; Puerto Rico		
Anasco Bay	1.3 (1–2) FW; 4.5 (8–9) DW	1
West coast	4.6 (1.4–5.0) FW; 36 (22–60) DW	1
Brown shrimp, <i>Penaeus aztecus</i> ; Texas		
Exoskeleton	6.2 DW; Max. 17.9 DW	1
Muscle	1.4 DW; Max. 1.9 DW	1
Viscera	5.7 DW; Max. 5.8 DW	1
Zooplankton; New York Bight vs. Long Island Sound	1.7–4.6 DW vs. 0.9–4.5 DW	22
Annelids, marine		
Sandworm, <i>Nereis diversicolor</i> ; whole; British Columbia; various locations	2.1–5.2 DW	10
Polychaete worms, 3 species; whole; California	(3.8–18.7) DW	1
Echinoderms		
Starfish, <i>Asterias rubens</i>		
Gonad	2.4 DW	10
Pyloric caeca	4.1 DW	10
Other tissues	0.7–1.5 DW	10
Rock boring sea urchin, <i>Echinometra lucunter</i> ; Puerto Rico; skeleton vs. whole	51 (42–78) DW vs. 37 DW	1
Sea urchin, <i>Tripneustes esculentus</i> ; Puerto Rico		
Ovary	1.4 FW	1
Skeleton	35 (18–54) DW	1
Testes	22 FW	1
Tunicate, <i>Halocynthia roretzi</i> ; whole	0.1 FW	10

FISHES AND ELASMOBRANCHS

Rock bass, <i>Ambloplites rupestris</i> ; near smelter; Sudbury, Ontario, Canada		
Gills	31.7 FW	1
Kidneys	17.3 FW	1
Livers	17.0 FW	1
Muscle	12.5 FW	1
Whitetip shark, <i>Carcharhinus longimanus</i>		
Liver	0.05 FW; 0.1 DW	1
Skin	1.9 FW; 7.3 DW	1
Vertebrae	1.6 FW; 4.9 DW	1
White sucker, <i>Catostomus commersoni</i> ; muscle; near smelter vs. reference site	13.2 FW vs. 0.1 FW	1
Blackfin icefish, <i>Chaenocephalus aceratus</i> ; Antarctica; muscle vs. liver	0.2 DW vs. 0.3 (0.2–0.5) DW	19
Lake whitefish, <i>Coregonus clupeaformis</i> ; muscle; northern Quebec; 1989–90	<0.01 FW	23
Lumpfish, <i>Cyclopterus lumpus</i> ; United Kingdom; all tissues	3.2–5.2 FW	1

Table 6.6 (continued) Nickel Concentrations (milligrams of nickel per kilogram fresh weight [FW] or dry weight [DW]) in Field Collections of Representative Plants and Animals

Taxonomic Group, Organism, and Other Variables	Concentration (mg/kg) ^a	Reference ^b
Northern pike, <i>Esox lucius</i> ; muscle Canada		
Ontario; near smelter	13.3 FW	1
Northern Quebec, 1989–91	<0.05–0.05 FW	23
Illinois vs. New York	0.15 (0.08–0.19) FW vs. (0.2–3.8) FW	1
Muskellunge, <i>Esox masquinongy</i> ; muscle; New York	0.2–1.3 FW	1
Chain pickerel, <i>Esox niger</i> ; muscle; New York	0.1–0.25 FW	1
Pickerel, <i>Esox</i> sp.; near smelter; Sudbury, Ontario		
Gills	16.0 FW	1
Kidneys	51.6 FW	1
Livers	14.4 FW	1
Muscle	13.8 FW	1
Skipjack tuna, <i>Euthynnus pelamis</i> ; muscle Peru	2.0 FW; 5.0 DW	1
Puerto Rico	0.5 FW; 2.2 DW	1
Fishes, 10 species; muscle; Bay of Bengal, India	0.7–6.1 DW	24
Atlantic cod, <i>Gadus morhua</i> ; all tissues	1.6–4.6 FW	1
Brown bullhead, <i>Ameiurus nebulosus</i> ; near smelter; Canada		
Gills	11.1 FW	1
Kidneys	11.8 FW	1
Livers	10.7 FW	1
Muscle	9.5 FW	1
Yellowtail flounder, <i>Pleuronectes ferruginea</i> ; New York Bight; liver vs. muscle	0.2–1.1 FW vs. <0.2–0.4 FW	1
Marine fishes		
Liver; 5 species; New York Bight; 1971–73	<0.2–1.7 FW	25
Most species; all tissues	Usually <0.3 FW; rarely >3.0 FW in uncontaminated areas; Max. 16.0 DW	10
Muscle		
New Zealand, 9 species	0.02–0.07 FW	1
United Kingdom, 8 species	2.1–3.5 DW	1
Atlantic croaker, <i>Micropogonias undulatus</i> ; Texas; muscle vs. skin	2.7 DW vs. 3.8 DW	1
Smallmouth bass, <i>Micropterus dolomieu</i> ; muscle; New York vs. Illinois	(0.16–1.2) FW vs. 0.13 (0.08–0.19) FW	1
Largemouth bass, <i>Micropterus salmoides</i> ; muscle; New York vs. Illinois	(0.18–1.9) FW vs. 0.11 (0.05–0.23) FW	1
Dover sole, <i>Microstomus pacificus</i> ; California; muscle vs. liver	0.2 (0.1–0.3) FW vs. 1.4–2.6 FW	1
Hump rock cod, <i>Notothenia gibberifrons</i> ; muscle; Antarctica	0.22 DW	19
Rainbow trout, <i>Oncorhynchus mykiss</i>		
Kidney, liver	Usually <1.5 FW	5
Muscle	Usually <0.5 FW	5
Kelp bass, <i>Paralabrax clathratus</i> ; California		
Gonad	1.5–2.2 DW	1
Liver	3.9–7.6 DW	1
Muscle	5.0–6.4 DW	1
Skin	9.0–10.2 DW	1
Winter flounder, <i>Pleuronectes americanus</i>		
New York Bight; muscle vs. skin	<0.3–0.5 FW vs. <0.3–1.0 FW	1
Texas; muscle vs. skin	3.3 (0.6–7.4) DW vs. 4.4 (2.9–7.4) DW	1

Table 6.6 (continued) Nickel Concentrations (milligrams of nickel per kilogram fresh weight [FW] or dry weight [DW]) in Field Collections of Representative Plants and Animals

Taxonomic Group, Organism, and Other Variables	Concentration (mg/kg) ^a	Reference ^b
Lake trout, <i>Salvelinus namaycush</i> ; whole less head and viscera; New York		
Ages 1–4 years	Max. 0.009 FW	1
Ages 5–8 years	Max. 0.022 FW	1
Ages 9–12 years	Max. 0.022 FW	1
Sharks, 10 species; British and Atlantic waters; 1984–88; inshore species vs. offshore species		
Gills	0.3–1.8 FW vs. 1.7–1.9 FW	26
Gonads	<0.02–8.3 FW vs. 1.7 FW	26
Heart	No data vs. 2.8 FW	26
Jaws	5.7 FW vs. 0.3 FW	26
Kidneys	0.07–1.2 FW vs. 1.6 FW	26
Liver	<0.02–0.8 FW vs. 1.9–3.2 FW	26
Muscle	<0.02–1.8 FW vs. 1.4–2.6 FW	26
Pancreas	0.9 FW vs. No data	26
Skin	<0.02–3.4 FW vs. 1.0–2.0 FW	26
Spleen	<0.02–0.8 FW vs. 1.3 FW	26
Vertebrae	0.5–2.4 FW vs. 0.2–10.8 FW	26
South Carolina; gamefish; 1990–93; whole		
Spotted seatrout, <i>Cynoscion nebulosus</i>	Max. 12.6 FW	27
Southern flounder, <i>Paralichthys lethostigma</i>	Max. 8.2 FW	27
Red drum, <i>Sciaenops ocellatus</i>	Max. 2.9 FW	27
Scup, <i>Stenotomus chrysops</i> ; Texas		
Muscle	1.0 (0.5–2.0) DW	1
Skin	4.9 (2.8–7.4) DW	1
Viscera	3.5 DW	1
AMPHIBIANS		
Maryland; 1991; tadpoles		
Northern cricket frog, <i>Acris crepitans</i> ; whole	2.4–10.0 DW	28
Gray treefrog, <i>Hyla versicolor</i> ; whole	2.0–7.1 DW	28
Green frog, <i>Rana clamitans</i> ; body vs. gut coil	4.7 DW vs. 16.4 DW	28
BIRDS		
Wood duck, <i>Aix sponsa</i> ; ducklings; liver; Ontario, Canada; polluted area	0.2 FW	29
Mallard, <i>Anas platyrhynchos</i>		
Canada; nickel-contaminated areas vs. reference site		
Liver	0.1–1.4 FW vs. 0.2 FW	29
Muscle (breast)	0.1–0.8 FW vs. 0.6 FW	29
New Jersey; Raritan Bay; contaminated environment; liver vs. salt gland	0.1–2.5 FW vs. 9.7 FW	30, 31
Primary flight feathers; 1975; various distances from nickel smelter		
20–30 km	2.0–12.5 DW; Max. 36.7 DW	32
50–60 km	0.2–3.8 DW	32
85 km	0.2–1.5 DW	32
95–140 km	0.0–4.3 DW	32
Reference site	0.0–0.4 DW	32
Black duck, <i>Anas rubripes</i>		
Canada; ducklings; nickel-contaminated vs. reference site		
Kidney	0.3 FW vs. 0.3 FW	29
Liver	0.6 FW vs. 0.4 FW	29
Canada; primary feathers; contaminated vs. noncontaminated areas	2.5–3.7 DW vs. 0.2–1.5 DW	32
Raritan Bay, New Jersey; liver vs. salt gland	0.2–2.7 FW vs. 15.2 FW	30, 31

Table 6.6 (continued) Nickel Concentrations (milligrams of nickel per kilogram fresh weight [FW] or dry weight [DW]) in Field Collections of Representative Plants and Animals

Taxonomic Group, Organism, and Other Variables	Concentration (mg/kg) ^a	Reference ^b
Gadwall, <i>Anas strepera</i> ; Canada; muscle; contaminated area	0.3 FW	29
Antarctica; February-March 1989		
Gentoo penguin, <i>Pygoscelis papua</i> ; muscle vs. liver	<0.03 DW vs. 0.09 DW	19
Adelie penguin, <i>Pygoscelis adeliae</i> ; muscle vs. liver	<0.03 DW vs. 0.06 DW	19
Chinstrap penguin, <i>Pygoscelis antarctica</i>		
Feces	3.5 (3.2–3.7) DW	19
Liver	0.07 DW	19
Muscle	<0.03 DW	19
Blue eyed cormorant, <i>Phalacrocorax atriceps</i> ; muscle	0.29 DW	19
South giant petrel, <i>Macronectes giganteus</i> ; muscle	0.06 DW	19
Redhead, <i>Aythya americana</i> ; Texas and Louisiana; liver; winter 1987–88	<4.0 DW	33
Ring-necked duck, <i>Aythya collaris</i> ; ducklings; contaminated vs. reference location		
Kidney	0.3 FW vs. 0.1 FW	29
Liver	0.5 FW vs. 0.2 FW	29
Greater scaup, <i>Aythya marila</i> ; contaminated areas		
Ontario; muscle	0.2 FW	29
New Jersey; liver vs. salt gland	0.3–3.6 FW vs. 2.7 FW	30, 31
Canvasback, <i>Aythya valisineria</i> ; Louisiana; winter 1987–88; liver	Usually <1.0 DW; Max. 2.0 DW	34
Ruffed grouse, <i>Bonasa umbellus</i>		
Canada; nickel-contaminated vs. reference areas		
May		
Feathers, primaries	7.3 DW vs. 2.9 DW	35
Dung	19.4 DW vs. <0.5 DW	35

6.6 NICKEL DEFICIENCY EFFECTS

6.6.1 General

Nickel is reportedly an essential micronutrient for maintaining health in certain species of plants, invertebrates, birds, and mammals, including humans (NAS 1975; Spears et al. 1979; Sunderman et al. 1984; Norseth 1986; USEPA 1986; Sigel and Sigel 1988; Hausinger 1993; USPHS 1993; Stangl and Kirchgessner 1996, 1997). However, it has not yet been proven that nickel is essential for humans (Norseth and Piscator 1979; USPHS 1993), and the evidence for marine tunicates and land snails is inconclusive (Hausinger 1993). To prevent nickel deficiency in rats and chickens, diets should contain at least 50 µg Ni/kg ration; cows and goats require more than 100 µg Ni/kg ration, perhaps reflecting the increased use of nickel by rumen bacteria (USPHS 1993). In humans, nickel deficiency is not a public health concern because daily oral intake normally exceeds 170 µg of nickel (USPHS 1993).

Nickel is considered essential to animals because it is present in the fetus or newborn, is homeostatically regulated, the metabolic pool of nickel is specifically influenced by hormonal substances or pathologic processes, certain metalloproteins contain nickel, and because nickel deficiency has been induced experimentally in certain species of birds and animals (NAS 1975; USPHS 1977; Kirchgessner and Schnegg 1980). In general, the nickel deficiency syndrome can be cured or prevented by trace amounts of nickel (NAS 1975). However, nickel administration may not be successful in reversing all abnormalities produced by nickel deprivation (USPHS 1977).

Nickel deficiency effects from dietary deprivation of nickel is now documented in at least 17 animal species, including chickens, cows, goats, pigs, rats, and sheep (USPHS 1977, 1993; Norseth and Piscator 1979; USEPA 1985; Norseth 1986; WHO 1991). According to Kirchgessner and Schnegg (1980), nickel deficiency can be induced only by very low nickel concentrations in the diet — not by its bioavailability. Signs of nickel deficiency include delayed gestation periods and fewer offspring; decreased growth and sometimes dwarfism; anemia; skin eruptions; brittle hair; reduced oxygen consumption; decreased levels of serum proteins; enhanced urinary nitrogen excretion; reduced tissue iron and zinc concentrations; reduced hemoglobin and hematocrit values; abnormal liver morphology and lipid metabolism; reduced liver glucose, lipids, glycogen, and triglycerides; and reduced activity of several enzymes, including dehydrogenases, transaminases, and alpha-amylases (USEPA 1980, 1985, 1986; WHO 1991; USPHS 1993; Stangl and Kirchgessner 1996).

6.6.2 Bacteria and Plants

Nickel is essential for the active synthesis of urease in plant cells and of various hydrogenases in bacteria (Thauer et al. 1980; USEPA 1986; WHO 1991; Hausinger 1993). In several species of higher plants, including jack beans (*Canavalia* sp.), soybeans (*Glycine max*), rice (*Oryza sativa*), and tobacco (*Nicotiana tabacum*), nickel is required for effective urea metabolism and urease synthesis (Kasprzak 1987; Sigel and Sigel 1988). Root growth of onions (*Allium* sp.) is stimulated at 60 to 600 µg/Ni²⁺/L culture solution (Donghua and Wushing 1997). Some terrestrial plants, such as *Alyssum* spp., accumulate nickel and require it for growth (Thauer et al. 1980). In bacteria, nickel is required for the growth of *Oscillatoria* sp. and *Alcaligenes* sp., for the synthesis of carbon monoxide dehydrogenase in *Clostridium posterianum*, and as a component of coenzyme F₄₃₀ in *Methanobacterium* spp. (Babich and Stotzky 1982a; Kasprzak 1987). Nickel deficiency in bacteria may adversely affect reproductive processes, such as endospore formation, and cause a decrease in nickel-containing intracellular pigments in strains of *Bacillus cereus* (Thauer et al. 1980); however, both of these observations require verification.

6.6.3 Birds

All studies demonstrating nickel deficiency in birds were conducted on a single species; specifically, chicks of the domestic chicken, *Gallus* sp. The relevance of these results to avian wildlife species is unknown. Chicks grew normally when fed nickel-deficient diets (2 to 15 µg Ni/kg ration) for 3 to 4 weeks, but these chicks had liver histopathology, decreased concentrations of yellow lipochrome pigments in liver, low hematocrit, skin dermatitis, leg thickening, altered lengths of leg bones, and decreased plasma cholesterol (Nielsen et al. 1975a; Hausinger 1993). Adverse effects of nickel-deficient diets (<20 µg Ni/kg ration) were reversed by the addition of nickel to the diet (Ling and Leach 1979). Chicks fed diets containing 25 to 2500 µg Ni/kg ration for 3 to 4 weeks grew normally and all organs appeared normal (Nielsen et al. 1975a). Nickel-deficient chicks (40 to 80 µg Ni/kg ration), when compared to controls (3 to 5 mg Ni/kg ration), had swollen hock joints, reduced length-to-width ratios of tibias, scaly dermatitis of the legs, orange-yellow discoloration of the legs, fat-depleted livers, altered liver metabolism, and elevated concentrations of nickel in liver, spleen, and aorta (Sunderman et al. 1972; NAS 1975; USEPA 1980; USEPA 1985). Chicks fed nickel-deficient diets of 44 µg Ni/kg ration for 30 days had markedly lower nickel concentrations in serum and livers than did controls fed diets containing 3.4 mg Ni/kg ration; nickel deficient chicks had 1.6 µg Ni/L in serum vs. 4.2 in controls and 64 µg Ni/kg DW liver vs. 82 in controls (Sunderman et al. 1972). Livers of nickel-deficient chicks had an altered gross appearance, reduced oxidative ability, and decreased lipid phosphorus concentrations (Nielsen et al. 1975a). Nickel deficiency in chicks may be associated with thyroid hormone imbalance (Nielsen et al. 1975a), but this needs verification.

6.6.4 Mammals

In humans, there is no evidence of a nickel deficiency syndrome (USEPA 1985) or proof that nickel is essential (Norseth and Piscator 1979; Norseth 1986).

Cows (*Bos* sp.) fed nickel-deficient diets containing less than 100 µg Ni/kg ration had reduced growth and survival (Hausinger 1993). Nickel-deficiency in cows was exacerbated when diets were also low in protein, but effects were lessened when diets were supplemented with 5 mg Ni/kg ration (Spears et al. 1979). Lambs from domestic sheep (*Ovis aries*) fed a low nickel diet (30 µg Ni/kg ration) for 97 days had lower growth, higher mortality, and altered blood and tissue chemistry when compared to controls fed a diet containing 5 mg Ni/kg ration (Spears et al. 1979). Lambs given diets containing 65 µg Ni/kg DW ration had disrupted metabolism (USEPA 1980).

Adults and offspring of breeding goats (*Capra hircus*) and swine (*Sus* sp.) fed nickel-deficient diets (<100 µg Ni/kg ration) or control diets (10 mg Ni/kg ration) for 6 years had normal conception and abortion rates. However, nickel-deficient goats and pigs had delayed pregnancies, reduced litter sizes, lower birth rates, lower weight gains during suckling, and significant increases in mortality during the suckling period; mortality was 41% higher than controls in kids and 51% higher than controls in piglets (Anke et al. 1978). Nickel-deficient adult goats had lower nickel concentrations in kidneys, liver, and other tissues than did controls, specifically, 0.2 to 0.6 mg Ni/kg DW tissue vs. 0.6 to 1.2 mg Ni/kg DW in controls (Anke et al. 1980a). Kids of nickel-deficient ewes (100 µg Ni/kg DW ration for 6 years vs. control diet of 300 µg Ni/kg ration) had inhibited growth starting at age 8 weeks and reduced survival (Anke et al. 1980b). During lactation, hemoglobin concentrations and hematocrits of nickel-deficient goats were significantly lower than control values (Anke et al. 1980b). Nickel-deficient pigs had rough coats, decreased growth, and impaired reproduction (USEPA 1980; Hausinger 1993).

Signs of nickel deficiency in the laboratory white rat (*Rattus* sp.) include retarded growth, anemia, a reduction in hematocrit and hemoglobin values, decreased enzyme activities (malate dehydrogenase, glucose-6-phosphate dehydrogenase, alpha amylase), a reduction in liver total lipids

and phospholipids, and altered tissue concentrations of fatty acids, iron, copper, and zinc (Nielsen et al. 1975b; Norseth and Piscator 1979; Nielsen 1980b; Norseth 1986; Hausinger 1993; Stangl and Kirchgessner 1996, 1997). Nickel concentrations in fur, kidneys, and muscle of rats fed nickel-deficient diets (15 µg Ni/kg DW ration) were about 66% lower than those of controls given 20 mg Ni/kg ration (Kirchgessner and Schnegg 1980). Signs of nickel deficiency in rats were usually reversed by supplementing the diet with nickel (Ling and Leach 1979) at more than 50 µg Ni/kg ration (USEPA 1985). Rats fed nickel-deficient diets (<5 µg Ni/kg ration) for three generations produced offspring that were anemic and grew poorly in the first two generations and that had impaired reproduction in all generations (USEPA 1980; Sevin 1980). In another three-generation study, rats fed nickel-deficient diets containing 2 to 15 µg Ni/kg ration had increased perinatal mortality, unthrifty appearance of young rats, decreased physical activity, decreased liver cholesterol, and liver histopathology compared to controls fed diets containing 3 mg Ni/kg ration (Nielsen et al. 1975b).

6.7 LETHAL AND SUBLETHAL EFFECTS

6.7.1 General

Nickel toxicity reduces photosynthesis, growth, and nitrogenase activity of algae; fermentative activity of a mixed rumen microbiota; growth rate of marine bacteria; metabolism of soil bacteria; and mycelial growth, spore germination, and sporulation of fungi (Babich and Stotzky 1982a). Adverse effects of excess nickel have also been observed with yeasts, higher plants, protozoans, molluscs, crustaceans, insects, annelids, echinoderms, fishes, amphibians, birds, and mammals (USEPA 1975). As discussed later, sensitive species of aquatic organisms are adversely affected at nominal concentrations of 11 to 113 µg Ni²⁺/L.

In birds, mortality occurred in young individuals of sensitive species when rations contained more than 500 mg Ni/kg (Outridge and Scheuhammer 1993). Nickel accumulated in avian tissues at dietary loadings as low as 0.7 to 12.5 mg Ni/kg ration (Cain and Pafford 1981; Eastin and O’Shea 1981; Stoewsand et al. 1984); however, nickel intoxication in some species tested was not always reflected by elevated tissue nickel concentrations (Outridge and Scheuhammer 1993).

In mammals, the toxicity of nickel is a function of the chemical form of nickel, dose, and route of exposure. Exposure to nickel by inhalation, injection, or cutaneous contact is more significant than oral exposure. Toxic effects of nickel to humans and laboratory mammals are documented for respiratory, cardiovascular, gastrointestinal, hematological, musculoskeletal, hepatic, renal, dermal, ocular, immunological, developmental, neurological, and reproductive systems (NAS 1975; Nielsen 1977; USEPA 1980, 1986; WHO 1991; USPHS 1993).

6.7.2 Terrestrial Plants and Invertebrates

In general, the effects of long-term, low-level exposure to nickel are shown in growth inhibition with no other visible signs (WHO 1991). However, many species of plants growing on soils contaminated with excess nickel show stunted and discolored roots and tops, wilting, chlorosis, necrosis, twisted stalks, thickening of leaf tissues, and failure of leaves to fold to form compact heads (NAS 1975; Frank et al. 1982; WHO 1991; Barman and Bhargava 1997; Donghua and Wusheng 1997). In solution culture, 1 mg of soluble nickel/L is toxic to sensitive plants (NRCC 1981; Outridge and Scheuhammer 1993; Donghua and Wusheng 1997). Accumulations of 50 mg Ni/kg DW plant and higher are toxic to most plants (NAS 1975; NRCC 1981; WHO 1991). Depending on soil conditions and chemical form, nickel in soil is toxic when concentrations exceed 500 mg Ni/kg DW soil with more than 25 mg Ni/L extractable in a 2.5% acetic acid solution

(NRCC 1981). Accumulation and toxic effects occur in vegetables grown on soils treated with sewage sludge and in vegetation close to nickel-emitting sources (WHO 1991). Nickel was shown experimentally to decrease growth of soybeans (*Glycine max*) when administered as particulate nickel through the atmosphere or in the rooting medium (Ormrod et al. 1986). Crop plants are the most sensitive group of terrestrial vegetation tested against nickel. Adverse effects on chlorophyll metabolism and growth occur at soil water concentrations as low as 1 mg Ni/L (Outridge and Scheuhammer 1993). Radishes, beets, cabbages, celery, and lettuce planted in organic soils contaminated by aerial fallout from a nearby nickel smelter and containing between 1570 and 6550 mg Ni/kg DW soil have decreasing yields with increasing soil nickel concentrations (Frank et al. 1982). No radishes or cabbages were suitable for marketing. Celery, lettuce, and beets were reduced from a normal yield on soil with 1300 mg Ni/kg to zero on soils with 4800 mg/kg. Dried cabbage heads and celery tops had as much as 400 mg Ni/kg (Frank et al. 1982). Decreased yields of alfalfa (*Medicago sativa*) occur when plant nickel content exceeds 44 mg/kg DW (NAS 1975). Decreased yield of oats (*Avena sativa*) was associated with nickel concentrations more than 60 mg/kg DW grain, more than 28 mg/kg DW oat straw, or more than 500 mg Ni/kg DW soil (NAS 1975). Signs of nickel toxicity in oats decrease in severity with increasing magnesium concentrations in culture solution during exposure for 35 days (Proctor and McGowan 1976).

Temperature, pH, chlorophyll, and various metals all modify the toxicity of nickel to fungi (Babich and Stotzky 1982b). A reduction in the toxicity of nickel to the mycelial growth rates of five species of filamentous fungi occurs when pH increases from acidic to alkaline (*Achyla* sp., *Saprolegnia* sp.); at elevated concentrations of magnesium, zinc, or lead (*Achyla* sp.); at chlorophyll or humic acid contents equivalent to 1% (*Saprolegnia* sp., *Cunninghamella blakesleean*a, *Aspergillus clavatus*); and at increased temperatures of 33°C vs. 23°C (*Aspergillus flavus*; Babich and Stotzky 1982b). Growth of sensitive species of filamentous fungi is inhibited at 10 mg Ni/L and abnormal mycelia occur at 50 mg/L (Babich and Stotzky 1982a). Histidine may govern nickel accumulation in the approximately 400 known species of nickel-hyperaccumulating plants. Nickel hyperaccumulator plants, including 48 of 170 species of *Alyssum* spp., contain as much as 3% of the dry leaf biomass as nickel (Kramer et al. 1996). Exposing hyperaccumulator species of *Alyssum* to nickel elicits a large and proportional increase in the levels of free histidine, which is shown to be coordinated with nickel in vitro. Supplying histidine to a nonaccumulating species greatly increases both nickel tolerance and capacity for nickel transport to the shoot, indicating that enhanced production of the amino acid histidine is responsible for the nickel hyperaccumulation phenotype in *Alyssum* (Kramer et al. 1996).

Data on nickel toxicity to terrestrial invertebrates are scarce. A soil concentration of 757 mg/kg DW soil is lethal to 50% of earthworms (*Eisenia foetida*) in 14 days, and higher concentrations of 1200 to 12,000 mg/kg DW soil for shorter periods produced reduced growth and survival in the same species (WHO 1991). Earthworms are less sensitive to nickel if the medium is rich in microorganisms and organic matter, thus, making the nickel less bioavailable (WHO 1991).

6.7.3 Aquatic Organisms

Signs of nickel poisoning in fishes include surfacing, rapid mouth and opercular movements, and, prior to death, convulsions and loss of equilibrium (Khangarot and Ray 1990). Destruction of the gill lamellae by ionic nickel decreases the ventilation rate and may cause blood hypoxia and death (Ellgaard et al. 1995). Other signs of nickel poisoning in fishes include decreased concentrations of glycogen in muscle and liver with simultaneous increases in levels of lactic acid and glucose in blood (Ghazaly 1992), depressed hydrogen peroxide production in tissues and a reduction in superoxide dismutase (Bowser et al. 1994), and contractions of vascular smooth muscle — signs similar to those associated with hypertension in mammals (Evans et al. 1990). Ionic nickel is lethal to sensitive species of aquatic organisms at 11 to 113 µg/L. Deaths occur among embryos of rainbow

trout at 11 to 90 µg/L, daphnids at 13 µg/L, embryos of channel catfish at more than 38 µg/L, embryos of the narrow-mouthed toad at 50 µg/L, and embryos of largemouth bass at 113 µg/L (Table 6.7). Species intermediately resistant to nickel died at 150 to 410 µg Ni/L, including mysid shrimp at 150 µg/L, freshwater snails at 237 µg/L, clam embryos at 310 µg/L, and embryos of salamanders at 410 µg/L (Table 6.7). Aquatic bacteria and yeasts are comparatively tolerant to nickel. Sensitive species of freshwater eubacteria and actinomycetes show reduced growth at 5 mg Ni/L; for marine eubacteria, growth inhibition begins at 10 to 20 mg/L (Babich and Stotzky 1982a). Sensitive species of yeasts show growth inhibition at 1.0 mg Ni/L (*Torulopsis glabrata*); resistant species of yeasts (*Rhodotorula* sp., *Cryptococcus terrens*) show a reduction in growth at 5 to 20 mg Ni/L (Babich and Stotzky 1982a; WHO 1991).

The biocidal properties of nickel are modified by many variables. For example, nickel is most lethal at pH 8.3 and least lethal to freshwater crustaceans and fishes at pH 6.3 (Schubauer-Berigan et al. 1993); less toxic to algae when copper is reduced or absent (NRCC 1981) and chelating agents, such as EDTA, are present (Lee and Lustigman 1996); most lethal to echinoderm embryos prior to gastrulation (Timourian and Watchmaker 1972); and more toxic to estuarine amphipods and clams under conditions of decreased salinity in the 0.5 to 3.5% range and increased temperature in the 5 to 15°C range (WHO 1991).

Representative nickel-sensitive aquatic species show sublethal effects at 11.7 to 125 µg Ni/L. These effects include altered immunoregulatory mechanisms in tissues of the rainbow trout at 11.7 µg/L (Bowser et al. 1994), inhibited reproduction of daphnids at 30 µg/L, growth inhibition of freshwater and marine algae at 30 to 125 µg/L, reduced growth of rainbow trout at 35 µg/L, accumulation from the medium by mussels at 56 µg/L, and abnormal development of sea urchin embryos at 58 µg/L (NRCC 1981; WHO 1991; Outridge and Scheuhammer 1993; Table 6.7).

Bioconcentration factors (BCF) for nickel vary among organisms under laboratory conditions. For freshwater species, typical BCF values for nickel are about 10 for algae, 61 for fathead minnows, and 100 for cladocerans; for marine mussels and oysters, typical BCF values range between 299 and 414 (USEPA 1980). The alga *Thalassiosira rotula* can accumulate as much as 90 mg Ni/kg DW (Dongmann and Nurnberg 1982). Other species of aquatic plants can extract nickel from water and concentrate it to as much as 10,000 mg/kg DW (NRCC 1981). The alga *Anacystis nidulans* can develop tolerance to nickel and other metals under laboratory conditions (Whitton and Shehata 1982), and this may account for high BCF values in this species. Nickel at 50 µg/L was accumulated from seawater by softshell clams (*Mya arenaria*) more rapidly during summer at water temperatures of 16° to 22°C than during winter at 0° to 10°C. No accumulations occurred at 10 µg Ni/L in winter, but clams accumulated twice as much nickel over controls in summer (Eisler 1977a). Embryos of sea urchins actively accumulate nickel from seawater at all dose levels tested (Timourian and Watchmaker 1972). Bioconcentration factors for rainbow trout after exposure for 6 months to 1.0 mg Ni/L were 0.8 for muscle, 2.9 for liver, and 4.0 for kidneys (Calamari et al. 1982). Fish can accumulate nickel from food and water. Levels up to 13 mg Ni/kg DW occurred in northern pike (*Esox lucius*) and pickerel (*Esox* sp.) from a contaminated river (NRCC 1981). Common carp (*Cyprinus carpio*) and tilapia (*Tilapia nilotica*) exposed for 16 days to 1.0 mg Ni/L had elevated concentrations in livers of 49 to 77 mg Ni/kg DW (Canli and Kargin 1995). Goldfish (*Carassius auratus*) that died during immersion in solutions containing more than 35 mg Ni/L showed elevated concentrations in tissues, but most of the nickel was washed off with water, and it is not clear if accumulation occurred after death (Kariya et al. 1968). Nickel accumulates in fish tissues and causes alterations in gill structure, including hypertrophy of respiratory and mucus cells, separation of the epithelial layer from the pillar cell system, cauterization and sloughing, and necrosis of the epithelium (Nath and Kumar 1989). Although aquatic organisms can accumulate nickel from their surroundings, there is little evidence of significant biomagnification of nickel levels along food chains (NRCC 1981; Sigel and Sigel 1988; WHO 1991).

Table 6.7 Nickel Effects on Selected Aquatic Plants and Animals

Taxonomic Group, Organism, Dose, and Other Variables	Effect	Ref. ^a
ALGAE AND MACROPHYTES		
Alga, <i>Anabaena inequalis</i>		
125 µg/L	Growth inhibited	1
10.0 mg/L	Photosynthesis inhibited	1
20.0 mg/L	Nitrogenase activity inhibited	1
Blue-green alga, <i>Anacystis nidulans</i>		
160 µg/L	Growth of wild strains inhibited 50%	2
1.3 mg/L	Growth of nickel-tolerant strain inhibited 50%	2
10.0 mg/L	Decreased growth in 14 days	3
50.0 mg/L	No growth in 14 days	3
Freshwater algae, 4 species		
100–700 µg/L	Reduced growth at 50 mg CaCO ₃ /L	4
Green algae, 4 species		
100 µg/L	Growth inhibition at 20°C	1
Giant kelp, <i>Macrocystis pyrifera</i>		
2.0 mg/L	Photosynthesis inhibited 50%	4
Diatom, <i>Navicula pelliculosa</i>		
100 µg/L	Growth inhibited 50% in 14 days	1
Alga, <i>Phaeodactylum tricornutum</i>		
1.0 mg/L	Reduced growth	4
Alga, <i>Scenedesmus acutiformis</i> ; from lake containing 2.5 mg Ni/L		
1.9 mg/L	Growth reduced 47%	1
3.0 mg/L	Growth reduced 82%	1
Marine diatom, <i>Thalassiosira rotula</i>		
30 µg/L	Growth inhibited	5
300 µg/L	Toxic threshold	5
ROTIFERS		
Rotifer, <i>Philodina acuticornis</i>		
2.9–7.4 mg/L	LC50 (96 h) at 25 mg CaCO ₃ /L	4
MOLLUSCS		
Eastern oyster, <i>Crassostrea virginica</i>		
100 µg/L, embryos	None dead in 48 h	6
1.18 mg/L embryos	LC50 (48 h)	6
3.0 mg/L, embryos	All dead in 48 h	6
12.0 mg/L, larvae	LC50 (12 days); normal growth in survivors	7
Freshwater snail, <i>Juga plicifera</i>		
124 µg/L	No adverse effects in 96 h	1
237 µg/L	LC50 (96 h)	1
Freshwater mussel, <i>Lamellidens marginalis</i>		
Exposed for 15 days to 22 mg Ni/L; tissue concentrations, in mg/kg fresh weight (FW), experimental vs. controls		
Foot	218 vs. 122	8
Gills	570 vs. 153	8
Hepatopancreas	327 vs. 160	8
Mantle	277 vs. 145	8
Muscle	186 vs. 130	8
110 mg/L	LC50 (96 h)	8
Northern quahog, <i>Mercenaria mercenaria</i>		
100 µg/L, embryos	No deaths in 48 h	6
310 µg/L, embryos	LC50 (48 h)	6

Table 6.7 (continued) Nickel Effects on Selected Aquatic Plants and Animals

Taxonomic Group, Organism, Dose, and Other Variables	Effect	Ref. ^a
600 µg/L, embryos	All dead in 48 h	6
5.7 mg/L, larvae	LC50 (8–10 days); survivors had reduced growth	7
Softshell clam, <i>Mya arenaria</i> ; adults		
10.0–50.0 mg/L	No deaths in 168 h	9, 11
112.0 mg/L	LC50 (168 h)	9
200.0 mg/L	All dead in 168 h	9
320.0 mg/L	LC50 (96 h)	9
Common mussel, <i>Mytilus edulis</i>		
Exposed to 0, 13, 25, 30, 56 or 107 µg Ni/L for 4 weeks	No accumulations in soft parts at 30 µg/L and lower. After 4 weeks, the 56 µg/L group had 32 mg Ni/kg dry weight (DW) soft parts, and the 107 µg/L group had 41 mg Ni/kg DW soft parts vs. 12 mg/kg DW in controls	10
Exposed to 0, 20.0, 40.0, or 80.0 mg/L for 96 h	No deaths in any group. No byssal thread secretion in 40 and 80 mg/L groups. Nickel concentrations, in mg/kg DW soft parts, were 12 in controls, 400–420 in intermediate dose groups, and 820 in the high dose group	10
Mud snail, <i>Nassarius obsoletus</i> ; adults		
10.0 mg/L	No deaths in 168 h	9
25.0 mg/L	All dead in 168 h	9
72.0 mg/L	LC50 (96 h)	9
ARTHROPODS		
Aquatic insects, 5 species		
4.0–33.5 mg/L	LC50 (96 h) at 42–50 mg CaCO ₃ /L	4
Caddisfly, <i>Clistoronia magnifica</i>		
295–734 µg/L	MATC ^b at 50 mg CaCO ₃ /L	4
Copepods, 4 species		
600–9700 µg/L	LC50 (96 h)	4
Copepod, <i>Cyclops abyssorum prealpinus</i>		
15.0 (8.0–26.0) mg/L	LC50 (48 h)	12
Daphnid, <i>Ceriodaphnia dubia</i>		
13 µg/L	LC50 (48 h) at pH 8.0–8.5	13
>200 µg/L	LC50 (48 h) at pH 6.0–6.5	13
Daphnid, <i>Daphnia hyalina</i>		
1.9 (1.5–2.5) mg/L	LC50 (48 h)	12
Daphnid, <i>Daphnia magna</i>		
10.2–21.4 µg/L	MATC ^b at 51 mg CaCO ₃ /L	4
30–95 µg/L	Reproduction impaired in 21 days	4
100 µg/L	Growth inhibited in 9 days	4
101–150 µg/L	MATC ^b at 105 mg CaCO ₃ /L	4
220–570 µg/L	MATC ^b at 205 mg CaCO ₃ /L	4
360 (330–400) µg/L	LC50 (21 days)	14
500 µg/L	LC50 (9 days) at 60 mg CaCO ₃ /L	4
510 µg/L	LC50 (96 h) at 45 mg CaCO ₃ /L	4
540 µg/L	Population biomass reduced 10% in 21 days	14
950 (670–1300) µg/L	Population biomass reduced 50% in 21 days	14
2.34 mg/L	LC50 (96 h) at 100 mg CaCO ₃ /L	4
4.96 mg/L	LC50 (96 h) at 206 mg CaCO ₃ /L	4
Daphnid, <i>Daphnia pulicaria</i>		
1.8–2.2 mg/L	LC50 (48 h) at 44–48 mg CaCO ₃ /L	4
2.4–3.8 mg/L	LC50 (48 h) at 194–244 mg CaCO ₃ /L	4
Copepod, <i>Eudiaptomus padanus</i>		
3.6 (2.8–4.6) mg/L	LC50 (48 h)	12
Amphipod, <i>Gammarus</i> sp.		
13.0 mg/L	LC50 (96 h)	4

Table 6.7 (continued) Nickel Effects on Selected Aquatic Plants and Animals

Taxonomic Group, Organism, Dose, and Other Variables	Effect	Ref. ^a
Amphipod, <i>Hyalella azteca</i>		
890 µg/L	LC50 (96 h) at pH 8.0–8.5	13
2.0 mg/L	LC50 (96 h) at pH 6.0–6.5	13
Mysid shrimp, <i>Mysidopsis bahia</i>		
61–141 µg/L	MATC ^b	4
Mysid shrimp, <i>Mysidopsis bigelowi</i>		
510–640 µg/L	LC50 (96 h)	4
Mysid shrimp, <i>Mysidopsis formosa</i>		
150 µg/L	LC50 (96 h)	4
Copepod, <i>Nitocra spinipes</i>		
6.0 mg/L	LC50 (96 h)	15
Hermit crab, <i>Pagurus longicarpus</i>		
10.0 mg/L	No deaths in 168 h	9
47.0 mg/L	LC50 (96 h)	9
50.0 mg/L	All dead in 168 h	9
ANNELIDS		
Oligochaete, <i>Lumbriculus variegatus</i>		
26.0 mg/L	LC50 (96 h) at pH 8.0–8.5	13
100.0 mg/L	LC50 (96 h) at pH 6.0–6.5	13
Sandworm, <i>Nereis diversicolor</i> ; adults		
10.0 mg/L	No deaths in 168 h	9
25.0 mg/L	LC50 (96–168 h)	9
50.0 mg/L	All dead in 168 h	9
Polychaete annelids, 3 species		
17.0–49.0 mg/L	LC50 (96 h)	4
Oligochaete, <i>Tubifex tubifex</i>		
80–61,400 µg/L; various water hardnesses	LC50 (48 h) range; most sensitive in soft waters; survivors had increased respiration rate	16, 17
ECHINODERMS		
Sea urchin, <i>Arbacia punctulata</i> ; embryos		
17.0 mg/L	More than 50% dead in 42 h	4
Starfish, <i>Asterias forbesi</i> ; adults		
5.0 mg/L	No deaths in 168 h	9
13.0 mg/L	LC50 (168 h)	9
50.0 mg/L	All dead in 168 h	9
150.0 mg/L	LC50 (96 h)	9
Sea urchin, <i>Lytechinus pictus</i> ; embryos; exposed continuously from fertilization through hatching to 5.8, 58, 580, 5800, 58,000, or 580,000 µg Ni/L, as nickel chloride		
5.8 µg/L group	Normal growth and development	18
58 and 580 µg/L groups	Normal development through gastrulation, but larvae developed abnormally (no dorsoventral symmetry)	4, 18
58.0 mg/L and higher	Normal cleavage, but gastrulation unsuccessful	18
Sea urchin, <i>Strongylocentrotus purpuratus</i>		
Sperm held in 0.6, 5.9, 59, 590, or 5900 µg Ni/L for 50 min	0.6 and 5.9 µg/L had no effect on sperm motility; 59 µg/L had initial depressing effect followed by increased motility; 590 µg/L had initial depressing effect in motility with recovery; 5900 µg/L caused significant depression in sperm motility	19
Sea urchins, various species; embryos		
180 µg/L	No adverse effects on development	20
370–1470 µg/L	Embryonic development inhibited	20

Table 6.7 (continued) Nickel Effects on Selected Aquatic Plants and Animals

Taxonomic Group, Organism, Dose, and Other Variables	Effect	Ref. ^a
FISHES		
Rock bass, <i>Ambloplites rupestris</i> 2.48 mg/L	LC50 (96 h) at 26 mg CaCO ₃ /L	4
Climbing perch, <i>Anabas testudineus</i> 146.0 mg/L for 30 days	No deaths; significant depletion of glycogen and total proteins in liver and gonads	21
American eel, <i>Anguilla rostrata</i> 13.0 mg/L	LC50 (96 h)	4
Zebradanio, <i>Brachydanio rerio</i> ; exposed from 2 h after fertilization through hatching and larval stages until day 16; 11 different doses as nickel sulfate hexahydrate 40 µg/L >40 µg/L 80 µg/L 1024 µg/L	No effect on hatching time Delayed hatching time No effect on larval survival No effect on embryonic survival	22 22 22 22
Goldfish, <i>Carassius auratus</i> 500 µg/L for 2 weeks 25 mg/L 75 mg/L 100 mg/L	Some accumulation in scales and otoliths, but not statistically significant Swimming activity reduced 31% in 96 h LC25 (96 h) LC88 (96 h)	23 24 24 24
Giant gourami, <i>Colisa fasciata</i> ; adults 64 mg/L as nickel sulfate (equivalent to 0.8 times the LC50 [96 h] value); gonads examined after 96 h	Testicular degeneration (spermatogonial activity reduced, germ cells in testicular lobules degenerating, congested blood vessels); ovaries histologically different, oocytes resorbed	25
Common carp, <i>Cyprinus carpio</i> 750 µg/L, larvae 1.0 mg/L for 16 days (in mixture containing 1.0 mg/L each of Cd, Cr, and Pb salts); adults 1.3–40.0 mg/L 8.0 mg/L for 15 days, adults 8.0 mg/L for 15 days (sublethal exposure); nickel concentrations (in mg/kg FW) in tissues of experimentals at end of exposure vs. controls Brain Gill Kidney Liver Muscle 10.4–10.6 mg/L	LC50 (257 h) at 128 mg CaCO ₃ /L Maximum nickel concentrations, in mg/kg DW, were 77 in liver, 49 in gill, 39 in brain, and 19 in muscle; other metals tested showed time-dependent increases in tissues LC50 (96 h) No deaths. Disrupted protein metabolism in gills and kidneys 41 vs. 25 103 vs. 31 80 vs. 50 97 vs. 32 58 vs. 30 LC50 (96 h) at 55 mg CaCO ₃ /L	4 26 4, 27 8 29 29 29 29 29 4
Carp, <i>Cyprinus carpio communis</i> Fingerlings; exposed to 2.5, 5, 7.5, or 10 mg Ni/L for 30 days	No deaths; protein content significantly decreased over time in dose-dependent pattern in brain, intestine, and muscle	30
Orange chromite, <i>Etroplus maculatus</i> Exposed to 10, 30, 60, 80, or 100 mg Ni/L for 96 h at 3 salinities (2.5, 5, or 15 ppt)	At 2.5 ppt salinity, whole body nickel concentrations increased from 19 to 232 mg/kg DW in a dose-dependent manner (vs. control of 12.5 mg/kg DW); at 15 ppt salinity, nickel increased from 20 to 113 mg/kg DW; in combination with copper salts, nickel uptake increased at intermediate salinities	31

Table 6.7 (continued) Nickel Effects on Selected Aquatic Plants and Animals

Taxonomic Group, Organism, Dose, and Other Variables	Effect	Ref. ^a
Fishes; most species; adults		
4–14 mg/L	LC50 (96 h), soft water	1
24–44 mg/L	LC50 (96 h), hard water	1
Banded killifish, <i>Fundulus diaphanus</i>		
46.1 mg/L	LC50 (96 h) at 53 mg CaCO ₃ /L	4
Mummichog, <i>Fundulus heteroclitus</i>		
50 mg/L	No deaths in 168 h	9
150 mg/L	LC50 (96 h)	9
250 mg/L	All dead in 168 h	9
Channel catfish, <i>Ictalurus punctatus</i> ; from fertilization through day 4 posthatch		
38 (18–68) µg/L	LC10	28
710 (490–1010) µg/L	LC50	28
Spot, <i>Leiostomus xanthurus</i>		
70 mg/L	LC50 (96 h), adults	1
Pumpkinseed, <i>Lepomis gibbosus</i>		
5.2 mg/L	LC50 (96 h) at 20 mg CaCO ₃ /L	4
8.0 mg/L	LC50 (96 h) at 55 mg CaCO ₃ /L	4
Bluegill, <i>Lepomis macrochirus</i>		
5.4 mg/L	LC50 (96 h) at 20 mg CaCO ₃ /L	4
39.6 mg/L	LC50 (96 h) at 360 mg CaCO ₃ /L	4
Atlantic silverside, <i>Menidia menidia</i>		
8.0 mg/L	LC50 (96 h)	4
Tidewater silverside, <i>Menidia peninsulae</i> ; larvae		
38.0 mg/L	LC50 (96 h)	1
Largemouth bass, <i>Micropterus salmoides</i>		
113 (61–185) µg/L; exposed from fertilization through day 4 after hatching	LC10	28
2.02 mg/L, embryos	LC50 (8 days) at 93–105 mg CaCO ₃ /L	4
2.06 (1.48–2.84) mg/L; exposed from fertilization through day 4 after hatching	LC50	28
White perch, <i>Morone americana</i>		
13.6 mg/L	LC50 (96 h) at 55 mg CaCO ₃ /L	4
Striped bass, <i>Morone saxatilis</i>		
6.2 mg/L	LC50 (96 h) at 54 mg CaCO ₃ /L	4
Coho salmon, <i>Oncorhynchus kisutch</i>		
16.7 mg/L	LC50 (96 h), alevins	32
18.0 mg/L	LC50 (96 h), juveniles	32
Rainbow trout, <i>Oncorhynchus mykiss</i>		
11 µg/L; embryos exposed from fertilization through day 4 after hatching	LC10	28
23.9 µg/L	Avoidance by adults	33
<35 µg/L; chronic exposure; newly fertilized eggs	No adverse effects	33
50 µg/L; embryos exposed from fertilization through day 4 after hatching	LC50 (28 days) at 93–105 mg CaCO ₃ /L	4, 28
60 µg/L; fertilization through day 4 after hatching	LC50 at 125 mg CaCO ₃ /L	1
90 µg/L; fertilization through day 4 after hatching	LC50 at 174 mg CaCO ₃ /L	1
134 µg/L; chronic exposure of eyed eggs and larvae	No adverse effects	33
230–535 µg/L	MATC ^b at 50 mg CaCO ₃ /L	4
1.0 mg/L, as hexahydrate nickel chloride; exposure for 6 months plus 3-month postexposure observation period in uncontaminated media; juveniles	All fish appeared outwardly normal at all times. After 6 months of exposure, tissue concentrations, in mg Ni/kg FW, were 4.0 in kidneys, 2.9 in liver, and 0.8 in muscle. Nickel concentrations following the 3-month	34

Table 6.7 (continued) Nickel Effects on Selected Aquatic Plants and Animals

Taxonomic Group, Organism, Dose, and Other Variables	Effect	Ref. ^a
7.8–10.9 mg/L	postexposure period (vs. controls), in mg/kg FW, were 2.5 (1.5) in kidneys, 1.8 (1.5) in liver, and 0.6 (0.5) in muscle	32, 33
25.1 mg/L	LC50 (96 h), juveniles	32
31.7 mg/L	LC50 (96 h), alevins	35
35.7 mg/L, adults	LC50 (96 h); adults; hard water	4
Fed diet containing 61 mg Ni/kg DW ration (and other metals found in activated sewage sludge) for 10 weeks	LC50 (48 h) at 42 mg CaCO ₃ /L	36
Isolated R1 liver cells exposed to culture media containing 84 mg Ni/L	Whole body nickel concentration increased from 0.33 mg/kg DW to 0.63 mg/kg DW	
Isolated liver cells in 116 mg Ni/L	50% inhibition of neutral red dye uptake	35
Tilapia, <i>Oreochromis niloticus</i> 1.5 or 3.0 mg/L for 10 days	Cytotoxic	35
Fathead minnow, <i>Pimephales promelas</i> 109–433 µg/L 380–730 µg/L 730–1600 µg/L; lifetime exposure	Significant depletion in liver and muscle glycogen; significant increase in plasma glucose; differences more pronounced at higher dose MATC ^b at 44 mg CaCO ₃ /L MATC ^b at 210 mg CaCO ₃ /L No adverse effects on growth or survival; reproduction inhibited	37 4 4, 38
3.1 mg/L >4.0 mg/L 4.6–9.8 mg/L 25.0–32.2 mg/L 42.0–44.5 mg/L	LC50 (96 h) at pH 8.0–8.5 LC50 (96 h) at pH 6.0–6.5 LC50 (96 h) at 20 mg CaCO ₃ /L LC50 (96 h) at 210 mg CaCO ₃ /L LC50 (96 h) at 360 mg CaCO ₃ /L	13 13 4 4 4

^b MATC = maximum acceptable toxicant concentration. Lower value in each MATC pair is highest concentration tested producing no measurable effect on growth, survival, reproduction, or metabolism during chronic exposure; higher value is lowest concentration tested producing a measurable effect.

6.7.4 Birds

In mallards (*Anas platyrhynchos*), nickel accumulates in tissues when diets contain as little as 12.5 mg Ni/kg DW ration (Table 6.8). Metabolic upset and altered bone densities occur in mallards fed diets containing 800 mg Ni/kg ration for 90 days (Cain and Pafford 1981; Eastin and O'Shea 1981). Inhibited growth and reduced survival occur in mallards at dietary loadings of 1200 mg Ni/kg ration (Table 6.8). Dietary nickel concentrations of 0.074 mg Ni/kg ration have no adverse effects on Coturnix quail (*Coturnix risoria*). However, Japanese quail (*Coturnix japonica*) fed diets containing 0.71 mg Ni/kg ration — when compared to controls fed diets containing 0.48 mg Ni/kg — have significantly elevated nickel concentrations in liver (Table 6.8). Increased concentrations of nickel in the diets of domestic chickens (*Gallus* sp.) were associated with decreased growth and survival and increased nickel concentrations in bone and kidney (Ling and Leach 1979). Dietary loadings of 500 mg Ni/kg ration and higher were associated with reduced growth and high mortality in some strains of chickens, but not others (Table 6.8). No developmental abnormalities

Table 6.8 Nickel Effects on Birds

Organism, Dose, and Other Variables	Effect	Ref. ^a
MALLARD, <i>Anas platyrhynchos</i>		
Breeding adults 20-months old fed diets containing 0, 12.5, 50, 200, or 800 mg Ni/kg ration for 90 days. All birds killed at day 90 and examined		
All groups	No effect on egg production, hatchability, or survival of ducklings; adults had normal blood chemistry and no organ histopathology; nickel accumulated in kidneys at all doses and in feathers, blood, and livers of birds fed high doses	1, 9
50 mg/kg group	Feathers contained 5.2 mg Ni/kg dry weight (DW) vs. 0.9 mg/kg DW in controls	1
800 mg/kg group	Abnormal black, tarry feces in test birds. Mean nickel concentrations, in mg/kg fresh weight (controls), were 1.9 (0.09) in kidneys, 0.52 (0.12) in livers, and 0.14 (0.005) in blood. Newly grown feathers had 68 (range 8–558) mg Ni/kg DW vs. 0.9 (0.5–1.6) mg/kg DW in controls	1
Ducklings age 1 day fed diets containing 0, 200, 800, or 1200 mg Ni/kg fresh weight (FW) ration, as nickel sulfate, for 90 days		
800 mg/kg group and lower	No effect on growth or survival	2
800 mg/kg group	Lower bone density in females at day 60	2
1200 mg/kg group	Tremors and paresis beginning at day 14; 71% dead by day 60. Survivors weighed less at day 28 than did birds fed other diets. Lower bone density evident at day 30. Livers and kidneys of survivors had <1.0 mg Ni/kg FW; dead birds had as much as 22.7 mg Ni/kg FW liver and 74.4 mg Ni/kg FW kidney	2
JAPANESE QUAIL, <i>Coturnix japonica</i>		
For 2 generations quail ate diets containing wheat (<i>Triticum aestivum</i>) grown on sludge-amended soils (980 µg Ni/kg DW wheat) or control wheat (400 µg Ni/kg DW). Total diets contained 710 µg Ni/kg DW (sludge-grown wheat) or 480 µg Ni/kg DW (controls)	Nickel concentrations in livers of birds fed sludge-grown wheat were significantly elevated in males (210 µg Ni/kg DW vs. 130 in controls) and females (120 vs. 80 µg Ni/kg DW); mixed function oxidase activities were elevated in livers of both sexes when compared to controls	3
COTURNIX QUAIL, <i>Coturnix risoria</i>		
Fed diets containing 74 µg Ni/kg ration for 4 generations	No observed adverse effects	4
DOMESTIC CHICKEN, <i>Gallus</i> sp.		
Chicks given single intraperitoneal injection of 10 mg Ni (as nickel chloride)/kg body weight (BW)	Initial increase in plasma glucose after 15 min followed by hypoglycemia 60–120 min after injection. Starved chicks remained hyperglycemic during 120 min postinjection observation period	5
Day-old Plymouth Rock males fed semipurified diets for 3 weeks		
300 mg Ni/kg diet	Reduced growth rate; elevated kidney nickel concentration of 4.2 mg/kg FW vs. 0.13 in controls	6, 9
500 mg Ni/kg diet	Some deaths. Kidneys had 7.6 mg Ni/kg FW and bone had 1.9 mg Ni/kg FW vs. 0.1 mg Ni/kg bone FW in controls. Addition of 100 mg copper, iron, zinc, or cobalt/kg ration did not reverse adverse effects	6

Table 6.8 (continued) Nickel Effects on Birds

Organism, Dose, and Other Variables	Effect	Ref. ^a
700 mg/kg diet	Growth retardation; kidneys had 9.7 mg Ni/kg FW	6
1100 mg Ni/kg diet	High mortality and anemia; kidneys had 11.5 mg Ni/kg FW; possible breakdown in urinary excretion mechanisms	6
Broiler chicks fed diets for 4 weeks containing 500 mg Ni (as nickel sulfate or nickel acetate)/kg ration	Normal growth in body weight	4, 5, 7
As above at 700 mg Ni/kg ration	Decreased growth in body weight	4, 5, 7
As above at 900 or 1300 mg Ni/kg ration	Marked reduction in growth; nitrogen retention decreased in 1300 mg/kg group	4, 7
Embryos; age 4 or 8 days; white leghorn strain; injected into yolk or onto the chorioallantoic membrane; 3.6 mg Ni/kg FW embryo (0.2 mg nickel as nickel chloride hexahydrate/egg)	LD50 (18 days postinjection); no developmental abnormalities in survivors	8

^a 1, Eastin and O'Shea 1981; 2, Cain and Pafford 1981; 3, Stoewsand et al. 1984; 4, NAS 1975; 5, Nielsen 1977; 6, Ling and Leach 1979; 7, Weber and Reid 1968; 8, Ridgway and Karnofsky 1952; 9, Outridge and Scheuhammer 1993.

occurred in chicks from survivors challenged by nickel during embryogenesis (USPHS 1977). Chick embryos receiving a single injected dose of 3.6 mg Ni/kg embryo, however, experienced 50% mortality within 18 days (Ridgway and Karnofsky 1952). Chicks are more resistant than embryos to injected nickel. Chicks injected with 10 mg Ni/kg BW survived but had disrupted glucose metabolism; effects were exacerbated by starvation (Nielsen 1977).

6.7.5 Mammals

Outridge and Scheuhammer (1993), in their excellent review of nickel hazards, draw six major conclusions regarding nickel toxicity in mammals:

1. Lifetime exposure of resistant species of mammals to diets containing 2500 mg Ni/kg DW or to drinking water containing 10,000 mg Ni/L are not lethal.
2. Lethal nickel doses in mammals are usually derived from studies with laboratory animals injected with nickel and its compounds, not from realistic exposure regimens.
3. Inhaled nickel is at least 100 times more toxic than ingested nickel because it is more readily absorbed from the lungs than from the gastrointestinal tract, and death is more often the result of respiratory failure than of nervous system effects. For example, oral ingestion of 0.05 mg Ni/kg BW and inhalation at 0.005 Ni/m³ are equally effective threshold doses in rats (USPHS 1977).
4. Large differences in sensitivity to nickel exist between closely-related taxonomic species, such as rats and mice.
5. Threshold effects on lung function or morphology in several species of laboratory mammals occur at airborne nickel concentrations of 0.1 to 0.2 mg/m³, depending on nickel compound and duration of exposure.
6. Juveniles were usually more sensitive to nickel than adults.

Nickel salts administered by intravenous or subcutaneous injection are comparatively toxic. For all routes of parenteral administration, the LD50 (lethal dose to 50% of the sample) range for injected nickel salts is 6 mg Ni/kg BW for dogs given nickel oxide intravenously to 600 mg Ni/kg BW for mice given nickel disodium EDTA intraperitoneally (Nielsen 1977).

Several trends were evident among sensitive species of mammals tested against nickel through administration routes other than injection ([Table 6.9](#)).

1. Nickel carbonyl is lethal to mice, rats, and cats at 0.067–0.24 mg Ni/L.
2. Inhalation of nickel compounds other than nickel carbonyl causes significant effects in humans, rats, mice, rabbits, and dogs, with respiratory effects being most common.
3. Nickel-contaminated drinking water has adverse effects on rat reproduction and may neurologically affect the eyes of humans, although this needs to be verified.
4. Diets containing nickel carbonate, nickel chloride, or nickel sulfate cause reduced growth, disruptions of food intake and thyroid function, and emphysema and pneumonia in calves, dogs, mice, or rats.
5. Dermal application of nickel sulfate hexahydrate causes skin and testicular damage.
6. Single oral doses of 136 to 410 mg Ni/kg BW as nickel acetate are lethal to mice.

Nickel carbonyl ($\text{Ni}(\text{CO})_4$) is the only nickel compound known to cause severe acute effects, such as pulmonary damage and death; acute toxic effects of other nickel compounds to mammals are a minor risk (Norseth and Piscator 1979; Sevin 1980; WHO 1991). In fatal cases, death occurs 3 to 13 days after exposure. Recovery from nickel carbonyl poisoning usually occurs within 70 days after exposure, but sometimes may take up to 6 months (Sunderman 1970; Sevin 1980; WHO 1991). Nickel carbonyl is a volatile, colorless liquid formed when finely divided nickel or its compounds come into contact with carbon monoxide. It is unstable under atmospheric conditions, and if inhaled, nickel is deposited in highly active form on the respiratory mucosa on contact. Nickel carbonyl is widely used commercially as a catalyst but is one of the most toxic gases encountered in industrial operations (Sunderman 1970; Norseth and Piscator 1979; USEPA 1980, 1986). Exposure to air containing more than 50 mg $\text{Ni}(\text{CO})_4/\text{m}^3$ for 0.5 to 2.0 h may be fatal to humans (WHO 1991). Intraperitoneal injection of nickel carbonyl was the most toxic route of administration; for all routes of administration, LD₅₀ values for various test mammals ranged between 13 and 65 mg/kg BW (WHO 1991; [Table 6.9](#)). Nickel carbonyl toxicity is due, in part, to its volatility and lipophilicity (Sigel and Sigel 1988). Signs of nickel carbonyl poisoning, which strongly resemble those of viral pneumonia, include headache, vertigo, nausea, vomiting, insomnia, and irritability followed by an asymptomatic interval and then the onset of insidious, persistent signs that include chest pains, dry coughing, cyanosis, sweating, visual and gastrointestinal disturbances, severe weakness, paralysis of the hind limbs, and convulsions. The lungs are the primary target organs in all animals tested, although the liver, kidneys, adrenal glands, spleen, and brain are also affected (Sunderman 1970; Nielsen 1977; Mushak 1980; USEPA 1980, 1986; Norseth 1986; WHO 1991).

Adverse effects in mammals by inhalation of nickel compounds other than nickel carbonyl occur with aerosols of both soluble and insoluble nickel compounds (USEPA 1980). Inhalation of nickel by humans and other mammals produces respiratory, hepatic, renal, dermal, immune system, and body weight effects (WHO 1991; USPHS 1993). Respiratory effects of nickel include asthma, nasal septal perforations, chronic rhinitis and sinusitis, and increased risk of chronic respiratory tract infections (USPHS 1977; USEPA 1986; WHO 1991; Zhang et al. 1998); immunological, genotoxic, and carcinogenic effects were also observed (USPHS 1993). Lung reactions in the form of asthma were attributed to sensitization by nickel (Norseth and Piscator 1979). Insoluble forms of inhaled nickel are more persistent in lungs than are soluble forms, as judged by 90-day studies with nickel chloride (soluble) and nickel oxide (insoluble) given to rodents by intratracheal administration (English et al. 1981). Severity of respiratory toxicity was higher with increasing solubility of the nickel compound tested and not with increasing burden of nickel on the lung; insoluble nickel oxide had the lowest toxicity but the highest lung burden. Nickel sulfate was more toxic than nickel subsulfide, which was more toxic than nickel oxide (USPHS 1993).

Local effects noted in guinea pigs, rats, mice, and hamsters caused by inhalation of metallic nickel powder (15 mg/m³), nickel subsulfide (0.97 mg/m³), or nickel oxide (53 mg/m³) include nasal sinus inflammations, ulcers, lung irritation, nickel accumulations in lungs, emphysema, and

increased viral respiratory infections (Norseth 1986; WHO 1991). Rats inhaling nickel subsulfide at 2.5 mg/m³ for 22 days had nasal and lung histopathology within 4 days and disrupted enzyme activities and elevated nickel accumulations within 7 days (Benson et al. 1995). Repeated inhalation of nickel subsulfide by rats for 3 months resulted in chronic inflammation in the lung and atrophy of the olfactory epithelium (Benson et al. 1995). Rats exposed via inhalation of nickel sulfate hexahydrate of 635 µg Ni/m³ for 6 h daily over 16 days had no outward signs of toxicity; however, internal examination revealed lesions on the olfactory epithelium (Evans et al. 1995). Rats and mice died following inhalation exposure for 16 days to equal doses of nickel sulfate or nickel subsulfide, but not nickel oxide (USPHS 1993). Rats showed epithelial hyperplasia after inhalation exposure to aerosols of nickel chloride or nickel oxide and pulmonary fibrosis after inhalation exposure to nickel subsulfide; a similar syndrome was reported in rabbits after high-level inhalation exposure to nickel-graphite dust (WHO 1991). Dogs exposed to nickel powder for 6 months by way of inhalation developed lung pneumosclerosis causing cardiac insufficiency (USPHS 1977). Rats exposed to airborne nickel dusts (100 µg Ni/m³, 12 h daily for 2 months) had respiratory irritation (NRCC 1981). Single exposures of mice to 250 µg Ni/m³ for 2 h depressed the humoral immune response (NRCC 1981). Rats exposed to 1000 µg Ni dust/m³ (5 days/week for 3 to 6 months) had high accumulations of nickel in the lungs and kidneys and interstitial fibrosis (NRCC 1981).

Nickel and nickel salts are comparatively nontoxic when taken orally because of homeostatic mechanisms that control nickel metabolism and limited intestinal absorption (Nielsen 1977). In cattle, young calves fed nickel carbonate at concentrations as high as 1000 mg Ni/kg ration for 8 weeks had nephritic kidneys, with degree of severity increasing with dietary nickel level. However, dietary nickel did not affect growth or food consumption of calves or cause histopathology of the rumen, abomasum, duodenum, liver, or testes (O'Dell et al. 1970). Human and animal data indicate that death is unlikely from oral nickel exposure except when exposed accidentally to high levels (USPHS 1993). Oral exposure studies for humans were limited to acute intoxication and include death (due to cardiac arrest) and the effects of gastrointestinal (nausea, cramps, diarrhea, vomiting), hematological (increase in reticulocytes), hepatic (increase in serum bilirubin), renal (albuminuria), and neurological damage. A child who accidentally ingested 20.36 grams of Ni/kg BW as crystals of nickel sulfate died from heart failure (USPHS 1993). Oral LD₅₀ doses of nickel chloride to rats produced depression of the nervous system, edema of the mucous membranes of the mouth and nose, diffusions from the oral cavity, lacrimation, bleeding from the nose, and diarrhea (USPHS 1977). Prior to death, rats were lethargic, ataxic, and with irregular breathing and cool body temperatures (USPHS 1993).

Nickel is a reproductive toxicant in animals. Specific effects of nickel on reproduction include degenerative changes in the testes, epididymis, and spermatozoa of rats; adverse effects on embryo viability of rats and hamsters; and delayed embryonic development of rodents (Smialowicz et al. 1984; USEPA 1986; USPHS 1993). Nickel salts given by injection cause intrauterine mortality and decreased weight gain in rats and mice (WHO 1991). Inhibited testosterone and reduced growth occur in male rats given 2.32 mg Ni/kg BW as nickel acetate via intramuscular injection. Females given the same treatment had increased uterine weights (USPHS 1977). Nickel given in drinking water of rats for three generations at concentrations which do not interfere with growth or survival (i.e., 5 mg/L) was intolerable for normal reproduction (Schroeder and Mitchener 1971). All generations of rats given nickel in drinking water had increased proportions of runts and increased neonatal mortality when compared to controls. In the third generation of nickel-treated rats, there were reductions in litter size and a reduction in the proportion of males (Schroeder and Mitchener 1971). Excess nickel inhibits prolactin secretion in rats. Because prolactin influences milk production, the observation that suckling pups from nickel-exposed dams were most severely affected lends support to the concept that nickel plays a role in lactation at the pituitary level (Nielsen et al. 1975b).

Table 6.9 Nickel Effects on Selected Mammals

Organism, Route of Exposure, Dose, and Other Variables	Effect	Reference ^a
COW, <i>Bos</i> sp.		
Diet		
63 mg Ni/kg ration for 8 weeks as nickel carbonate; male calves	Normal growth and food consumption	1, 2
250 mg Ni/kg ration for 42 days; lactating cows	Negligible transfer of nickel from diet to milk	3
250 mg Ni/kg DW ration for 8 weeks as nickel carbonate; male calves; equivalent to daily intake of 1218 mg nickel	No accumulations in tissues; slight (13%) reduction in food intake and growth rate (11%)	1, 2
1000 mg Ni/kg dry weight (DW) ration for 8 weeks as nickel carbonate; male calves; equivalent to daily intake of 1410 mg nickel	Abnormal rumen fluid composition; nickel accumulations in tissues; marked reduction in food intake and growth rate. During a 6-week postexposure recovery period, growth rate was same as in controls	1, 2
1750 mg Ni/kg ration; adult females	No detectable nickel in milk	2
<i>In vitro</i> culture; isolated brain cells exposed for 20 h to graded concentrations of nickel chloride up to 116 mg Ni/L	Time- and dose-dependent effects on kinetics of brain microtubule polymerization; effects reversed on removal of Ni ²⁺ from culture media	4
DOMESTIC DOG, <i>Canis familiaris</i>		
Diet		
0, 100, 1000, or 2500 mg Ni/kg ration for 2 years as nickel sulfate hexahydrate	No significant adverse effects at 1000 mg Ni/kg ration and lower. At 2500 mg Ni/kg, adverse effects observed on growth and blood chemistry; livers and kidneys enlarged; lung lesions; hyperplasia of bone marrow	5
Equivalent to 25 or 63 mg Ni/kg BW daily, as nickel sulfate, for 2 years	No serious adverse effects at low dose; high dose group had emphysema, pneumonia, low hematocrit, increased liver and kidney weight, and a 40% decrease in body weight gain	6
Inhalation		
2.7 mg Ni/L, as nickel carbonyl (Ni(CO) ₄), for 75 min	LC80 (1–5 days postexposure)	8
5 to 6 mg Ni powder/m ³ , 10 min daily for 6 months; observed for additional 19 months following treatment	No change in weight or general condition. At 3 months after treatment, leukocyte and primary neutrophil counts were low, and nickel was elevated in liver and kidneys. At 12 months, blood flow was reduced in small vessels of lungs. At 19 months, survivors had increased pulse and respiration rates	7
Intravenous injection, single dose		
6 to 7 mg Ni/kg BW, as nickel oxide	Lethal	2
10 to 20 mg Ni/kg BW as colloidal nickel	Death preceded by gastroenteritis, tremors, and paralysis	2, 9
10 to 20 mg Ni/kg BW as nickel chloride	Some deaths	2, 9
Oral		
12 mg/kg BW daily for 200 days	Tolerated without ill effects	10
1000–3000 mg Ni/kg BW as powdered nickel	Tolerated	9
Subcutaneous injection; single dose of 500 mg Ni/kg BW as nickel sulfate hexahydrate	Some deaths	2
DOMESTIC GOAT, <i>Capra hircus</i>		
Pulmonary macrophages cultured <i>in vitro</i> for 20 h with media containing 14.5–58.0 mg Ni/kg as nickel chloride	Concentration-dependent decrease in viability of alveolar macrophages; highest dose had survival of <50%. Death associated with release of superoxide anions	11

Table 6.9 (continued) Nickel Effects on Selected Mammals

Organism, Route of Exposure, Dose, and Other Variables	Effect	Reference ^a
GUINEA PIG, <i>Cavia</i> sp.		
Drinking water; 2.5 mg Ni/L for 4 months	No accumulations in hair; all values were between 3.4 and 4.6 mg Ni/kg DW hair	12
Inhalation; 15 mg Ni/m ³ as elemental nickel; lifetime exposure	Excess blood, swelling, hemorrhage, and increased frequency of lesions in the pharyngeal area	7
Intravenous injection; 62 mg Ni/kg BW as nickel sulfate; single injection	LD50	2
Subcutaneous injection; males given 0.0001, 0.001 or 1.0 mg Ni/kg BW daily as nickel chloride for 15 days were mated with fertile females	No effect on female gestation period, number of litters or offspring, weight of offspring, or offspring development	7
HAMSTER, <i>Cricetus</i> sp.		
Gavage; 5 mg of nickel oxide	After 24 h, no increase in nickel content of lungs, liver, kidney or carcass	7
Inhalation Exposed to nickel oxide aerosols at concentrations of 2–160 µg/L (2 to 160 mg/m ³) and particle size of 1 to 2.5 µm 15 mg Ni/m ³ as elemental nickel; lifetime exposure 39 mg Ni/m ³ as nickel oxide for 3 weeks 48.4 mg/m ³ as nickel oxide for 61 days	45 days after exposure about 50% of the original dose remained in lungs with no significant accumulations in other tissues	10
	No significant effect on survival or health	7
	Inflammation and congestion of lungs; emphysema	7
	No deaths	6
DOMESTIC CAT, <i>Felis domesticus</i>		
Inhalation; nickel carbonyl 0.19 mg/L for 30 min 3.0 mg/L for 75 min	LC50 (0.2 h-6 days after exposure)	8
	LC50 (1–5 days after exposure)	8
	Tolerated, with no apparent ill effects	2, 9, 10
HUMAN, <i>Homo sapiens</i>		
Dermal; <59 µg Ni/L; nickel-sensitive persons	No contact allergic reaction	14
Dialysis; 23 patients; nickel leached into dialysate from a nickel-plated stainless steel water heater tank	At plasma nickel concentrations of about 3 mg/L, patients had adverse effects including headaches, nausea, vomiting, and weakness; recovery occurred 3 to 13 h after cessation of dialysis	8
Drinking water Equivalent to 0.012 or 0.05 mg Ni/L as nickel sulfate 250 mg Ni/L in contaminated drinking water 32 workers in an electroplating plant drank water accidentally contaminated with nickel sulfate and nickel chloride at 1630 mg Ni/L; estimated intake of 0.5–2.5 g, equivalent to 8.3–41.6 mg/kg BW	Neurological effect on eyes at high dose; no adverse effects at low dose	6
	Stomach ache, increased red blood cell number, increased protein in urine	6
	Symptoms included nausea, vomiting, abdominal discomfort, diarrhea, giddiness, lassitude, headache, cough, and shortness of breath, and persisted for at least 2 h and sometimes 2 days. Serum nickel concentrations on day 1 after exposure were 286 (13–1340) µg/L vs. 50 µg/L in nonaffected workers; for urine these concentrations were 5.8 (0.2–37.0) mg/L vs. 4.0 µg/L	8
Inhalation >0.04 mg Ni/m ³ air, usually as nickel oxide or metallic nickel	Chronic bronchitis, emphysema, reduced lung capacity, and increased incidence of deaths from respiratory disease among workers occupationally exposed	6

Table 6.9 (continued) Nickel Effects on Selected Mammals

Organism, Route of Exposure, Dose, and Other Variables	Effect	Reference ^a
30 mg Ni/L air as nickel carbonyl for 30 min	Lethal	13
Chronic exposure		
Nickel aerosols, occupational exposure	Lung cancer, nasal sinusitis, chronic rhinitis	10
Nickel particulates	Chronic respiratory infections	10
Oral		
Low nickel diet fed to patients with chronic nickel dermatitis	Significant improvement in 6 weeks; adverse effects when placed on normal diet	10
Accidental ingestion of nickel sulfate crystals (15–20 grams) by 2.5 year-old female child	Death in 4 h of heart failure; blood had 7.5 mg Ni/kg, urine 50 mg/L, and liver 25 mg Ni/kg FW	6, 8
Placental tissue incubated for as long as 24 h in media containing 145 mg Ni/L	When compared to controls, treated tissues had increased permeability, lipid peroxidation, and nickel concentration over time. Treatment with ascorbic acid or zinc decreased nickel-induced placental lipid peroxidation and permeability, but had no effect on nickel tissue concentrations	43
MONKEYS		
Various species; different forms of nickel in diet; as much as 1000 mg Ni/kg ration for 24 weeks	No adverse effects on growth, behavior, or blood chemistry	10, 13
DOMESTIC MOUSE, <i>Mus</i> spp.		
Diet		
Young mice fed diets containing 0, 1100 or 1600 mg Ni/kg ration as the acetate salt for 4 weeks	Food consumption and growth reduced in the male 1600 mg/kg group and the female 1100 and 1600 mg/kg groups. All nickel groups had significant decreases in liver cytochrome oxidase and isocitric dehydrogenase activities; in heart and kidney homogenates, malic dehydrogenase activity decreased in the high nickel groups	15, 16
Equivalent to >1.4 mg Ni/kg BW daily for 2 years as nickel chloride or nickel sulfate	Decreased liver weight	6
Equivalent to 108 mg Ni/kg BW daily for 180 days as nickel sulfate	Renal tubular damage at the corticomedullary junction	6
Drinking water		
Equivalent to >23 mg Ni/kg BW for 6–30 h as nickel chloride, nickel sulfate, or nickel nitrate	Abnormal sperm in mature males	6
150 mg/L as nickel sulfate for 6 months	No deaths	6
160 mg/L as nickel chloride in drinking water of pregnant females from gestation day 2 to day 7	Increased incidence of spontaneous abortions	6
Inhalation		
Nickel carbonyl		
0.01 mg/L for 120 min	All dead	8
0.067 mg/L for 30 min	LC50 (0.2 h–6 days after exposure)	8, 9
Nickel oxide		
>3.9 mg/m ³ for as long as 13 weeks	Adverse respiratory effects including chronic inflammation, fibrosis, macrophage hyperplasia, interstitial infiltrates, and increased lung weight	6
23.6 mg/m ³ for 16 days	No deaths	6
Nickel subsulfide		
>0.11 mg/m ³ for 16–91 days	Adverse respiratory effects	6
7.3 mg/m ³ for 16 days	All dead	6

Table 6.9 (continued) Nickel Effects on Selected Mammals

Organism, Route of Exposure, Dose, and Other Variables	Effect	Reference ^a
Nickel sulfate		
>0.1 mg/m ³ for 16–91 days	Adverse respiratory effects	6
1.6 mg/m ³ for 16 days	All dead	6
Isolated Leydig cells incubated with 3.6–58.0 mg Ni/L for 48 h; testosterone production measured in testicular interstitial cells	A dose-related depression in testosterone production at doses not producing any general toxic or significant cytotoxic action	44
Single intramuscular injection of 18.3 mg Ni/kg BW as nickel chloride	Involution of thymus and suppression of cellular and humoral activity and transient immunosuppressive effects within 2 days of injection with responses returning to normal within a few days	17
Single intraperitoneal injection		
Nickel acetate		
11 mg/kg BW	Adverse effects	21
32 mg/kg BW	LD50 (48 h)	7
39–50 mg/kg BW; adult males; age 9–15 weeks	LD50 (5 days postinjection)	20
48–54 mg/kg BW; adult females; age 9–15 weeks	LD50 (5 days postinjection)	20
89–97 mg/kg BW; juveniles; age 3 weeks	LD50 (5 days postinjection)	20
Nickel chloride		
Pregnant females given 1.2, 2.0, 3.0, 3.5, 4.6, 5.7, or 6.9 mg Ni/kg BW between days 7 and 11 of gestation	Dose-related increase in fetal deaths and malformations	8
3.1 mg Ni/kg BW	Normal spleen lymphocyte function	18
Pregnant mice given 4.6 mg Ni/kg BW on day 16 of gestation and killed 2 to 48 h after injection	Maximum nickel concentrations in tissues (in mg/kg FW) were reached in blood (19.8) and placentas (3.9) 2 h following injection; those in liver (4.9), spleen (1.3), and kidneys (56.2) were reached 4 h after injection; and maximum concentration in fetal tissues (1.1) was reached after 8 h. Authors estimate that all nickel is excreted in 42 to 84 h	19
9.3–12.3 mg Ni/kg BW	Immunosuppression in spleen lymphocyte function	18
26 mg Ni/kg BW	LD50 (48 h)	7
Nickel chloride hexahydrate; 48 mg Ni/kg BW	LD50 (48 h)	7
Nickelocene; 27 mg Ni/kg BW	Adverse sublethal effects	21
Nickel oxide; >744 mg/kg BW	LD50 (72 h)	7
Nickel perchlorate heptahydrate; 100 mg Ni/kg BW	LD50 (12 h)	7
Nickel sulfate; 21–38 mg Ni/kg BW	LD50 (10–30 days)	7
Oral, single dose		
Nickel acetate; 136–410 mg Ni/kg BW	LD50 (72–120 h)	7, 21
Nickelocene; 186 mg/kg BW	LD50	21
Single subcutaneous injection of 10, 20, or 40 mg Ni/kg BW every 3 days for 4 treatments	Depressed testosterone production of Leydig cells at 20 mg/kg BW and higher; normal histology	44
RABBIT, <i>Oryctolagus</i> sp.		
Inhalation		
Metallic nickel dust		
>0.2 mg/m ³ for about 8 months	Alterations in alveolar macrophages; impaired cellular function	6
1.0 mg/m ³ for 3 or 6 months, 5 days weekly, 6 h daily; lungs examined	At both 3 and 6 months, there was a two- to threefold increase in volume density of alveolar Type II cells; after 6 months, lungs had foci of pneumonia, suggesting a higher susceptibility to pulmonary	

Table 6.9 (continued) Nickel Effects on Selected Mammals

Organism, Route of Exposure, Dose, and Other Variables	Effect	Reference ^a
Nickel carbonyl; 1.4 mg/L for 50 min	Infections due to a decrease in function of alveolar macrophages	22
Nickel chloride; >0.2 mg/m ³ for about 8 months	Alveolar cell degeneration within 5 days; LC80 (120 h)	8, 10
Single intravenous injection; nickel chloride	Alterations in alveolar macrophages	6
10 mg/kg BW	Transient hyperglycemia 1–4 h after injection	7
15 mg/kg BW	Pronounced hyperglycemia 1–4 h after injection, returning to normal after 24 h	7
15–20 mg/kg BW	Pancreas histopathology	7
Single subcutaneous injection; various nickel salts; 1300 mg/kg Ni/BW	Lethal	9
LABORATORY WHITE RAT, <i>Rattus</i> sp.		
Dermal; nickel sulfate hexahydrate; dose equivalent to 40, 60, or 100 mg Ni/kg BW daily for 30 days (rats licked skin so exposure route may be oral in part)	No adverse effects in 40 mg/kg BW group. High dose groups had skin damage (atrophy, acanthosis, hyperkeratinization) and testicular damage (abnormal seminiferous tubules, tubular lumens filled with degenerated sperm)	6, 8, 10
Diet		
Weanlings fed rations containing 0, 100, 500, or 1000 mg Ni/kg, as nickel acetate, for 6 weeks	At high doses (500, and 1000 mg/kg), rats had depressed growth, low hematocrit and hemoglobin, and low tissue cytochrome oxidase and alkaline phosphatase activities; the 1000 mg/kg group (vs. controls) had elevated nickel concentrations — in mg Ni/kg DW — of 2.1 (0.9) in heart, 40.7 (5.0) in kidney, 4.0 (0.7) in liver, and 7.2 (1.6) in testes	38
0, 100, 1000, or 2500 mg Ni/kg ration, as nickel sulfate hexahydrate, for 2 years	No histopathology in any group; at 1000 and 2500 mg Ni/kg ration, rats had depressed growth, lower liver weights, and increased heart weights	5
0, 250, 500, or 1000 mg Ni/kg ration, as nickel sulfate hexahydrate, for 3 generations; equivalent to 0.7, 12.5, 25, or 50 mg Ni/kg BW daily; reproductive study	Higher incidence of stillborns and fetal mortalities noted only in the first generation at all nickel dietary levels; weanling body weight was lower at 1000 mg Ni/kg ration in all generations	5, 6, 21
0.08 mg Ni/kg ration for 55 days	No adverse effects	2
250 mg Ni/kg ration for 16 months	Normal growth	16
1000 mg Ni/kg ration (as nickel carbonate or nickel catalysts) for 8 weeks	Normal growth	10
1000 mg Ni/kg ration for 13 days; juveniles	Altered blood chemistry, diminished food intake, and reduced growth within a few days	39
Dietary equivalent of 1, 25, or 100 mg/kg BW daily for 4 months; nickel chloride	Thyroid function affected; decreased iodine uptake at 1 mg/kg BW, increased at 25 mg/kg BW, and decreased at 100 mg/kg BW	7
Dietary equivalent of >1.4 mg Ni/kg BW daily for 2 years; nickel chloride or nickel sulfate	Decreased liver weight	6
Drinking water		
5 mg/L; lifetime exposure	No effect on growth or survival	35, 36
5 mg/L for 3 generations; diets contained 0.31 mg Ni/kg FW ration	Significant increase in mortality of young rats in all generations; significant increase in runts in first and third generations; litter size decreased with each generation; total number of rats reduced; few males were born in the third generation	35
225 mg/L for 4 months as nickel chloride	Depressed growth rate; lower serum triglyceride and cholesterol concentrations	13, 40

Table 6.9 (continued) Nickel Effects on Selected Mammals

Organism, Route of Exposure, Dose, and Other Variables	Effect	Reference ^a
Inhalation		
Nickel carbonyl ($\text{Ni}(\text{CO})_4$)		
0.1 mg/L for 20 min	Some deaths after exposure	8
0.24 mg/L for 30 min	LC50 (0.2 h-6 days)	2, 8, 9
0.24–1.0 mg/L for 30 min	Lung histopathology within 10 days	10
0.9 mg/L for 30 min	LC80 (2 h–several months)	8
100 mg/L for 15 min	About 26% of the inhaled nickel was excreted in urine within 4 days; absorption estimated at 50%	10
160 mg/m ³ on days 7–8 of gestation or 300 mg/m ³ on day 7	Increased fetal mortality; reduced body weight in live pups; 16% incidence of fetal malformations (anophthalmia, microphthalmia, cystic lungs, hydronephrosis)	8
Nickel chloride (NiCl_2); 0.05–5.0 mg/m ³ for 2 to 4 weeks	Significant decrease in iodine uptake by thyroid	10
Nickel dust; 15 mg/m ³ ; lifetime exposure	Increased frequency of adenoidal lesions and chronic sinus inflammation and ulceration	7
Nickel oxide (NiO)		
0.06 mg/m ³ ; lifetime exposure	Survival time decreased from 125 weeks in controls to 88 weeks; body weight loss after 13 months; alveolar proteinosis and marked lung enlargement	6
0.2 mg/m ³ for 1 year	Pneumonia and bronchial epithelial metaplasia	6
0.5 mg/m ³ for 1 month	Bronchial gland hyperplasia 20 months after exposure	6
1.6 mg/m ³ on gestation days 1–21	Decrease in fetal body weight	6
>3.9 mg/m ³ for as long as 13 weeks	Adverse respiratory effects	6
11.7 mg/m ³ , 8 h daily, 5 days weekly, for 4 weeks	Significant increase in tumor necrosis factor for alveolar macrophages	24
23.6 mg/m ³ for 16 days	No deaths	6
Nickel subsulfide (Ni_3S_2)		
Equivalent to 0, 0.4, or 1.8 mg Ni/m ³ ; 6 h daily for as long as 22 days	The high dose group had reduced survival, nose and lung histopathology, and disrupted enzyme activity levels; survivors were lethargic and grew poorly. At day 22, nickel concentrations in lungs, in mg/kg FW, were <1.8 in controls, 12 in the low dose group and 34.0 in the high dose group	26
Equivalent to 0.11, 0.44, or 1.8 mg Ni m ³ for as long as 13 weeks; exposures were 6 h daily and 5 days weekly	Dose-dependent increase in pulmonary lesions; atrophy of the nasal olfactory epithelium at 0.44 mg/m ³ and higher	26
Equivalent to 0.73 mg/m ³ for 78 weeks plus 30 weeks of postexposure observation; exposure for 6 h daily and 5 days weekly	Pulmonary tumor growth (14% incidence in lung tumors vs. 1% in controls) and increased mortality (95% dead vs. 69% in controls)	6, 25
7.3 mg/m ³ for 16 days	LC20	6
Nickel sulfate (NiSO_4)		
50 µg/rat	Half-time persistence in lung of 32 h; lung inflammatory responses disrupted lung enzyme activity	29
>0.1 mg/m ³ for as long as 13 weeks	Adverse respiratory effects	6
0.635 mg/m ³ for 16 days, 6 h daily	Induced lesions of olfactory epithelium but no measurable changes in olfactory function	31
1.6 mg/m ³ for 16 days	No deaths	6
Single intramuscular injection, unless noted otherwise		
Metallic nickel; 110 mg/kg BW	Lowest toxic dose	2
Nickel acetate		
Males and females given 2.32 mg Ni/kg BW daily for 4 days	Males had inhibited testosterone levels and reduced growth, while females had increased uterine weights	7
420 mg/kg BW	Lowest toxic dose	2

Table 6.9 (continued) Nickel Effects on Selected Mammals

Organism, Route of Exposure, Dose, and Other Variables	Effect	Reference ^a
Nickel chloride		
Females given 1.5–2.0 mg/kg BW daily on days 6–10 of gestation	Significant intrauterine mortality, but body weight of live pups was normal	8
Females given 2.0 mg/kg BW twice daily on days 6–10 of gestation	No congenital abnormalities	34
12 mg/kg BW to pregnant and nonpregnant females; tissues analyzed 24 h following injection	Relative tissue concentrations were kidney > serum > adrenal=lung=ovary > spleen=heart=liver > muscle. Nickel concentration in pituitary gland was significantly higher in pregnant rats	34
16 mg Ni/kg BW on day 8 of gestation	Reduction in number of live pups and diminished body weight of fetus on day 20 of gestation and of weanlings 4 to 8 weeks after birth; no developmental abnormalities	34
23–98 mg/kg BW	LD50 (7 days)	7, 21, 23, 80
Nickel oxide		
7 mg Ni/kg BW	Significantly increased levels of serum alkaline phosphatase, amylase, aspartate transaminase, and lipoperoxide. Daily injections of copper-zinc superoxide dismutase prevented these changes	28
180 mg/kg BW	Toxic	2
Nickel subsulfide		
80 mg Ni/kg BW on day 6 of gestation	Reduction in mean number of live pups	34
90 mg/kg BW	Lowest toxic dose	2
Nickel sulfate; 12–16 mg/kg BW on day 8 of gestation	Reduction in mean number of live pups; reduced body weight in fetuses on day 20 of gestation and in pups 4–8 weeks after birth	8
Nickel sulfide; 7 mg/kg BW	Disrupted serum enzyme activity	28
Single intraperitoneal injection, unless indicated otherwise		
Nickel acetate		
8 mg/kg BW	Toxic	21
24 (19–28) mg/kg BW	LD50 (48 h)	7, 8
Nickel carbonyl; 13 mg/kg BW	LD50	8
Nickel chloride		
4 mg/kg BW	Tissue concentrations at 24 h (and at 15 min) after injection, in mg/kg FW, were 2.7 (16.1) in kidney, 0.3 (4.7) in liver, 1.2 (5.9) in blood, and 0.9 (1.4) in placenta	33
6.0 (5.5–6.5) mg/kg BW	LD50 (7 days) for females pregnant 19 days	33
6.3 (5.6–7.1) mg/kg BW	LD50 (7 days) for females pregnant 12 days	33
8.0 mg/kg BW	Rapid transient increase in serum glucose and decrease in serum insulin	40
9.3 (8.5–10.2) mg/kg BW	LD50 (7 days) for virgin females	33
11–19 mg/kg BW	LD50 (7 days)	2, 7, 8
Nickelocene; 16–59 mg/kg BW	LD50, usually within 14 days	8, 21
Nickel oxide; >690 mg/kg BW	LD50 (3 days)	7
Nickel sulfate; 3 or 6 mg/kg BW daily for 7 or 14 days; killed 48 h after last injection	Highest nickel concentrations were in myocardium (5.7 mg/kg FW vs. 2.2 in controls) and spleen (2.1 vs. 0.6), followed by kidney, bone, and other tissues	37
Single intrarenal injection of nickel subsulfide equivalent to 39 mg/kg BW	Pronounced erythrocytosis; increased hematocrit and reticulocyte count	30
Intratracheal injection		
Single injection of ultrafine particles of nickel metal (20 nm diameter) at 5 mg Ni/kg BW and examined 1–30 days later	Severe lung inflammation, cytotoxicity, and increased epithelial permeability	42

Table 6.9 (continued) Nickel Effects on Selected Mammals

Organism, Route of Exposure, Dose, and Other Variables	Effect	Reference ^a
Nickel chloride; 1.0 mg/kg BW; examined 6 and 72 h after injection	At 6 h, tissue nickel concentrations were elevated in kidneys, lungs, adrenals, liver, pancreas, spleen, heart, and testes, in that order; by 72 h, 90% of the nickel was excreted, mostly (75%) in the urine	7
Nickel oxide; >110 mg/kg BW	LD50 (72 h)	7
Single intravenous injection of nickel carbonyl		
11 mg/kg BW; day 7 of gestation	High incidence of fetal deaths and malformations; reduced body weight in live pups	8
22 mg/kg BW	LD50, usually within 14 days	8
65 mg/kg BW	Massive lung histopathology within 6 days	10
Single oral exposure, unless indicated otherwise		
Nickel acetate		
116–120 mg/kg BW	Toxic	21
304–410 mg/kg BW	LD50 (7 days)	7, 8
Nickel chloride		
0.35 mg/kg BW daily for 28 days	Hyperglycemia, decreased body weight, reduced food and water intake	6
8.6 mg/kg BW daily for 91 days	LD25; decreased body weight in survivors	6
116 mg/kg BW	Toxic	6, 21
285 mg/kg BW	LD50, usually within 14 days	7
Nickel fluoborate ($\text{Ni}(\text{BF}_4)_2$); 500 mg/kg BW	Lethal	2
Nickel hexahydrate; 8.5 mg/kg BW daily for 91 days	Death preceded by lethargy, ataxia, irregular breathing, hypothermia, salivation, squinting, and loose stools	6
Nickel nitrate ($\text{Ni}(\text{NO}_3)_2$); 1620 mg/kg BW	LD50, usually within 14 days	2
Nickelocene		
154 mg/kg BW	Toxic	21
471–525 mg/kg BW	LD50, usually within 14 days	8
Nickel sulfate		
25 mg/kg BW daily for 120 days	Infertility	8
66 mg/kg BW	LD50, usually within 14 days	6
Single subcutaneous injection		
Nickel carbonyl; 21 mg/kg BW	LD50 within several days	8
Nickel chloride		
10 or 20 mg/kg BW; young males; observed for 7 days	Increased prolactin levels that persisted for 4 days; increased insulin levels on days 1 and 2	8
11.9 mg/kg BW	5% dead	27
59.5 mg/kg BW given 16 h prior to sacrifice	Significant increase in hepatic glutathione S-transferase activity	32

^a 1, O'Dell et al. 1970; 2, NAS 1975; 3, Stevens 1991; 4, Lin and Chou 1990; 5, Ambrose et al. 1976; 6, USPHS 1993; 7, USPHS 1977; 8, WHO 1991; 9, Sunderman 1970; 10, USEPA 1980; 11, Waseem et al. 1993; 12, Scheiner et al. 1976; 13, Nielsen 1977; 14, USEPA 1975; 15, Weber and Reid 1969; 16, Ling and Leach 1979; 17, Smialowicz et al. 1984; 18, Graham et al. 1975; 19, Lu et al. 1981; 20, Hogan 1985; 21, USEPA 1985; 22, Hohansson et al. 1981; 23, Sunderman et al. 1983; 24, Morimoto et al. 1995; 25, Ottolenghi et al. 1974; 26, Benson et al. 1995; 27, Iscan et al. 1992; 28, Novelli et al. 1995; 29, Hirano et al. 1994; 30, Oskarsson et al. 1981; 31, Evans et al. 1995; 32, Iscan et al. 1993; 33, Mas et al. 1985; 34, Sunderman et al. 1978; 35, Schroeder and Mitchener 1971; 36, Schroeder et al. 1974; 37, Mathur et al. 1978; 38, Whanger 1973; 39, Schnegg and Kirchgessner 1976; 40, Clary 1975; 41, Ho and Furst 1973; 42, Zheng et al. 1998; 43, Chen and Lin 1998; 44, Forgacs et al. 1998.

The most commonly observed toxic reaction to nickel and nickel compounds in the general human population is nickel dermatitis and skin sensitivity arising from dermal contact with metals containing nickel (Sunderman 1970; NAS 1975; Norseth and Piscator 1979; USEPA 1980, 1986; WHO 1991; USPHS 1993). Studies on occupational dermatitis, which is the most prevalent

occupational disease, show that 8% of the cases are due to nickel (Sunderman et al. 1984). Nickel dermatitis in occupational exposure begins as an itching or burning in the web of the fingers, spreading to the fingers, the wrists, and the forearms; the eruption is similar to atopic dermatitis (NAS 1975; USEPA 1980, 1986). Once an individual is dermally sensitized to nickel, even minimal contact (i.e., 0.007 to 0.04 mg Ni/kg BW daily) by any route of exposure may elicit a reaction (USEPA 1980; WHO 1991; USPHS 1993; Hughes et al. 1994). Nickel, in fact, is the most common allergen tested in North America; about 1 to 5% of human males and 7 to 14% of females are contact sensitized to nickel (NAS 1975; Nielsen 1977; Sevin 1980; USEPA 1980, 1986; Sunderman et al. 1984; USPHS 1993; Ikarashi et al. 1996). Nickel contact hypersensitivity has been documented worldwide, with 10% of the female population and 1% of the male population affected. Of these, 40 to 50% have vesicular hand eczema that, in some cases, can be severe and lead to loss of working ability (WHO 1991). Nickel contact dermatitis is decreasing in occupational exposure, but increasing elsewhere due to increasing contact with nickel alloys in jewelry, coins, zippers, tools, pots and pans, stainless steel, detergents, prostheses, and certain hair dressings (NAS 1975; Nielsen 1977; USEPA 1980; Sunderman et al. 1984; WHO 1991; USPHS 1993). Nickel is a major allergen for women, and between 1970 and 1980 there was a two- to threefold increase in the number of cases (Sunderman et al. 1984). In recent years, the incidence of nickel allergy has increased disproportionately in young females due to an increased frequency of ear piercing by this group to accommodate nickel-plated jewelry (Ikarashi et al. 1996).

Although contact allergy to nickel is common in humans, experimental sensitization in animals is only successful under special conditions (WHO 1991). Dermal studies with nickel salts and small laboratory mammals show that primary nickel sensitization typically takes place beneath nickel-containing metal objects that are in contact with the skin for hours and exposed to friction and sweating; nickel is released from nickel-containing objects by the action of blood, sweat, or saliva; ionic nickel diffuses through the skin at sweat-duct and hair-follicle openings, with a special affinity for keratin; and nickel subsequently binds to proteins, including amino and carboxyl groups of keratin and serum albumin (NAS 1975; USEPA 1980; USPHS 1993). Rats, guinea pigs, and rabbits absorbed and subsequently distributed 55 to 77% of nickel applied dermally (USPHS 1977, 1993). Dermal effects in animals after dermal exposure to nickel include distortion of the dermis and epidermis, hyperkeratinization, atrophy of the dermis, and biochemical changes (USPHS 1993; Ikarashi et al. 1996). For example, in rats treated dermally with more than 40 mg Ni/kg BW daily as nickel hexahydrate for 30 days, distortion of the epidermis and dermis occurred by day 15, and hyperkeratinization, vacuolization, hydropic degeneration of the basal layer, and atrophy of the epidermis occurred by day 30 (USPHS 1993). Skin irritation and death from nickel salts is reported in rabbits when nickel was applied dermally to abraded skin; no negative effects occurred in rabbits when the same dose was applied to intact skin (USPHS 1977). As was the case for humans, allergic reactions occur in laboratory animals after oral nickel challenge in sensitized individuals (USPHS 1993).

Nickel affects endocrine and enzymatic processes. Nickel-induced endocrine effects include inhibition of insulin production in pancreas, prolactin in hypothalamus, amylase excretion in parotid gland, and iodine uptake in thyroid (Mushak 1980; USEPA 1980, 1986; USPHS 1977; WHO 1991). Inhibition of enzyme activity by nickel is reported for RNA polymerase, ATPase, dialkyl fluorophosphate, and aspartase (NAS 1975). Inhibition of ATPase is associated with neurological abnormalities, such as tremors, convulsions, and coma; altered hormone release or action; and internal rearrangement of calcium ions in muscle that might cause paralysis and abnormal heart rhythm (Nielsen 1977). Nickel increases the duration of the action potential of excitable membranes of nerve and muscle tissues; this effect is competitive with and imitative of those of calcium (NAS 1975). Nickel hexahydrate at 14.8 mg Ni/kg BW disrupts hepatic monooxygenases; mice were more sensitive to this disruption than rats or guinea pigs (Iscan et al. 1992). Nickel is also reported to activate various enzymes, including bovine pancreatic ribonuclease, pancreatic deoxyribonuclease, carboxypeptidase, arginase, phosphoglucomutase (Sevin 1980), and calcineurin — a calmodulin-dependent phosphoprotein phosphatase (USEPA 1986). Nickel affects the activity of heme

oxygenase, thereby affecting the absorption of hemoglobin iron. Nickel, like many other metals and metalloids, induces heme oxygenase activity in tissues of mice, hamsters, and guinea pigs in a dose-related manner (Sunderman et al. 1983).

Systemic effects of nickel exposure include hyperglycemia, increased levels of plasma glucagon, damage to the pancreatic islet cells, decreased body weight, reduced food and water intake, and hypothermia (NAS 1975; USEPA 1980; USPHS 1993). Acute administration of nickel salts caused prompt hyperglucagonemia and subsequent hyperinsulinemia in rats, rabbits, and guinea pigs (WHO 1991). Nickel chloride given orally to young male rabbits at 500 µg daily for 5 months produced a decrease in liver glycogen and an increase in muscle glycogen, with prolonged hyperglycemia (NAS 1975). Nickel increased glucose metabolism in rats injected intratracheally with 0.5 mg ionic nickel. This phenomenon probably reflected the influence of nickel on the production or secretion of insulin through decreased production of pituitary hormone secretions — specifically, prolactin — which control insulin concentrations (USPHS 1977). Nickel significantly affects the activity of hepatic glutathione S-transferases (GST); these compounds play important roles in the detoxification of electrophilic xenobiotics, such as nickel, epoxides, and diolepoxydes (Iscan et al. 1993), and readily eliminate the cytotoxic products of lipid peroxidation, particularly the organic peroxides (Coban et al. 1996). The influence of nickel chloride on hepatic GST activity levels depends on the animal species tested, being depressed in mice, unchanged in rats, and increased in guinea pigs (Iscan et al. 1992). In humans, nickel toxicity is not related to GST depletion or increased lipid peroxidases *in vitro*, whereas in rat kidney, nickel toxicity may be due to GST depletion and stimulation of lipid peroxidases (Coban et al. 1996).

Nickel affects the immune, cardiac, and excretory systems. Nickel adversely affects the immune system by reducing host resistance to bacterial and viral infections, suppressing phagocytic activity of macrophages, reducing the number of T-lymphocytes (thereby suppressing the natural kill cell activity) and increasing susceptibility to allergic dermatitis (WHO 1991; USPHS 1993). In mice, nickel chloride suppresses the activity of natural killer cells within 24 h of a single intramuscular injection (USEPA 1986). Nickel-induced cardiovascular effects include vasoconstriction, inhibition of contraction by myocardial muscle, and a reduction in coronary vascular flow (USEPA 1986; WHO 1991; USPHS 1993). Nickel salts are demonstrably cardiotoxic in dogs (Sigel and Sigel 1988). Cats injected intravenously with NiCl₂ had altered heart rhythms, conductivity, and calcium metabolism (Nielsen 1977). Nickel is a nephrotoxin with greatest adverse effect on the glomerular epithelium of the kidney. Kidneys from mammals exposed to nickel showed renal tubular damage, protein loss, and weight changes (USPHS 1993).

Nickel accumulations in tissues and organs of mammals vary significantly with species, route of administration, sex, and general health. No significant accumulations of nickel were observed in liver or kidney of Holstein calves fed diets containing 1000 mg Ni/kg ration for 21 weeks (Stevens 1992). In lactating dairy cows, no transfer of soluble nickel was observed from diet to tissues (Stevens 1992). In rats, guinea pigs, rabbits, sheep, dogs, and other species of mammals, nickel tends to accumulate in kidneys and other tissues after nickel exposure (as quoted in Eastin and O'Shea 1981). Nickel-poisoned rats had elevated accumulations primarily in myocardium (5.7 mg/kg FW vs. 2.2 in controls) and spleen (2.1 mg/kg FW vs. 0.6), followed by kidney, bone, and other tissues (Mathur et al. 1978). In rats, nickel accumulated mainly in lung and secondarily in heart tissues after intratracheal administration of nickel chloride; nickel was retained for at least 40 days after dosing (Novelli and Rodrigues 1991). In rodents, nickel accumulates in endocrine tissues, including the pituitary, adrenals, and pancreas (Mushak 1980; USEPA 1980). High nickel concentrations in the pituitary gland of rodents were associated with inhibition of insulin release and decreased prolactin secretion (Clary 1975). Rat weanlings fed diets containing 500 mg Ni/kg ration as nickel acetate show elevated nickel accumulations in plasma, erythrocytes, heart, liver, testes, and especially kidneys. High accumulations were associated with reductions in growth, hematocrit, hemoglobin, cytochrome oxidase, and alkaline phosphatase (Whanger 1973; Nielsen 1977). Male guinea pigs accumulated higher concentrations of nickel in hair than did females after

exposure for 4 months to drinking water containing 2.5 mg Ni/L (Scheiner et al. 1976). Invading microorganisms can change the distribution of ^{63}Ni in mice infected with coxsackie B3 virus. Infected mice had high accumulations of ^{63}Ni in the pancreas and the wall of the ventricular myocardium. Healthy mice had almost no ^{63}Ni accumulations in these tissues, but residues were elevated in blood, kidney, and lung (Ilback et al. 1992).

Excretion of ingested nickel by rats, regardless of amount ingested, usually occurs through the feces within 48 h (Ho and Furst 1973). Most nickel administered to rats through a variety of routes, and irrespective of chemical form, is usually excreted within a few days; however, excretion is slower for nickel powder and from lungs (USPHS 1977). Nickel caused a twofold increase in urinary corticoid excretion in guinea pigs (USPHS 1977), increased urinary excretion of protein in rats (USPHS 1977), and increased urinary excretion of B-2-macroglobulin in nickel refinery workers (USPHS 1993). Nickelemia was associated with increased urinary B-2-macroglobulin levels, and 5 of 11 workers with urinary nickel concentrations more than 100 $\mu\text{g}/\text{L}$ had increased urinary B-2-macroglobulin ($>240 \mu\text{g}/\text{L}$; (USPHS 1993).

6.8 PROPOSED CRITERIA AND RECOMMENDATIONS

While nickel may be carcinogenic, perhaps in all forms, there is little or no detectable risk in most sectors of the nickel industry at current exposure levels, including some processes that had previously been associated with very high lung and nasal cancer risks (WHO 1991). Research is ongoing to clarify the hazards of nickel to humans, including chronic inhalation carcinogenicity studies of nickel subsulfide, nickel oxide, and nickel sulfate hexahydrate in rats and mice (USPHS 1993). Nevertheless, additional research on nickel-induced cancer has been proposed, including research on (1) route of administration (USPHS 1993); (2) oxidative state of nickel (Kasprzak 1987); (3) effect of nickel on nucleic acid synthesis (Sunderman 1981); (4) interaction effects with asbestos (USEPA 1980), zinc and magnesium (Furst and Radding 1980), tobacco smoke (NRCC 1981), and agents thought to inhibit nickel carcinogenesis, such as manganese, copper, and aluminum (Furst and Radding 1980); (5) role of diet in nickel carcinogenesis (Furst and Radding 1980) and specificity and mechanism of uptake of nickel ion from the gastrointestinal tract (Hausinger 1993); and (6) nickel immunosuppressive mechanisms, especially effects of nickel on natural killer cell activity and the relation between suppression of these cells and the known carcinogenesis of nickel compounds (Smialowicz et al. 1984). Large-scale studies are needed to establish the upper limits of cancer risk from nickel (WHO 1991).

Humans have been shown to develop sensitivity to nickel (USPHS 1993). The use of nickel in products that may release the metal when in contact with the skin should be regulated (WHO 1991). Among various subgroups of the U.S. population who may be at special risk for adverse effects of nickel are those who have nickel hypersensitivity and suffer chronic flare-ups of skin disorders with frank exposure (USEPA 1986). The role of oral nickel exposure in dermatic responses by sensitive individuals suggests that nickel-limited diets resulted in marked improvement of hand eczema and that nickel added to the diets appeared to aggravate the allergic response (USEPA 1986). More research is needed on the role of nickel in contact dermatitis, including the role of oral nickel exposure, and the pathogenesis and therapy of nickel dermatitis (NAS 1975; Sunderman et al. 1984; USEPA 1986). Additional dermal exposure studies are needed to determine if testicular effects result from both oral and dermal exposure to nickel (USPHS 1993).

Animal experimental models of nickel-induced skin sensitivity are few and have been conducted only under very specialized conditions (USEPA 1986). Studies examining the mechanism of nickel contact sensitization and its extent in wildlife are needed (USPHS 1993). The importance of the surface properties and crystalline structure of nickel compounds in relation to their reactivity and protein-binding activities is well documented. It is therefore necessary to identify clearly the nickel compounds to which exposure occurs (Sunderman et al. 1984). Acute and chronic dermal and

inhalation studies using all nickel compounds would determine if certain compounds are more effective in eliciting allergic dermatitis (USPHS 1993).

To protect terrestrial vegetation against decreased growth and other toxic effects, nickel residues in leaves should contain less than 44 to less than 50 mg/kg DW; soils should contain less than 50 to less than 250 mg Ni/kg DW; and sewage sludge applied to agricultural soils should be limited to 30 to 140 kg Ni/surface ha at the low end and 50 to 560 kg/ha at the high end ([Table 6.10](#)). Research is needed on the direct effects on vegetation of nickel from airborne deposition, the effects of soil acidification on mobility and toxicity of nickel in soil, differences in nickel metabolism between tolerant and nickel-sensitive plants (NRCC 1981), and on the interactions of nickel and organic acids in nickel-accumulating plants and in the surrounding soils (Lee et al. 1978).

To protect freshwater plants and animals against nickel, a proposed range of less than 25 to 96 µg total recoverable Ni/L is recommended by various authorities ([Table 6.10](#)). This range will protect most species of freshwater biota. However, certain species have reduced survival within this range, including embryos of rainbow trout (*Oncorhynchus mykiss*) at 11 µg/L (Birge and Black 1980), daphnids (*Ceriodaphnia dubia*) at 13 µg/L (Schubauer-Berrigan et al. 1993), and embryos of the narrow-mouthed toad (*Gastrophryne carolinensis*) at 50 µg/L (Birge and Black 1980; USEPA 1980). Mixtures of metals are additive or more-than-additive in toxicity and, in some cases, will exceed the recommended water-quality criteria based on the individual metals. Such additive effects were demonstrated for daphnids and rainbow trout using water-quality criteria developed in the Netherlands for mixtures of nickel salts and those of arsenic, cadmium, chromium, copper, lead, mercury, or zinc (Enserink et al. 1991). To protect marine life, the 24-h average for total recoverable Ni/L should not exceed 7.1 µg/L, and the maximum concentration should not exceed 140 µg/L at any time ([Table 6.10](#)). The maximum concentration level for marine life protection needs to be reexamined because 30 µg Ni/L adversely affects growth of marine diatoms (Dongmann and Nurnberg 1982), 56 µg/L results in nickel accumulations in mussels (Friedrich and Filice 1976), 58 µg/L causes abnormal sea urchin development (Timourian and Watchmaker 1972), and 59 µg/L has adverse effects on motility of sperm of sea urchins (Timourian and Watchmaker 1977). In aquatic systems, research is needed to determine the mechanisms of nickel toxicity to biota, the transport of nickel, its interaction with other inorganic and organic chemicals, and its mobility in sediments under various environmental conditions (NRCC 1981).

To protect birds, diets should contain at least 50 µg Ni/kg ration to prevent nickel deficiency, but less than 200 mg Ni/kg ration in the case of young birds and less than 800 mg/kg ration in the case of adults to prevent adverse effects on growth and survival ([Table 6.10](#)). Nickel residues in avian kidneys in excess of 10 mg/kg DW or in liver in excess of 3 mg/kg DW are sometimes associated with adverse effects (Outridge and Scheuhammer 1993); however, nickel accumulates in kidneys of mallards (*Anas platyrhynchos*) at dietary concentrations as low as 12.5 mg Ni/kg ration (Eastin and O’Shea 1981). In general, tissue concentrations of nickel were not reliable indicators of potential toxicity in mammals and birds because adverse effects, including death, frequently occurred in the absence of elevated tissue nickel concentrations (Outridge and Scheuhammer 1993). For monitoring birds, analysis of kidneys, bone, and feathers is the most likely to reveal elevated exposure to environmental nickel contamination; nickel concentrations in liver and spleen often do not reflect elevated exposure (Outridge and Scheuhammer 1993).

To protect humans and other mammals, proposed air-quality criteria range from 0.01 to less than 1.0 mg/m³ for metallic nickel and slightly soluble nickel compounds, 0.015–0.5 mg/m³ for water soluble nickel compounds, and 0.005 to 0.7 mg/m³ for nickel carbonyl ([Table 6.10](#)). Inhalation of nickel subsulfide concentrations (0.11 to 1.8 mg Ni/m³) near the current threshold limit value of 1 mg Ni/m³ can produce detrimental changes in the respiratory tract of rats after only a few days of exposure (Benson et al. 1995). Additional animal studies are recommended to identify minimally effective inhalation exposure levels for the various nickel compounds (USPHS 1993). Continued monitoring of nickel refining, nickel-cadmium battery manufacture, and nickel powder metallurgy installations is recommended because ambient air levels of bioavailable nickel at these

installations in excess of 1 mg/m³ can sometimes still be found (NAS 1975; Sevin 1980; Sunderman et al. 1984; Chau and Kulikovsky-Cordeiro 1995).

Most species of mammals had normal growth and survival during chronic exposure to diets equivalent to 0.8 to 40 mg Ni/kg BW daily (Outridge and Scheuhammer 1993). Reduced growth and survival sometimes occurred when sensitive species of wildlife were fed diets containing 500 to 2500 mg Ni/kg ration, equivalent to 10 to 50 mg Ni/kg BW daily (Outridge and Scheuhammer 1993). Proposed criteria for nickel by way of the diet or drinking water range from 2 µg total Ni/kg BW daily (USPHS 1993) to 443 µg total Ni/kg BW daily (USEPA 1980) for soluble nickel compounds, less than 1.0 mg Ni/kg FW diet, and less than 350 µg Ni/L drinking water ([Table 6.10](#)). Further research is needed to clarify the role of nickel in mammalian nutrition, including dietary requirements of nickel and identification of the chemical forms of nickel present in foods and their bioavailability (NAS 1975; Sunderman et al. 1984; Hausinger 1993). Studies are needed on the absorption and cellular uptake, transport, and metabolism of well-characterized nickel species following different routes and types of administration (NAS 1975; WHO 1991; Hausinger 1993) and on the transfer of dietary nickel to tissues of lactating dams and juveniles (Stevens 1992). Because young female laboratory mice were more susceptible to dietary nickel than were adults, it is possible that no-observable-adverse-effect-levels (NOAELs) derived from adult animals may be inappropriately high for neonates and juveniles (Outridge and Scheuhammer 1993). Studies that compare the toxicokinetics of humans and animals concurrently could be helpful in determining which species of animal is the most appropriate model for assessing the effects of nickel in human health (USPHS 1993). Animal studies designed to examine neurological effects after inhalation or oral exposure are needed to determine, in part, if human exposure to nickel will cause permanent neurological damage (USPHS 1993).

Nickel affects reproduction of selected mammals. Drinking water containing 5 mg Ni/L — equivalent to 0.2 to 0.4 mg Ni/kg BW daily — had adverse effects on rat reproduction and iron metabolism (Outridge and Scheuhammer 1993). Dogs given the equivalent of 1.3 mg Ni/kg BW daily had decreased litter survival (Hughes et al. 1994). Nickel is known to cross the placental barrier and reach the fetus in mammals and humans. More information is needed on the effects of *in utero* nickel exposure in pregnant women (USEPA 1986; Chashchin et al. 1994). Such information may be obtained using appropriate animal models (USPHS 1977). Multigenerational inhalation studies are recommended to determine if developmental effects result from both inhalation and oral exposure (USPHS 1993).

Biomarkers of nickel exposure and effects include nickel concentrations in feces and urine and changes in serum antibodies and serum proteins (USPHS 1993). Levels of carnosine, a dipeptide, seem to reflect the extent of nickel-induced damage to olfactory mucosa of rats, although the rodent olfactory system is more resilient than the human's (Evans et al. 1995). Studies on the availability of trace levels of nickel in food and water and in air would be helpful to relate levels of nickel found in the hair, nails, blood, and urine to levels of nickel in internal organs (USPHS 1993). Nickel concentrations in human tissues now considered elevated include 4.6 µg/L in serum, 11.9 µg/L in plasma, and 100 to 129 µg/L in urine ([Table 6.10](#)). Treatment of mammals suffering from nickel poisoning is usually through administration of various classes of chelating agents, including dithiocarb (sodium diethyl-dithiocarbamate — the drug of choice in the management of nickel carbonyl poisoning), EDTA salts, BAL (2,3-dimercaptopropanol), and penicillamine (Norseth and Piscator 1979; Norseth 1986). In all cases, the agents accelerate urinary excretion of absorbed nickel before extensive tissue injury occurs (USEPA 1980).

The nomenclature of nickel compounds should be further standardized (WHO 1991). Analytical methods must be developed and standardized in order to facilitate speciation of nickel compounds in atmospheric emissions, biological materials, and in other environmental samples (NAS 1975; WHO 1991). Studies are needed to elucidate the biogeochemical nickel cycle on a global scale and determine its potential for long-range transport (WHO 1991).

Table 6.10 Proposed Nickel Criteria for Protection of Natural Resources and Human Health

Resource, Criterion, and Other Variables	Effective Nickel Concentration	Reference ^a
AQUATIC LIFE, FRESHWATER		
Sediments		
Great Lakes		
Safe	Less than 20 mg/kg dry weight (DW)	1
Moderately polluted	20–50 mg/kg DW	1
Heavily polluted	More than 50 mg/kg DW	1
Wisconsin; for disposal in water	Less than 100 mg/kg DW	1
Water		
Canada; safe level	Less than 25 µg/L	2
Rainbow trout, <i>Oncorhynchus mykiss</i> ; safe level	Less than 29 µg/L	3
Toxic effects expected	30–50 µg/L	4
Ontario, Canada; from sediment disposal in water; final water concentration	Less than 50 µg/L	1
The Netherlands; safe level	Less than 50 µg/L	5
United States; water hardness of 50 mg CaCO ₃ /L	24-h average not to exceed 56 µg total recoverable nickel/L; maximum concentration not to exceed 1100 µg/L at any time	6
Sweden; safe level	Less than 80 µg/L	7
United States; water hardness of 100 mg CaCO ₃ /L	24-h average not to exceed 96 µg total recoverable Ni/L; maximum concentration not to exceed 1800 µg/L at any time	6
United States; water hardness of 200 mg CaCO ₃ /L	24-h average not to exceed 160 µg total recoverable Ni/L; maximum concentration not to exceed 3100 µg/L at any time	6
AQUATIC LIFE, MARINE		
Water	24-h average not to exceed 7.1 µg total recoverable Ni/L; maximum concentration not to exceed 140 µg/L at any time	6
BIRDS		
Diet		
Domestic chicken, <i>Gallus</i> sp.; to prevent nickel deficiency in chicks	More than 50 µg/kg ration	8, 9, 10
Mallard, <i>Anas platyrhynchos</i>		
Ducklings; no adverse effects	Less than 200 mg/kg ration	4
Adults; no adverse effects	Less than 800 mg/kg ration	4
Adults; adverse effects	More than 800 mg/kg fresh weight (FW) ration	11
Tissue concentrations		
Adverse effects expected; most species		
Kidney	More than 10 mg/kg DW	4
Liver	More than 3 mg/kg DW	4
Internal organs, most species		
Normal	Less than 3 mg/kg DW	4
Nickel-contaminated environments	As much as 30 mg/kg DW	4
Mallard; liver or kidney; significant exposure to dietary nickel that may be harmful	More than 1.0 mg/kg FW	11

Table 6.10 (continued) Proposed Nickel Criteria for Protection of Natural Resources and Human Health

Resource, Criterion, and Other Variables	Effective Nickel Concentration	Reference ^a
CROPS AND OTHER TERRESTRIAL VEGETATION		
Plant residues		
Alfalfa, <i>Medicago sativa</i>		
Normal	0.3–3.2 mg/kg DW	12
Decreased growth	44.0 mg/kg DW	12
Terrestrial vegetation		
Hyper-accumulator plants	More than 1000 mg/kg DW	13
Most species		
Normal	0.05–5.0 mg/kg DW	13
Toxic	More than 50 mg/kg DW	13
Sewage sludge; maximum addition to agricultural soils		
Europe	30–75 kg sludge/ha soil	1
South Africa	200 mg/kg DW sludge	24
United States; soils with low exchange capacity vs. soils with high exchange capacity		
Maryland	140 kg/ha vs. 280 kg/ha	1
Massachusetts	56 kg/ha vs. 112 kg/ha	1
Minnesota and Vermont	56 kg/ha vs. 112–224 kg/ha	1
Missouri	140 kg/ha vs. 280–560 kg/ha	1
New York, all soils	34–50 kg/ha	1
Oregon	50 kg/ha vs. 100–200 kg/ha	1
Wisconsin	50–100 kg/ha vs. 150–200 kg/ha	1
Soils; suitability for crop production		
Canada; Alberta; acidic soils; acceptable	Less than 250 mg/kg DW	1
The Netherlands		
Background	50 mg/kg DW	1
Moderate contamination	100 mg/kg DW	1
Unacceptable and requires cleanup	More than 500 mg/kg DW	1
Russia; maximum acceptable concentration; extractable by ammonium acetate buffer at pH 4.6	4.0 mg/kg soil	1
South Africa, no phytotoxicity or elevated nickel concentrations in crops	38 mg/kg DW soil	24
United States; New Jersey; acceptable	Less than 100 mg/kg DW soil	1
MAMMALS, EXCEPT HUMANS		
Air		
Laboratory white rat, <i>Rattus</i> sp.		
Adverse effects; nickel sulfate	More than 0.1 mg/m ³	9
No adverse effects		
Nickel refinery dust	Equivalent to less than 0.84 mg/kg BW daily	9
Nickel subsulfide	Equivalent to less than 1.7 mg/kg BW daily	9
Nickel sulfate	Less than 0.1 mg/m ³	9
Rodents, <i>Mus</i> spp., <i>Rattus</i> spp.		
Adverse effects; nickel oxide, nickel sulfate	More than 0.02 mg/m ³	14
No adverse effects; nickel chloride, nickel subsulfide	Less than 0.1 mg/m ³	4
Diet		
To prevent deficiency		
Rats, <i>Rattus</i> spp.	More than 50 µg/kg ration	9, 10, 15
Ruminants (<i>Bos</i> spp.), swine (<i>Sus</i> spp.)	More than 100 µg/kg DW ration ^b	9, 10

Table 6.10 (continued) Proposed Nickel Criteria for Protection of Natural Resources and Human Health

Resource, Criterion, and Other Variables	Effective Nickel Concentration	Reference ^a
No observable adverse effects during chronic exposure		
Cattle, <i>Bos</i> spp.	Less than 0.5 mg/kg DW ration	10
Dogs (<i>Canis</i> sp.), rats (<i>Rattus</i> spp.), monkeys (<i>Macaca</i> spp.)	Less than 1.0 mg/kg ration	4
Rat	Equivalent to 16.7 µg/kg BW daily ^c	9
Various species	Less than 100 mg/kg ration, equivalent to 0.8 to less than 40.0 mg/kg BW daily	4
Adverse effects expected		
Cattle		
Adults	More than 50 mg/kg ration	16
Calves	More than 5 mg/kg ration, equivalent to more than 0.16 mg/kg BW daily	4, 16
Dogs	Equivalent to more than 1.3 mg/kg BW daily	14
Mammals, most species	More than 500 to 2500 mg/kg diet, equivalent to 10–50 mg Ni/kg BW daily	4
Drinking water		
Adverse effects observed		
Rat	5 mg/L, equivalent to 0.35 mg/kg BW daily	4
Most species	200–225 mg/L	4
Tissue residues		
Evidence of significant nickel exposure		
Kidney	More than 10 mg/kg DW	4
Liver	More than 3 mg/kg DW	4
HUMAN HEALTH		
Air		
Cancer risk		
Increased risk; soluble nickel compounds	More than 1 to 2 mg/m ³	13
No increased risk; metallic nickel	Less than 0.5 mg/m ³	13
Industrial plant; United States; nickel carbonyl		
Safe	Daily average less than 1.0 µg/L; single air sample less than 40 µg/L	17
Discontinue operations	More than 1 to 5 µg/L daily average; single air sample more than 200 to 2000 µg/L	17
Shut down plant	Daily average more than 5 µg/L; single air sample more than 2000 µg/L	17
Outside industrial plant; nickel carbonyl		
Acceptable	Less than 0.3 µg/L monthly average	17
Shut down plant	More than 1.0 µg/L monthly average	17
Safe		
Canada		
Soluble nickel compounds	Less than 0.1 mg/m ³	18
Sparingly soluble nickel compounds	Less than 1.0 mg/m ³	18
Nickel carbonyl	Less than 0.12 mg/m ³ (equivalent to less than 0.35 mg Ni(CO) ₄ /m ³)	18
Former Soviet Union		
Nickel metal, nickel monoxide and sulfide dust, soluble nickel compounds	Less than 0.5 mg/m ³	19
Nickel carbonyl	Less than 0.005 mg/m ³	19
Germany; nickel carbonyl	Less than 0.7 mg/m ³	19
Sweden; nickel metal	Less than 0.01 mg/m ³	19

Table 6.10 (continued) Proposed Nickel Criteria for Protection of Natural Resources and Human Health

Resource, Criterion, and Other Variables	Effective Nickel Concentration	Reference^a
United States		
Nickel carbonyl	Less than 0.007 mg/m ³	19
Nickel metal and relatively insoluble nickel compounds; 8 h daily, 40 h weekly	Less than 1.0 mg/m ³	6, 9, 19
Inorganic nickel in workplace (elemental and all nickel compounds except organonickel compounds with a covalent C-Ni bond, such as nickel carbonyl); 10-h work shift, 40-h workweek, over a working lifetime	Less than 0.015 mg/m ³	20, 25
Water soluble nickel compounds; 8 h daily, 40 h weekly	Less than 0.1 mg/m ³	9, 19
Oral, via diet and drinking water		
Safe chronic exposure via diet or drinking water; soluble nickel compounds	Less than 0.002 mg/kg BW daily	9
Diet; Australia; marine fish muscle; acceptable concentration	Less than 1.0 mg/kg FW	21
Drinking water		
Acceptable daily intake for 70-kg person (with a safety factor of 1000)	0.031 mg daily (equivalent to 0.443 µg/kg BW daily)	6
Concentrations developed for noncarcinogenic effects		
Daily intake, lifetime exposure, 70-kg adult (safety factor of 100)	Less than 350 µg/L	15
Daily intake, 10-day health advisory for 10-kg child (with safety factor of 100)	Less than 1.0 mg/L	15, 25
Daily intake, 10-day health advisory for 70-kg adult (with safety factor of 100)	Less than 3.5 mg/L	15, 25
Water containing edible fishery products		
From ingestion through water and nickel-contaminated fishery products	Less than 13.4 µg total recoverable Ni/L	6
From consumption of fish and shellfish products alone	Less than 101.0 µg/L	6
Tissue residues		
Plasma; total nickel; nickel workers; considered elevated	More than 11.9 µg/L	22
Serum; total nickel		
Normal	Less than 2.6 µg/L, excretion of 2.6 µg daily	22
Elevated (near nickel mine)	More than 4.6 µg/L, excretion of 7.9 µg daily	22
Urine; nickel carbonyl		
Mild exposure	Less than <0.1 mg/L during the first 8 h after exposure	22, 23
Significant exposure	More than 0.1 mg/L during the first 8 h after exposure	23
Urine; total nickel; nickel workers; considered elevated	More than 129 µg/L	22

^a 1, Beyer 1990; 2, Rutherford and Mellow 1994; 3, Nebeker et al. 1985; 4, Outridge and Scheuhammer 1993; 5, Enserink et al. 1991; 6, USEPA 1980; 7, Sreedevi et al. 1992a; 8, Nielsen et al. 1975a; 9, USPHS 1993; 10, Hausinger 1993; 11, Cain and Pafford 1981; 12, Jenkins 1980b; 13, WHO 1991; 14, Hughes et al. 1994; 15, USEPA 1985; 16, Stevens 1991; 17, NAS 1975; 18, NRCC 1981; 19, Sevin 1980; 20, USPHS 1977; 21, Sharif et al. 1993; 22, Norseth and Piscator 1979; 23, Norseth 1986; 24, Steyn et al. 1996; 25, USPHS 1995.

^b Elevated requirement may reflect increased use by rumen bacteria.

^c Based on no observable adverse effects during chronic exposure to diets containing 100 mg Ni (as soluble salts) per kg ration (= 5 mg Ni/kg BW daily) divided by uncertainty factor of 300.

6.9 SUMMARY

Nickel is found in air, soil, water, food, and household objects; ingestion or inhalation of nickel is common, as is dermal exposure. Recent estimates suggest that as much as 28,100 tons of nickel are introduced into the atmosphere each year from natural sources and as much as 99,800 tons from human activities. In the atmosphere, nickel is mostly suspended onto particulate matter. In natural waters, the dominant chemical species is Ni^{2+} in the form of $(\text{Ni}(\text{H}_2\text{O})_6)^{2+}$. In alkaline soils, the major components of the soil solution are Ni^{2+} and Ni(OH)^+ ; in acidic soils, the main solution species are Ni^{2+} , NiSO_4 , and NiHPO_4 .

Nickel is an essential micronutrient for maintaining health in certain species of plants and animals. Its deficiency effects from dietary deprivation have been induced experimentally in many species of birds and mammals. To prevent nickel deficiency in rats and chickens, diets should contain at least 50 μg Ni/kg ration, while cows and goats require more than 100 μg Ni/kg rations, perhaps reflecting the increased use by rumen bacteria. Nickel deficiency is not a public health concern for humans because daily oral intake is sufficient to prevent deficiency effects.

Nickel contamination from anthropogenic activities occurs locally from emissions of metal mining, smelting, and refining operations; combustion of fossil fuels; nickel plating and alloy manufacturing; land disposal of sludges, solids, and slags; and disposal as effluents. Nickel concentrations in living organisms and abiotic materials tend to be elevated in the vicinity of nickel smelters and refineries, nickel–cadmium battery plants, sewage outfalls, and coal ash disposal basins.

Adverse effects of excess nickel are documented for bacteria, algae, yeasts, higher plants, protozoans, molluscs, crustaceans, insects, annelids, echinoderms, fishes, amphibians, birds, and mammals. To protect terrestrial vegetation against decreased growth and other toxic effects, nickel concentrations in leaves should contain less than 50 mg Ni/kg DW (and in some cases less than 44 mg Ni/kg DW), growing soils should contain less than 250 mg Ni/kg DW (and in some cases <50 mg Ni/kg DW), and sewage sludge applied to agricultural soils should be limited to 30 to 140 kg Ni/surface ha at the low end and 50 to 560 kg/surface ha at the high end. To protect freshwater plants and animals against nickel, a proposed range of less than 25 to 96 μg total recoverable Ni/L is recommended by various authorities; however, certain species have reduced survival within this range. To protect marine organisms, the 24-h average for total recoverable nickel per liter should not exceed 7.1 $\mu\text{g}/\text{L}$ and the maximum concentration should not exceed 140 $\mu\text{g}/\text{L}$ at any time. However, certain marine organisms show adverse effects to as little as 30 μg Ni/L.

To protect young birds against adverse effects of excess nickel on their growth and survival, diets should contain less than 200 mg Ni/kg ration; diets of older birds should contain less than 800 mg Ni/kg ration. Nickel concentrations in avian tissues in excess of 10 mg/kg DW kidney or 3 mg/kg DW liver are sometimes associated with adverse effects.

Toxic effects of nickel to humans and laboratory mammals are documented for respiratory, cardiovascular, gastrointestinal, hematological, musculoskeletal, hepatic, renal, dermal, ocular, immunological, developmental, neurological, and reproductive systems. Nickel toxicity in mammals is governed by the chemical form of nickel, dose, and route of exposure. Mammalian exposure to nickel by inhalation or cutaneous contact was more significant than oral exposure. To protect humans and other mammals against respiratory effects, proposed air-quality criteria are 0.01 to less than 1.0 mg/m³ for metallic nickel and sparingly soluble nickel compounds and 0.005 to 0.7 mg/m³ for nickel carbonyl. Most species of mammals tested had normal growth and survival during chronic exposure to dietary nickel (equivalent to 0.8 to 40 mg Ni/kg BW daily) and reduced growth and survival when fed diets containing 500 to 2500 mg Ni/kg ration (equivalent to 10 to 50 mg Ni/kg BW daily). Proposed nickel criteria for sensitive species by way of the diet or drinking water now range from 2 to less than 443 μg total Ni/kg BW daily for soluble nickel compounds, less than 1.0 mg Ni/kg FW diet, and less than 350 μg Ni/L in drinking water. Nickel concentrations in human tissues now considered elevated include 4.6 $\mu\text{g}/\text{L}$ serum, 11.9 $\mu\text{g}/\text{L}$ plasma, and 100 to 129 $\mu\text{g}/\text{L}$ urine; comparable data for mammalian wildlife are lacking.

Some forms of nickel are carcinogenic to humans and animals, but only when exposure is by the respiratory route. Toxic and carcinogenic effects of nickel compounds are associated with nickel-mediated oxidative damage to DNA and proteins and to inhibition of cellular antioxidant defenses. Some nickel compounds are weakly mutagenic in a variety of test systems, but much of the evidence is inconclusive or negative. In mammals, no teratogenic effects of nickel compounds occur by way of inhalation or ingestion, except from nickel carbonyl. Inhaled nickel carbonyl results in comparatively elevated nickel concentrations in lung, brain, kidney, liver and adrenals, and is the most hazardous form of nickel.

Overall, nickel is not an immediate threat to the health of plants, animals, and humans at environmentally encountered levels, except in the case of nickel carbonyl, and progress has been made toward minimizing or eliminating occupational nickel exposure.

CHAPTER 7

Silver

7.1 INTRODUCTION

Silver (Ag) found in the body of mammals (including humans) has no known biological purpose and is suspected of being a contaminant (Smith and Carson 1977). Silver, as ionic Ag⁺, is one of the most toxic metals known to aquatic organisms in laboratory testing, although large industrial losses to the aquatic environment are probably infrequent because of its economic value as a recoverable resource (National Association of Photographic Manufacturers [NAPM] 1974; Nebeker et al. 1983). Silver, however, is of concern in various aquatic ecosystems because of the severity of silver contamination in the water column, sediments, and biota. San Francisco Bay, for example, is affected by discharges of silver in wastewater outfalls and by the diagenic remobilization of silver from contaminated sediments in the estuary (Luoma and Phillips 1988; Rivera-Duarte and Flegal 1993).

The principal industrial use of silver is as silver halide in the manufacture of photographic imaging materials; other products include jewelry, coins, indelible inks, and eating utensils (Klaassen et al. 1986). In medicine, silver salts are used as caustics, germicides, antiseptics, and astringents; the use of silver nitrate for prophylaxis of ophthalmia neonatorum in the eyes of newborn infants is a legal requirement in some states (Klaassen et al. 1986). Long-term industrial or medical exposure to silver and its compounds may increase blood concentrations of silver to levels which can have toxic effects, such as induction of sarcomas, anemia, and enlargement of the heart (Aoki et al. 1993). Repeated occupational handling of silver objects, especially after repeated minor injuries, may result in localized argyria — a bluish-gray discoloration of the skin at the exposed site (Fowler and Nordberg 1986). In humans, the most common noticeable effects of chronic exposure to silver and its compounds are generalized argyria, localized argyria, and argyrosis (argyria of the eye, usually; Smith and Carson 1977). Generalized argyria consists of a slate-gray pigmentation of the skin and hair caused by deposition of silver in the tissues, a silver coloration of the hair and fingernails, and a blue halo around the cornea and in the conjunctiva. Acute toxic effects in humans have resulted only from accidental or suicidal overdoses of medical forms of silver (Smith and Carson 1977).

Ecological and toxicological aspects of silver are reviewed by Smith and Carson (1977), the U.S. Environmental Protection Agency [USEPA] (1980, 1987), Lockhart (1983), the U.S. Public Health Service [USPHS] (1990), Andren et al. (1993, 1994), Andren and Bober (1995), Eisler (1996), Mukherjee (1997), and Ratte (1999).

7.2 SOURCES AND USES

7.2.1 General

About 2.47 million kg of silver are lost each year to the domestic biosphere, mostly (82%) as a result of human activities. As discussed later, the photography industry accounts for about 47% of all silver discharged into the environment from anthropogenic sources. In 1990, about 50% of the refined silver consumed domestically was used to manufacture photographic products; 25% in electrical and electronic products; 10% in electroplated ware, sterlingware, and jewelry; 5% in brazing alloys; and 10% in other products and processes.

7.2.2 Sources

Silver is a rare but naturally occurring metal, often found deposited as a mineral ore in association with other elements (USPHS 1990). Argentite is the main ore from which silver is extracted by cyanide, zinc reduction, or electrolytic processes (Fowler and Nordberg 1986). Silver is frequently recovered as a by-product from smelting of nickel ores in Canada, from lead-zinc and porphyry copper ores in the United States, and from platinum and gold deposits in South Africa (Smith and Carson 1977). About 12 to 14% of the domestic silver output is recovered from lead ores and about 4% from zinc ores. Secondary sources of silver comprise new scrap generated in the manufacture of silver-containing products; coin and bullion; and old scrap from electrical products, old film and photoprocessing wastes, batteries, jewelry, silverware, and bearings (Smith and Carson 1977).

Silver is produced in 68 countries, but most (75%) of the world's silver (excluding the former Soviet bloc) is mined in the United States, Mexico, Canada, Australia, and Japan. The United States produces about 50% of the world's supply of refined silver (Smith and Carson 1977). The primary silver mines of the United States are in the Coeur d'Alene mining district in the northern Idaho panhandle (USPHS 1990). Between 1949 and 1970, the United States consistently accounted for less than 15% of the global silver production and consumed 34 to 64% (Heyl et al. 1973). Since 1951, silver consumption in the United States has exceeded its extraction from ore (USPHS 1990). In 1979, about 95% of the silver in domestic production was from Idaho, Nevada, Arizona, Colorado, Utah, Montana, and Missouri (U.S. Bureau of Mines 1980). End-use categories of silver consumed domestically in 1979 included photography (39%), electrical and electronic components (25%), sterlingware and electroplated materials (15%), and brazing alloys and solders (8%). In 1979, the photographic industry was located mainly in New York, and most other end-use manufacturers were in Connecticut, New York, Rhode Island, and New Jersey (U.S. Bureau of Mines 1980).

World production of silver increased from 7.4 million kg in 1964 to 9.06 million kg in 1972 and to 9.67 million kg in 1982 (Fowler and Nordberg 1986). In 1986, 13.06 million kg of silver was produced globally; the United States produced 1.06 million kg in 1986 but consumed 3.94 million kg (USPHS 1990). In 1990, the estimated world mine production of silver was 14.6 million kg; major producers were Mexico with 17% of the total, the United States with 14%, Peru with 12%, the former Soviet Union with 10%, and Canada with 9% (Reese 1991). In the United States during 1990, about 160 mines produced silver worth an estimated value of \$320 million; most (71%) of the 1990 mine production was in Nevada (32%), Idaho (21%), Montana (11%), and Arizona (7%). In 1990, 22 major refiners of commercial grade silver and more than 5000 silver fabricating and manufacturing firms were located primarily in the northeastern states. Of the silver imported into the United States in 1990, 44% came from Mexico, 34% from Canada, 5% from Peru, and 4% from Chile. Most was exported after transformation to sterlingware, coinage, and other finished products. Melting and refining old scrap silver in 1990 accounted for 500,000 kg of silver (Reese 1991).

Table 7.1 Estimated Release of Silver to the Environment in the United States in 1978

Compartment and Source Category	Metric Tons ^a
ATMOSPHERE	
Metals production	30
Urban refuse combustion	10
Coal and petroleum combustion	9
Iron and steel production	7
Cloud seeding	3

Alloys and solders	60
Other	5

^a Of the total silver released to the domestic environment in 1978 (2,470,700 kg), about 3.7% entered the atmosphere, 28.5% the aquatic environment, and 67.8% the terrestrial ecosystem.

Data from U.S. Public Health Service (USPHS). 1990. Toxicological profile for silver. *Agen. Toxic Subs. Dis. Reg.* TP-90-24. 145 pp.; Purcell, T.W. and J.J. Peters. 1998. Sources of silver in the environment. *Environ. Toxicol. Chem.* 17:539-546.

Emissions from smelting operations, manufacture and disposal of certain photographic and electrical supplies, coal combustion, and cloud seeding are some of the anthropogenic sources of silver in the biosphere (Freeman 1979). Fallout from cloud seeding with silver iodide is not always confined to local precipitation; silver residuals have been detected several hundred kilometers downwind of seeding events (Freeman 1979). In 1978, the estimated loss of silver to the environment in the United States was 2.47 million kg, mostly to terrestrial and aquatic ecosystems; the photography industry alone accounted for about 47% of all silver discharged into the environment from anthropogenic sources (Smith and Carson 1977; Table 7.1). In California, anthropogenic sources contributed 50% more silver to sediments of coastal basins than natural sources, as judged by sedimentary basin fluxes of $0.09 \mu\text{g}/\text{cm}^2$ in anthropogenic sources of silver and $0.06 \mu\text{g}/\text{cm}^2$ in natural sources (Bruland et al. 1974). Sometimes, liquid effluents from the nuclear industry contained significant quantities of radiosilver-110m (Berthet et al. 1992). In Lake Michigan, storms contribute a large fraction of the annual load of tributary-derived silver; concentrations of particle-bound silver in many rivers during storms were more than $0.1 \mu\text{g}/\text{L}$ (Shafer et al. 1995).

Most of the silver lost to the environment each year enters terrestrial ecosystems, where it is immobilized in the form of minerals, metal, or alloys; agricultural lands may receive as much as 80,000 kg of silver from photoprocessing wastes in sewage sludge. An estimated 150,000 kg of silver enter the aquatic environment every year from the photography industry, mine tailings, and electroplaters (Smith and Carson 1977). During processing of photographic paper and film, silver is generally solubilized as the tightly bound thiosulfate complex. Silver thiosulfate in secondary biological waste treatment plants is converted to insoluble silver sulfide, which is removed in the sludge; only trace amounts of complexed and adsorbed silver are discharged into the aquatic environment. The silver incorporated into the sludge is immobile and should not restrict the use of sludge for the enrichment of soils (Dagon 1973; Bard et al. 1976; Cooley et al. 1988). The atmosphere receives 300,000 kg of silver each year from a variety of sources, but atmospheric concentrations are not known to exceed the occupational threshold limit value of 10 µg total Ag/m³ (Smith and Carson 1977).

Daily intake of total silver from all sources by humans in the United States ranged from 70 to 88 µg; diet accounted for 35 to 40 µg daily (USEPA 1980). Sources of elevated dietary silver include seafood from areas near sewage outfalls or industrial sources and crops grown in areas with high ambient levels of silver in the air or soil (USPHS 1990). Most occupational exposures to silver occur through inhalation of silver-containing dusts or dermal exposure to photographic compounds. Dermal routes of human exposure to silver include handling of silver-containing processing solutions used in radiographic and photographic materials, dental amalgams, and silver sulfadiazine cream and solutions for treating burns (USPHS 1990).

7.2.3 Uses

Silver was used for ornaments and utensils for almost 5000 years, and as a precious metal, a monetary medium, and a basis of wealth for more than 2000 years. Until the late 1960s, it was used extensively for coinage (Heyl et al. 1973). Since 1970, U.S. coinage has not contained silver, although minting of as many as 45 million silver-clad subsidiary coins has been authorized (Smith and Carson 1977). Industrial consumption of silver in the United States between 1966 and 1972 totaled 4.67 million kg, primarily in the manufacture of photographic materials, electrical contacts and conductors, and sterlingware (Table 7.2). In 1973, silver was used mainly in photographic materials (29%), electrical and electronic components (22%), sterlingware (20%), electroplated ware (10%), brazing wares (20%), dental and medical products, catalysts, bearings, and jewelry (9%; Heyl et al. 1973). In 1986, photographic materials accounted for 45% of the silver consumption in the United States; electrical and electronic components, 25%; jewelry, sterlingware, and electroplated ware, 11%; alloys and solders, 5%; and mirrors, dental amalgam, medical supplies, chemicals, water purification, and cloud seeding, 14% (USPHS 1990). Silver, as silver iodide, is used in the United States for weather modification including rain and snow making and hail suppression; as much as 3110 kg of silver is used for this purpose annually (Smith and Carson 1977). Silver nitrate in hair dyes has been in use regularly for almost 200 years (USEPA 1980), even though its use may lead to argyria (Smith and Carson 1977). In 1990, about 50% of the refined silver consumed domestically was used to manufacture photographic and X-ray products; 25% in electrical and electronic products; 10% in electroplated ware, sterlingware, and jewelry; 5% in brazing alloys; and 10% in other uses (Reese 1991).

Because of its bacteriostatic properties, silver compounds are used in filters and other equipment to purify the water in swimming pools and drinking water, and in the processing of foods, drugs, and beverages (Smith and Carson 1977; USEPA 1980; USPHS 1990). Activated charcoal filters coated with metallic silver to yield water concentrations of 20 to 40 µg Ag/L are used in filtering systems of swimming pools to control bacteria (USEPA 1980). Silver may also function as an algicide in swimming pools if chlorine, bromine, and iodine are absent; it prevents growth of blue-green algae at 80 to 140 µg Ag/L (Smith and Carson 1977). Aboard orbiting Russian space stations

Table 7.2 Industrial Domestic Use of Silver During 1966–72 (Total silver used was 4.67 million kg)

Category	Percent of Total
Photographic materials	28.1
Contacts and conductors	20.2

Smith, I.C. and B.L. Carson. 1977. *Trace Metals in the Environment*. Volume 2. *Silver*. Ann Arbor Sci. Publ., Ann Arbor, MI. 469 pp.

and spaceships, potable water is routinely treated with 100 to 200 µg Ag/L to eliminate microorganisms; sterilization is usually complete in 20 min (Smith and Carson 1977). Silver-containing ceramic water filters are used to purify potable water in Swiss ski resorts, German breweries, British ships, oil tankers, drilling rigs, U.S. home consumption, and more than half the world's airlines. Monovalent and metallic silver compounds are considered excellent disinfectants; however, Ag²⁺ and Ag³⁺ are about 50 to 200 times more effective than Ag⁺ or Ag⁰ (Antelman 1994), possibly because of their higher oxidation states (Kirschenbaum 1991).

Silver nitrate was used for many years as eye drops in newborns to prevent blindness caused by gonorrhea (USPHS 1990). Laws in many states still require that a few drops of a 1 to 2% silver nitrate solution be applied to the conjunctiva of the eyes of newborn infants to prevent ophthalmia neonatorum by transmittal of gonorrhea from the mother (USEPA 1980; USPHS 1990). This treatment is still required in Denmark but no longer in Japan or Australia (USEPA 1980). Silver nitrate is not used in many U.S. hospitals because of the dangers of chemical conjunctivitis and has been replaced by antibiotics (USEPA 1980). In the United States, several silver-containing pharmaceuticals were used topically on skin or mucous membranes to assist in healing burn patients and to combat skin ulcers (Smith and Carson 1977; USEPA 1980). Oral medicines containing silver include silver acetate-containing antismoking lozenges; breath mints coated with silver; and silver nitrate solutions for treating gum disease (USPHS 1990). The widespread medical use of silver compounds for topical application to mucous membranes and for internal use has become nearly obsolete in the past 50 years because of the fear of argyria and the development of sulfonamide and antibiotic microbials (Smith and Carson 1977).

7.3 CHEMISTRY AND METABOLISM

7.3.1 General

Silver occurs naturally in several oxidation states, the most common being elemental silver (Ag⁰) and the monovalent ion (Ag⁺). Soluble silver salts are, in general, more toxic than insoluble salts. In natural waters, the soluble monovalent species is the form of environmental concern. Sorption is the dominant process that controls silver partitioning in water and its movements in soils and sediments. As discussed later, silver enters the animal body through inhalation, ingestion, mucous membranes, and broken skin. The interspecies differences in the ability of animals to accumulate, retain, and eliminate silver are large. Almost all of the total silver intake is usually

Table 7.3 Some Properties of Silver and Silver Nitrate

Variable	Silver	Silver Nitrate
Alternate names	Argentum, argentum crede Cl 77820, shell silver, silver atom, silver colloidal, silflake, silpowder, silver	Lunar caustic fused silver nitrate, molded silver nitrate argenti, nitratas, nitric acid silver (I) salt, nitric acid silver (1+) salt, silver (1+) nitrate
CAS number	7440-22-4	7761-88-8
Chemical formula	Ag	AgNO_3
Molecular weight	107.87	169.89
Physical state	Solid metal	Solid crystalline
Boiling point	2212°C	Decomposes at 440°C
Solubility	Insoluble in water; soluble in nitric acid but not sulfuric acid	Soluble in water to 1220 g/L; soluble in ethanol and acetone
Density	10.5	4.35

Data from Lockhart, H.B., Jr. 1983. Silver compounds. Pages 16–32 in *Encyclopedia of Chemical Technology*, 3rd ed. John Wiley & Sons, NY. U.S. Public Health Service (USPHS). 1990. Toxicological profile for silver. *Agen. Toxic Subs. Dis. Reg.* TP-90-24. 145 pp.

excreted rapidly in feces; less than 1% of the total silver intake is absorbed and retained in tissues, primarily liver, through precipitation of insoluble silver salts. In mammals, silver usually interacts antagonistically with selenium, copper, and Vitamin E; in aquatic environments, ionic or free silver interferes with calcium metabolism in frogs and marine annelids and with sodium and chloride uptake in gills of fishes.

7.3.2 Physical and Chemical Properties

Silver is a white, ductile metal occurring naturally in its pure form and in ores (USEPA 1980). Silver has the highest electrical and thermal conductivity of all metals. Some silver compounds are extremely photosensitive and are stable in air and water, except for tarnishing readily when exposed to sulfur compounds (Heyl et al. 1973). Metallic silver is insoluble in water, but many silver salts, such as silver nitrate, are soluble in water to more than 1220 g/L (Table 7.3). In natural environments, silver occurs primarily in the form of the sulfide or is intimately associated with other metal sulfides, especially those of lead, copper, iron, and gold, which are all essentially insoluble (USEPA 1980; USPHS 1990). Silver readily forms compounds with antimony, arsenic, selenium, and tellurium (Smith and Carson 1977). Silver has two stable isotopes (^{107}Ag and ^{109}Ag) and 20 radioisotopes; none of the radioisotopes of silver occurs naturally, and the radioisotope with the longest physical half-life (253 days) is $^{110\text{m}}\text{Ag}$. Several compounds of silver are potential explosion hazards: silver oxalate decomposes explosively when heated; silver acetylide (Ag_2C_2) is sensitive to detonation on contact; and silver azide (AgN_3) detonates spontaneously under certain conditions (Smith and Carson 1977).

Silver occurs naturally in several oxidation states, usually as Ag^0 and Ag^+ ; other possible oxidation states of silver are Ag^{2+} and Ag^{3+} (USPHS 1990). In surface freshwater, silver may be found as the monovalent ion; in combination with sulfide, bicarbonate, or sulfate; as part of more complex ions with chlorides and sulfates; and adsorbed onto particulate matter (USPHS 1990). In the aqueous phase, silver at the lowest concentrations exists as either a simple AgSH or as a simple polymer $\text{HS}-\text{Ag}-\text{S}-\text{Ag}-\text{SH}$ (Bell and Kramer 1999). At higher concentrations, colloidal Ag_2S or polysulfide complexes are formed. Silver^+ binds strongly with sulfur $^{2-}$ in inorganic and organic species, resulting in ng/L aqueous dissolved concentrations (Bell and Kramer 1999). Trace levels of dissolved silver in the presence of ferric sulfide are rapidly adsorbed and silver remaining in solution remains as acanthite (Ag_2S); however, silver thiolate complexes can be the dominant dissolved species in highly contaminated waters near urban centers or in waters with high levels of natural organic matter (Adams and Kramer 1998). The most important and crucial aspect of silver thiolate chemistry is the rapid exchange of Ag^+ among thiolates whereby Ag^+ can transfer

onto, or off, particulate materials or the cells of an organism. Silver thiolates also react rapidly with H_2S or HS^- as ligands to form Ag_2S , although the reverse process is slow (Bell and Kramer 1999). Soluble silver salts are more toxic than insoluble salts, and soluble silver ion (Ag^+) is the most toxic chemical species. In natural waters, the soluble monovalent species is the form of environmental concern (USEPA 1980). The argentous ion (Ag^+) does not hydrolyze appreciably in solution and is considered to be a mild oxidizing agent (Smith and Carson 1977). Hypervalent silver species, such as Ag^{2+} and Ag^{3+} , are significantly more effective as oxidizing agents than Ag^0 and Ag^+ (Kouadio et al. 1990; Kirschenbaum 1991; Sun et al. 1991) but are unstable in aqueous environments, especially at water temperatures near 100°C (Smith and Carson 1977). In natural waters, silver may exist as metalloorganic complexes or be adsorbed to organic materials (USEPA 1980). In freshwater and soils, the primary silver compounds under oxidizing conditions are bromides, chlorides, and iodides; under reducing conditions, the free metal and silver sulfide predominates (USPHS 1990). In river water, one study showed silver present as the monovalent ion (Ag^+) at 53 to 71% of the total silver, as silver chloride (AgCl) at 28 to 45%, and as silver chloride ion (AgCl_2^-) at 0.6 to 2.0% (USPHS 1990). Increasing salinity of brackish and marine waters increased concentrations of silver chloro complexes (AgCl^0 , AgCl_2^- , AgCl_3^{2-} , AgCl_4^{3-}); these chloro complexes retain some silver in dissolved form, and relatively small anthropogenic quantities can substantially enrich the environment (Luoma 1994; Andren et al. 1995). In the open ocean, the principal dissolved form of silver is AgCl_2^- , but the most bioavailable form may be the neutral monochloro complex AgCl (Bryan and Langston 1992).

Sorption is the dominant process that controls silver partitioning in water and its movement in soils and sediments (USEPA 1980; USPHS 1990). Silver may leach from soils into groundwater; the leaching rate increases with decreasing pH and increasing drainage (USPHS 1990). Silver adsorbs to manganese dioxide, ferric compounds, and clay minerals, and these compounds are involved in silver deposition into sediments; sorption by manganese dioxide and precipitation with halides reduce the concentration of dissolved silver, resulting in higher concentrations in sediments than in the water column (USEPA 1980). Under reducing conditions, adsorbed silver in sediments may be released and subsequently reduced to metallic silver, or it may combine with reduced sulfur to form the insoluble silver sulfide (USEPA 1980). Sediments may be a significant source of silver to the water column. In one study, anoxic sediments containing 1.0 to 27.0 grams of silver/kg DW and 10 mmoles of acid volatile sulfide/kg DW were resuspended in oxygenated seawater for several hours to days. The seawater in contact with sediment containing 10.8 g/kg had 20 µg Ag/L; seawater in contact with sediments containing 27 g Ag/kg had about 2000 µg Ag/L, which seems to be the solubility of silver in seawater (Crecelius and Phillips 1995).

The global biogeochemical movements of silver are characterized by releases to the atmosphere, water, and land by natural and anthropogenic sources, long-range transport of fine particles in the atmosphere, wet and dry deposition, and sorption to soils and sediments (USPHS 1990). The chief source of silver contamination of water is silver thiosulfate complexes in photographic developing solutions that photofinishers discard directly to sewers (Smith and Carson 1977). Secondary waste treatment converts most of the silver thiosulfate complex to insoluble silver sulfide and forms some metallic silver (Lytle 1984). About 95% of the total silver is removed in publicly owned treatment works from inputs containing municipal sewage and commercial photoprocessing effluents; effluents usually contained less than 0.07 µg ionic silver/L and concentrations were independent of the influent silver concentration (Lytle 1984; Shafer et al. 1998). Silver in sewage treatment plant effluents may be associated with suspended particles or be present as thiosulfate complex, colloidal silver complex, colloidal silver chloride, silver sulfide, or soluble organic complexes (Smith and Carson 1977). Silver on suspended matter and in colloidal forms and insoluble salts ultimately settles out in the sediments. At the water treatment plant, most of the silver is precipitated after treatment with lime or adsorbed after treatment with alum-flocculent. Chlorination converts some silver to silver chloride or to a soluble silver chloride complex (Smith and Carson 1977). Aerobic biodegradation of a photoprocessing wastewater containing 1.85 mg total Ag/L did not adversely

affect the activated sludge process (Pavlostathis and Maeng 1998). Practically all silver became associated with the sludge solids at 1840 mg Ag/kg mixed liquor suspended solids. When fresh sludge and aerobically digested sludge solids were subjected to leaching procedures, the resulting silver concentration was at least 40 times lower than the regulatory limit of 5 mg/L (Pavlostathis and Maeng 1998).

Forms of silver in atmospheric emissions are probably silver sulfide, silver sulfate, silver carbonate, silver halides, and metallic silver (Smith and Carson 1977). About 50% of the silver released into the atmosphere from industrial operations is transported more than 100 km and is eventually deposited in precipitation (USPHS 1990). Minute amounts of ^{110m}Ag have been detected in natural waters and are attributed to atmospheric fallout from nuclear explosions (Smith and Carson 1977).

A variety of spectrographic, colorimetric, polarographic, and other analytical techniques are used for routine measurement of silver in biological and abiotic samples. The detection limit of silver in biological tissues with scanning electron microscopy and X-ray energy spectrometry is 0.02 $\mu\text{g}/\text{kg}$ and sometimes as low as 0.005 $\mu\text{g}/\text{kg}$. In air, water, and soil samples, the preferred analytical procedures include flame and furnace atomic absorption spectrometry, plasma emission spectroscopy, and neutron activation (Fowler and Nordberg 1986; USPHS 1990). Sensitive anodic stripping voltammetry techniques have recently been developed to measure free silver ion in surface waters at concentrations as low as 0.1 $\mu\text{g}/\text{L}$ (Schildkraut 1993; Song and Osteryoung 1993; Schildkraut et al. 1998).

7.3.3 Metabolism

The acute toxicity of silver to aquatic species varies drastically by the chemical form and correlates with the availability of free ionic silver (Wood et al. 1994). In natural aquatic systems, ionic silver is rapidly complexed and sorbed by dissolved and suspended materials that are usually present. Complexed and sorbed silver species in natural waters are at least one order of magnitude less toxic to aquatic organisms than the free silver ion (Rodgers et al. 1994; Ratte 1999). Thus, silver nitrate — which is strongly dissociated — is extremely toxic to rainbow trout (*Oncorhynchus mykiss*); the 7-day LC₅₀ value is 9.1 $\mu\text{g}/\text{L}$. Silver thiosulfate, silver chloride, and silver sulfide were relatively benign (7-day LC₅₀ values >100,000 $\mu\text{g}/\text{L}$), presumably due to the abilities of the anions to remove ionic silver from solution (Wood et al. 1994, 1996b; Hogstrand et al. 1996).

For freshwater fish, the acute toxicity of silver is caused solely by Ag^+ , interacting at the gills, inhibiting basolateral Na^+ , K^+ -ATPase activity. Disruption of this enzyme inhibits active Na^+ and Cl^- uptake and, therefore, osmoregulation by the fish (Wood et al. 1999). The primary toxic mechanism of silver in rainbow trout is the interruption of ionic regulation at the gills, stopping active Na^+ and Cl^- uptake without increasing passive efflux, thereby causing net ion loss (Webb and Wood 1998). However, concentrations of silver in the gills of rainbow trout did not correlate to Ag^+ concentrations in the medium, and no correlation was found between gill silver levels and either Na^+ influx rates or gill Na^+/K^+ ATPase activity (Bury et al. 1999b). Morgan et al. (1995) suggest that the sites of action of silver toxicity in rainbow trout may be inside the cells of the gill epithelium rather than at the external surface and linked to carbonic anhydrase — a gill enzyme involved in Na^+ and Cl^- transport. Silver concentrations and metallothionein levels in gills and livers of rainbow trout increased with increasing exposure to silver; internal toxicity associated with increased silver accumulations may be lessened by the formation of silver-induced metallothioneins (Hogstrand et al. 1996). A key toxic effect of Ag^+ in freshwater is the inhibition of branchial Na^+ , K^+ -ATPase activity, which leads to blockade of active Na^+ and Cl^- across the gills; increased metabolic ammonia production and internal buildup occur as part of this acute stress syndrome (Hogstrand and Wood 1998). The probable cause of hyperventilation in rainbow trout exposed to silver nitrate was a severe metabolic acidosis manifested in decreased arterial plasma pH and HCO_3^- levels. Lethality of ionic silver to trout is probably due to surface effects at the gills — disrupting Na^+ , Cl^- , and H^+ — causing secondary fluid volume disturbance, hemoconcentration, and eventual cardiovascular collapse (Wood et al. 1994, 1995, 1996a, 1996b). Acidosis in rainbow

trout — due to a net uptake of acidic equivalents from the water — in the intracellular compartment accounts for the continual loss of K⁺ to the water in the absence of any change in plasma K⁺ (Webb and Wood 1998).

In seawater, silver nitrate is less toxic than in freshwater (Wood et al. 1995; Wood et al. 1999). This difference is probably due to the low concentration of free Ag⁺ (the toxic moiety in freshwater) in seawater, the high levels of chloride, and the predominance of negatively charged silver-chloro complexes. However, high levels of silver nitrate are toxic to marine invertebrates despite the absence of Ag⁺, and this is attributed to the bioavailability of stable silver-chloro complexes (Wood et al. 1995; Ratte 1999). In seawater, in contrast to freshwater, plasma Na⁺ and Cl⁻ rise rather than fall, and death may result from the elevated Na⁺ and Cl⁻ concentrations combined with dehydration (Hogstrand and Wood 1998). Osmoregulatory failure occurs in marine teleosts exposed to high concentrations of Ag⁺, and the intestine is the main toxic site of action (Wood et al. 1999).

Ionic silver interferes with calcium metabolism of frogs and marine polychaete worms. Silver ions cause muscle fibers of frogs (*Rana* spp.) to deteriorate by allowing excess calcium to enter the cell. Studies with frog skeletal muscle fibers exposed to 1.08 mg/L showed that silver activated the calcium ion channel by acting on sulfhydryl groups in a calcium ion channel protein (Aoki et al. 1993). In marine polychaetes contaminated with silver, the calcium content of nephridial cells was reduced, although silver was not detected in the calcium vesicles (Koechlin and Grasset 1988). Silver binds with protein sulfhydryl groups, and this process protects the worm against silver poisoning (Koechlin and Grasset 1988). In marine molluscs, however, sulfide anion was the ligand of silver (Truchet et al. 1990). In marine gastropods (*Littorina littorea*), silver was stored in the basement membranes of the digestive system; in clams (*Scrobicularia plana*), it was stored in the basement membrane of the outer fold of the mantle edge and in the amoebocytes (Truchet et al. 1990). The availability of free silver in marine environments was strongly controlled by salinity because of the affinity of silver for the chloride ion (Sanders et al. 1991). Silver sorbs readily to phytoplankton and to suspended sediments. As salinity increases, the degree of sorption decreases. Nearly 80% of silver sorbed to suspended sediments at low salinities desorb at higher salinities, but desorption does not occur when silver is associated with phytoplankton. Thus, silver incorporation in or on cellular material increases the retention of silver in the estuary, reducing the rate of transport (Sanders and Abbe 1987).

Silver may enter the body of mammals through inhalation, ingestion, mucous membranes, or broken skin (Smith and Carson 1977; USEPA 1980; Klaassen et al. 1986; USPHS 1990). In most cases of occupational argyrosis, absorption occurs via the respiratory tract or at the eyes (Smith and Carson 1977; USEPA 1980). Silver is retained by all body tissues; tissue concentrations are related to the dose, form of administered silver, and route of exposure. Silver also accumulates in mammalian tissues with increasing age of the individual, even if none is administered intentionally. Inside the body, silver is transported mainly in the protein fractions of plasma, presumably as silver albuminate or silver chloride (Smith and Carson 1977; USEPA 1980). In mammals, the highest concentrations of silver are usually found in the liver and spleen and to some extent in the muscles, skin, and brain (Fowler and Nordberg 1986). The primary sites of silver deposition in the human body are the liver, skin, adrenals, lungs, muscle, pancreas, kidney, heart, and spleen. Silver is also deposited in blood vessel walls, the trachea, and bronchi (Smith and Carson 1977). Dogs exposed to silver by inhalation accumulated most of the administered dose in the liver; concentrations in the lung, brain, skin, and muscle were lower (USEPA 1980; Fowler and Nordberg 1986). Intravenous injection of silver produces accumulations in the spleen, liver, bone marrow, lungs, muscle, and skin (Klaassen et al. 1986). Intestinal absorption of silver by rodents, canids, and primates has been recorded at 10% or less after ingestion of radioactive silver; a value of 18% was estimated in a single human given radiosilver acetate (USEPA 1980; Klaassen et al. 1986), and about 3 to 10% of the absorbed silver is retained in the tissues (Smith and Carson 1977). In a human given radioactive silver, more than 50% of the whole-body burden of silver was found in the liver after 16 days (Fowler and Nordberg 1986).

Deposition of silver in tissues of warm-blooded animals results from precipitation of relatively insoluble silver salts, such as silver chloride and silver phosphate (USPHS 1990). These insoluble salts may be transformed into soluble silver sulfide albuminates that bind or complex with RNA, DNA, and proteins, or they may be reduced to metallic silver by ascorbic acid or catecholamines. In humans with argyria, the blue or gray skin discoloration is caused by the photoreduction of silver chloride to metallic silver during exposure to ultraviolet light. Metallic silver, in turn, is oxidized and bound as black silver sulfide (USPHS 1990). Silver sulfide (Ag_2S) is localized in extracellular structures such as basement membranes and in macrophageous cells (Baudin et al. 1994). Before storage as a stable mineral combination, silver binds to proteins that contain a large proportion of sulfhydryl groups such as metallothioneins (Fowler and Nordberg 1986). The last stage in the catabolic pathway of these proteins leads to storage of silver after reaction with a sulfur ligand (Baudin et al. 1994). These mechanisms explain why liver, the most important organ for protein synthesis, shows the highest capacity for silver accumulation. High concentrations of silver in the digestive tract are linked to the numerous basement membranes contained in its tissues. Interspecies differences in the ability to accumulate, retain, and eliminate silver are large (Baudin et al. 1994).

The enzyme-inhibiting action of silver ions may be due to the binding of sulfhydryl groups of some enzymes. Binding, in certain enzymes, is probably at a histidine imidazole group; in the case of glucose oxidase, silver ions compete with molecular oxygen as a hydrogen acceptor (Smith and Carson 1977). About 60% of the silver in liver and kidneys of silver-injected rats were in the cytosol fractions bound to the high-molecular-weight proteins and metallothionein fractions; however, in spleen and brain only 30% of the total tissue silver was found in the cytosol fractions (Fowler and Nordberg 1986). At moderate doses (0.4 mg Ag/kg BW) in rats, the liver handles most of the absorbed silver from the body in the bile; at higher doses, silver deposits are markedly increased in the skin (USEPA 1980). In house sparrows (*Passer domesticus*), a silver-binding protein was identified in liver after radiosilver-110m injection; the protein was heat-stable, resistant to low pH, and of low molecular weight (Kumar and Bawa 1979). The properties of the hepatic silver-binding protein in birds were similar to other studied metallothioneins, but more research is needed to distinguish differences from mammalian metallothioneins (Kumar and Bawa 1979).

Most absorbed silver is excreted into the intestines by way of the liver into the bile and subsequently excreted in feces; urinary excretion of silver is generally very low (USEPA 1980; Fowler and Nordberg 1986; Klaassen et al. 1986; USPHS 1990). Rodents, monkeys, and dogs given radioactive silver salts by oral and other routes excreted more than 90% of the absorbed dose in the feces (Fowler and Nordberg 1986). Rats injected intravenously with radioactive silver nitrate excreted silver in bile mainly bound to a low-molecular-weight complex similar to glutathione (Fowler and Nordberg 1986). Excretion was faster, and percentages excreted by mice, rats, monkeys, and dogs were larger when silver was administered orally than by intravenous or intraperitoneal injection (Smith and Carson 1977).

Among mammals, low doses of ingested silver were eliminated from the body within 1 week (USPHS 1990). In rats, mice, and rabbits, about 99% of a single oral dose of silver was eliminated within 30 days (USEPA 1980). Time for 50% clearance of silver in rats, mice, monkeys, and dogs after oral ingestion was about 1 day; this short half-time is due, in part, to fecal elimination of unabsorbed silver. The half-times were longer (1.8 to 2.4 days) after intravenous injection (Fowler and Nordberg 1986). Rodents dosed with silver accumulated high initial concentrations in the liver, which greatly decreased within 10 days; however, silver concentrations in spleen and brain were retained for longer periods. The biological half-time of radiosilver in rats given a single intraperitoneal injection was 40 h in whole blood, plasma, kidney, and liver; 70 h in spleen; and 84 h in brain. After exposure by inhalation, dogs cleared 59% of an administered dose of radiosilver-110m from the lungs in 1.7 days and from the liver in 9 days (Fowler and Nordberg 1986). The mean daily intake of silver in humans is about 88 µg; about 60 µg is excreted daily in the feces (Smith and Carson 1977). In humans, the whole-body effective half-time of persistence was 43 days.

(USEPA 1980). The biological half-time of silver in the lungs of an exposed person was about 1 day; in liver it was 52 days (Fowler and Nordberg 1986). In humans, 80% of the retained silver in lung was cleared in about 1 day; 50% of the remainder was usually cleared in 3 days (USEPA 1980). In persons who had accidentally inhaled radiosilver-110m, most of the inhaled silver had a half-time persistence of about 1 day, probably because of rapid mucociliary clearance, swallowing, and fecal excretion; most of the absorbed radiosilver translocated to the liver (USEPA 1980).

Silver interacts competitively with selenium, Vitamin E, and copper and induces signs of deficiency in animals fed adequate diets or aggravates signs of deficiency when diets were lacking one or more of these nutrients; antagonistic effects of silver have been described in dogs, pigs, rats, sheep, chicks, turkey poult, and ducklings (USEPA 1980). Conversely, the addition of selenium, copper, or Vitamin E to diets of turkey poult decreased the toxicity of diets containing 900 mg Ag/kg (Fowler and Nordberg 1986). Dietary administration of silver acetate antagonized selenium toxicity; silver prevented growth depression and death in chicks fed diets containing excess selenium (USEPA 1980). The addition of selenium to the diets of rats exposed to silver in drinking water prevented growth retardation but increased the concentration of silver in liver and kidneys (Fowler and Nordberg 1986). Silver deposits in rat liver, kidneys, and other internal organs were in the form of sulfides; under high selenium exposure, the sulfur can be replaced with selenium (USPHS 1990) and formation of silver selenide deposits in the liver may be considered a silver detoxification process (USEPA 1980).

7.4 CONCENTRATIONS IN FIELD COLLECTIONS

7.4.1 General

Silver is comparatively rare in the earth's crust — 67th in order of natural abundance of the elements; the crustal abundance is an estimated 0.07 mg/kg and predominantly concentrated in basalt (0.1 mg/kg) and igneous rocks (0.07 mg/kg; Heyl et al. 1973). Silver concentrations in nonbiological materials tend to be naturally elevated in crude oil and in water from hot springs and steam wells. Anthropogenic sources associated with the elevated concentrations of silver in nonliving materials include smelting, hazardous waste sites, cloud seeding with silver iodide, metals mining, sewage outfalls, and especially the photoprocessing industry. Silver concentrations in biota were greater in organisms near sewage outfalls, electroplating plants, mine wastes, and silver-iodide seeded areas than in conspecifics from more distant sites.

7.4.2 Nonbiological Materials

Maximum concentrations of total silver recorded in selected nonbiological materials were 36.5 ng/m³ in air near a smelter in Idaho; 2 µg/m³ in atmospheric dust; 0.1 µg/L in oil well brines; 6 µg/L in groundwater near a hazardous waste site; 8.9 µg/L in seawater from Galveston Bay, Texas; 260 µg/L in the Genesee River, New York — the recipient of photoprocessing wastes; 300 µg/L in steam wells; 300 µg/L in treated photoprocessing wastewaters; 4500 µg/L in precipitation from clouds seeded with silver iodide; 31 mg/kg in some Idaho soils; 43 mg/L in water from certain hot springs; 50 mg/kg in granite; as much as 100 mg/kg in crude oils; 150 mg/kg in some Genesee River sediments; and 27,000 mg/kg in some solid wastes from photoprocessing effluents ([Table 7.4](#)). It is emphasized that only a small portion of the total silver in each of these compartments is biologically available. For example, typical publicly owned treatment works receiving photoprocessing effluents show silver removal efficiencies greater than 90%; the mean concentration of free silver ion present in the effluents from these plants ranged from 0.001 to 0.07 µg/L (Lytle 1984; Bober et al. 1992).

^b 1, USEPA 1980; 2, USPHS 1990; 3, Smith and Carson 1977; 4, Freeman 1979; 5, Fowler and Nordberg 1986; 6, Connell et al. 1991; 7, Bryan and Langston 1992; 8, Morse et al. 1993; 9, Berrow 1991; 10, Bloom and Crecelius 1987; 11, NAPM 1974.

Silver is usually found in extremely low concentrations in natural waters because of its low crustal abundance and low mobility in water (USEPA 1980). One of the highest silver concentrations recorded in freshwater (38 µg/L) occurred in the Colorado River at Loma, Colorado, downstream of an abandoned gold–copper–silver mine, an oil shale extraction plant, a gasoline and coke refinery, and a uranium processing facility (USEPA 1980). The maximum recorded value of silver in tapwater in the United States was 26 µg/L — significantly higher than finished water from the treatment plant (maximum of 5.0 µg/L) — because of the use of tin–silver solders for joining copper pipes in the home, office, or factory (USEPA 1980).

In general, silver concentrations in surface waters of the United States decreased between 1970–74 and 1975–79, although concentrations increased in the north Atlantic, Southeast, and lower Mississippi basins (USPHS 1990). About 30 to 70% of the silver in surface waters may be ascribed to suspended particles (Smith and Carson 1977), depending on water hardness or salinity. For example, sediments added to solutions containing 2 µg Ag/L had 74.9 mg Ag/kg DW sediment after 24 h in freshwater, 14.2 mg/kg DW at 1.5% salinity and 6.9 mg/kg DW at 2.3% salinity (Sanders and Abbe 1987). Riverine transport of silver to the ocean is considerable: suspended materials in the Susquehanna River, Pennsylvania — that contained as much as 25 mg silver/kg — resulted in an estimated transport of 4.5 metric tons of silver to the ocean each year (USEPA 1980). The most recent measurements of silver in rivers, lakes, and estuaries using clean techniques show levels of about 0.01 µg/L for pristine, nonpolluted areas and 0.01 to 0.1 µg/L in urban and industrialized areas (Ratte 1999).

Emissions of silver from coal-fired power plants may lead to accumulations in nearby soils (Fowler and Nordberg 1986). Silver in soils is largely immobilized by precipitation to insoluble salts and by complexation or adsorption by organic matter, clays, and manganese and iron oxides (Smith and Carson 1972).

Silver can remain attached to oceanic sediments for about 100 years under conditions of high pH, high salinity, and high sediment concentrations of iron, manganese oxide, and organics (Wingert-Runge and Andren 1994). Estuarine sediments that receive metals, mining wastes, or sewage usually have higher silver concentrations (>0.1 mg/kg DW) than noncontaminated sediments. Silver is tightly bound by sewage sludge, and elevated silver concentrations in sediments are often characteristic of areas near sewage outfalls. In the absence of sewage, silver in oxidized sediments is associated with oxides of iron and with humic substances (Bryan and Langston 1992). Sediments

in the Puget Sound, Washington, were significantly enriched in silver, in part, from human activities; concentrations were higher in fine-grained particles (Bloom and Crecilius 1987). Marine annelids and clams accumulate dissolved and sediment-bound forms of silver. Uptake of silver from sediments by marine polychaete annelids decreased in sediments with high concentrations of humic substances or copper but increased in sediments with elevated concentrations of manganese or iron (Bryan and Langston 1992).

7.4.3 Plants and Animals

Maximum concentrations of total silver recorded in field collections of living organisms ([Table 7.5](#)), in mg Ag/kg DW, were 1.5 in liver of marine mammals, 2 in liver and 6 in bone of trout from ecosystems receiving precipitation from silver-iodide seeded clouds, 7 in kidneys and 44 in liver of birds from a metals-contaminated area, 14 in marine algae and macrophytes, 30 in whole annelid worms from San Francisco Bay, 72 in skin of humans afflicted with argyria, 110 in whole mushrooms, 133 to 185 in soft parts of clams and mussels near sewage and mining waste outfalls, and 320 in whole gastropods from South San Francisco Bay. Silver concentrations in conspecifics from areas remote from anthropogenic contamination were usually lower by one or more orders of magnitude ([Table 7.5](#)). The strong bioaccumulation of silver in marine benthic organisms from sediments is a major cause for concern, and one with potential for adverse effects on reproduction (Ratte 1999). High accumulation of silver from marine sediments is attributed, in part, to the formation of stable chlorocomplexes of silver with chlorine which, in turn, favor the distribution and accumulation of silver (Ratte 1999).

Silver is a normal trace constituent of many organisms (Smith and Carson 1977). In terrestrial plants, silver concentrations are usually less than 1.0 mg/kg ash weight (equivalent to less than 0.1 mg/kg DW) and are higher in trees, shrubs, and other plants near regions of silver mining. Seeds, nuts, and fruits usually contain higher silver concentrations than other plant parts (USEPA 1980). Silver accumulations in marine algae (max. 14.1 mg/kg DW) are due mainly to adsorption rather than uptake; bioconcentration factors of 13,000 to 66,000 are not uncommon (USPHS 1990; Ratte 1999).

Silver concentrations in molluscs vary widely between closely related species and among conspecifics from different areas (Bryan 1973; Eisler 1981; [Table 7.5](#)). The inherent differences in ability to accumulate silver among bivalve molluscs are well documented (oysters \gg scallops \gg mussels; Brooks and Rumsby 1965; Eisler 1981). The highest silver concentrations in all examined species of molluscs were in the internal organs, especially in the digestive gland and kidneys (Eisler 1981; Miramand and Bentley 1992; [Table 7.5](#)). Elevated concentrations of silver (5.3 mg/kg DW) in shells of limpets from uncontaminated sites suggest that silver may actively participate in carbonate mineral formation (Navrot et al. 1974), but this needs verification. In general, silver concentrations were elevated in molluscs collected near port cities and in the vicinities of river discharges (Fowler and Oregoni 1976; Berrow 1991), electroplating plant outfalls (Eisler et al. 1978; Stephenson and Leonard 1994), ocean dumpsites (Greig 1979), and urban point sources, including sewage outfalls (Alexander and Young 1976; Smith and Carson 1977; Martin et al. 1988; Anderlini 1992; Crecilius 1993), and from calcareous sediments rather than detrital organic or iron oxide sediments (Luoma and Jenne 1977).

Season of collection (Fowler and Oregoni 1976; Sanders et al. 1991) and latitude (Anderlini 1974) also influenced silver accumulations. Seasonal variations in silver concentrations of Baltic clams (*Macoma balthica*) were associated with seasonal variations in soft tissue weight and frequently reflected the silver content in the sediments (Cain and Luoma 1990). Oysters from the Gulf of Mexico vary considerably in whole-body concentrations of silver and other trace metals. Variables that modify silver concentrations in oyster tissues include the age, size, sex, reproductive stage, general health, and metabolism of the animal; water temperature, salinity, dissolved oxygen,

and turbidity; natural and anthropogenic inputs to the biosphere; and chemical species and interactions with other compounds (Presley et al. 1990). Silver concentrations in whole American oysters (*Crassostrea virginica*) from the Chesapeake Bay were reduced in summer and at increasing water salinities, and elevated near sites of human activity. Chemical forms of silver taken up by oysters included the free ion (Ag^+) and the uncharged AgCl^0 (Sanders et al. 1991; Daskalakis 1995). Declines in tissue silver concentrations of the California mussel (*Mytilus californianus*) were significant between 1977 and 1990; body burdens decreased from 10 to 70 mg/kg DW to less than 2 mg/kg DW and seem to be related to the termination of metal-plating facilities in 1974 and the decreased mass emission rates by wastewater treatment facilities (Stephenson and Leonard 1994).

Among arthropods, pyrophosphate granules isolated from barnacles have the capability to bind and effectively detoxify silver and other metals under natural conditions (Pullen and Rainbow 1991). In a Colorado alpine lake, silver concentrations in caddisflies and chironomid larvae usually reflected silver concentrations in sediments; seston, however, showed a high correlation with lake water silver concentrations from 20 days earlier (Freeman 1979).

Silver concentrations in fish muscle rarely exceeded 0.2 mg/kg DW and usually were less than 0.1 mg/kg FW; livers contained as much as 0.8 mg/kg FW, although values greater than 0.3 mg/kg FW were unusual; and whole fish contained as much as 0.225 mg/kg FW (Table 7.5). Livers of Atlantic cod (*Gadus morhua*) contained significantly more silver than muscles or ovaries; a similar pattern was evident in other species of marine teleosts (Hellou et al. 1992; Szefer et al. 1993; Table 7.5). Accumulations of silver in offshore populations of teleosts is unusual, even among fishes collected near dump sites impacted by substantial quantities of silver and other metals. For example, of 7 species of marine fishes from a disposal site in the New York Bight and examined for silver content, concentrations were highest (0.15 mg/kg FW) in muscle of blue hake (*Antimora rostrata*; Greig et al. 1976). Similarly, the elevated silver concentration of 0.8 mg/kg FW in liver of winter flounder (*Pleuronectes americanus*) was from a specimen from the same general area (Greig and Wenzloff 1977b).

Silver concentrations in muscle of Antarctic birds were low (0.01 mg/kg DW) when compared to livers (0.02 to 0.46 mg/kg DW) or feces (0.18 mg/kg DW; Szefer et al. 1993). Silver concentrations in avian tissues, especially in livers, were elevated in the vicinity of metals-contaminated areas and in diving ducks from the San Francisco Bay (Table 7.5). Birds with elevated concentrations of silver in tissues — as much as 44 mg/kg DW in liver in the common eider (*Somateria mollissima*) — seemed outwardly unaffected (Bryan and Langston 1992).

Silver in mammalian tissues is usually present at low or nondetectable concentrations (Klaassen et al. 1986). The concentration of silver in tissues of 3 species of seals collected in the Antarctic during 1989 was highest in liver (1.55 mg/kg DW) and lowest in muscle (0.01 mg/kg DW); intermediate in value were kidney (0.29 mg/kg DW) and stomach contents (0.24 mg/kg DW; Szefer et al. 1993). The mean concentration of silver in livers from normal female California sea lions (*Zalophus californianus*), having normal pups, was 0.5 mg/kg DW (Martin et al. 1976). Mothers giving birth to premature pups had only 0.4 mg Ag/kg DW liver. In general, *Zalophus* mothers delivering premature pups had lower concentrations in liver of silver, cadmium, copper, manganese, mercury, and zinc than mothers delivering normal pups (Martin et al. 1976). Silver concentrations in tissues of Antarctic seals were related to, and possibly governed by, concentrations of other metals (Szefer et al. 1994). In muscle, silver inversely correlated with zinc; in liver, silver positively correlated with nickel, copper, and zinc; and in kidney, correlations between silver and zinc and between silver and cadmium were negative (Szefer et al. 1994). In humans, USEPA (1980) states that silver is present in placentas and fetal livers, that silver concentrations in tissues increase with age, and that variations in tissue concentrations of silver are wide. The average daily intake of silver from all sources by humans is 88 μg , but very little of the silver ingested from nontherapeutic sources is retained (Smith and Carson 1977).

Table 7.5 Silver Concentrations (milligrams of silver per kilogram fresh weight [FW], dry weight [DW], or ash weight [AW]) in Field Collections of Selected Plants and Animals

Taxonomic Group, Organism, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
ALGAE, MACROPHYTES, AND HIGHER PLANTS		
Marine algae and macrophytes, 24 species		
9 species	<0.1–2.0 DW	1
11 species	2.1–10.0 DW	1
4 species	10.1–14.1 DW	1
Higher terrestrial plants	0.2–<1.0 AW	2, 3
CNIDARIANS		
Corals, 34 species	<1.0 DW	1
Various, 10 species	Max. 0.1 DW	1
MOLLUSCS		
Cephalopods, 7 species; digestive gland	3.0–46.0 DW	4
Cephalopods, French coast of English Channel, October 1987		
Octopus, <i>Eledone cirrhosa</i>		
Digestive gland	2.0–4.4 DW	4
Digestive tract	0.5 DW	4
Other tissues	<0.3 DW	4
Whole	0.8 DW	4
Cuttlefish, <i>Sepia officinalis</i>		
Digestive gland	4.9–7.4 DW	4
Kidney	0.7 DW	4
Other tissues	<0.3 DW	4
Whole	0.7 DW	4
Clam, <i>Corbicula</i> sp.; San Francisco Bay, 1983–86; soft parts	0.07–0.2 DW	5
American oyster, <i>Crassostrea virginica</i> ; soft parts		
Connecticut	6.1 FW	6
East coast	0.3–5.0 DW	7, 55
Georgia	28.0–82.0 DW	8
Gulf coast	0.6–6.0 DW; Max. 7.0 DW	7, 9, 10
Louisiana	5.5 DW	11
Maryland, Chesapeake Bay, 1986–88	2.0–6.0 DW	12
Northeast coast	0.8–2.3 FW	13
Red abalone, <i>Haliotis rufescens</i> ; California		
Digestive gland	14.0–60.0 DW	14
Foot	1.0–44.0 DW	14
Gills	13.0–129.0 DW	14
Mantle	16.0–54.0 DW	14
Periwinkle, <i>Littorina littorea</i> ; soft parts; Looe estuary, UK vs. uncontaminated site; 1988	10.7 (3.1–17.4) DW vs. 4.1 (3.4–5.0) DW	15
Baltic clam, <i>Macoma balthica</i> ; soft parts; San Francisco Bay		
Near sewage outfall	32.0–133.0 DW	11, 16
Reference site	<1.0 DW	11
Molluscs, marine; edible tissues; 18 species		
10 species	<0.1 FW	17
5 species	0.1–0.3 FW	17
3 species	0.3–0.7 FW	17
Molluscs; south San Francisco Bay, 1982; soft parts		
Mud snail, <i>Nassarius obsoletus</i>	Max. 320.0 DW	16
Clam, <i>Macoma nasuta</i>	Max. 5.1 DW	16
Softshell clam, <i>Mya arenaria</i>	Max. 34.0 DW	16
Clam, <i>Tapes japonica</i>	Max. 65.0 DW	16

7.5 LETHAL AND SUBLETHAL EFFECTS

7.5.1 General

As discussed later, free silver ion is lethal to representative species of sensitive aquatic plants, invertebrates, and teleosts at water concentrations of 1.2 to 4.9 µg/L. Adverse effects occur on development of trout at concentrations as low as 0.17 µg/L and on phytoplankton species composition and succession at 0.3 to 0.6 µg/L. Aquatic organisms accumulate silver from environmental sources. No data were found on effects of silver on avian or mammalian wildlife, and all studied effects were on poultry and small laboratory mammals. Silver was not mutagenic, carcinogenic, or teratogenic to tested animals by normal routes of exposure. Adverse effects of silver on poultry occur at 1.8 mg/kg FW whole egg by way of injection (reduced survival), 10 mg/kg in diets (reduced hemoglobin with copper-deficient diet), 200 mg/kg in diets (growth suppression with copper-adequate diet), or when given drinking water containing 100 mg Ag/L (liver necrosis). Effects of silver on sensitive species of mammals include death at 13.9 to 20.0 mg/kg BW by intraperitoneal injection, histopathology of kidney and brain at 250 to 450 µg Ag/L drinking water, tissue accumulations at 6 mg/kg diet, and liver necrosis when fed diets containing more than 130 mg/kg. In humans, generalized argyria seems to be declining, which may be due to improved work conditions.

7.5.2 Terrestrial Plants

In general, accumulation of silver by terrestrial plants from soils is low, even if the soil is amended with silver-containing sewage sludge or the plants are grown on tailings from silver mines — where silver accumulates mainly in the root systems (Ratte 1999). Germination was the most sensitive stage to plants grown in solutions containing various concentrations of silver nitrate. Adverse effects on germination were expected at concentrations greater than 0.75 mg Ag/L for lettuce, and 7.5 mg/L for ryegrass (*Lolium perenne*) and other plants tested (Ratte 1999). Smith and Carson (1977) report that sprays containing 9.8 mg dissolved Ag/L kill corn (*Zea mays*), and sprays containing 100 to 1000 mg dissolved Ag/L kill young tomato (*Lycopersicon esculentum*) and bean (*Phaseolus* spp.) plants. Seeds of corn, lettuce (*Lactuca sativa*), oat (*Avena sativa*), turnip (*Brassica rapa*), soybean (*Glycine max*), spinach (*Spinacia oleracea*), and Chinese cabbage (*Brassica campestris*) were planted in soils amended with silver sulfide and sewage sludge to contain as much as 106 mg Ag/kg DW soil (Hirsch et al. 1993; Hirsch 1998c). All plants germinated and most grew normally at the highest soil concentration of silver tested. Yields of lettuce, oat, turnip and soybean were higher on soils amended with silver-laden, waste-activated sludge than control soils, but growth of Chinese cabbage and lettuce was adversely affected at 14 mg Ag/kg DW soil and higher. Silver concentrations in edible portions from all plants at all soil levels of silver tested, except lettuce, were less than 80 µg/kg DW, suggesting that availability of sludge-borne silver sulfide to most agricultural crops is negligible. Lettuce grown in soil containing 5 mg Ag/kg DW had about 0.5 mg Ag/kg DW leaves, and in 120 mg/kg DW soil as much as 2.7 mg Ag/kg DW leaves vs. 0.03 mg/kg DW in controls (Hirsch et al. 1993; Hirsch 1998c).

7.5.3 Aquatic Organisms

In fish and amphibian toxicity tests with 22 metals and metalloids, silver was the most toxic element as judged by acute LC₅₀ values (Birge and Zuiderveen 1995). In solution, ionic silver is extremely toxic to aquatic plants and animals (Nehring 1976; Nelson et al. 1976; Calabrese et al. 1977a; Gould and MacInnes 1977; Smith and Carson 1977; USEPA 1980; Buhl and Hamilton 1991; Bryan and Langston 1992), and water concentrations of 1.2 to 4.9 µg/L killed sensitive species of aquatic organisms, including representative species of insects, daphnids, amphipods, trout, flounders, sticklebacks, guppies, and dace (Table 7.6). At nominal water concentrations of 0.5 to 4.5 µg/L, accumulations in most species of exposed organisms were high and had adverse effects on growth in algae, clams, oysters, snails, daphnids, amphipods, and trout; molting in mayflies; and histology in mussels (Table 7.6).

In general, silver ion was less toxic to freshwater aquatic organisms under conditions of low dissolved Ag⁺ concentration, increasing water pH, hardness, sulfides, and dissolved and particulate organic loadings; under static test conditions when compared to flowthrough regimens; and when animals were adequately nourished when compared to starvation (Erickson et al. 1998; Bury et al. 1999a, 1999b; Karen et al. 1999; Ratte 1999; Wood et al. 1999). It is now agreed that increasing concentrations of dissolved organic carbon affords the highest protective effects (Berry et al. 1999; Karen et al. 1999). Among all tested species, the individuals most sensitive to silver were the young and those exposed to low water hardness or salinity (Smith and Carson 1977; USEPA 1980; Le Blanc et al. 1984; Erickson et al. 1998; Shaw et al. 1998; Table 7.6). In the case of seawater-acclimatized rainbow trout, silver-induced mortality was greater at higher salinities, but the increased toxicity with salinity was linked to an incomplete hypoosmoregulatory ability and not to an increase in a more toxic AgCl_n species (Ferguson and Hogstrand 1998). Sediment chemistry can affect toxicity of silver to marine amphipods (*Ampelisca abdita*) exposed for 10 days to sediments supplemented with various concentrations of silver (Berry et al. 1999). In general, sediments with an excess of acid volatile sulfide (AVS) relative to simultaneously extracted metal (SEM) were generally not toxic to marine amphipods. Sediments with an excess of SEM relative to AVS, and no measurable AVS, were generally toxic. Sediments with measurable AVS were not toxic (Berry et al. 1999). It is emphasized that silver-induced stress syndromes vary widely among animal classes. Among marine organisms, for example, silver ion was associated with respiratory depression in marine gastropods and cunners (*Tautogolabrus adspersus*), a teleost. However, silver ion increased oxygen consumption in 6 species of bivalve molluscs (Gould and MacInnes 1977).

Sensitive aquatic plants accumulated silver from water containing as little as 2 µg Ag/L to whole-cell burdens as high as 58 mg Ag/kg DW; grew poorly at 3.3 to 8.2 µg Ag/L during exposure for 5 days; and died at concentrations greater than 130 µg Ag/L (Table 7.6). Some metals seem to protect aquatic plants against adverse effects of silver. Algae in small lakes that contained elevated concentrations of metals, especially copper and nickel, had higher tolerances to silver than conspecifics reared in the laboratory under conditions of depressed concentrations of heavy metals (USEPA 1980). Species composition and species succession in Chesapeake Bay phytoplankton communities were significantly altered in experimental ecosystems continuously stressed by low concentrations (0.3 to 0.6 µg/L) of silver (Sanders and Cibik 1988; Sanders et al. 1990). At higher concentrations of 2 to 7 µg/L for 3 to 4 weeks, silver inputs caused disappearance of *Anacystis marina*, a mat-forming blue-green alga; increased dominance by *Skeletonema costatum*, a chain-forming centric diatom; and cell burdens of 8.6 to 43.7 Ag mg/kg DW (Sanders and Cibik 1988). Dissolved silver speciation and bioavailability were important in determining silver uptake and retention by aquatic plants (Connell et al. 1991). Silver availability was controlled by the concentration of free silver ion (Ag⁺) and the concentrations of other silver complexes, such as AgCl (Sanders and Abbe 1989). Silver uptake by phytoplankton was rapid in proportion to silver concentration and inversely proportional to water salinity. Silver incorporated by phytoplankton was not lost as the salinity increased, and silver associated with cellular material was largely retained

in the estuary (Sanders and Abbe 1989). Diatoms (*Thalassiosira* sp.), for example, readily accumulated silver from the medium. Once incorporated, silver was tightly bound to the cell membrane, even after the cells were mechanically disrupted (Connell et al. 1991).

The ability to accumulate dissolved silver from the medium ranges widely between species. Some reported bioconcentration factors (mg Ag per kg FW organism/mg Ag per liter of medium) are 210 in diatoms, 240 in brown algae, 330 in mussels, 2300 in scallops, and 18,700 in oysters (USEPA 1980). Silver is the most strongly accumulated of all trace metals by marine bivalve molluscs (Luoma 1994). Studies with radiosilver-110m suggest that the half-time persistence of silver is 27 days in mussels, 44 to 80 days in clams, and more than 180 days in oysters (Fisher et al. 1994). In oysters and other bivalve molluscs, the major pathway of silver accumulation was from dissolved silver; uptake was negligible from silver adsorbed onto suspended sediments or algal cells, and oysters eliminated adsorbed silver in the feces (Abbe and Sanders 1990; Sanders et al. 1990). Sometimes, benthic bivalve molluscs accumulated silver from certain sediments. Sediment-bound silver was taken up by the Baltic clam (*Macoma balthica*) at 3.6 to 6.1 times the concentration in calcite sediments but less than 0.85 times from manganeseous, ferrous, and biogenic CaCO_3 sediments (USEPA 1980). In oysters, silver associated with food was unavailable for incorporation, which may be due to the ability of silver to adsorb rapidly to cell surfaces and to remain tightly bound despite changes in pH or enzymatic activity (Connell et al. 1991). Silver concentrations in American oysters (*Crassostrea virginica*) held in seawater solutions containing 1.0 mg Ag/L for 96 h rose from 6.1 mg/kg FW soft parts to 14.9 mg/kg FW. In gills, these values were 5.9 and 33.9 mg/kg FW (Thurberg et al. 1974). A similar pattern was evident in common mussels (*Mytilus edulis*) and quahog clams (*Mercenaria mercenaria*; Thurberg et al. 1974). Adult surf clams (*Spisula solidissima*) immersed for 96 h in seawater containing 10 μg Ag/L had 1.0 mg Ag/kg FW soft tissues vs. 0.08 mg/kg in controls (Thurberg et al. 1975). Oysters accumulated radiosilver-110m from the medium by factors of 500 to 32,000 (Pouvreau and Amiard 1974). Uptake of dissolved silver by oysters was higher at elevated temperatures in the range of 15 to 25°C (Abbe and Sanders 1990). American oysters maintained near a nuclear power plant in Maryland that discharged radionuclides on a daily basis into the Chesapeake Bay accumulated radiosilver-110m; accumulations were higher in summer and fall than in winter and spring (Rose et al. 1988).

Marine gastropods exposed to concentrations as low as 1.0 μg Ag/L for as long as 24 months showed histopathology and accumulations as high as 34 mg Ag/kg FW soft parts; higher exposure concentrations of 5 and 10 μg Ag/L were associated with inhibited reproduction and whole-body burdens as high as 87 mg Ag/kg FW (Nelson et al. 1983). Histopathological findings in silver-exposed mussels (*Mytilus edulis*) were typical of argyria in humans and other mammals that have absorbed organic or inorganic silver compounds (Calabrese et al. 1984). Juvenile Pacific oysters (*Crassostrea gigas*) exposed for 2 weeks to solutions containing 20 μg Ag/L had high silver accumulations in tissues and a reduced capacity to store glycogen; however, after 30 days of depuration, glycogen storage capacity was restored and 80% of the soluble silver and 27% of the insoluble forms were eliminated, suggesting recovery to a normal physiological state (Berthet et al. 1990). About 70% of the insoluble silver in Pacific oysters was sequestered as Ag_2S , a stable mineral form that is not degradable, thereby limiting the risk of silver transfer through the food chain (Berthet et al. 1990). Most (69 to 89%) of the silver accumulated from the medium in soft tissues of oysters and clams was sequestered in amoebocytes and basement membranes. In scallops and mussels, silver was stored in basement membranes and pericardial gland. In all species of bivalve molluscs, sequestered silver was in the form of silver sulfide (Berthet et al. 1992). American oysters excreted about 60% of their accumulated silver in soft tissues within 30 days of transfer to silver-free seawater; soluble forms were preferentially eliminated, and insoluble forms retained (Berthet et al. 1992). Interspecies differences in ability to retain silver among bivalve molluscs are large, even among closely related species of crassostreid oysters. For example, the half-time persistence of silver was about 149 days in American oysters but only 26 days in Pacific oysters (USPHS 1990).

Table 7.6 Effects of Silver on Representative Aquatic Plants and Animals (Concentrations are in micrograms of free silver (Ag^+) per liter of medium added at start unless indicated otherwise.)

Taxonomic Group, Organism, Silver Concentration (ppb), and Other Variables	Effects	Reference ^a
BACTERIA, ALGAE, AND MACROPHYTES		
Bacteria, freshwater <i>Escherichia coli</i> 1000–2000 (as Ag^{+3})	All dead in 0.5–5.0 min	1
<i>Streptococcus faecalis</i> 1000–2000 (as Ag^{+3})	All dead in 0.5–5.0 min	1
Various species 100–200	All dead in 15–20 min	2
Bacteria, marine Isolated from tubes of deep-sea polychaete annelids		
3000	Lowest concentration tested that inhibited growth in 50% of strains during 10-day exposure	3
20,000	Silver-resistant strains (55% of all strains tested) survived at least 24 h	3
40,000	Some strains survived during 10-day exposure	3
Alga, <i>Chlorella</i> spp. 50–100	Growth inhibition	4
Waterweed, <i>Eloea canadensis</i> 100	Respiration inhibited	4
Freshwater algae and macrophytes, 13 species 30–7500	Adverse effects	4
Freshwater plants 26	Bioconcentration factor (BCF) of 200	2
Duckweed, <i>Lemna minor</i> 270	Phytotoxic	4
Marine algae, 3 species 2	After 24 h algae contained 27.8–58.6 mg silver/kg dry weight (DW) at 1% salinity, 16.4–33.4 mg/kg at 1.5% salinity, and 9.8–25.2 mg Ag/kg DW at 2.0% salinity BCF between 13,000 and 66,000 at equilibrium	5
Marine algae, 4 species; various concentrations Blue-green alga, <i>Phormidium inundatum</i> 80–140	Controls growth in swimming pools	2
Marine alga, <i>Prorocentrum mariae-lebouriae</i> 3.3 6.7 8.2	50% growth reduction in 5 days at 0.75% salinity 50% growth reduction in 5 days at 1.5–2.25% salinity 50% growth reduction in 5 days at 3% salinity	6 6 6
Marine algae, various species Radiosilver-110m at 3 microcuries/L	BCF of 1600 to 2800 in 38 days	7
Marine plants 60	BCF of 200	2
Alga, <i>Scenedesmus</i> spp. 100–200	100% growth inhibition	4
Marine alga, <i>Skeletonema costatum</i> 5.9 15.4 20.0 130–170	50% growth reduction in 5 days at 0.75% salinity 50% growth reduction in 5 days at 1.5% salinity 50% growth reduction in 5 days at 2.25–3.0% salinity 50% reduction in cell numbers in 96 h	6 6 6 4
PROTOZOANS		
Ciliate, <i>Fabrea salina</i> ; held in seawater solution containing radiosilver-110m	Bioconcentration factor (volume/volume basis) of 7000 to 40,000 within 24 h	39

Table 7.6 (continued) Effects of Silver on Representative Aquatic Plants and Animals (Concentrations are in micrograms of free silver (Ag^+) per liter of medium added at start unless indicated otherwise.)

Taxonomic Group, Organism, Silver Concentration (ppb), and Other Variables	Effects	Reference ^a
Protozoan, <i>Spirostomum ambiguum</i>		
8.8	LC50 (24 h) at 2.8 mg CaCO_3/L	8
15.3	LC50 (24 h) at 250 mg CaCO_3/L	8
NEMATODES		
Free-living nematode, <i>Caenorhabditis elegans</i>		
102 (95% confidence interval [CI] of 10 to 4980)	LC50 (96 h)	9
5000 (95% CI of 3000 to 10,000)	LC50 (24 h)	9
MOLLUSCS		
Bay scallop, <i>Argopecten irradians</i> , juveniles		
22	Oxygen consumption elevated after 96 h	10
33	LC50 (96 h); survivors with elevated silver concentrations	10
Freshwater snails; <i>Australorbis</i> sp., <i>Taphius</i> sp.		
30–100	Inhibited feeding and coordination	2
Bivalves, 4 species		
10	Elevated oxygen consumption after exposure for 30–90 days	10, 11
Scallop, <i>Chlamys varia</i> , adults		
20	After 14 days soft parts contained 18 mg Ag/kg DW vs. 1.7 in controls	12
100	LC50 (115 h)	12
Asiatic clam, <i>Corbicula fluminea</i>		
4.5	Adverse effects on growth after exposure for 21 days; residues of 1.65 mg Ag/kg FW soft parts were associated with reduced growth	13
7.8	No deaths in 21 days	13
26.0	Some deaths in 21 days	13
155 (116–208); exposed for 96 h then transferred to uncontaminated media for 96 h	LC50 for juveniles at end of observation period	13
Pacific oyster, <i>Crassostrea gigas</i>		
2–10	5 to 8% of embryos exposed for 48 h were abnormal (retarded shell growth, reduced size, erratic swimming behavior) vs. 1% in controls; no significant effect on embryogenesis	14
13.5–15.5	Significant effect on embryogenesis; 25–37% of embryos developed abnormally	14
18–32	95–98% of embryos exposed for 48 h were abnormal	14
20	Soft parts of adults exposed for 28 days contained 188.0 mg Ag/kg DW vs. 3.0 mg/kg DW in controls	12
Juveniles held in 20 μg Ag/L for 14 days then transferred to uncontaminated seawater for 23 days	No histopathology. During exposure, but not depuration, glycogen storage capacity was diminished. During depuration, silver concentrations decreased from 31.3 mg/kg DW soft parts to 12.8 vs. <10.0 in controls. Most of the insoluble accumulated silver was sequestered as Ag_2S in amoebocytes and basement membranes	15
100	LC50(209 h), adults	12

Table 7.6 (continued) Effects of Silver on Representative Aquatic Plants and Animals (Concentrations are in micrograms of free silver (Ag^+) per liter of medium added at start unless indicated otherwise.)

Taxonomic Group, Organism, Silver Concentration (ppb), and Other Variables	Effects	Reference ^a
American oyster, <i>Crassostrea virginica</i>		
0.1 (controls) vs. 2; adults exposed for 14 days in large enclosures with natural phytoplankton assemblages	In controls, phytoplankton had 0.03 mg Ag/kg DW and oyster soft parts 0.8 mg/kg DW. In the 2.0 $\mu\text{g/L}$ group, phytoplankton had 8.6 mg Ag/kg DW and oysters 2.8 mg/kg DW; oyster growth rate significantly reduced	16
5 or 7; conditions as above	Phytoplankton had 24–44 mg Ag/kg DW and oysters 4.8–6.6 mg Ag/kg DW	16, 17
5.8	LC50 (48 h), embryos	10, 48
10	LC100 (48 h), embryos	4
25	LC50 (12 days), juveniles	10
500–1000	Adults exposed for 96 h had 12.4–14.9 mg Ag/kg FW in body and 34–38 mg Ag/kg FW in gills	11
Slipper limpet, <i>Crepidula fornicata</i>		
1, 5, or 10; exposed for 24 months and observed for effects on growth, reproduction, histology and accumulations	Growth reduced in the 5 and 10 $\mu\text{g/L}$ groups and reproduction inhibited in the 10 $\mu\text{g/L}$ group. All test groups showed deposition of silver in connective tissues and basement membranes. Maximum silver concentrations (mg/kg FW soft parts) were recorded for the controls at 12 months (2.8), for the 1.0 $\mu\text{g/L}$ group at 12 months (34.0), for the 5.0 $\mu\text{g/L}$ group at 6 months (54.1), and for the 10.0 $\mu\text{g/L}$ group at 6 months (86.7). After 24 months, silver-exposed groups contained between 5.4 and 8.0 mg Ag/kg FW soft parts	18
Zebra mussel, <i>Dreissena polymorpha</i> , adults		
400	No deaths in 28 days; soft parts at 28 days contained 147–184 mg Ag/kg DW vs. 0.02–1.8 mg/kg DW in controls	12
Hardshell clam, <i>Mercenaria mercenaria</i>		
21.0	LC50 (48 h), embryos	10
32.4	LC50 (10 days), juveniles	10
500–1000	Adults exposed for 96 h had 0.8–1.0 mg Ag/kg FW in soft parts and 6.9–7.6 mg Ag/kg FW in gills. Controls (<1.5 $\mu\text{g/L}$) had 0.4 mg Ag/kg FW soft parts and 1.6 mg/kg FW in gills	11
Softshell clam, <i>Mya arenaria</i>		
100	Increased oxygen consumption after 96 h	11
500	After exposure for 96 h adults had 10.4 mg Ag/kg FW soft parts vs. 0.3 mg Ag/kg FW in controls	11
1000	All adults died within 96 h	11
Common mussel, <i>Mytilus edulis</i>		
Exposed continuously for 21 months to 0.0 (control), 1, 5, or 10 $\mu\text{g Ag/L}$ from age 2.5 months (4.5 mm in shell length) and observed for growth, accumulations, and histopathology	No effect on growth. Silver concentrations (mg/kg FW soft parts) for controls ranged between 0.2 and 0.7; maximum concentrations in the 1 $\mu\text{g/L}$ group (9.1) occurred at 18 months; for the 5 $\mu\text{g/L}$ group, residues were highest (11.9) at 18 months; for the 10 $\mu\text{g/L}$ group, concentrations were highest (15.3) at 12 months. All silver-exposed groups had histopathology of basement membranes and connective tissues	19
Juveniles (16.1 mm shell length) and adults (53.4 mm shell length) were continuously exposed for 12 months to 0.0 (control), 5, 25, or 50 $\mu\text{g Ag/L}$ and observed for growth and accumulations	Growth inhibition of the 50 $\mu\text{g/L}$ group after 6 months but growth normal after 12 months; growth of other groups as in controls. At 12 months residues, in mg Ag/kg FW soft parts, for juveniles (adults) were 0.2 (0.1) in controls, 9.9 (2.0) in the 5 $\mu\text{g/L}$ group, 8.0 (2.0) in the 25 $\mu\text{g/L}$ group, and 10.7 (3.0) in the 50 $\mu\text{g/L}$ group	19

Table 7.6 (continued) Effects of Silver on Representative Aquatic Plants and Animals (Concentrations are in micrograms of free silver (Ag^+) per liter of medium added at start unless indicated otherwise.)

Taxonomic Group, Organism, Silver Concentration (ppb), and Other Variables	Effects	Reference ^a
100	Increasing oxygen consumption with increasing water salinity	11
500 or 1000	Adults exposed for 96 h had 3.7–5.2 mg Ag/kg FW soft parts	11
Radiosilver-110m	BCF after 1 day were 860 in soft parts and 8 in shell; after 9 days these values were 2550 in soft parts and 11 in shell	20
Mussel, <i>Mytilus galloprovincialis</i> , adults		
10	Growth normal after 21-month exposure	12
20	After 28 days soft parts contained 15 mg Ag/kg DW vs. 0.08 mg Ag/kg DW in controls (<0.1 μg Ag/L)	12
25	Growth depressed after 21-month exposure	12
50	Severe tissue histopathology after 14 days	12
100	LC50 (110 h)	12
Mud snail, <i>Nassarius obsoletus</i>		
1.0	Inhibition of embryonic development	21
Clam, <i>Potamocorbula amurensis</i> ; exposed for 14 days at 1.8% salinity to 0.1, 0.2, 0.5, 1.0, or 2.0 μg Ag^+/L	Silver concentrations in soft parts rose in a dose-dependent manner from <1.0 mg Ag/kg DW to about 14.0 mg Ag/kg DW	42
Clam, <i>Scrobicularia plana</i> , adults		
20	Normal after 14 days	12
50	No deaths in 16 days; severe histopathology	12
100	LC50 (250 h)	12
200	LC50 (96 h)	12
Surf clam, <i>Spisula solidissima</i>		
10	Elevated oxygen consumption in juveniles after 96 h	10
14; 1-h exposure 60 min after fertilization	50% of embryos developed abnormally in 48 h	21
100	Lethal to juveniles in 96 h	10

BRYOZOANS

Bryozoan, <i>Victorella</i> sp.		
0.18 (control), 2, or 10	Silver concentrations, in mg/kg DW whole animal, after 24 h were 11.5 in controls, 38.3 in the 2 $\mu\text{g}/\text{L}$ group, and 180.0 in the 10 $\mu\text{g}/\text{L}$ group	22

ARTHROPODS

Copepod, <i>Acartia tonsa</i>		
36	LC50 (96 h)	4
Amphipod, <i>Ampelisca abdita</i>		
Controls	15% dead in 10 days	50
30	LC50 (10 days)	50
Chironomid, <i>Chironomus tentans</i> ; larvae		
57	LC50 (10 days)	49
Sediments supplemented with silver nitrate, in g Ag/kg DW sediment		
0.03 (1 μg Ag/L in overlying water = OW; 3 μg Ag/L in pore water = PW)	All survived exposure for 10 days	49
0.2 (16 $\mu\text{g}/\text{L}$ OW, 34 $\mu\text{g}/\text{L}$ PW)	87% survival in 10 days	49
0.5 (13 $\mu\text{g}/\text{L}$ OW, 127 $\mu\text{g}/\text{L}$ PW)	83% survival in 10 days	49
1.1–2.7	LC50 (10 days)	49
1.2 (156 $\mu\text{g}/\text{L}$ OW, 7979 $\mu\text{g}/\text{L}$ PW)	53% survival in 10 days	49
3.1 (34,600 $\mu\text{g}/\text{L}$ OW, 1,389,000 $\mu\text{g}/\text{L}$ PW)	All died within 10 days	49

Table 7.6 (continued) Effects of Silver on Representative Aquatic Plants and Animals (Concentrations are in micrograms of free silver (Ag^+) per liter of medium added at start unless indicated otherwise.)

Taxonomic Group, Organism, Silver Concentration (ppb), and Other Variables	Effects	Reference ^a
Daphnid, <i>Daphnia magna</i>		
0.4–15.0	LC50 (96 h) at 38–75 mg CaCO_3/L	4
0.9	50% of starved daphnids immobilized in 48 h	23
1.6–19.4	MATC ^b	23
3.5	50% reduction in growth of nonstarved daphnids in 21 days	23
4.1	Reduced survival during 21-day exposure	23
10.5	Reproduction inhibited during 21-day exposure	23
12.5	50% of nonstarved daphnids immobilized in 48 h	23
45–49	LC50 (96 h) at 255 mg CaCO_3/L	4
Daphnids, <i>Daphnia</i> spp.		
10 (0.25–49.0)	LC50 (96 h)	9
Mayfly, <i>Ephemerella grandis</i>		
<1.0	LC50(14 days), naiads	24
4.0–8.8	LC50(7–15 days), adults	4
60 or 120	On death, whole mayflies contained 25.3 and 28.7 mg $\text{Ag}/\text{kg DW}$	24
Scud (amphipod), <i>Gammarus pseudolimnaeus</i>		
4.5 (3.7–5.5)	LC50 (96 h) at 44 mg CaCO_3/L	25
American lobster, <i>Homarus americanus</i>		
6.0	Altered enzyme activity after 30 days but no effect on survival, oxygen consumption, or osmoregulation	10
Amphipod, <i>Hyalella azteca</i>		
0.95	No observable effects after 21-day exposure	13
1.4	Reduced growth after 20 days	13
1.9 (1.4–2.3)	LC50 (96 h)	13
Mayfly, <i>Isonychia bicolor</i>		
1.6	Molting inhibited after 20 days	13
6.8 (5.5–7.8)	LC50 (96 h)	13
Stonefly, <i>Leuctra</i> sp.		
0.69	Adverse effects after 12 days	13
2.5 (1.7–3.2)	LC50 (96 h)	13
Mysid shrimp, <i>Mysidopsis bahia</i>		
250.0	LC50 (96 h)	4
Grass shrimp, <i>Palaemonetes pugio</i>		
2.0	After 2 weeks whole shrimps contained 0.5 mg $\text{Ag}/\text{kg DW}$ vs. 0.36 in controls	22
5.0	After 2 weeks whole shrimps had 3.7 mg $\text{Ag}/\text{kg DW}$	22
10.0	Whole shrimps contained 4.5 mg $\text{Ag}/\text{kg DW}$ after exposure for 2 weeks	22
For 2 weeks shrimp ate <i>Artemia</i> nauplii containing 0.72 mg $\text{Ag}/\text{kg DW}$, or bryozoans (<i>Victorella</i> sp.) containing elevated silver burdens (38–180 mg $\text{Ag}/\text{kg DW}$), or control bryozoans (11.5 mg $\text{Ag}/\text{kg DW}$)	Silver concentration (mg/kg DW whole body) in shrimp on <i>Artemia</i> diet was 0.19 vs. 0.09 in silver-free <i>Artemia</i> diet; 0.26–0.62 in the high-silver bryozoan diet and 0.36 in the control bryozoan diet	22
Stonefly, <i>Pteronarcys californica</i>		
4.0–9.0	LC50 (96 h)	24
50.0	On death, whole stoneflies contained 9.1 mg $\text{Ag}/\text{kg DW}$	24
105.0	Dead stoneflies had 13.2 mg $\text{Ag}/\text{kg DW}$	24
Mayfly, <i>Stenonema</i> sp.		
3.9 (2.5–5.7)	LC50 (96 h)	13

Table 7.6 (continued) Effects of Silver on Representative Aquatic Plants and Animals (Concentrations are in micrograms of free silver (Ag^+) per liter of medium added at start unless indicated otherwise.)

Taxonomic Group, Organism, Silver Concentration (ppb), and Other Variables	Effects	Reference ^a
Midge, <i>Tanytarsus dissimilis</i> 3160 (2490–4010)	LC50 (48 h) at 44 mg CaCO_3/L	25
ANNELIDS		
Marine polychaete, <i>Sabellav. pavonina</i> Adults immersed in seawater containing 50 $\mu\text{g Ag/L}$ for 8 weeks then transferred to silver-free media for 8 weeks	During immersion, the maximum whole body silver concentration was 22.1 mg/kg DW vs. 0.8 in controls; main sites of accumulation were the connecting tissues of nephridia and gut. No histopathology. A constant elimination of silver in urine occurs simultaneously with silver accumulation. During depuration, new connective tissue formed and silver concentrations were reduced by 88%	26
ECHINODERMATA		
Sea urchin, <i>Arbacia lixula</i> 0.5	Reduced embryo development after 52 h	4
FISHES		
Mottled sculpin, <i>Cottus bairdi</i> 5.3 14.0	LC50 (96 h) at 30 mg CaCO_3/L LC50 (96 h) at 250 mg CaCO_3/L	4 4
Sheepshead minnow, <i>Cyprinodon variegatus</i> 1400	LC50 (96 h), juveniles	4
Common carp, <i>Cyprinus carpio</i> Held in radiosilver-110m solutions for 41 days then transferred to uncontaminated media for 42 days	Whole body BCF during immersion rose rapidly and progressively to 51 at day 19, then more slowly to 73 at day 41. At day 41, BCF for liver was 866, for digestive tract 560, for kidneys 299, for spleen 155, and for air bladder 109. During depuration, 68% of the silver was eliminated — about 31% during the first 3 days and 37% in the next 39 days. In both uptake and depuration phases, 71–77% of all radiosilver was present in liver and digestive tract	27
Mummichog, <i>Fundulus heteroclitus</i> 30–40	Inhibited liver enzyme activity after 4 days	2, 4
Mosquitofish, <i>Gambusia affinis</i> 23.5 (17.2–27.0)	LC50 (96 h), juveniles	13
Threespine stickleback, <i>Gasterosteus aculeatus</i> 3 4 10	Lethal in 10–30 days Lethal in 7 days Lethal in 96 h	2 2 2
Flagfish, <i>Jordanella floridae</i> 9.2 (8.0–10.7)	LC50 (96 h) at 44 mg CaCO_3/L	25
Bluegill, <i>Lepomis macrochirus</i> 31.7 (24.2–48.4) 70.0	LC50 (96 h) Survival as in controls after 6 months; whole body contained 0.3 mg Ag/kg ash weight	13 28
Atlantic silverside, <i>Menidia menidia</i> 110.0 400.0	LC50 (96 h), larvae LC50 (96 h), juveniles	4 4

Table 7.6 (continued) Effects of Silver on Representative Aquatic Plants and Animals (Concentrations are in micrograms of free silver (Ag^+) per liter of medium added at start unless indicated otherwise.)

Taxonomic Group, Organism, Silver Concentration (ppb), and Other Variables	Effects	Reference ^a
Largemouth bass, <i>Micropterus salmoides</i>		
7.0	Survival of young of year as in controls after continuous exposure for 6 months. After 4 months, viscera contained 0.6 mg Ag/kg ash weight, gills 0.38, and carcass 0.016 mg Ag/kg ash weight	28
70.0	All dead within 24 h. Prior to death, bass had reddened gills, body tremors, and erratic swimming	28
Tidepool sculpin, <i>Oligocottus maculosus</i>		
119.0	LC50 (168 h); 2.5% salinity	46
331.0	LC50 (96 h); 2.5% salinity	46
472.0	LC50 (168 h); 3.2% salinity	46
664.0	LC50 (96 h); 3.2% salinity	46
Chum salmon, <i>Oncorhynchus keta</i>		
Eggs were exposed in freshwater to 4 µg Ag/L for 14 days prior to hatch. After hatching, larvae were exposed to 4 µg Ag/L in salt water for 14 days during yolk-sac resorption. Fry were then transferred to uncontaminated salt water and fed a high metals diet for 64 days (diet contained — in µg metal/kg feed DW — 2 Ag, 255 Cd, 6670 Cu, 1320 Pb, and 96,000 Zn)	At end of study, experimentals had a small, but significant, decline in survival. Just prior to transfer to uncontaminated salt water, experimentals contained 62 µg Ag/kg whole body DW vs. 4 in controls. After 64 days in uncontaminated salt water, whole alevins contained 18 µg Ag/kg DW vs. 4 in controls	29
Coho salmon, <i>Oncorhynchus kisutch</i>		
11.1 (7.9–15.7)	LC50 (96 h), alevins	30
12.5 (10.7–14.6)	LC50 (96 h), juveniles	30
Rainbow trout, <i>Oncorhynchus mykiss</i>		
0.03–0.06	MATC ^b after 13-month exposure beginning at eyed embryo stage	4
0.09–0.17	MATC ^b after exposure of eyed eggs and subsequent developmental stages for 18 months in soft water	31
0.18–0.40	MATC ^b ; 10-month exposure starting with newly-fertilized embryos	4
0.6	All eyed eggs survived 10-week exposure	31
1.2	40% of eyed eggs dead in 39 days	31
2.0	Inhibition of Na^+ and Cl^- influx across gills in mature trout after 72 h	44
2.2	All eyed eggs dead in 60 days	31
4.8–8.9	LC50 (144 h); juveniles	13, 44
5.3–8.1	LC50 (96 h); water hardness 20–31 mg CaCO_3/L	31
7.6–10.9	LC50 (96 h)	4, 23, 41
10.0	LC50 (28 days) at 93–105 mg CaCO_3/L	4
13.0	LC50 (96 h); water hardness 350 mg CaCO_3/L	31
16.1 (12.8–20.2)	LC50 (96 h); alevins	30
19.2 (16.0–23.1)	LC50 (96 h); juveniles	30
Juveniles fed diets containing 0, 3, 30, 300, or 3000 mg Ag/kg DW ration for 58 days as silver sulfide (Ag_2S)	At day 43, the 3000 mg/kg diet had 4 times more silver in livers than did controls; however, there was no significant elevation in silver burdens of kidneys, gills or intestine. Daily food consumption rates were lowered by 14–22% in groups receiving 30 mg Ag/kg ration and higher, possibly because of decreased palatability of the silver-laden diets. Growth rates, however, were the same for all groups.	51
Steelhead trout, <i>Oncorhynchus mykiss</i>		
0.1–1.1	Growth reduced during chronic exposure from egg through swimup fry	23

Table 7.6 (continued) Effects of Silver on Representative Aquatic Plants and Animals (Concentrations are in micrograms of free silver (Ag^+) per liter of medium added at start unless indicated otherwise.)

Taxonomic Group, Organism, Silver Concentration (ppb), and Other Variables	Effects	Reference ^a
0.5 and 1.3	Survival reduced at low dose when exposed continuously from egg through swimup; all dead at high dose	23
9.2	LC50 (96 h)	23
100.0	LC50 (62 h); eyed embryos	32
200.0	LC50(96 h); eyed embryos	32
401.0; seawater acclimatized	No deaths in 96 h at 1.5 or 2.0% salinity; LC50 (96 h) at 2.5% salinity and LC67 (96 h) at 3.0% salinity	47
Chinook salmon, <i>Oncorhynchus tshawytscha</i>		
33.0	Fry survived exposure for 48 h	2
40.0–44.0	Lethal to fry in 48 h	2
Summer flounder, <i>Paralichthys dentatus</i>		
4.7	LC50 (96 h); larvae	4
8.0–48.0	LC50 (96 h); embryos	4
Fathead minnow, <i>Pimephales promelas</i>		
5.3–20.0	LC50 (96 h) at water hardness of 25–75 mg CaCO_3/L	4
5.6–7.4	LC50 (96 h); flow-through tests	23
9.4–9.7	LC50 (96 h); static tests	23
10.7 (10.6–10.8)	LC50 (96 h) at 44 mg CaCO_3/L	25
29.0	LC100 (96 h)	33
110.0–270.0	LC50 (96 h) at water hardness of 255 mg CaCO_3/L	4
Guppy, <i>Poecilia reticulata</i>		
4.3	Lethal	2
Winter flounder, <i>Pleuronectes americanus</i>		
10.0	Depressed liver transaminase activity after 60 days	10
54, 92, 180, or 386	No significant effect of lowest dose on growth or survival during exposure for 18 days of embryo through yolk-sac absorption. At 92 $\mu\text{g}/\text{L}$, 31% died; at 180 $\mu\text{g}/\text{L}$, 97% died; at 386 $\mu\text{g}/\text{L}$, hatch was reduced 24% and all larvae died	34
200.0–450.0	LC50 (96 h); embryos	4
Speckled dace, <i>Rhinichthys osculus</i>		
4.9	LC50 (96 h) in soft water	4
14.0	LC50 (96 h) in hard water	4
Brown trout, <i>Salmo trutta</i>		
Fingerlings exposed to radiosilver-110m for 57 days then transferred to clean freshwater for 28 days	After 57 days the whole body BCF was 2.7 with about 70% of total radiosilver concentrated in the liver (BCF for liver was 282); during depuration, 23% of whole fish radiosilver was excreted but concentration in liver was unchanged	35
Fingerlings were fed a diet containing radiosilver-110m for 34 days then fed a clean diet for 27 days	After 34 days, about 12% of the silver fed was retained; liver contained 63% of the total radioactivity. After 27 days of depuration 31% of the radiosilver was lost from whole trout, but liver contained 79% of the total radioactivity	36
Cunner, <i>Tautogolabrus adspersus</i>		
120, 250, or 500; after 96 h, gill tissues were excised and gill oxygen consumption monitored for 4 h	Gill tissue oxygen consumption was significantly lower than controls at all silver concentrations tested in a dose-dependent manner	37
500	After 96 h, gill tissue respiration was reduced and liver enzyme activity altered. Similar effects seen for silver nitrate and silver acetate	38
>500	Lethal after 96 h	37
Arctic grayling, <i>Thymallus arcticus</i>		
6.7 (5.5–8.0)	LC50 (96 h); alevins	30
11.1 (9.2–13.4)	LC50 (96 h); juveniles	30

Table 7.6 (continued) Effects of Silver on Representative Aquatic Plants and Animals (Concentrations are in micrograms of free silver (Ag^+) per liter of medium added at start unless indicated otherwise.)

Taxonomic Group, Organism, Silver Concentration (ppb), and Other Variables	Effects	Reference ^a
AMPHIBIANS		
Early life stages exposed to silver nitrate from fertilization through 4 days after hatching		
Leopard frog, <i>Rana pipiens</i>		
0.7–0.8	10% mortality or abnormal development of embryos and larvae	43
10.0	50% mortality or gross terata of embryos and larvae	43
5 species		
1–34	10% mortality or gross terata of embryos and larvae	43
10–240	50% mortality or abnormal development of embryos and larvae	43

^b MATC = maximum acceptable toxicant concentration. Lower value in each MATC pair indicates highest concentration tested producing no measurable adverse effect on growth, survival, reproduction, or metabolism during chronic exposure; higher value indicates lowest concentration tested producing a measurable effect.

Among arthropods, grass shrimp (*Palaemonetes pugio*) rapidly incorporate silver dissolved in brackish water in proportion to its concentration but not from planktonic or detrital food sources containing elevated silver burdens (Connell et al. 1991). Variations in ability of decapod crustaceans to accumulate radiosilver-110m from seawater are large, as judged by concentration factors that ranged from 70 to 4000 (Pouvreau and Amiard 1974). The reasons for this variability are unknown but may be associated with hepatopancreas morphology. It is generally acknowledged that hepatopancreas or digestive gland is the major repository of silver in decapods (Greig 1975; Greig et al. 1977a, 1977b). Aquatic insects concentrate silver in relative proportion to environmental levels (Nehring 1976), and more efficiently than most fish species (Diamond et al. 1990). Whole-body bioconcentration factors (BCF) of silver in 3 species of aquatic insects ranged from 21 to 240 in water containing 30 to 65 mg CaCO₃/L during exposure of 3 to 15 days; in bluegill sunfish (*Lepomis macrochirus*), this value was less than 1 after exposure for 28 days (USEPA 1980). Molt frequency of the stonefly (*Isonychia bicolor*) was a sensitive indicator of silver stress over time, and 1.6 µg total Ag/L over a 20-day period inhibited molting (Diamond et al. 1990). In freshwater sediments supplemented with silver nitrate, a high proportion of the dissolved silver fraction was not readily bioavailable to cause lethality to dipteran insect larvae (Call et al. 1999). Porewater concentrations of dissolved silver that killed 50% of the dipteran larvae were up to 275 times greater than the 10-day water-only LC50 value of 57 µg/L, indicating that most of the dissolved fraction was not readily bioavailable to cause death. Concentrations of silver in these sediments that caused significant adverse effects — 200 to 500 mg Ag/kg DW — in dipteran larvae were markedly above silver concentrations usually reported in the environment (Call et al. 1999).

Silver ion (Ag⁺) was the most toxic chemical species of silver to fishes. Silver ion was 300 times more toxic than silver chloride to fathead minnows (*Pimephales promelas*), 15,000 times more

toxic than silver sulfide, and more than 17,500 times more toxic than silver thiosulfate complex. In all cases, toxicity reflected the free silver ion content of tested compounds (Le Blanc et al. 1984); a similar pattern was noted in rainbow trout (Hogstrand et al. 1996). Silver was less toxic to fathead minnows under conditions of increasing water hardness between 50 and 250 mg CaCO₃/L, increasing pH between 7.2 and 8.6, and increasing concentrations of humic acid and copper. Starved minnows were more sensitive to ionic silver than minnows fed regularly (Brooke et al. 1994). Eggs of rainbow trout (*Oncorhynchus mykiss*) exposed continuously to silver concentrations as low as 0.17 µg/L had increased embryotoxicity and hatched prematurely; resultant fry had a reduced growth rate (Davies et al. 1978). Removal of the egg capsule of eyed embryos of steelhead trout (*O. mykiss*) significantly lowered the resistance of the embryos to salts of silver, copper, and mercury but not zinc and lead (Rombaugh 1985). Silver accumulation in gills of juvenile rainbow trout exposed to 11 µg Ag/L for 2 to 3 h was significantly inhibited by various cations (Ca²⁺, Na⁺, H⁺) and complexing agents (dissolved organic carbon, thiosulfate, chloride). These variables must be considered when constructing predictive models of silver binding to gills (Janes and Playle 1995).

Largemouth bass (*Micropterus salmoides*) and bluegills accumulated silver from the medium; accumulations increased with increasing concentrations of ionic silver and increasing duration of exposure (Coleman and Cearly 1974). Dietary silver sulfide exposure at or below 3000 mg Ag/kg ration is physiologically benign to juvenile rainbow trout over a 58-day period, although other forms of silver at dietary concentrations as low as 3 mg/kg DW ration can accumulate in liver of juvenile trout at concentrations 12-fold greater than controls after 3 months (Galvez and Wood 1999). Bioconcentration factors of radiosilver-110m and various species of teleosts were as high as 40 after 98 days (Pouvreau and Amiard 1974). However, flounders (*Pleuronectes platessa*) and rays (*Raja clavata*) fed nereid polychaete worms labeled with radiosilver-110m retained about 4.2% of the ingested dose after 3 days (Pentreath 1977), which suggests that the high silver concentration factors reported by Pouvreau and Amiard (1974) may have been due to loosely bound adsorbed silver. Flounders (*Pleuronectes* sp.) held in seawater solutions containing 40 µg Ag/L for 2 months had elevated silver concentrations in the gut (0.49 mg Ag/kg FW) but less than 0.05 mg/kg in all other examined tissues (Pentreath 1977). Similarly exposed rays (*Raja* sp.) contained 1.5 mg Ag/kg FW in liver, 0.6 in gut, 0.2 in heart, and 0.05 to 0.18 mg/kg FW in spleen, kidney, and gill filament (Pentreath 1977). Liver is usually considered the major repository of silver in teleosts (Garnier et al. 1990). In tidepool sculpins (*Oligocottus maculatus*), ionic silver was more toxic at lower salinities, longer exposure durations, and increasing medium ammonia concentrations; however, there was no correlation between whole-body silver burden and toxicity at 2.5% salinity, and no uptake at 3.2% salinity (Shaw et al. 1998).

At concentrations normally encountered in the environment, food chain biomagnification of silver in aquatic systems is unlikely (Connell et al. 1991; Ratte 1999), although regular ingestion of fish from contaminated waters may significantly affect dietary silver intake (USEPA 1980). Silver — as thiosulfate-complexed silver at nominal concentrations of 500 or 5000 µg Ag/L — was concentrated and magnified over a 10-week period in freshwater food chains of algae, daphnids, mussels, and fathead minnows (Terhaar et al. 1977), although the mechanisms of accumulation in this study were imperfectly understood. Sediments contaminated with silver sulfide (Ag₂S), however, do not seem to pose a major route of entry into the aquatic food web. Juvenile amphipods (*Hyalella azteca*) held on sediments containing as much as 753 mg Ag/kg DW, as silver sulfide, for 10 days had normal growth and survival (Hirsch 1998a). Aquatic oligochaetes (*Lumbriculus variegatus*) held on sediments containing 444 mg Ag/kg DW, as silver sulfide, for 28 days had a low bioconcentration factor of 0.18 (Hirsch 1998b). Fisher and Wang (1998) show that trophic transfer of silver in marine herbivores, especially mussels, is dependent on the silver assimilation efficiency from ingested food particles, feeding rate, and silver efflux rate. Silver assimilation efficiency is usually less than 30% and lower for sediment than for phytoplankton. Silver assimilation efficiency and distribution from ingested phytoplankton particles is modified by gut passage time, extracellular and intracellular digestion rates, and metal desorption at lowered pH. The kinetic

model of Fisher and Wang (1998) for mussels predicts that either the solute or particulate pathway can dominate and is dependent on silver partition coefficients for suspended particles, and silver assimilation efficiency.

7.5.4 Birds and Mammals

No data were found on the effects of silver compounds on avian or mammalian wildlife. All controlled studies with silver were with domestic poultry, livestock, or small laboratory mammals. Signs of chronic silver ion intoxication in tested birds and mammals included cardiac enlargement, vascular hypertension, hepatic necrosis, anemia, lowered immunological activity, altered membrane permeability, kidney pathology, enzyme inhibition, growth retardation, and a shortened life span (Smith and Carson 1977; Freeman 1979; Fowler and Nordberg 1986; USPHS 1990).

Silver affects turkeys (*Meleagris gallopavo*) and domestic chickens (*Gallus* spp.). Turkey poult on diets containing 900 mg Ag/kg of feed for 4 weeks had reduced growth, hemoglobin, and hematocrit and an enlarged heart (USEPA 1980). Chicken eggs injected with silver nitrate at 0.1 mg Ag/egg (equivalent to about 1.8 mg Ag/kg egg FW) had a 50% reduction in survival but no developmental abnormalities (Ridgway and Karnofsky 1952). Adverse effects of silver were reported in normal chicks fed diets containing 200 mg Ag/kg ration (growth suppression) or given drinking water containing 100 mg Ag/L (liver necrosis; Smith and Carson 1977). Chicks on copper-deficient diets had adverse effects at 10 mg Ag/kg ration (reduced hemoglobin; reversible when fed copper-adequate diet) and at 50 to 100 mg Ag/kg ration (growth suppression and increased mortality). Chicks deficient in Vitamin E experienced reduced growth when given drinking water containing 1500 mg Ag/L. Chickens infected with *Salmonella pullorum-gallinarum* and *Escherichia coli* were cured with aerosol treatments containing 10 µg Ag/L air (Smith and Carson 1977).

Studies with small laboratory mammals (which require verification) show that long-term exposure to high levels of silver nitrate in drinking water may result in sluggishness and enlarged hearts; however, these effects have not been observed in silver-exposed humans (USPHS 1990). Concentrations as high as 200 µg Ag/L in drinking water of test animals for 5 months had no significant effect on animal health or metabolism (USEPA 1990), but 400 µg Ag/L for 5 months caused kidney damage, and 500 µg/L for 11 months was associated with impaired conditioned-reflex activities, immunological resistance, and altered brain nucleic acid content (USEPA 1980). Diets deficient in Vitamin E or selenium caused rapidly fatal hepatocellular necrosis and muscular dystrophy in rats if they contained the dietary-intake equivalent of 130 mg Ag/kg BW daily, a comparatively high silver ion intake (Smith and Carson 1977; USPHS 1990).

The extent of absorption of an administered dose of silver depends on silver speciation, the presence and extent of silver-binding proteins, and other variables. But absorption depends mainly on the transit time through the gastrointestinal tract; the faster the transit time, the less silver is absorbed. Transit times ranged from about 8 h in mice and rats to about 24 h in monkeys, dogs, and humans (USPHS 1990). Route of administration affected the excretion rate of silver. Clearance of silver from mammals 2 days after silver was administered intravenously ranged from 15% in dogs to 82% in mice; clearance rates were intermediate in monkeys and rats. When silver was administered orally, clearance was more rapid, and extended from 90.4% in dogs to 99.6% in mice. The half-time persistence of silver administered orally to mice was 0.1 day for the short-lived component and 1.6 days for the long-lived component. Other species of tested laboratory animals had biphasic or triphasic whole-body silver-excretion profiles that differed significantly from mice. Monkeys, for example, had a biphasic excretion profile with peaks at 0.3 and 3.0 days; rats had a triphasic profile with peaks at 0.1, 0.7, and 5.9 days; and dogs had half-time persistence peaks at 0.1, 7.6, and 33.8 days (USPHS 1990).

Ionic silver is lethal to mice (*Mus* spp.) at 13.9 mg/kg BW by intraperitoneal injection, to rabbits (*Oryctolagus* spp.) at 20 mg/kg BW intraperitoneally, to dogs (*Canis familiaris*) at 50 mg/kg BW

by intravenous injection, to humans at greater than 166 mg/kg BW in a single dose, and to rats (*Rattus* spp.) at 1586 mg/L drinking water for 37 weeks (Table 7.7). Sublethal effects are reported in rabbits given 250 µg Ag/L drinking water (brain histopathology), in rats given 400 µg Ag/L drinking water for 100 days (kidney damage), in mice given 95 mg Ag/L drinking water for 125 days (sluggishness), in guinea pigs (*Cavia* sp.) given 81 mg Ag/cm² skin applied daily for 8 weeks (reduced growth), and in rats given diets containing 6 mg Ag/kg for 3 months (high accumulations in kidneys and liver) or 130 to 1110 mg/kg diet (liver necrosis; Table 7.7).

The connections between human cancers and silver as a causal agent are tenuous (USEPA 1980). All available evidence is negative or inconclusive on silver's ability to induce cancer, mutagenicity, or birth defects in animals by normal routes of exposure (USEPA 1980; USPHS 1990). Silver pellets, however, implanted under the skin of rodents, have caused sarcomas, malignant fibrosarcomas, fibromas, fibroadenomas, and invasions of muscle with connective tissue; in these cases, silver seems to act as a nonspecific irritant rather than as a specific carcinogen (Smith and Carson 1977; USEPA 1980). Intratumoral injections of colloidal silver promotes cancer growth in rats, possibly by producing an area of lowered tissue resistance that allows resistant cancer cells to grow freely (Smith and Carson 1977). However, silver nitrate seems to be a tumor inhibitor in mice (USEPA 1980).

In humans, acute toxic effects of silver have resulted only from accidental or suicidal overdoses of medical forms of silver. Symptoms of acute silver poisoning in patients dying after intravenous administration of Collargo (silver plus silver oxide) included gastrointestinal disturbances, pulmonary edema, tissue necrosis, and hemorrhages in bone marrow, liver, and kidney (Smith and Carson 1977; USEPA 1980). High sublethal doses of silver nitrate taken orally cause some patients to experience violent abdominal pain, abdominal rigidity, vomiting, and severe shock. Systemic effects among recovering patients are unlikely, although degenerative liver changes may occur (USEPA 1980). In humans, skin contact with silver compounds may cause mild allergic reactions such as rash, swelling, and inflammation (USPHS 1990); industrial and medicinal exposures to silver may cause lesions of the kidneys and lungs, and arteriosclerosis (Klaassen et al. 1986); colloidal silver compounds may interfere with nasal ciliary activity (Smith and Carson 1977); and exposure to dust containing high levels of silver compounds, such as silver nitrate or silver oxide, may cause breathing problems, lung and throat irritation, and stomach pain (USPHS 1990).

Chronic exposure of humans to silver or silver compounds frequently resulted in generalized argyria (slate-gray pigmentation of the skin and hair caused by deposition of silver), localized argyria (limited areas of pigmentation usually associated with medicinal silver applications), or argyrosis (argyria of the eye). Every silver compound in common chemical use has caused generalized argyria, usually from medical and occupational exposures (Smith and Carson 1977; USEPA 1980). In generalized argyria, skin pigmentation was highest in light-exposed areas, although silver concentrations in light-exposed and dark-exposed skin were the same (USEPA 1980). In severe cases of argyria, the skin can become black with a metallic luster, the eyes can be affected to the point that vision is disturbed, and the respiratory tract can be impaired (Klaassen et al. 1986). Individual variability in susceptibility to argyria is great and this is probably explained by the variability in absorption and retention of silver (Smith and Carson 1977). Generalized argyria as an occupational disease is unusual but has been reported in workers who make silver nitrate or are involved in mirror plating, glass bead silverying, silver Christmas cracker manufacturing, photographic plate manufacturing, and silver mining. Generalized argyria was also associated with chronic inhalation or ingestion of silver fulminate, silver nitrate, silver albuminate, and silver cyanide (Smith and Carson 1977). Improved workplace ventilation and sanitation among silver nitrate workers effected a decline in general argyria (USEPA 1980).

Localized argyria is rare and usually occurs when silver compounds contact broken skin or mucous membranes (Smith and Carson 1977). Localized argyria has been reported in workers who handle metallic silver in filing, drilling, polishing, turning, engraving, forging, soldering, or smelting

Table 7.7 Effects of Silver on Selected Mammals

Organism, Route of Administration, Dose, and Other Variables	Effects	Reference ^a
DOMESTIC DOG, <i>Canis familiaris</i>		
Inhalation route. Anesthetized dogs exposed to metallic silver particles about 0.5 µm in diameter; total dose deposited of 25 µg	About 3% (0.8 µg) of the deposited silver was found in liver and blood 6h after exposure. Clearance from the lung to the blood was triphasic, with half-times of 1.7, 8.4, and 40 days	1
Intratracheal route. Elemental silver deposited in lungs	After 6 h, 96.9% remained in the lung, 2.4% in liver, 0.35% in blood, 0.14% in gall bladder and bile, 0.1% in intestines, 0.06% in kidneys, and 0.02% in stomach. After 225 days, 0.49% of the initial dose was detected in liver, and 0.01–0.03% each in brain, gall bladder, intestines, lungs and trachea, bone, stomach and contents, heart, and muscle. If lung is excluded, liver contained 77% of the total silver body burden between 6 h and 225 days postexposure	1
Intravenous injection route 0.003 µg/kg body weight (BW) daily 500 mg (estimated at 50 mg/kg BW), single injection Oral route; 0.005 µg/kg BW daily	15% cleared in 2 days All dead within 24 h with hemolysis and lung edema 90.4% cleared in 2 days	1 2 1
GUINEA PIG, <i>Cavia</i> sp.		
Dermal application of 81 mg silver nitrate to 3.1 cm ² of skin daily for 8 weeks	Growth rate reduced 10–20%	1
HUMANS, <i>Homo sapiens</i>		
External route 0.25% silver nitrate solution in eyes for 3 weeks 3 to 5% colloidal silver compounds in eyes for 5–10 weeks	Argyrosis Argyrosis	2 2
Inhalation route 0.25 mg/m ³ air 1–2 mg/m ³ air; occupational exposure	Possibility of generalized argyria in 20 years Argyrosis of cornea and conjunctiva	2 3
Clearance half-time Feces Lung Urine	>300 days Biexponential profile; 1 day and 52 days <54 days	1 1 1
Oral route 80 µg/kg BW, single dose 0.7 mg silver weekly in diet 2–30 grams of silver nitrate, single dose 50–260 grams of metallic silver >600 grams over 1.2 years; given as silver nitrate to treat epilepsy and GI symptoms	21% of dose retained in body after 1 week Possibility of generalized argyria At dosages >10 grams death usually occurs within a few hours to a few days Gastric fullness, anorexia, gastric pain, diarrhea Generalized argyria evident 2 years after last dose	1 2 2, 3 2, 3 2
MONKEYS, Various		
Intravenous administration of 0.01 µg/kg BW daily Oral administration of 0.01 µg/kg BW daily	44.1% excreted in 2 days 94.3% cleared in 2 days	1 1

Table 7.7 (continued) Effects of Silver on Selected Mammals

Organism, Route of Administration, Dose, and Other Variables	Effects	Reference ^a
DOMESTIC MOUSE, <i>Mus</i> spp.		
Drinking water route; 95 mg/L for 125 days	Sluggishness	1
Intraperitoneal route		
13.9 mg/kg BW, single injection	LD50(30 days)	3
35.0 mg/kg BW, single injection; pretreated with single injection of 3.5 mg Ag/kg BW 24 h earlier	Only 3 of 10 pretreated mice died within 7 days vs. 8 of 10 nonpretreated mice	3
Intravenous injection; 1.0 µg/kg BW daily	82% cleared in 2 days	1
Oral route; 1.1 µg/kg BW daily	99.6% cleared in 2 days	1
RABBIT, <i>Oryctolagus</i> sp.		
Drinking water route		
Equivalent to 2.5 µg Ag/kg BW daily	No observable adverse effects	2
Equivalent to 25 or 250 µg Ag/kg BW daily for 11 months	Brain histopathology; altered conditioned reflexes	2
Equivalent to 500 or 5000 µg Ag/kg BW daily for 11 months	Lowered immunological activity; pathology of vascular, nerve, brain, and spinal cord tissues	3
Intraperitoneal injection route; 20 mg/kg BW, single injection	All dead within 2 h. Silver granules in liver parenchyma and kidney tubules	3
LABORATORY WHITE RAT, <i>Rattus</i> spp.		
Diet		
Equivalent to 6 mg/kg BW daily	After 12 weeks, kidneys and liver were impregnated with silver	2
130–1110 mg/kg ration	Liver necrosis which could be prevented by adding Vitamin E	2
Drinking water route		
50 µg/L (equivalent to 0.0025 mg Ag/kg BW daily) for 11 months	Normal in all variables measured (conditioned reflex activity, gastric secretion, blood serum enzymes, histology)	3
200 µg/L for 6 months	Normal conditioned reflex activity	3
<400, 400, 700, or 1000 µg/L for 100 days	At <400 µg/L, rats seemed healthy with normal tissuey histology. At 400 µg/L, hemorrhages noted in kidney. At 700 µg/L, kidney and liver histopathology was evident. At 1000 µg/L, spleen was pigmented and kidney and liver damage more pronounced	3
500 µg/L (equivalent to 0.025 mg Ag/kg BW daily) for 6 to 11 months	Abnormal conditioned reflex activity; increased liver weight and liver RNA concentration	3
5 mg/L for 6 months	Signs of intoxication beginning at days 25–27	3
20 mg/L for 3 months	Decreased growth; abnormal liver; increased levels of blood amino acids	3
20 mg/L for 5 months	Pathology in stomach, small intestine, and liver; altered blood serum enzyme activity; growth depressed 36%	3
20 mg/L for 6 months	Increased brain DNA and RNA	2
129 mg/L (about 18 mg/kg BW daily) for 17.8 weeks	Silver accumulations in brain and CNS; reduced motor activity	1
634 mg/L (89 mg Ag/kg BW daily) for 2 years	No effect on male fertility; no silver deposits in testes	1
635–660 mg/L; lifetime exposure beginning shortly after weaning	Lifespan normal; hypertrophy of left ventricle, suggesting vascular hypertension; skin normal but internal organs and eyes darkened by silver deposits	3
1200 mg/L for several months	Degenerative kidney changes	3

Table 7.7 (continued) Effects of Silver on Selected Mammals

Organism, Route of Administration, Dose, and Other Variables	Effects	Reference ^a
1500 mg/L for 2–4 weeks; Vitamin E-deficient rats	Liver necrosis and death. Prevented by adding Vitamin E	2
1586 mg/L for 37 weeks	Some deaths beginning at week 23; survivors weighed about 50% less than controls	1
2500 mg/L for 3 months, then silver-free water for 16 months	At end of exposure livers had 6.7–7.0 mg Ag/kg FW and kidneys 3.7–7.1 mg/kg FW; 16 months after exposure livers had 1.6 mg/kg FW and kidneys 6.0 mg/kg FW	3
2589 mg/L, (equivalent to 362 mg Ag/kg BW daily) for 2 weeks	25% died; water intake decreased beginning at day 1; survivors poorly groomed and listless	1
Intramuscular injection route		
Given radiosilver-110m alone or in combination with 4.0 mg Ag/kg BW daily for 6 days. Percent of tracer dose recovered vs. percent tracer plus 4.0 mg/kg BW		
Blood	0.5 vs. 3.0	1
Bone	0.2 vs. 2.2	1
Feces	96.6 vs. 37.3	1
GI tract	1.1 vs. 8.2	1
Heart, lungs	0.06 vs. 0.6	1
Kidney	0.07 vs. 0.6	1
Liver	0.4 vs. 33.7	1
Muscle	0.2 vs. 2.4	1
Skin	0.2 vs. 7.4	1
Spleen	0.01 vs. 2.7	1
Urine	0.6 vs. 1.8	1
Intravenous injection route		
0.2 µg/kg BW daily	70.7% excreted in 2 days vs. 98.4% in 2 days when administered orally	1
Isolated hepatocytes exposed for 20 h		
<275 µg/L	Not cytotoxic	4
500, 2000, or 5000 µg/L	Silver accumulated in nuclear fraction of hepatocytes at all concentrations; DNA repair synthesis was stimulated at 2000 µg/L; moderately cytotoxic at 5000 µg/L	5
1100 µg/L	Protein synthesis activity inhibited 50%	4
1980 µg/L	Almost complete inhibition of protein synthesis activity	4
Subcutaneous injection route		
7 mg/kg BW, single injection	Adverse effects on spermatogenesis and on testes histology	2, 3
Oral route		
123 mg/kg BW, as silver cyanide	Acute oral LD50	6
200–400 mg/kg BW, as silver arsenate	Acute oral LD50	6
500–800 mg/kg BW, as silver nitrate	Acute oral LD50	6
CARIBOU, <i>Rangifer tarandus</i>		
Ratio of silver concentration (mg/kg FW) in tissues to silver concentration (mg/kg FW) in lichen diet		
Bone	Bioconcentration factor (BCF) of 3.0	3
Kidney	BCF of 1.3	3
Liver	BCF of 80.0	3
Muscle	BCF of 0.3	3

^a 1, USPHS 1990; 2, Smith and Carson 1977; 3, USEPA 1980; 4, Denizeau et al. 1990; 5, Denizeau and Marion 1989; 6, Lockhart 1983.

operations. Silver polishers exposed for 25 years or more (range 2 to 38 years) sometimes exhibit increased densities in their lung X-rays due to silver impregnation of the elastic membranes of the pulmonary vessels. In one case, an Italian physician who dyed his facial hair with a silver dye for 25 years developed argyria in the conjunctiva of both eyes (Smith and Carson 1977).

7.6 RECOMMENDATIONS

Most measurements of silver concentrations in natural waters prior to the use of clean techniques are considered inaccurate. Until analytical capabilities that exceed the dissolved-particulate classification are developed, it will be necessary to rely on laboratory and theoretical modeling studies to fully understand chemical speciation of silver in natural waters (Andren et al. 1995).

Factors governing the environmental fate of silver are not well characterized, including silver transformations in water and soil and the role of microorganisms (USPHS 1990). The toxic potential of silver chloride complexes in seawater and the role of sediments as sources of silver contamination for the food web needs more research (Ratte 1999). Food chain transfer of silver requires more current information on sources and forms of silver and data on concentrations in field collections of flora and fauna, especially near hazardous waste sites (USPHS 1990). Although silver in sewage sludge is mostly immobilized, data are limited on silver concentrations in flesh and milk of livestock pastured or fed grains raised on soils amended with sewage sludge (Smith and Carson 1977). Data are needed on partition coefficients and vapor pressures of silver compounds (USPHS 1990) and on silver concentrations in emissions from cement producers and smelters and refineries of copper, lead, zinc, silver, iron, and steel (Smith and Carson 1977). Also, technology to recapture silver from waste media before it reaches the environment must be improved (USPHS 1990).

Silver criteria in aquatic ecosystems are under constant revision by regulatory agencies. For example, total recoverable silver is no longer recommended by the U.S. Environmental Protection Agency in silver criteria formulation and should be replaced by dissolved silver (USEPA 1995a). Dissolved silver more closely approximates the bioavailable fraction of silver in the water column than does total recoverable silver (USEPA 1995b). Dissolved silver criteria recommended are about 0.85 times those of total recoverable silver under certain conditions but may vary considerably depending on other compounds present in solution (USEPA 1995b).

The proposed human drinking water criteria of 50 to <200 µg total Ag/L do not seem to represent a hazard to human health, although much lower concentrations adversely affect freshwater and marine organisms (Smith and Carson 1977; [Table 7.8](#)). Proposed silver criteria for the protection of freshwater aquatic life during acute exposure now range from 1.2 to 13.0 µg total recoverable silver per liter ([Table 7.8](#)). If all total recoverable silver were in the ionic form, these proposed criteria would overlap the 1.2 to 4.9 µg/L range found lethal to sensitive species of aquatic plants and animals, and this indicates that the proposed freshwater acute silver criteria need to be reexamined. For freshwater aquatic life protection during chronic exposure, the proposed criterion of less than 0.13 µg total recoverable silver per liter ([Table 7.8](#)) is probably protective, but the proposed silver criterion of 2.3 µg total silver/L to protect marine life ([Table 7.8](#)) needs to be reconsidered because phytoplankton species composition and succession are significantly altered at 0.3 to 0.6 µg total silver/L and because some species of marine algae and molluscs show extensive accumulations at 1.0 to 2.0 µg total silver/L. Limited but insufficient data were available on correlations between tissue residues of silver with health of aquatic organisms ([Table 7.8](#)); additional research seems needed on the significance of silver residues in tissues.

In aquatic environments, more research is needed on the chemical speciation of silver to evaluate risk to the organism and its consumers (USEPA 1987; Berthet et al. 1992). Most silver criteria formulated for the protection of aquatic life are now expressed as total recoverable silver per liter ([Table 7.8](#)), but total silver measurements do not provide an accurate assessment of potential hazard. Silver ion (Ag⁺), for example, is probably the most toxic of all silver chemical species and must

Table 7.8 Proposed Silver Criteria for the Protection of Natural Resources and Human Health

Resource, Criterion, and Other Variables	Effective Silver Concentration	Reference ^b
AGRICULTURAL CROPS		
Soils	<100 mg total silver/kg dry weight soil for most species; <10 mg/kg for sensitive species	7
FRESHWATER AQUATIC LIFE PROTECTION		
Acute exposure		
Total recoverable silver	<1.32 µg/L	1
Acid-soluble silver ^a	Four-day average shall not exceed 0.12 µg/L more than once every three years; 1-h average not to exceed 0.92 µg/L more than once every three years	8
Acute exposure		
Total recoverable silver, in µg/L, should not exceed $e^{(1.72[\ln(\text{hardness})]-6.52)}$ at any time.		
Examples follow:		
50 mg CaCO ₃ /L	<1.2 µg/L	2
100 mg CaCO ₃ /L	<4.1 µg/L	2
200 mg CaCO ₃ /L	<13.0 µg/L	2
Chronic exposure	<0.12 to <0.13 µg total recoverable silver/L	1, 2
Tissue residues		
Adverse effects on growth of the Asiatic clam, <i>Corbicula fluminea</i>	>1.65 mg total silver/kg soft tissues, fresh weight basis	1
MARINE LIFE PROTECTION		
Acute exposure		
Total recoverable silver	<2.3 µg/L at any time	2
Acid-soluble silver ^a	Four-day average concentration not to exceed 0.92 µg/L more than once every three years on average and the 1-h concentration not to exceed 7.2 µg/L more than once every three years	8
Tissue residues		
Marine clams, soft parts		
Normal	<1 mg total silver/kg dry weight	3
Stressful or fatal	>100 mg total silver/kg dry weight	3
HUMAN HEALTH		
Air, United States		
Current level of exposure, nationwide	100 µg total silver daily per person	2
Short-term exposure limit (15 min; up to 4 times daily with 60 min intervals at <0.01 mg Ag/m ³ air)	<0.03 mg total silver/m ³	2
Threshold limit value (8 h daily, 5 days weekly)		
Aerosol silver compounds	<0.01 mg total silver/m ³	2, 4, 5
Metallic silver dust	<0.1 mg total silver/m ³	5
Diet, United States		
Current level of exposure	35 to 40 µg daily per person	2
Drinking water		
United States		
Long-term exposure (>10 days)	<50 µg total silver/L	2, 5, 6
Proposed long-term exposure	<90 total silver µg/L	5
Short-term exposure (1–10 days)	<1142 µg total silver/L	5
California	<10 µg/L	2
Germany	<100 µg/L	2
Space vehicles		
Former Soviet Union	Max. 200 µg total silver/L	2

Table 7.8 (continued) Proposed Silver Criteria for the Protection of Natural Resources and Human Resource, Criterion, and Other Variables

Resource, Criterion, and Other Variables	Effective Silver Concentration	Reference ^b
United States	100 to Max. 200 µg total silver/L	2
Switzerland	<200 µg total silver/L	2
Groundwater	<50 µg total silver/L	5

^a Silver that passes through a 0.45 µm membrane after the sample has been acidified to a pH between 1.5 and 2.0 with nitric acid.

^b 1, Diamond et al. 1990; 2, USEPA 1980; 3, Bryan and Langston 1992; 4, Smith and Carson 1977; 5, USPHS 1990; 6, Fowler and Nordberg 1986; 7, Hirsch et al. 1993; 8, USEPA 1987.

be accurately measured in the assessment of silver risks in aquatic environments (Le Blanc et al. 1984; Hogstrand and Wood 1998; Bury et al. 1999b; Ratte 1999), perhaps as acid-soluble silver (USEPA 1987). Little is known of the biocidal properties of Ag²⁺ and Ag³⁺, which are the active ingredients in disinfectants and used increasingly in water purification systems of drinking water and swimming pools (Antelman 1994). The effects of these silver species on organism health clearly must be researched (USPHS 1990). Silver interactions with other metals and compounds in solution are not well defined. For example, mixtures of salts of silver and copper markedly increased the survival of oyster embryos, but only when copper concentrations were less than 6 µg/L and total silver less than 11 µg/L (Coglianese and Martin 1981).

The current freshwater acute ambient water-quality criterion for silver in the United States recognizes that water calcium levels may modify toxicity; however, studies with rainbow trout suggest that calcium and sodium were not as important as chloride or dissolved organic carbon in ameliorating adverse effects of silver (Bury et al. 1999b; Karen et al. 1999). Dissolved organic carbon was considered more important than hardness for predicting the toxicity of ionic silver in natural waters to daphnids and fishes (Karen et al. 1999). Incorporating an organic carbon coefficient into the silver criterion equation will enhance the criterion values for site specificity (Karen et al. 1999). The present proposed silver criteria for aquatic life protection could be further improved by taking into account the important geochemical modifiers of silver (Hogstrand and Wood 1998). For example, complexation of Ag⁺ by chloride, dissolved organic carbon and sulfide are important in reducing silver toxicity, and AgNO₃ as Ag⁺ is less toxic in seawater (LC50 [96 h] range of 320 to 2700 µg/L) than in freshwater (5 to 70 µg/L). More research is needed on the buildup of ammonia in Ag⁺-poisoned teleosts and its effects on their ability to swim. In any event, it is debatable whether silver discharges into the freshwater environment ever result in Ag⁺ levels high enough to cause acute toxicity (Hogstrand and Wood 1998). Laboratory tests with AgNO₃ reportedly overestimate acute silver toxicity because of the abundance in the field of natural ligands which bind Ag⁺ and reduce its toxicity. Also, there is little credible evidence that internal silver accumulations in freshwater biota play any role in acute toxicity or that dietary silver causes toxicity. In marine environments, current acute silver criteria seem overly stringent for aquatic life protection, with more research needed on chronic toxicity to euryhaline fishes — including the toxic potential of accumulated silver (Hogstrand and Wood 1998).

No studies have been conducted with silver and avian or mammalian wildlife, and it is unreasonable to extrapolate the results of limited testing with domestic poultry and livestock to wildlife to establish criteria or administratively enforced standards. Research on silver and avian and terrestrial wildlife merits the highest priority in this subject area. No silver criteria are available for the protection of avian and mammalian health, and all criteria now proposed are predicated on human health (Table 7.8). As judged by the results of controlled studies with poultry and small laboratory mammals, safe concentrations of silver ion were less than 250 µg/L in drinking water of mammals, less than 100 mg/L in drinking water of poultry, less than 6 mg/kg in diets of mammals, less than 10 mg/kg in copper-deficient diets of poultry, less than 200 mg/kg in copper-adequate diets of poultry, and less than 1.8 mg/kg in chicken eggs. The proposed short-term (10-day) allowable limit of 1142 µg Ag/L in drinking water for human health protection (Table 7.8) should

be reconsidered because it is 4.6 times higher than the value that produced adverse effects in sensitive laboratory mammals. Additional animal studies are needed to elucidate the effects of silver and silver compounds on reproduction, development, immunotoxicity, neurotoxicity, absorption, distribution, metabolism, and excretion; and on oral, dermal, and inhalation routes of exposure (USPHS 1990). In animals, there is also the need to establish a target organ for intermediate exposures to silver; to establish suitable biomarkers of silver exposures and effects; and to measure effects of chronic silver exposures on carcinogenicity (USPHS 1990). These studies should be implemented with suitable sentinel organisms including waterfowl, aquatic mammals, and other species of wildlife.

It is emphasized that silver and its compounds do not pose serious environmental health problems to humans from 50 µg/L in drinking water and 10 µg/m³ in air (Smith and Carson 1977). The only proven effect of chronic exposure to silver is argyria from occupational or therapeutic exposure to much larger amounts of silver (minimum necessary absorption of 910 µg, equivalent to about 15 µg/kg BW) than can feasibly be ingested or inhaled from environmental sources. Regular ingestion of fish, meat, and plants from silver-contaminated areas probably does not cause argyria (Smith and Carson 1977). Humans at special risk for argyria include those treated with silver-containing medicinals and people marginally deficient or deficient in copper, selenium, or Vitamin E (USEPA 1980). There is no recognized effective treatment for argyria, although the condition seems to be relatively stationary when exposure to silver is discontinued (Fowler and Nordberg 1986). Absorption and retention of silver from food and medicinals is imperfectly understood (Smith and Carson 1977), suggesting the need for additional animal studies.

Finally, alternatives exist to the use of silver in various materials and processes. These include substitution of aluminum and rhodium for silver in mirrors and other reflecting surfaces; tantalum replacement of silver in surgical plates, pins, and sutures; stainless steel as an alternative material to silver in the manufacture of table flatware; and, in photography, film with reduced silver content (Reese 1991).

7.7 SUMMARY

Ecological and toxicological aspects of silver (Ag) and silver salts in the environment are briefly summarized with an emphasis on natural resources. Subtopics include sources and uses, chemistry and metabolism, concentrations in field collections, lethal and sublethal effects, and recommendations for the protection of natural resources. Elevated silver concentrations in biota occur in the vicinities of sewage outfalls, electroplating plants, mine waste sites, and silver-iodide seeded areas; in the United States, the photography industry is the major source of anthropogenic silver discharges into the biosphere. Maximum concentrations recorded in field collections, in mg total silver/kg dry weight (tissue), were 1.5 in mammals (liver), 6 in fish (bone), 14 in plants (whole), 30 in annelid worms (whole), 44 in birds (liver), 110 in mushrooms (whole), 185 in bivalve molluscs (soft parts), and 320 in gastropods (whole). Humans afflicted with silver poisoning (argyria) contained 72 mg total Ag/kg dry weight skin and 1300 mg total Ag/kg fresh weight whole body. Silver and its compounds are not known to be mutagenic, teratogenic, or carcinogenic. Under normal routes of exposure, silver does not pose serious environmental health problems to humans at less than 50 µg total Ag/L drinking water or 10 µg total Ag/m³ air. Free silver ion, however, was lethal to representative species of sensitive aquatic plants, invertebrates, and teleosts at nominal water concentrations of 1.2 to 4.9 µg/L; at sublethal concentrations, adverse effects were significant between 0.17 and 0.6 µg/L. No data were found on effects of silver on avian or mammalian wildlife; all studied effects were on poultry, small laboratory animals, and livestock. Silver was harmful to poultry at concentrations as low as 1.8 mg total Ag/kg whole egg fresh weight by way of injection, 100 mg total Ag/L in drinking water, or 200 mg total Ag/kg in diets; sensitive mammals were

adversely affected at total silver concentrations as low as 250 µg/L in drinking water, 6 mg/kg in diets, or 13.9 mg/kg whole body. Proposed criteria for the protection of living organisms from silver are listed and discussed.

CHAPTER 8

Tin

8.1 INTRODUCTION

Interest in the toxicity of tin compounds dates to the early 1800s when investigators demonstrated that inorganic tin compounds produced muscular weakness, loss of pain sensation, and immobility in dogs (Reiter and Ruppert 1984; Idemudia and McMillan 1986b). In humans, organotins can be assimilated by inhalation, absorption through the skin, and from food and drinking water (Zuckerman et al. 1978). The first documented case of organotin poisoning of humans was in 1880 when workers complained of headaches, general weakness, nausea, and diarrhea after exposure to triethyltin acetate vapors (Reiter and Ruppert 1984). Renewed interest in the toxicity of organotin compounds resulted from a medical tragedy in France in 1954. “Stalinon,” a proprietary compound of diethyltin diiodide plus linoic acid used to treat furuncles and other skin infections, caused 217 poisonings and 111 deaths (Piver 1973; Duncan 1980; Idemudia and McMillan 1986b). The identified toxic components in Stalinon were triethyltin contaminants; victims received a total dose of 3 grams over a 6- to 8-week period. Symptoms included constant severe headache, rapid weight loss, vomiting, urine retention, vertigo, hypothermia, abdominal pain, and visual and psychic disturbances. Some of the more severely affected patients had convulsions. Death usually occurred in coma or from respiratory or cardiac failure. In survivors, headaches and diminished visual acuity remained for at least 4 years.

World production of organotin compounds is about 30,000 tons, although relatively few organotin compounds, perhaps only 25, are produced and used to any great extent (Laughlin and Linden 1985). Diorganotins are used in the manufacture of antioxidants, whereas triorganotins are used as general biocides against microbial and invertebrate pests and in marine antifouling paints (Laughlin and Linden 1985). The first antifouling paints incorporating an organotin compound as a biocide were developed in 1961. Because of their effectiveness and availability in a variety of colors, tributyltin antifouling paints are the most commonly used type, replacing copper-, mercury-, and lead-based paints (Stebbing 1985). Worldwide synthesis of tributyltin compounds is about 900 metric tons annually for all applications (Laughlin et al. 1986a). Tributyltins are highly toxic to aquatic plants and animals, readily accumulate in fish and molluscs from contaminated localities, and are present in some harbors where their release from antifouling paints — found usually on small boats and recreational craft — is the putative source (Walsh et al. 1985; U.S. Environmental Protection Agency [USEPA] 1986; Laughlin et al. 1986a). Tributyltin is a contributory factor and probably a major cause for the reproductive failure of the European flat oyster (*Ostrea edulis*) in some locations (Thain and Waldock 1986). In fact, tributyltins are capable of causing adverse biological effects at levels far below those of any previously reported marine pollutant (Lawler and Aldrich 1987; van Slooten and Tarradellas 1994; Matthiessen and Gibbs 1998).

The widespread agricultural applications of trialkyltin biocidal agents have greatly increased the relative exposure risks to workers handling these materials (Rosenberg et al. 1985). Internationally, tin was recognized as a potential environmental contaminant at the Paris and Helsinki conventions in 1974; in later conventions, organotin compounds were moved to the “black list” (Vrijhof 1985). Due to the increasing use of organotin compounds as a class, the Canadian government, in 1979, placed organotins on Canada’s Category III Contaminant List. Category III indicates that additional data are needed on the occurrence, persistence, and toxicity of organotins for preparation of informed environmental and human health risk assessments (Chau et al. 1984). In 1982, the use of tributyltin paints was curtailed in France, and in 1985 the United Kingdom introduced regulations to limit sales of tributyltin paints that released the biocide at high rates (Huggett et al. 1992).

Many reviews and bibliographies are available on the environmental impacts of inorganic and organic tin compounds (Barnes and Stoner 1959; Piver 1973; Kimbrough 1976; CEC 1978; Zuckerman et al. 1978; Duncan 1980; Watanabe 1980; WHO 1980; Blunden and Chapman 1982; Blunden et al. 1984, 1985; Krigman and Silverman 1984; Reiter and Ruppert 1984; Reuhl and Cranmer 1984; Wilkinson 1984; Hall and Pinkney 1985; Laughlin and Linden 1985; McMillan and Wenger 1985; Thompson et al. 1985; Blunden and Chapman 1986; Cardwell and Sheldon 1986; Chang 1986; Maton 1986; Sylph 1986a, 1986b; USEPA 1987; Snoeij et al. 1987; Eisler 1989; Maguire 1991; U.S. Public Health Service [USPHS] 1992; Fent 1996). These authorities agree that inorganic tin compounds are comparatively harmless and that many organotin compounds are potentially very hazardous to natural resources — especially tributyltin compounds to aquatic biota. One rare exception to this generalization involved 113 cases of acute gastrointestinal illness in Washington and Oregon in 1969 associated with ingestion of canned tomato juice contaminated by inorganic tin; detinning in many cans resulted in tin levels as high as 477 mg inorganic tin per liter of juice. It seems that excessive use of nitrate fertilizer on one tomato crop was the ultimate cause of the detinning (Barker and Runte 1972).

8.2 CHEMICAL AND BIOCHEMICAL PROPERTIES

8.2.1 General

The chemical, physical, and biochemical properties of inorganic tin compounds differ dramatically from those of representative organotin compounds. There is general agreement that inorganic tins are not highly toxic due to their poor absorption and rapid turnover rate in tissues and to their being essential for growth in at least one species (rat). Of the 260 known organotin compounds, all but a few are manufactured, and 36 are listed as toxic (Watanabe 1980). Most authorities agree on several points regarding organotin compounds:

- Information concerning the mechanism of toxic action is incomplete
- There is no evidence of carcinogenicity
- Trialkyltin compounds are the most toxic
- There are large differences in resistance between and within species.

8.2.2 Inorganic Tin

Elemental tin has an atomic number of 50, an atomic mass of 118.69, and exists in three allotropic forms: white tin at room temperature, nonmetallic grey tin at <13.3°C, and brittle tin at >161°C. White tin is a stable silver-white, lustrous, soft metal with a density of 7.27, a melting point of 231.9°C, and a boiling point of 2507°C. Tin has 10 stable isotopes (^{112}Sn , ^{114}Sn , ^{115}Sn , ^{116}Sn , ^{117}Sn , ^{118}Sn , ^{119}Sn , ^{120}Sn , ^{122}Sn , and ^{124}Sn), more than any other element. Inorganic tin

compounds exist in the $+2$ (stannous) and $+4$ (stannic) oxidation states. Stannous compounds are generally more polar than stannic compounds, are unstable in dilute aqueous solutions, are easily oxidized, and normally contain some Sn^{+4} . Stannic oxide occurs naturally as the mineral cassiterite, has a melting point of 1127°C , and has wide application in industry. Additional information on inorganic tin chemistry is listed in Zuckerman et al. (1978), WHO (1980), Davies and Smith (1982) and USPHS (1992).

Signs of inorganic tin poisoning in mammals include local effects such as vomiting, diarrhea, and eye and nose irritation; however, these vary considerably among species (WHO 1980). The major systemic effects include ataxia, twitching of limbs, weakness of limbs, paralysis, growth retardation, decreased hemoglobin levels, and — at extremely high doses — testicular degeneration, pancreatic atrophy, formation of spongy brain white matter, and kidney necrosis. In humans, symptoms of inorganic tin intoxication include nausea, vomiting, diarrhea, stomach ache, fatigue, and headache. The lowest concentration producing outbreaks was about 250 mg Sn per liter in canned orange and apple juice. Ingestion of 50 mg of tin through eating canned peaches that contained Sn concentrations of about 450 mg/kg caused acute symptoms in 2 of 7 human volunteers (WHO 1980). Inhalation of SnO_2 dust is a hazard in the deep-mining of tin; deposits in lungs are easily detectable as “stannosis” (Krigman and Silverman 1984).

Inorganic tin and its salts are not highly toxic due to their poor absorption, relative insolubility of their oxides, and rapid tissue turnover (WHO 1980; Hassett et al. 1984; Krigman and Silverman 1984; Blunden and Chapman 1986). The absorption of ingested inorganic tin is usually less than 5%, although up to 20% has been reported. Stannous compounds are more readily absorbed from the gastrointestinal tract than stannic compounds, but absorbed tin leaves the vascular system rapidly. Bone is the main site of tin deposition, followed by lung, liver, and kidney. Penetration of the blood-brain and placental barriers by inorganic tin seems to be very slight. Except for lung, inorganic tin does not accumulate in organs with increasing age. Absorbed inorganic tin is excreted mainly in the urine, although excretion through the bile may account for up to 15% of the total. Tin and its inorganic compounds do not produce significant dermatitis or allergic reactions to skin epithelium, and results of all long-term studies of carcinogenicity, teratogenicity, and mutagenicity have been negative to date (WHO 1980).

WHO (1980) reviewed the half-time ($T_{1/2}$) of inorganic tins in animals. Studies with Sn^{+2} in mouse, rat, monkey, and dog show that in all species elimination is a four-compartment process regardless of the route of administration (i.e., intraperitoneal or intravenous). The $T_{1/2}$ for the longest-lived tin component was >3 months. In studies with rats, for example, radiotin-113 in skeleton following intramuscular administration had a $T_{1/2}$ of 3 to 4 months, but for oral administration of Sn^{+2} and Sn^{+4} it was only 28 to 40 days in bone and 10 to 20 days in liver and kidney. Inorganic tin can be biomethylated by microorganisms in the aquatic environment and subsequently mobilized in the ecosystem (Tugrul et al. 1983; Yemencioglu et al. 1987). The process is slow and usually does not proceed beyond the monomethyltin stage (Zuckerman et al. 1978), although dimethyltin formation by *Pseudomonas* bacteria has been reported (Smith 1978b). Tin is an essential nutrient for growth in the rat, and a tin-deficient diet leads to reduced growth (WHO 1980; Krigman and Silverman 1984). The mechanism of action is unclear, but involves increasing metabolic activity of liver lysosomes and liver hydrolytic enzymes during regeneration (Dwivedi et al. 1985a, 1985b).

8.2.3 Organotins

Organotins are compounds with at least one tin–carbon bond. In most organotin compounds, tin is in the tetravalent oxidation state. Four series of organotin compounds are known: R_4Sn , R_3SnX , R_2SnX_2 , and RSnX_3 wherein R is usually a butyl, octyl, or phenyl group, and X is commonly chloride, fluoride, oxide, hydroxide, carboxylate, or thiolate (CEC 1978). The possible molecular composition and structure of the R groups are virtually unlimited (Laughlin et al. 1985). At least 260 organotin compounds are known, of which 36 are listed as toxic chemicals (Watanabe 1980).

Except for some methyltin compounds, all organotins are manufactured (Laughlin et al. 1985). Most commercially used organotins are characterized by low mobility in the environment because of low aqueous solubility, low vapor pressure, and high affinity for soils and organic sediments (Blunden and Chapman 1986). Solubility data for organotin compounds are incomplete. In general, their solubility in water is limited to about 5 to 50 mg/L, but they are very soluble in many common organic solvents (WHO 1980). The presence of chloride in seawater reduces the solubility of tributyltin and triphenyltin compounds, probably by association with the hydrated cation to form the covalent organotin chloride (Blunden et al. 1985). Organotin compounds are analyzed in aqueous media by spectrophotometric, fluorometric, and electrochemical techniques. However, if picomole per liter concentrations are required, additional techniques must be used. More work needs to be done on analytical detection methods of organotins in sediments and biota (Thompson et al. 1985).

Methylation of inorganic and methyltin compounds has been reported with the formation of mono-, di-, tri-, and tetramethyltin compounds. In addition, tributylmethyltin and dibutylmethyltin species have been found in harbor sediments, which suggests that some butyltin compounds may be methylated in aquatic systems (Guard et al. 1981; Thompson et al. 1985; Donard et al. 1987). Methyltin formation in the environment is due mainly to methyl donation from methylcobalamin and methyl iodide (Hamasaki et al. 1995). Photochemical reaction and transalkylation of inorganic tins produce methyltins; methylation of tin increases the toxicity of their original metal form, due in part to their higher volatility and lipophilicity. Methyltins are ubiquitous in the environment and have been measured in seawater, freshwater, rain, wastewaters, sediments, fish, invertebrates, birds, and humans (Hamasaki et al. 1995).

Abiotic and biological degradation of organotins generally occurs through sequential dealkylation or dearylation (Zuckerman et al. 1978; WHO 1980; Smith 1981b; Chau et al. 1984; Blunden et al. 1985). Organotin compounds undergo successive cleavage of tin–carbon bonds to ultimately produce inorganic tin as follows: R_4Sn (via k_4) to R_3SnX (k_3) to R_2SnX_2 (k_2) to $RSnX_3$ (k_1) to SnX_4 . The reaction rate, k , usually proceeds as $k_4 > k_3 > k_2 = k_1$. The breaking of a Sn–C bond can occur by a number of different processes, including ultraviolet irradiation (UV), biological cleavage, chemical cleavage, gamma irradiation, and thermal cleavage (WHO 1980; Blunden and Chapman 1982, 1986; Blunden et al. 1985; Thompson et al. 1985). In general, UV and biological cleavage are the most important processes. The main abiotic factors that seem to limit organotin persistence in the environment are elevated temperatures, increased intensity of sunlight, and aerobic conditions (Table 8.1). A probable environmental degradation scheme for tributyltin and triphenyltin compounds is shown in Figure 8.1.

The tendency of an organotin compound to be concentrated by an organism depends on its partition behavior between lipid and aqueous phases. In general, compounds highly soluble in octanol and only slightly soluble in water have high K_{ow} values. K_{ow} values of organotins increase with number and molecular weight of organic groups attached to the tin atom, with significant bioaccumulation potential for organotins with R groups of butyl and larger (Thompson et al. 1985). K_{ow} values for tributyltins in seawater vary from 5500 to 7000, but can be significantly modified by salinity and speciation products (Laughlin et al. 1986b). Thus, organotins would be expected to accumulate in lipid-rich surface microlayers of natural waters (Cardwell and Sheldon 1986) and in biota (as discussed later). However, the ability of microorganisms, algae, and higher organisms to reduce various organotins to less toxic metabolites that can be excreted rapidly seems to preclude food chain biomagnification and to lessen the potential hazards to natural resources from consumption of organisms with elevated organotin residues (Table 8.1; Cardwell and Sheldon 1986).

Most authorities now agree on five points: (1) information concerning the mechanism of the toxic action of organotin compounds is inadequate; (2) results of all studies with various organotins for possible carcinogenicity are negative; (3) triorganotin compounds are the most toxic group of organotins; (4) large inter- and intraspecies differences exist in resistance to organotin compounds; and (5) organotins can alter enzyme activity levels in many organs and tissues including brain, liver, and kidney (Piver 1973; Duncan 1980; WHO 1980; Davies and Smith 1982; Maguire et al. 1982; Arakawa and Wada 1984; Dwivedi et al. 1985b; Blunden and Chapman 1986; Maguire 1991).

Table 8.1 Biological and Abiotic Degradation Times of Selected Organotins

Degradation Route, Organism or Compartment, and Tin Compound	Time for 50% Degradation and Other Variables (reference)
BIOLOGICAL	
Microorganisms	
Tributyltin	1 to 2 weeks in aerated medium in dark, 6 to 13 weeks in aerated medium in light, <1 year in anaerobic medium (Cardwell and Sheldon 1986)
Triphenyltin	60 to 140 days under aerobic, light conditions (Smith 1981b)
Algae, <i>Ankistrodesmus falcatus</i>	
Tributyltin	25 days (Maguire et al. 1984)
Bivalve molluscs, 3 species	
Tributyltin	10 to 14 days (Cardwell and Sheldon 1986; Laughlin et al. 1986a)
Sheepshead minnow, <i>Cyprinodon variegatus</i>	
Tributyltin	14 to 28 days (Cardwell and Sheldon 1986)
ABIOTIC	
Distilled water	
Tributyltin	>89 days at initial concentration of 0.7 mg Sn/L, 18 days at 2.0 to 4.0 mg Sn/L (Walsh et al. 1986a)
Freshwater	
Tributyltin	3 to 89 days (Duncan 1980; Smith 1981b; Ward et al. 1981; Maguire and Tkacz 1985; Walsh et al. 1985)
Triphenyltin	8 months at 1.0 to 2.5 mg/L, 100 days at 0.5 mg/L (Duncan 1980)
Diphenyltin	2 to 3 days (Soderquist and Crosby 1980)
Seawater	
Tributyltin	6 to 19 days; most rapid at low initial concentrations under high illumination (Seligman et al. 1986; Harino et al. 1998)
Triphenyltin	About 140 days (Duncan 1980)
Sediments	
Trimethyltin	About 80 days at 16°C to form the more volatile $(CH_3)_4Sn$ (Guard et al. 1981)
Tributyltin	At least 10 months at 20°C (Maguire and Tkacz 1985)
Tributyltin	360–775 days (Harino et al. 1998)

In aquatic systems, triorganotins were the most toxic group of organotins tested, followed in decreasing order of toxicity by diorganotins, tetraorganotins, and monoorganotins (Argese et al. 1998). Within each series, butyltin and phenyltin compounds seemed most toxic. Organotin toxicity increases with an increase in the length of the linear carbon chain; degradation processes, which involve the gradual breaking of Sn–C bonds, lead to the formation of compounds of low toxicity. Different biochemical mechanisms can account for the toxic effects of each structural class of organotins. For triorganotins, the derangement of energy-coupled processes, which occur at the membrane level, seems to be the most probable mode of action in aquatic organisms (Argese et al. 1998).

The monoorganotin compounds, $RSnX_3$, have a generally low toxicity and do not seem to have any important biological action in mammals (Duncan 1980; Davies and Smith 1982; Krigman and Silverman 1984; Blunden and Chapman 1986). Dialkylorganotins, R_2SnX_2 , are associated with hepatotoxicity (ethyl, propyl, butyl, and pentyltins), immunotoxic effects to T-cells (butyl and octyltins), and skin and eye irritation (methyl, ethyl, propyl, butyl, and octyltins; Watanabe 1980; Krigman and Silverman 1984). The diorganotins combine with coenzymes or enzymes possessing dithiol groups and exert their toxic action by inhibiting alpha-keto acid oxidation and blocking mitochondrial respiration (Duncan 1980; WHO 1980; Davies and Smith 1982). Resistance to diorganotin toxicity varies widely among species. For example, dibutyltins and dioctyltins — unlike other organotins tested — were toxic to rat thymocytes but did not induce similar effects on lymphoid atrophy in mice, guinea pigs, or Japanese quail (Seinen et al. 1977b). Selected dibutyltins

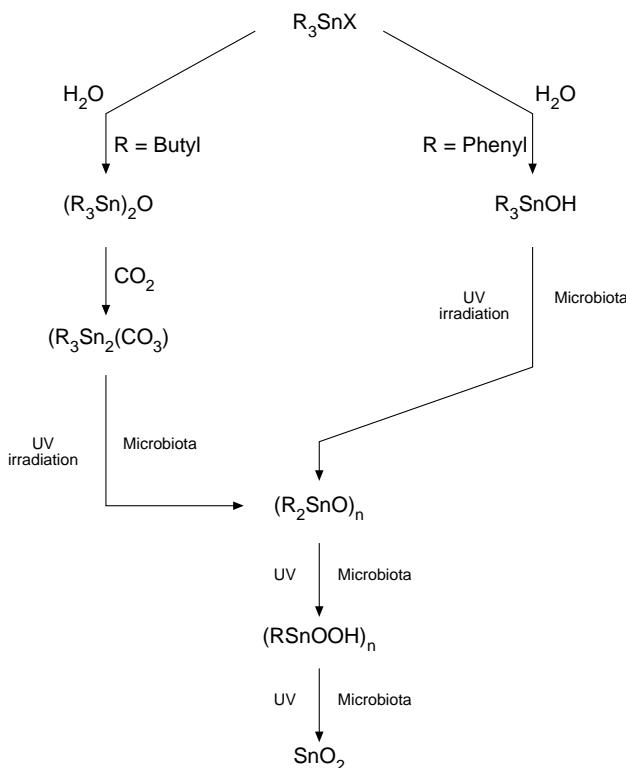

Figure 8.1 Environmental degradation scheme for tributyltin and triphenyltin compounds. (Modified from Smith, P.J. 1978b. *Structure/Activity Relationships for Di- and Triorganotin Compounds*. I.T.R.I. Rep. 569. 16 pp. Avail. from International Tin Research Institute, Greenford, Middlesex, U.K.; and Eisler, R. 1989. Tin hazards to fish, wildlife, and invertebrates: a synoptic review. *U.S. Fish Wildl. Serv. Biol. Rep.* 85(1.15). 83 pp.)

are effective as antihelminthics and are used to kill parasitic worms in chickens and turkeys without harm to host birds (Davies and Smith 1982).

In any member of the organotin series R_nSnX_{4-n} , progressive substitution of organic groups at tin produces a maximum biological activity for the triorganotin derivatives, R_3SnX (Davies and Smith 1982). Among triorganotin compounds, trimethyltins are highly toxic to insects, birds, and mammals; triethyltins to mammals; tripropyltins to Gram-negative bacteria; tributyltins to fish, molluscs, fungi, and Gram-positive bacteria; triphenyltins to fish, fungi, and molluscs; and tricyclohexyltins to mites (Duncan 1980; Davies and Smith 1982; Blunden and Chapman 1986; Maguire 1991). In mammals, the lower triorganotin homologues (trimethyltins, triethyltins) are essentially neurotoxic, the intermediate trialkyltins and triphenyltins are primarily immunotoxic, and the higher homologues are only slightly toxic or not toxic (Krigman and Silverman 1984; Snoeij et al. 1985). The toxicity of triorganotin compounds is probably due to their ability to bind to proteins and to inhibit mitochondrial oxidative phosphorylation (Smith 1978b; Duncan 1980; WHO 1980; Davies and Smith 1982; Blunden and Chapman 1986). Triorganotins also interfere with phagocytosis and exocytosis and other pathways where sulfhydryl groups play a pivotal role (Elferink et al. 1986), and inhibit uptake of gamma-aminobutyric acid and Na^+/K^+ -ATPase in brain (Costa 1985). Impairment of phagocytosis and related activities of polymorphonuclear leukocytes may enhance susceptibility for infection (Elferink et al. 1986).

Trimethyltins are the most toxic trialkyltins to mammals, regardless of the nature of the substituent (X group), according to Smith (1978b). They induce pathological lesions in brain and overt neurological and behavioral changes in rodents (Chang 1986). Trimethyltins are neurotoxins

that damage the limbic system, cerebral cortex, and brain stem and can traverse the placenta and accumulate in the fetus (Reuhl and Cranmer 1984). Trimethyltins (but not inorganic, monomethyl, or dimethyltins) inhibit brain protein synthesis by 47% and can cause a decrease of 4.2°C in body temperature of mice within 1 hour postadministration of 3.0 mg/kg body weight (Costa and Sulaiman 1986). Raising the ambient temperature to 35°C prevented hypothermia in treated mice and resulted in only a 20% inhibition in protein synthesis. More research is needed on the role of protein synthesis in organotin-induced neurotoxicity.

Triethyltins modify phosphorylation processes in subcellular fractions of rat brain proteins (Piver 1973; Neumann and Taketa 1987). Signs of triethyltin poisoning in rodents include weakness of hind limbs, dyspnea, and peripheral vasodilation (Watanabe 1980). Internally, acute triethyltin intoxication is characterized by a transient edema of the central and peripheral nervous systems manifested by extensive intramyelinic vacuolation due to splitting of myelin lamellae. Changes are reversible (Watanabe 1980; Reuhl and Cranmer 1984). Neuronal death is reported following triethyltin intoxication during the neonatal period, possibly as a result of elevated intracranial pressure (Reuhl and Cranmer 1984). In rabbit brain, triethyltins alter activity of pyruvate dehydrogenase (Neumann and Taketa 1987).

Studies on tributyltin uptake and depuration from food or water by rats, crabs, oysters, and fish showed that in all species it was accumulated and metabolized, at least partly, within 48 h to dibutyltins, monobutyltins, and more polar metabolites. However, oysters (*Crassostrea virginica*) metabolized significantly less tributyltin than other species tested (Lee 1985). The accumulation of tributyltin compounds in different tissues correlated well with lipid content and supports a partitioning mode of uptake (Laughlin et al. 1986a). The mixed function oxygenase system from hepatic tissues was able to metabolize tributyltins by forming hydroxylated metabolites (Lee 1985). Tributyltins are also potent cytotoxicants in rabbit erythrocyte and skin cultures (Gray et al. 1985).

The potential of tricyclohexyltins to modify the inducibility of cytochrome P-450 by various substances, such as 3-methylcholanthrene, is of considerable toxicological importance (Rosenberg et al. 1985). Significant metabolic interactions can result from a combination of environmental chemicals and drugs that produce alterations in heme and mixed function oxygenase activity (Rosenberg et al. 1985), suggesting that more research is needed on interaction effects of organotins with other environmental substances or contaminants.

The biological effects of the tetraorganotin compounds, R_4Sn , seem to be caused entirely by the R_3SnX derivative that is produced by their rapid *in vivo* dealkylation (Duncan 1980; Davies and Smith 1982; Blunden and Chapman 1986). Increasing toxicity of tetra- and triorganotins in mammals has been shown to be associated with decreasing length of their ligands, as reflected by solubility in biological fluids (Arakawa et al. 1981). It is not known if damage is produced by the metal or by its alkyl derivative, but the presence of trialkyl groups seems to enhance the toxicity of tin — probably by increasing its partition into lipids, thus aiding the absorption of the metal and speeding its distribution to the site of action (Arakawa et al. 1981).

8.3 SOURCES AND USES

Metallic tin is derived mainly from the mineral cassiterite (SnO_2) and to a lesser extent from the sulfide ore stannite $Cu_2S-FeS-SnS_2$, although it can be derived from rarer minerals such as malayaite, $CaSnSiO_5$ (Blunden et al. 1985). Tin is one of the earliest metals known and has influenced our lives through the ages. Tin alloy artifacts dating from about 5000 years ago have been unearthed at Ur, the site of ancient Babylonia (Zuckerman et al. 1978). Today we are exposed to tin on a daily basis through the use of tin-plated food cans; of alloys such as pewter, bronze, brass, and solder; and from toothpaste containing stannous fluoride (Zuckerman et al. 1978). Inorganic tin compounds are also used in a variety of industrial processes such as the strengthening

of glass, as a base for colors, as catalysts in various chemical reactions, as stabilizers in perfumes and soaps, and as dental anticariogenic agents (WHO 1980; Crowe 1987; USPHS 1992). The use of organotin is extensive in antifouling marine paints, in molluscicides, and in agriculture, which sometimes causes serious adverse effects on nontarget biota (Crowe 1987). In Italy, however, use of organotin products in agriculture at recommended application levels had no adverse effects and did not accumulate in tissues in European hares, *Lepus europaeus*, sampled over a 12-month period (Anfossi et al. 1990a). Some treated plants of the family Chenopodiaceae had 3.4 mg Sn/kg FW in August (range 0.9 to 13.4), but mean values in other families of plants in August were lower and ranged between 0.3 and 1.2 mg Sn/kg FW (Anfossi et al. 1990a).

In 1975, the total world tin production was 236,000 tons, of which 72% was produced by China (10%), Indonesia (8%), Malaysia (35%), Thailand (7%), and 6% each by the U.K. and the former Soviet Union (WHO 1980). Annual mine production of tin in the United States is a comparatively low 3300 metric tons (USPHS 1992). The world production of recycled tin was about 20,000 tons, of which France produced about half (WHO 1980). About 25% of the tin used in the United States is recovered from scrap materials containing tin. This secondary production occurs in the United States at 7 detinning plants and 162 processing plants (USPHS 1992). The production and consumption of tin chemicals, especially organotins, has increased markedly in the past several decades ([Table 8.2](#)).

The United States is the major consumer of tin and organotin compounds, followed by Japan, the U.K., Germany, and France (WHO 1980). In 1976, for example, the United States consumed 11,000 tons of organotins, or about 39% of the world organotin production (Chau et al. 1984). The projected total demand for primary tin up to the year 2000 is estimated at 7.5 million tons. Total reserves currently are about 6.5 million tons; however, it is likely that new discoveries and increases in known reserves will result in sufficient new tin to meet the demand for this period (WHO 1980).

The uses of inorganic and organotin compounds are numerous and increasing (Crowe 1987; [Table 8.3](#)). Industrial consumption of organotins, for example, rose from about 5000 tons in 1965 to about 35,000 tons in 1985. The uses of nontoxic organotin compounds (R_2SnX_2 and $RSnX_3$ types) account for about 67% of the total world production, although use of R_3SnX types as selective biocides has increased disproportionately (Davies and Smith 1982). Tin now has more of its organometallic derivatives in commercial use than any other element (Blunden et al. 1985).

Biocidal applications of organotins to control marine fouling communities, agricultural pests, and as selective molluscicides merit additional comment. The use of antifoulants on ships is necessitated by the damage some organisms can cause to wooden structures and by the reduced fuel efficiency and speed due to drag when vessels become heavily fouled (Laughlin et al. 1984). Until recently, the most widely used antifouling paint contained a copper base that is biocidally active when copper leaches as an ion from the paint (Hall et al. 1987). However, short effective lifetimes and high costs have limited the usefulness of copper-based paints. Organocompounds of arsenic, mercury, or lead have also been used in antifouling paints, but these paints have been removed from the commercial market because of the toxicological risks during preparation and application and to their hazards to the environment (Blunden et al. 1985; Hall et al. 1987). Organotin coatings are promoted because of their excellent antifouling action, long lifetime (up to 4 years), and lack of corrosion (Messiha and Ikladious 1986). Organotin coatings, especially tributyltins, present potential environmental problems to nontarget aquatic biota due to their extreme toxicity (Eisler 1989; Maguire 1991).

Use of organotin antifouling paints on recreational and commercial water craft has increased markedly in recent years. In Maryland, for example, 50% to 75% of the recreational boats used in Chesapeake Bay are covered with organotin paints (Hall et al. 1988). The organotin biocide released by hydrolysis from the surface of the paint film into seawater provides the antifoulant action. In consequence, the depleted outer layer of paint film, containing hydrophilic carboxylate groups, is easily eroded by moving seawater exposing a fresh surface layer of organotin acrylate polymer. In continuing tests by the U.S. Navy, ablative organotin fouling coatings have demonstrated more than 48 months of protection (Blunden et al. 1985). As discussed later, the use of organotin

compounds in antifouling paints has been severely curtailed. Antifouling paints containing triphenyltin (TPT) will not be a suitable substitute for tributyltin (TBT) in paints designed to inhibit microbial biofilms (Pain and Cooney 1998). Up to 80% of bacteria resistant to six organotins, including TBT, isolated from estuarine sediments of Boston Harbor in Massachusetts were also resistant to TPT. All bacteria were resistant to at least six of eight metals tested, suggesting that resistance to metals — including nickel, cadmium, lead, copper, zinc, and mercury — may be associated with resistance to organotins (Pain and Cooney 1998).

Table 8.3 Major Uses of Inorganic and Organic Tin Compounds

Compounds, uses, and references (in parentheses)

Inorganic Tin Compounds: Tin plate, solder, brass, bronze, and other alloys; heat stabilizers for polyvinyl chloride manufacture; tin and tin alloy electroplating baths; catalysts for silicone and polyurethane foam production; in glass manufacture; flame retardants for woolen fabrics; in toothpastes and dentifrices; for control of parasitic worms in sheep; radiopharmaceuticals; in ceramic glazes and pigments; in fluorescent phosphors, in weighting and dying silk; stone polishing; corrosion inhibitors; color and perfume stabilizers in soaps (WHO 1980; Blunden et al. 1985; USPHS 1992).

Monoorganotins: Polyvinyl chloride stabilizers, catalysts, SnO_2 precursors (CEC 1978; WHO 1980; Chau et al. 1984; Blunden et al. 1985; Blunden and Chapman 1986).

Diorganotins: Catalysts for silicones, polyurethane foams; polyvinyl chloride stabilizers; precursor for forming SnO_2 films on glass; antihelmintics for poultry; lubricating oil additives (Piver 1973; CEC 1978; WHO 1980; Chau et al. 1984; Blunden et al. 1985; Blunden and Chapman 1986; USPHS 1992).

Triorganotins: Agrochemical fungicides, herbicides, miticides, insecticides, nematocides, acaracides, antifeedants; biocide in marine paints; slimicide in paper pulp mills and cooling towers; rodent repellent; molluscicides; wood preservative fungicides; disinfectants; stone preservation; textile, paper, and leather protection (Piver 1973; Hunter 1976; Kumpulainen and Koivistoinen 1977; CEC 1978; WHO 1980; Davies and Smith 1982; Chau et al. 1984; Subramanian 1984; Wilkinson 1984; Blunden et al. 1985; Maguire and Tkacz 1985; Thompson et al. 1985; Blunden and Chapman 1986; USPHS 1992).

Tetraorganotins: Used in manufacture of $\text{R}_n\text{SnX}_{4-n}$ compounds from SnCl_4 ; catalysts for olefin polymers; stabilizers for transformer oils; corrosion inhibitor in lubricating oils (CEC 1978; WHO 1980; Davies and Smith 1982)

Several organotins have been used extensively as agricultural pesticides, especially tricyclohexyltin and triphenyltin compounds (Hunter 1976; Kumpulainen and Koivistoinen 1977; Blunden et al. 1985). In general, these compounds showed low phytotoxicity, low toxicity to nontarget organisms, no evidence of development of resistant insect strains, and degradation to form harmless tin residues. It is probable that agricultural uses of organotins will increase. The toxicity of triorganotin compounds to aquatic invertebrates, especially slow release formulations of tributyltins, is usually high, and this property has been used advantageously to eradicate certain species of freshwater snails that are intermediate vectors of schistosomiasis, i.e., *Biomphalaria* spp., *Bulinus* spp. (Chliamovitch and Kuhn 1977; CEC 1978; Duncan 1980; Seinen et al. 1981). Unfortunately, nontarget biota, including some sensitive species of fishes, are killed at recommended application levels (USEPA 1987; Eisler 1989; Maguire 1991).

Organotins enter air, soil, and water primarily as a result of routine agricultural, industrial, municipal, and biocidal operations (Table 8.4). Deposition rates of organotins from air into soils and water are unknown at present, but may be significant around urban and industrialized areas. Total tin concentrations — primarily inorganic tin — in the atmosphere of the northern hemisphere are significantly higher than those in the southern hemisphere and are dominated by anthropogenic sources (Table 8.5). The most important of these seems to be the incineration of municipal wastes, which accounts for most of the tin flux to the atmosphere (Byrd and Andreae 1986a). Riverine fluxes of tin to the oceans vary between 36 and 71 million kg annually, almost all of it in particulate fractions (Byrd and Andreae 1986b).

8.4 CONCENTRATIONS IN FIELD COLLECTIONS

8.4.1 General

In aquatic environments, organotin concentrations were elevated in sediments, biota, and surface water microlayers collected near marinas, aquaculture rearing pens, and other facilities where organotin-based antifouling paints were used. In some cases, organotin concentrations in the water

Table 8.4 Possible Modes of Entry of Organotins into Air, Soil, and Water

Environmental Compartment and Organotin Group	Sources
AIR	
R ₃ SnX	Agricultural spraying, volatilization from biocidal treatments, antifouling paint sprays
R ₃ SnX, R ₂ SnX ₂ , RSnX ₃	Incineration of organotin-treated or -stabilized waste materials.
R ₂ SnX ₂ , RSnX ₃	Glass coating operations to produce SnO ₂ films
SOIL	
R ₃ SnX	Agricultural applications, wood preservation
R ₃ SnX, R ₂ SnX ₂ , RSnX ₃	Burial of waste materials containing organotins
WATER	
R ₃ SnX	Antifouling coatings, molluscicides, overspray from agricultural operations, land runoff from agricultural use, industrial processes (i.e., slimicides in paper manufacture)
R ₂ SnX ₂ , RSnX ₃	Leaching from organotin stabilized polyvinyl chloride

column were high enough to pose a substantial risk to sensitive species. Data are limited on concentrations of organotins in environmental samples, especially in samples from terrestrial ecosystems, and this may be attributed, in part, to limitations in routine chemical analytical capabilities.

8.4.2 Nonbiological Samples

Tin concentrations in water, air, soils, sediments, and other nonbiological materials are documented, but information is scarce except for aquatic systems (Maguire 1991; Table 8.6). In aquatic systems, several trends were evident. First, tin and organotin compounds tend to concentrate in

surface microlayers by factors up to 10,000 relative to subsurface water; in the case of organotins, this may be due to partitioning into the film of petroleum hydrocarbons commonly present on water surfaces (Maguire et al. 1982; Cleary and Stebbing 1987; Hall et al. 1987; Maguire 1991). Second, organotin concentrations, especially tributyltins, were highest in the vicinity of marinas and harbors, and this is consistent with its use as an antifouling agent in some paints for boats, ships, and docks (Chau et al. 1984; Maguire et al. 1986; Randall et al. 1986; Valkirs et al. 1986; Maguire 1991; Dawson et al. 1992; Harino et al. 1998). Peak tributyltin concentrations occurred in late spring and early summer in association with postwinter launching of freshly painted boats (Hall et al. 1987). Third, organotin levels throughout the water column of marinas in numerous freshwater and marine locations were sufficiently elevated to cause chronic toxic effects in sensitive organisms including algae, copepods, oysters, mussel larvae, and fish (Maguire et al. 1982, 1986; Waldock and Thain 1983; Chau et al. 1984; Maguire and Tkacz 1985; Beaumont and Newman 1986; Cardwell and Sheldon 1986; Thain and Waldock 1986; Cleary and Stebbing 1987; Hall et al. 1987; Stromgren and Bongard 1987). Fourth, methyltin species were infrequently detected. Their occurrence was positively correlated with the presence of relatively high concentrations of inorganic tin and was due primarily to biotic and abiotic methylation of both organotin and inorganic tin compounds (Chau et al. 1984; Maguire et al. 1986; Maguire 1991). Finally, butyltin species were detected in harbor sediments at concentrations that were toxicologically hazardous to benthic fauna (Waldock and Thain 1983; Chau et al. 1984; Maguire et al. 1986). Tributyltin species can be accumulated from the sediments by oligochaetes (*Tubifex tubifex*, *Limnodrilus hoffmeisteri*), thus making it potentially available to bottom-feeding fish; oligochaetes can also degrade tributyltins by a sequential debutylation, with Tb 1/2 estimates of 5 months in water and 4 months in water-sediment mixtures (Maguire and Tkacz 1985; Maguire 1991).

Tributyltin antifouling paints were banned for use in tin-based paints in the U.K. in 1987. Field work on the River Crouch Estuary showed that sediments from areas most contaminated with TBT in 1987 contained 0.16 mg TBT/kg DW; however, by 1992 this had declined to 0.02 mg TBT/kg DW. TBT declines were accompanied by increases in abundance and diversity of benthic fauna, especially bivalve molluscs and amphipod crustaceans (Rees et al. 1999; Waldock et al. 1999).

8.4.3 Biological Samples

Information on background concentrations of total tin in tissues of field populations of animals and plants was comparatively abundant when compared to organotin species (Table 8.7). Tin

concentrations in marine algae and macrophytes varied between 0.5 and 101 mg total Sn/kg dry weight and clearly demonstrated that most species of aquatic flora bioconcentrate tin from seawater (Table 8.7). Marine plants are also important in the cycling of tin. Living algae are effective in immobilizing tin from seawater and regulating the formation and degradation of toxic methyltin compounds (Donard et al. 1987). Dead and decaying algae accumulate inorganic and organotin compounds, release them, and ultimately remove tin from the estuary to the atmosphere by formation of tetramethyltins (Donard et al. 1987).

Organotin content in fish tissues is quite variable, ranging from a low of 3% to 6% of the total tin body burden (Tugrul et al. 1983) to 18% for goatfish (*Upeneus moluccensis*) to 5% for *Mullus barbatus*, another species of goatfish (Salihoglu et al. 1987). By contrast, the limpet (*Patella caerulea*) contains 35% to 75% of its total tin body burden as organotin (Tugrul et al. 1983).

In January 1982, France banned organotin compounds for use in antifouling paints. By 1985, tin and organotin concentrations in seawater and Pacific oysters (*Crassostrea gigas*) were 5 to 10 times lower than those found in 1982 (Alzieu et al. 1986). In Arcachon Bay, France, a decrease in the incidence and extent of anomalies in oyster calcification mechanisms was noted that seemed to be correlated with decreases in tin contamination (Alzieu et al. 1986). Crassostreid oysters can accumulate radiotin (Sn-113) to a higher degree than other species of bivalve molluscs, a characteristic that may be useful as a bioindicator in the event of contamination by this isotope (Patel and Ganguly 1973). Tributyltin and its degradation products continue to be detected in tissues of American oysters (*Crassostrea virginica*) from the Gulf of Mexico 10 years after the use of TBT-based paints was regulated. The likely sources for the tributyltin compounds include sediments, TBT-based paints on vessels longer than 25 meters, and shipyard wastes (Sericano et al. 1999). Fish, shellfish, and sediment samples from southwestern British Columbia in 1992/93 contained tributyltin and its metabolites dibutyltin and monobutyltin, strongly suggesting that tributyltin is a widespread contaminant in this geographic area and a continuing cause for concern despite restrictions on the use of organotin-based marine antifouling paints imposed in 1989 (Stewart and Thompson 1994).

Antifouling paints containing tributyltin compounds are used widely on netting panels of sea cages at fish and shellfish aquaculture units to minimize the obstruction of water exchange through the cages (Davies et al. 1987). Under these conditions, tributyltin paints were detrimental to the growth and survival of juvenile scallops and to calcium metabolism and growth of adult oysters (Paul and Davies 1986) and resulted in elevated concentrations of tributyltin in salmon tissues (Short and Thrower 1986; Davies and McKie 1987). Scallops (*Pecten maximus*) reared in sea pens for 31 weeks on nets coated with tributyltin oxide contained 2.5 mg total Sn/kg fresh weight soft parts (1.9 mg tributyltin/kg), but lost up to 40% during a 10-week depuration period. Scallop adductor muscle contained 0.53 mg tributyltin/kg, suggesting that this tissue (the one consumed by humans) is a probable tin storage site (Davies et al. 1986). Pacific oysters (*Crassostrea gigas*) reared for 31 weeks on tributyltin-exposed nets contained a maximum of 1.4 mg tributyltin/kg FW at week 16 (controls 0.12 mg/kg), but lost 90% during a 10-week depuration period (Davies et al. 1986). Atlantic salmon (*Salmo salar*) held for 3 months during summer in cages with tributyltin-treated net panels contained 0.75 to 1.5 mg tributyltin/kg fresh weight muscle vs. 0.28 mg/kg at the start (Davies and McKie 1987). Based on laboratory studies, it is probable that Atlantic salmon were exposed to approximately 1.0 µg tributyltin/L during this interval (Davies and McKie 1987). Chinook salmon (*Oncorhynchus tshawytscha*), reared in sea pens treated with tributyltin paints, contained <0.013 mg tributyltin/kg muscle fresh weight when introduced into the pens. Concentrations were 0.3 mg/kg after 3 months, 0.8 mg/kg at 13 months, and 0.9 mg/kg at 19 months. Cooking did not destroy or remove organotins from salmon muscle tissues (Short and Thrower 1986). Pink salmon (*Oncorhynchus gorbuscha*) and chum salmon (*Oncorhynchus keta*) fry cultured in TBT-treated marine net pens for 20 to 68 days prior to ocean release contained mean concentrations of 1.5 mg Sn/kg FW fry (chum) and 2.7 mg/kg FW (pinks) vs. <0.1 in controls; however, growth and survival were normal and returning adults 1 to 3 years later had no detectable TBT (Thrower and Short 1991).

Table 8.7 Tin Concentrations in Field Collections of Living Flora and Fauna (Unless indicated otherwise, all values are in mg total Sn/kg fresh weight [FW] or dry weight [DW] tissue.)

Diet and proximity to tributyltin affect butyltin concentrations in waterfowl (Kannan et al. 1998a). Seaducks that fed mainly on molluscs had higher concentrations of butyltins than predatory birds feeding on fish, other birds, and small mammals. Continued exposure of birds to butyltin compounds occurs in harbors and marinas where tributyltin is used on vessels >25 m in length (Kannan et al. 1998a).

8.5 EFFECTS

8.5.1 General

Inorganic tin compounds are of low toxicologic risk due largely to their low solubility, poor absorption, low accumulations in tissues, and rapid excretion. By contrast, some organotin compounds — especially trialkyltins — produce a variety of harmful effects resulting in impaired behavior and lowered growth, survival, and reproduction. Among aquatic organisms, tributyltin compounds were especially potent. Adverse effects were noted in molluscs at water concentrations of 0.001 to 0.06 µg/L and in algae, fish, and other species of invertebrates at 0.1 to 1.0 µg/L. Bioconcentration of organotins was high, but degradation was sufficiently rapid to preclude food chain biomagnification. Birds seem to be relatively resistant to organotins, and data suggest that diets containing 50 mg of tin as trimethyltin chloride/kg are fatal to ducklings in 75 days; however,

no deaths occurred in 75 days at 50 mg/kg of eleven other mono-, di-, tri-, and tetraalkyltin compounds. Trimethyltin was lethal to other species of birds tested at doses of 1 to 3 mg/kg body weight. Trimethyltins and triethyltins were the most toxic organotin compounds tested on small laboratory mammals. Neurotoxicological effects of trimethyltins were usually not reversible, while those caused by triethyltins were reversible after exposure. Adverse effects of trimethyltins were produced at concentrations as low as 0.15 mg/L in drinking water (learning deficits), 0.625 mg/kg BW (diet aversion), and 1.25 mg/kg BW (death).

8.5.2 Aquatic Organisms

Studies on lethal and sublethal effects of tin compounds to representative species of aquatic organisms demonstrate that organotin compounds are more toxic than inorganic tin compounds; triorganotin compounds are more toxic than mono-, di-, or tetraorganotin forms; and tributyltin compounds are the most toxic triorganotin compounds tested (Argese et al. 1998; [Table 8.8](#)). Adverse effects of tributyltins were noted at water concentrations of 0.001 to 0.06 µg/L in marine gastropod and bivalve molluscs, and at 0.1 to 1 µg/L in algae, echinoderms, fish, crustaceans, and coelenterates ([Table 8.8](#)). In order of toxicity, tributyltins were followed by tripropyltins (harmful effects recorded at 0.001 to 10 µg/L to gastropods, fish, and algae), triphenyltins (0.6 to 1 µg/L to diatoms and annelids), triethyltins (3.8 to 10 µg/L to fish and algae), trimethyltins (20 µg/L to algae and crustaceans), and tripentyltins (50 to 100 µg/L to gastropods). Because many organotin compounds are slow-acting poisons, short-term toxicity tests seriously underestimate the toxicity of these compounds (Laughlin and Linden 1985). Tributyltin chloride was more toxic to larvae of the horseshoe crab (*Limulus polyphemus*) than were salts of other metals tested — mercury, cadmium, chromium, zinc, copper, and lead — as judged by effects on survival, molting, and limb regeneration (Itow et al. 1998).

Table 8.8 Lethal and Sublethal Effects of Inorganic and Organic Tin Compounds in Ambient Medium to Selected Species of Aquatic Organisms

Compound and Organism	Medium (µg/L)	Effect	Ref ^a
INORGANIC TINS			
Dab (fish), <i>Limanda limanda</i>	35	No deaths in 96 h	1
Marine diatoms, 2 species	316–325	50% growth inhibition in 72 h	2
Freshwater cyanobacterium, <i>Synechocystis aquatilis</i>	1000–10,000 of Sn ²⁺ or Sn ⁴⁺	Inhibited growth and chlorophyll a content in 96 h, but only under alkaline conditions; Sn ²⁺ was more toxic than Sn ⁴⁺ ; toxicity of both tin species increased with increased tin concentration, increased exposure, and increased pH of the medium; humic acid reduced the toxicity of tin	43
MONOMETHYLTINS			
Marine diatom, <i>Skeletonema costatum</i>	78	50% growth inhibition in 72 h	2
DIMETHYLTINS			
Marine diatoms, 2 species	500	No effect on growth in 72 h	2
TRIMETHYLTINS			
Alga, <i>Scenedesmus quadricauda</i>	20	LC87 (30 days)	3
Alga, <i>Chlorella vulgaris</i>	20	LC100 (30 days)	3
Alga, <i>Asteromonas gracilis</i>	20	LC100 (12 days)	3
Cladoceran, <i>Daphnia magna</i>	20	LC61 (30 days)	3

Table 8.8 (continued) Lethal and Sublethal Effects of Inorganic and Organic Tin Compounds in Ambient Medium to Selected Species of Aquatic Organisms

Compound and Organism	Medium ($\mu\text{g/L}$)	Effect	Ref ^a
Marine diatoms, 2 species	214	50% growth inhibition in 72 h	2
TETRAMETHYLTINS			
Marine diatoms, 2 species	500	No effect on growth in 72 h	2
DIETHYLTINS			
Snail, <i>Biomphalaria glabrata</i>	50–100	LC50 (24 h)	4
Marine diatoms, 2 species	500	No effect on growth in 72 h	2
TRIETHYLTINS			
Marine diatom, <i>Thalassiosira pseudonana</i>	3.8	LC50 (72 h)	2
Sevyuga sturgeon, <i>Accipenser stellatus</i> , larvae	10	LC100 (48 h)	3
Common carp, <i>Cyprinus carpio</i>	10	BCFs after 45 days ranged between 5 in muscle and 88 in blood	3
Marine diatom, <i>Skeletonema costatum</i>	40.2	LC50 (72 h)	2
TETRAETHYLTINS			
Marine diatoms, 2 species	127–142	50% growth inhibition in 72 h	2
TRIPROPYLTINS			
Snail, <i>Lymnaea stagnalis</i>	0.001–1.0	Fecundity reduced after exposure for three months	3
Sheep sturgeon, <i>Accipenser nudiventris</i>	0.001	Larvae die on exposure from fertilization	3
<i>A. nudiventris</i>	0.01	Polarvae die when exposed continuously from fertilization	3
Loach (fish), <i>Misgurnis fossilis</i> , larvae	<1	Normal development	3
<i>M. fossilis</i>	10	No development	3
Algae, Lake Ontario	4	50% reduction in primary productivity in 4 h	3
Alga, <i>Ankistrodesmus falcatus</i>	14	50% growth reduction in 8 days	3
Snail, <i>B. glabrata</i>	40–280	LC50 (24 h)	4
MONOBUTYLTINS			
Golden orfe (fish), <i>Leuciscus idus melanotus</i>	>45,000	LC50 (48 h)	5
DIBUTYLTINS			
Duck mussel, <i>Anodonta anatina</i>	15	After 7 months, tin localized exclusively in epithelial cells of kidney, accompanied by significant decrease in cellular glycogen content	6, 29
Marine diatom, <i>S. costatum</i>	35–56	50% growth inhibition in 72 h	2
Golden orfe	1000	LC50 (48 h)	5
TRIBUTYLTINS
