Dogwhelk, <i>Nucella lapillus</i>	0.001–0.02	Development of male characteristics in 13% of female snails after 31 days, 27% in 91 days and 41% in 120 days. Whole body BCF values about 19,000 in 31 days, 36,000 in 91 days, 78,000 in 120 days	7

Table 8.8 (continued) Lethal and Sublethal Effects of Inorganic and Organic Tin Compounds in Ambient Medium to Selected Species of Aquatic Organisms

Compound and Organism	Medium ($\mu\text{g/L}$)	Effect	Ref ^a
<i>N. lapillus</i>	<0.002	No effect on imposex after exposure for 6 months	44
<i>N. lapillus</i>	0.002–0.128	Dose-related increase in frequency of imposex during exposure for 6–12 months. No effect on feeding rate (predation on <i>Mytilus edulis</i>) or activity patterns. Growth rate of females — but not males — reduced with increasing concentration. BCF values ranged from 7400 to 25,000 and decreased with increasing TBT exposure concentration; mussels accounted for about 40% of the accumulated TBT in whelks; the maximum concentration of TBT recorded in soft tissues of the 0.128 $\mu\text{g/L}$ group was 1.04 mg/kg FW after 12 months	44
Snail, <i>B. glabrata</i>	0.001	Reduction in egg deposition on continuous exposure from hatching	8
<i>B. glabrata</i>	0.1	Exposure for 34 days followed by 50-day recovery period produced 60% mortality, 80% reduction in egg deposition, and reduced growth	3
<i>B. glabrata</i>	0.4	LC99 (30 days)	9
<i>B. glabrata</i>	1.0	50% reduction in egg laying after exposure for 2–3 weeks	3
<i>B. glabrata</i>	3	BCF of 48 in muscle after 120 h	3
<i>B. glabrata</i>	7	LC100 (20 days)	9
<i>B. glabrata</i>	15	LC100 (5 days)	9
<i>B. glabrata</i>	75	LC100 (24 h)	4
Pacific oyster, <i>Crassostrea gigas</i>	0.01–0.02	Spat show reduced growth and hypoxia compensation after 2 weeks	10
<i>C. gigas</i>	0.15	Reduced growth and shell thickening after 8 weeks	11
<i>C. gigas</i>	0.2	BCF of about 6000 in adult soft tissues in 21 days, 11,400 in whole spat in 56 days	3
<i>C. gigas</i> , larvae	1.0	LC100 (12 days)	8
<i>C. gigas</i> , larvae	1.6	LC100 (48 h)	12
<i>C. gigas</i>	1.6	No growth. BCF after 8 weeks varied from 2300 to 3100	11
Copepod, <i>Eurytemora affinis</i>	0.0125	No adverse effects in 13 days	34
<i>E. affinis</i>	0.1	LC74 (13 days)	34
<i>E. affinis</i>	0.5	Reduction in brood size in 48 h	34
<i>E. affinis</i>	0.6	LC50 (72 h)	34
<i>E. affinis</i>	2.2	LC50 (48 h)	34
Common mussel, <i>Mytilus edulis</i>	0.05	Some larval deaths in 96 h	13
<i>M. edulis</i> , larvae	0.1	LC50 (15 days)	14
<i>M. edulis</i> , larvae	0.24	Growth reduction after 45 days	12, 14
<i>M. edulis</i>	0.31	No shell growth in 66 days	14
<i>M. edulis</i>	0.4	Reduction in shell growth rate in 7 days	15
<i>M. edulis</i> , adults	0.97	LC50 (66 days)	14, 16
<i>M. edulis</i> , larvae	0.5	LC100 (96 h)	13
European oyster, <i>Ostrea edulis</i>	0.06	Reduced growth rate in 10 days	14
<i>O. edulis</i>	0.24	No larval release after exposure for 74 days; BCF of 875	17
<i>O. edulis</i>	2.6	Reduced growth in 74 days; BCF of 397	17
<i>O. edulis</i> , larvae	3.4	LC50 (48 h)	17
Striped bass, <i>Morone saxatilis</i>			
Larvae, 13-days old	0.067	Body morphometry altered after exposure for 6 days	38
Larvae, 16-days old	0.44	After exposure for 7 days, no adverse effects on survival, growth, or morphometry	38

Table 8.8 (continued) Lethal and Sublethal Effects of Inorganic and Organic Tin Compounds in Ambient Medium to Selected Species of Aquatic Organisms

Compound and Organism	Medium (µg/L)	Effect	Ref ^a
Larvae, 21-days old	0.51	Notochord development inhibited during exposure for 7 days	38
Larvae, 13-days old	0.77	Survival reduced after exposure for 6 days	38
Larvae, 16-days old	1.5	All dead in 6 days	38
Copepod, <i>Temora longicarpus</i> ; held in outdoor enclosures containing plankton for 28 days	0.09	Inhibited reproduction	52
<i>T. longicarpus</i> , as above	0.15	50% reduction in numbers	52
<i>T. longicarpus</i> , as above	0.32	50% reduction in biomass	52
Marine algae, 3 species	0.1	Reduced growth rate in 48 h	18
Brittle star, <i>Ophioderma brevispinosa</i>	0.1	Arm regeneration inhibited	19
Three-spined stickleback, <i>Gasterosteus aculeatus</i>	0.1 or 1.0	After exposure in seawater for 7.5 months, hepatocytes were abnormal in the high dose group; reproduction normal in both groups	45
<i>G. aculeatus</i>	10.0	Exposure as above; 80% dead in 2 months. Survivors had gill histopathology and abnormal gill chloride cells and liver hepatocytes	45
Goldfish, <i>Carassius auratus</i>	0.13	BCF of 1934 during 21–28 days of exposure via gill intake	40
Daphnid, <i>Daphnia magna</i> ; gravid females exposed for 21 days	0.3–1.25	No adverse effects on survival or molting	51
<i>D. magna</i> , as above	1.25	Enhanced ability to metabolize testosterone	51
<i>D. magna</i> , as above	2.6	LC60 (21 days)	51
<i>C. auratus</i>	75,000	LC50 (24 h)	40
Sheepshead minnow, <i>Cyprinodon variegatus</i>	0.18–1.0	Maximum BCFs after 167 days were 1600 in muscle, 3900 in viscera, 52,000 in liver; no adverse effects on growth or reproduction	20
<i>C. variegatus</i>	0.96	LC50 (21 days)	8
<i>C. variegatus</i>	1.6	Maximum BCFs after 58 days were 1810 in muscle, 2120 in head, 4580 in viscera, and 2600 in whole fish. Loss after 28 days depuration ranged from 64% to 80%	20
<i>C. variegatus</i>	3.2	LC100 (21 days)	20
<i>C. variegatus</i>	5–8	LC50 (96 h)	3
<i>C. variegatus</i>	18	LC50 (7 days)	8
Oysters, several species	0.2	LC70 (113 days)	8
Rainbow trout, <i>Oncorhynchus mykiss</i>	0.2–1.0	Exposure of yolk-sac fry for 110 days produced liver dysfunction, reduced growth, and altered blood chemistry; no deaths	8, 21
<i>O. mykiss</i>	0.5 or 2.0	Exposure of 3-week-old hatchlings for 21 days. Dose-dependent increase in TBT accumulation and growth reduction. Treated fish had greater swimming stamina than controls but lacked circular orientation typical of controls. TBT tissue concentrations in head and body at 21 days ranged from 1.5–2.0 mg/kg FW vs. 0.05–0.11 in controls	46
<i>O. mykiss</i>	0.5 or 2.0	Age and exposure as above. Brain histopathology, especially optic system. In high dose group, myelin alterations in CNS where optic nerve enters the midbrain	47,48
<i>O. mykiss</i>	0.6–4.0	TBT concentrations in whole trout after exposure for 28 days were 2.5 mg/kg FW at 0.6 µg/L, 3.0 at 1.0 µg/L, 5.8 at 2.0 µg/L, and 7.4 mg/kg FW at 4.0 µg/L	50

Table 8.8 (continued) Lethal and Sublethal Effects of Inorganic and Organic Tin Compounds in Ambient Medium to Selected Species of Aquatic Organisms

Compound and Organism	Medium ($\mu\text{g/L}$)	Effect	Ref ^a
<i>O. mykiss</i>	1–6	Dose-related lymphocytic depletion and histopathology after exposure for 14 days of trout age 5 months	50
<i>O. mykiss</i>	1.4–20.0	LC50 (96 h)	5,22,49
<i>O. mykiss</i>	5	Kidney degeneration in 12 days, some deaths	21
<i>O. mykiss</i>	11.7	Bile duct pathology after 5 days; destruction of corneal epithelium after 7 days	3
<i>O. mykiss</i>	21	LC50 (48 h)	9
<i>O. mykiss</i>	28	LC50 (24 h)	23
Baltic amphipod, <i>Gammarus oceanicus</i> , larvae	0.3	Reduced survival after 5 weeks	24
<i>G. oceanicus</i>	3	LC100 (16 days)	3
Alga, <i>Skeletonema costatum</i>	0.33–0.36	50% growth inhibition in 72 h	2
Copepod, <i>Acartia tonsa</i>	0.4	50% immobilization in 144 h	25
<i>A. tonsa</i>	0.55	LC50 (6 days)	8
<i>A. tonsa</i>	1.0	LC50 (96 h)	25
Axolotl, <i>Ambystoma mexicanum</i> ; larvae with amputated forelimbs	0.5–50.0 for up to 49 days	All larvae in the 50 $\mu\text{g/L}$ group died within 24 h; 80% dead in the 15 $\mu\text{g/L}$ group within 7 days and 90% in 49 days; no deaths in other groups. TBT was slightly teratogenic to developing axolotl hindlimbs but had no measurable effect on skeletal patterns in regenerating forelimbs in the 0.5, 1.5, and 5 $\mu\text{g/L}$ groups	42
Fiddler crab, <i>Uca pugilator</i>	0.5	Limbs regenerated during 19 days showed a variety of deformities and retardation of regenerative growth	26, 35
<i>U. pugilator</i>	0.5–50	Non-dose dependent reduction in burrowing activity in 15 to 60 min; hyperactivity in 1 to 3 weeks	36
Mysid shrimp, <i>Metamysidopsis elongata</i> , juveniles	0.5–1.0	LC50 (96 h)	3
Freshwater minnow, <i>Phoxinus phoxinus</i> . Eggs and newly hatched larvae, exposed at 16°C or 21°C	0.69–0.82	All survived exposure for 6 days at 21°C, but 50% of larvae were abnormal (deformations, erratic swimming, paralysis)	41
As above	0.82–19.5	After 3–10 days, degenerative alterations of skin, muscle, kidney, eye, and spinal cord; effects more pronounced at higher doses and temperature	39
As above	4.3 and higher	In larvae, increased mortality, deformation of body axis, paralysis, and opaque eyes	39
As above	9.2	All dead in 4 days at 21°C; no sediments in assay containers	41
As above	10.4	90% dead in 9 days at 16°C; no sediments in assay containers	41
American oyster, <i>Crassostrea virginica</i>	0.73–1.9	Reduced larval growth in 66 days	16
<i>C. virginica</i> , larvae	0.9	50% immobilization in 48 h	12
Hydroid, <i>Campanularia flexuosa</i>	1.0	100% growth inhibition in 11 days	3
Cladoceran, <i>D. magna</i>	1.0	Reduced survival and impaired reproduction in 15 days	14
<i>D. magna</i>	1.7	LC50 (48 h)	12
<i>D. magna</i>	3	LC50 (24 h)	23
American lobster, <i>Homarus americanus</i>	1.0	No effect on larval metamorphosis in 6 days	8
<i>H. americanus</i> , larvae	5	LC100 (6 days)	25
<i>H. americanus</i> , larvae	20	LC100 (24 h)	3

Table 8.8 (continued) Lethal and Sublethal Effects of Inorganic and Organic Tin Compounds in Ambient Medium to Selected Species of Aquatic Organisms

Compound and Organism	Medium ($\mu\text{g/L}$)	Effect	Ref ^a
Shrimp, <i>Crangon crangon</i> , larvae	1.5	LC50 (96 h)	12
<i>C. crangon</i> , adults	41	LC50 (96 h)	12
Copepod, <i>Nitroca spinipes</i>	2	LC50 (96 h)	25
Round Crucian carp, <i>Carassius carassius grandoculis</i>	2	BCF after 7 days of about 500 in vertebra, 630 in muscle, 3160 in kidney, and 5020 in liver	27
Sole, <i>Solea solea</i> , larvae	2	LC50 (96 h)	3
Lugworm, <i>Arenicola cristata</i>	2	LC0 (168 h)	28
<i>A. cristata</i> , larvae	4	LC100 (96 h)	23
Algae, various species	3–16	50% reduction in primary productivity in 4 h to 8 days	3
Barnacle, <i>Balanus amphitrite</i>	4	LC50 (24 h) nauplii	3
Freshwater clam, <i>Anodonta anatina</i>	5	LC100 (6 weeks)	29
Mud snail, <i>Nassarius obsoletus</i>	5–6	Induced male characteristics in females in 64 days	3
<i>N. obsoletus</i>	8	LC50 (61 days)	3
Lake trout, <i>Salvelinus namaycush</i>	5.2	LC50 (96 h)	49
Tubifex worm, <i>Tubifex tubifex</i>	6	LC50 (48 h)	9
Amphipod, <i>Orchestia traskiana</i>	6	LC47 (9 days)	3
<i>O. traskiana</i>	10	LC80 (9 days)	3
<i>O. traskiana</i>	15	LC93 (9 days)	3
Mud crab, <i>Rithropanopeus harrisii</i>	6	BCFs after 4 days were 650 in muscle, 4400 in hepatopancreas, and 1300 in gill	37
<i>R. harrisii</i>	15	Weight loss after 15 days	3, 37
Bluegill, <i>Lepomis macrochirus</i>	7.6	LC50 (96 h)	12
<i>L. macrochirus</i>	33	LC50 (48 h)	8
Mysid shrimp, <i>Mysis dopsis bahia</i>	8	LC50 (96 h)	30
Mummichog (fish), <i>Fundulus heteroclitus</i>	9	Avoidance	3
<i>F. heteroclitus</i>	24	LC50 (96 h)	12
Crab, <i>Carcinus maenus</i>	10	LC50 (96 h)	3
Amphioxus, <i>Branchiostoma caribaeum</i>	10	LC100 (96 h)	30
Snail, <i>Neritina</i> sp.	10	LC100 (6 days)	3
Snails, <i>Biomphalaria</i> spp.	10–30	LC50 (24 h)	8
Channel catfish, <i>Ictalurus punctatus</i>	12	LC50 (96 h)	8
Marine diatom, <i>S. costatum</i>	14.7	LC50 (72 h)	2
Snail, <i>Lymnaea</i> sp.	15	LC100 (5 days)	3
Atlantic menhaden, <i>Brevoortia tyrannus</i>	15	Avoidance by juveniles	3
Speckled sanddab, <i>Citharichthys stigmaeus</i>	20	LC50 (96 h)	3
Grass shrimp, <i>Palaemonetes pugio</i>	20	LC50 (96 h)	30
Green alga, <i>Ankistrodesmus falcatus</i>	20	BCF of 30,000 at day 7	23
<i>A. falcatus</i>	40	BCF of 8600 at day 7	23
Guppy, <i>Poecilia reticulata</i>	21–30	LC50 (96 h)	8
<i>P. reticulata</i>	26 to 34	LC50 (48 h)	5
Mozambique tilapia, <i>Tilapia mossambica</i>	28	LC50 (24 h)	8
Duckweed, <i>Lemna media</i>	30	Reduced growth in 10 days	31
Snail, <i>Australorbis glabratus</i>	30	LC100 (5 days)	31

Table 8.8 (continued) Lethal and Sublethal Effects of Inorganic and Organic Tin Compounds in Ambient Medium to Selected Species of Aquatic Organisms

Compound and Organism	Medium (µg/L)	Effect	Ref ^a
European frog, <i>Rana temporaria</i> , tadpole	30	LC50 (5 days)	32
<i>R. temporaria</i> , tadpole	75	LC100 (24 h)	9
Harlequin fish, <i>Rasbora heteromorpha</i>	42	LC50 (48 h)	8
Jewelfish, <i>Hemichromis bimaculatus</i>	45	LC70 (48 h)	8
Fathead minnow, <i>Pimephales promelas</i>	45	LC50 (96 h)	8
Golden orfe	50	LC50 (48 h)	5
Cladoceran, <i>Daphnia longispina</i>	60	LC100 (72 h)	31

Results of acute toxicity tests with several organotin compounds and *Daphnia magna* indicated several distinct trends: toxicity increased with length of alkyl group from methyl to butyl; the anion substituents are relatively unimportant; and bioavailability is correlated with increasing solubility in lipids, which is a direct function of K_{ow} , the n-octanol/water partition coefficient (Vighi and Calamari 1985). Structure–activity relations seem to have high predictive capacity in hazard assessment, and those for organotins seem particularly promising (Vighi and Calamari 1985). For example, studies on the biocidal properties of structurally distinct diorganotins (R_2SnX_2) and triorganotins (R_3SnX) to zoeae of a marine crab show, within a homologous series, that diorganotins are less toxic than the corresponding triorganotins (Table 8.9). It was concluded that the toxicity of organotins to crab zoeae seems to be a function of the hydrophobic characteristics conferred by the number and structure of the organic ligands (Laughlin et al. 1985). Studies with yolk sac fry of the rainbow trout also demonstrate that triorganotins are at least two orders of magnitude more toxic than diorganotins (de Vries et al. 1991). The no-observable-effect-concentration (NOEC) for rainbow trout fry during exposure for 110 days was 40 µg/L for dibutyltin chloride, 60 µg/L for diphenyltin chloride, and 0.04 to 0.05 µg/L for various tributyltin compounds (de Vries et al. 1991). Alterations of steroid mechanisms, such as ability to metabolize testosterone, by TBT may be a more sensitive indicator of sublethal exposure in *Daphnia magna* than reproductive endpoints (Oberdorster et al. 1998).

Signs of tributyltin poisoning in rainbow trout and other freshwater fishes include sluggishness, loss of appetite, altered body pigmentation, air gulping, loss of positive rheotaxis, increased rate of opercular movements, increases in blood hemoglobin and hematocrit, damaged gills and cornea, increases in erythrocyte number, damage to epithelial cells of the bile duct, (Chliamovitch and Kuhn 1977; Thompson et al. 1985; Holm et al. 1991), decreased resistance to bacterial pathogens (de Vries et al. 1991), and peripheral blood neutrophilia and impaired antibody secreting mechanisms (Rice et al. 1995). These changes were consistent with the known inhibitory effects on

Table 8.9 Toxicity of Selected Diorganotin and Triorganotin Compounds to Zoeae of the Marine Mud Crab (*Rithropanopeus harrisi*) Exposed from Hatching to Age 14 Days

Compound Tested	Lowest Concentrations Tested (mg/L) Producing			
	Some Deaths, but <50% Mortality		At Least 50% Mortality

Modified from Laughlin, R.B., Jr., R.B. Johannesen, W. French, H. Guard, and F.E. Brinckman. 1985. Structure–activity relationships for organotin compounds. *Environ. Toxicol. Chem.* 4:343–351.

mitochondrial and oxidative phosphorylation of triorganotin compounds. Exposure to tributyltin may alter both cytochrome P-450 dependent metabolism, and induction response to other environmental pollutants (Fent and Stegeman 1993). Studies with scup (*Stenotomus chrysops*), a marine fish, show that a single intraperitoneal injection of 3.3, 8.1, or 16.3 mg tributyltin/kg BW results in a dose-dependent decrease in hepatic microsome ethoxyresorufin O-deethylase activity, cytochrome P-450 degradation to P420, and increase in liver concentrations from 8 to 202 mg Sn/kg FW (Fent and Stegeman 1993). Organotins also act on the microsomal electron transport system, the hemoprotein P-450, and the flavoproteins of freshwater fishes (Fent and Bucheli 1994). Cytopathological changes in trout brain induced by tributyltin or triphenyltin resemble the reactions observed in brains of mammals after triethyltin insult and are similar to symptoms in the brains of patients affected by a disease known as central pontine myelinosis (in which tin is detected in intramyelin vacuoles) or by multiple sclerosis (Triebeskorn et al. 1994c). In rainbow trout erythrocytes, tributyltin inhibits the uptake of Na^+ and Cl^- ions and interacts with the activity of the Na^+/H^+ exchanger (Virki and Nikinmaa 1993). Tributyltin compounds modify calcium flux across the plasma membrane in a dose-dependent manner in oyster toadfish (*Opsanus tau*), a marine species (Rice and Weeks 1990). At 50 $\mu\text{g}/\text{L}$, tributyltin facilitated an inward flux of calcium. At 500 $\mu\text{g}/\text{L}$ calcium mobilization was inhibited, resulting in impaired macrophage function (Rice and Weeks 1990). In trout hepatocytes, tributyltin mobilizes Ca^{+2} from intracellular stores. The cytoplasmic acidification following tributyltin exposure seems to be caused by the combination of intracellular Ca^{+2} and by direct action of tributyltin (Reader et al. 1994). Suppression of regeneration in echinoderms, and presumably other aquatic groups by organotins, may be due primarily to neurotoxicological action of organotins, or secondarily by direct action on tissue at the breakage point (Walsh et al. 1986b). In freshwater minnows (*Phoxinus phoxinus*) the toxicity of tributyltin compounds to early life stages is based on its eye- and skin-irritative activity, and on its activity against muscular, renal, and neuronal tissues (Fent and Meier 1992).

Imposex — the superimposition of male characteristics onto a functionally normal female reproductive anatomy — is a phenomenon documented in populations of marine gastropod molluscs in the vicinity of yacht basins and marinas and is a sensitive indicator of tributyltin contamination. A female with imposex displays one or more male characteristics, such as a penis, a vas deferens, or convolution of the normally straight gonadal oviduct. It is measured by frequency of occurrence in the adult females and by the intensity of expression of all male characteristics in bearer females. Imposex is prevalent in mud snails (*Nassarius obsoletus*) near estuarine marinas and has been induced experimentally in that species by exposure for 60 days to three tributyltin compounds at concentrations of 4.5 to 5.5 $\mu\text{g}/\text{L}$ (Smith 1981a, 1981b). Imposex has been documented extensively in declining populations of the common dogwhelk (*Nucella lapillus*), especially in southwestern England (Bryan et al. 1986, 1987; Gibbs and Bryan 1986; Davies et al. 1987; Gibbs et al. 1987). These authorities agree on six points: (1) dogwhelk populations near centers of boating and shipping activity show the highest degrees of imposex, coinciding with the introduction and increasing use of antifouling paints containing tributyltin compounds; (2) imposex is not correlated with tissue burdens of arsenic, cadmium, copper, lead, silver, or zinc, but with increasing concentrations of tributyltin and dibutyltin fractions; (3) transplantation of dogwhelks from a locality with little boating activity to a site near a heavily used marina causes a marked increase in the degree of imposex and in tissue accumulations of tributyltins; (4) imposex can be induced in female dogwhelks by exposure to 0.02 μg Sn/L leached from a tributyltin antifouling paint; after exposure for 120 days, 41% of the females had male characteristics and whole-body residues of 1.65 mg Sn/kg dry weight soft parts (vs. 0.1 in controls), of which almost all was tributyltin (1.64 vs. 0.08 mg/kg in controls). Concentrations as low as 0.0015 μg tributyltin/L can initiate imposex in immature females; (5) declining dogwhelk populations were characterized by a moderate to high degree of imposex, relatively fewer functional females, few juveniles, and a general scarcity of laid egg

capsules. Many females in late imposex contained aborted capsules as a result of oviduct blockage, resulting in sterility and premature death; and (6) there was no evidence that loss of tin leads to any remission of imposex; in fact, all evidence indicates that gross morphological changes that occur in late imposex are irreversible.

Signs of imposex were severe in some populations of whelks (*Thais* spp., *Vasum turbinellus*) sampled in eastern Indonesia in 1993 and are attributed to unrestricted use of paints containing tributyltin (Evans et al. 1995). Studies indicate that imposex in gastropod molluscs is caused by elevated testosterone titers that masculinize TBT-exposed females as a result of competitive inhibition of cytochrome P450-mediated aromatase (Matthiessen and Gibbs 1998). TBT-induced masculinization in gastropods (imposex and intersex) is a convincing example of endocrine disruption described in invertebrates that is unequivocally linked to an environmental contaminant (Matthiessen and Gibbs 1998). It is clear that additional research is needed on the imposex phenomenon in molluscs and on its implications for vertebrates and other taxonomic groups.

Biological factors known to modify lethal and sublethal effects of organotins include age of the organism, inherent interspecies resistance, and tissue specificity. Abiotic modifiers include exposure route, and physicochemical regimen. Early developmental stages were more sensitive to organotins than later developmental stages in marine annelids (Walsh et al. 1986a), mysid shrimp (Hall and Pinkney 1985), and rainbow trout (Thompson et al. 1985). Mortality of zoeae of fiddler crabs (*Uca pugilator*) to trimethyltins was greatest at elevated temperatures and low salinities (Thompson et al. 1985). Mussels exposed through a diet of algae showed slow accumulation of organotins when compared to exposure from the medium; the reverse was observed for crabs (Evans and Laughlin 1984; Hall and Pinkney 1985; Laughlin et al. 1986a). A marine diatom (*Thalassiosira pseudonana*) showed no adaptation or resistance to triphenyltins or tributyltins (Walsh et al. 1985), but another diatom (*Amphora coffeaeformis*) was extremely resistant (Thomas and Robinson 1986, 1987). Benthic fauna are probably capable of transferring organotins from sediments to bottom-feeding teleosts. For example, sediments spiked with 0.98 mg Sn/kg dry weight, as tributyltin, resulted in concentrations of 4.41 mg/kg whole-body dry weight in oligochaete annelid worms after 22 weeks, up from 0.38 at the start (Maguire and Tkacz 1985). Mortality was substantially higher when organisms were exposed simultaneously to organotins through water and sediments; in the case of grass shrimp (*Palaemonetes pugio*), the addition of contaminated sediments increased mortality by up to 1000 times (Clark et al. 1987). However, the addition of uncontaminated sediments to assay containers reduced the bioavailability of tributyltin to freshwater fishes by as much as 84% (Fent 1992).

Aside from direct toxic effects that antifouling paint residues may have on marine life, there is no evidence of any risk from cytogenetic damage. Tributyltins, for example, were not genotoxic to larvae of the mussel (*Mytilus edulis*), based on results of sister chromatid exchange and analysis of chromosomal aberrations (Dixon and Prosser 1986). Teratogenic effects, however, were detected in larvae of the lugworm (*Arenicola cristata*) at sublethal concentrations of tributyltins (Walsh et al. 1986a), and algae (*Nitzschia liebenthutii*) exposed to 15 mg inorganic Sn/L for 14 days had frustule abnormalities (Saboski 1977).

Bioconcentration of inorganic and organic tin compounds from the medium is considerable. Bioconcentration factors (BCFs) for inorganic tin and marine algae were about 1900; moreover, tin-resistant bacteria contained a remarkable 3.7 to 7.7 grams Sn/kg dry weight (Maguire et al. 1984; Eisler 1989; Maguire 1991). Partitioning or binding may control bioaccumulation of tributyltin by marine phytoplankton. A linear relation is documented for external concentrations of tributyltin compounds and cell burdens in the marine microalgae *Nannochloris* sp., *Chaetoceros gracilis*, and the cyanobacterium *Synechococcus* sp. However, the relation was not linear for the alga *Isochrysis galbana* (Chiles et al. 1989). BCFs for organotin compounds varied from about 400 to 30,000 among various species of molluscs, algae, and crustaceans and were highest when ambient tin concentrations were <1.0 µg/L, when exposure times were comparatively lengthy, and when organism lipid content was elevated (Thompson et al. 1985; Champ 1986; Laughlin et al. 1986a; Thain and Waldock 1986). Studies with freshwater minnows (*Phoxinus phoxinus*) demon-

strate a high potential for tributyltin bioconcentration in early life stages, and slow metabolism in embryo and yolk-sac larvae (Fent 1991). Sheepshead minnows (*Cyprinodon variegatus*) were unable to reach equilibrium with a medium containing 1.61 µg tributyltin/L after 58 days of exposure, and maximum BCF values recorded were 2600 in whole fish, 1810 in muscle, 4580 in viscera, and 2120 in the remainder of the carcass; however, whole-body loss was 52% after depuration for 7 days and 74% after 28 days (Ward et al. 1981). Sheepshead minnows were able to metabolize tributyltins into lower alkyl moieties, which were less toxic. Thus, even though significant bioconcentration occurred, the chronic toxicity of tributyltins to sheepshead minnow was not significantly greater than its acute toxicity (Ward et al. 1981).

Uptake of organotins through the medium is a more effective route than the diet, and triphenyltin compounds are more readily accumulated through dietary uptake than are tributyltin compounds. Tributyltin and triphenyltin compounds show BCF values of 1384 to 1974 in whole goldfish (*Carassius auratus*) after exposure for 21 to 28 days in media containing 0.13 to 0.14 µg Sn/L. But goldfish fed diets containing these same compounds at 1.7 to 1.9 µg Sn/kg ration for 28 to 35 days had BCF values of 0.04 to 0.1 (Tsuda et al. 1991). A nearly identical pattern was reported for willow shiner (*Gnathopodion caerulescens*), another freshwater teleost (Tsuda et al. 1992). Red sea bream (*Pagrus major*) fed tributyltin or triphenyltin compounds in the diet (8 to 1000 µg Sn/kg ration) for 8 weeks and simultaneously challenged with seawater containing 0.067 to 0.083 µg/L of triorganotin compounds accumulated 25% of their whole-body tin burden from the diet, regardless of tin concentration or chemical species in the ration. Tributyltin assimilation in red sea bream was 10% and retention 24%; for triphenyltin, assimilation was 13% and retention 60% (Yamada et al. 1994). American plaice (*Hippoglossoides platessoides*) given a single oral dose of ¹¹³Sn-tributyltin showed ¹¹³Sn distribution over the entire body — especially liver and gallbladder — with steady state achieved in 5 to 10 days; average retention efficiency of TBT over a 6-week period was 44%, with half-time persistence of 15 to 77 days (Rouleau et al. 1998).

8.5.3 Birds

Information is scarce on the effects of tin and organotin compounds on birds. Limited data suggest that triorganotin compounds, especially trimethyltins (and to a lesser extent triethyltins) are the most toxic (Table 8.10). Fleming et al. (1991), in a 75-day feeding study with mallard ducklings (*Anas platyrhynchos*) and 12 organotin compounds, concluded that (1) trimethyltin was the most toxic compound tested, (2) a dietary level of 50 mg of tin as trimethyltin chloride/kg food was fatal to all ducklings, (3) 5 mg trimethyltin chloride/kg ration killed 40%, but all survived at 0.5 mg/kg diet, (4) death was preceded by mild to severe tremors, progressing to ataxia and lethargy, (5) trimethyltin-stressed ducklings exhibited degeneration of the large neurons of the pons, medulla oblongata, gray matter of the spinal cord, and pyramidal cells of the cerebral cortex, (6) all ducklings survived exposure to 50 mg/kg ration of tetraethyltin, tetrabutyltin, tetraphenyltin, triethyltin chloride, tripropyltin chloride, tributyltin chloride, tributyltin oxide, triphenyltin chloride, tricyclohexyltin chloride, dimethyltin chloride, and dibutyltin chloride. Sublethal effects were recorded at 50 mg triethyltin chloride/kg ration (low body weight, vacuolization of spinal cord and brain white matter), at 50 mg tributyltin chloride/kg (enlarged liver), and at 50 mg tetrabutyltin/kg (elevated kidney weight; Fleming et al. 1991).

Dietary studies with Japanese quail (*Coturnix japonica*) showed that tributyltin oxide affected reproduction at a dose where no overt toxicity was observed. Dietary levels as low as 60 mg tributyltin oxide/kg ration for 6 weeks was associated with decreased hatchability and decreased survival of chicks, although adults fed and behaved normally (Coenen et al. 1992).

8.5.4 Mammals

Inorganic tin compounds and some heterocyclic organic tin compounds are of low toxicologic risk to mammals (Table 8.11), due largely to their low solubility, poor absorption, low tissue accu-

Table 8.10 Lethal and Sublethal Effects of Selected Organotin Compounds to Birds

Compound and Organism	Effect (reference)
DIALKYLTINS	
Japanese quail, <i>Coturnix japonica</i>	No measurable effect at dietary levels of 150 mg/kg ration for 2 weeks (Seinen et al. 1977b)
TRIALKYLTINS	
Mallard, <i>Anas platyrhynchos</i>	Ducklings fed diets containing 50 mg trimethyltin chloride/kg died within 60 days (Fleming et al. 1991)
Pigeon, <i>Columba</i> sp.	Trimethyltin injections (3 intramuscular injections, 2 weeks apart) at 1.0 mg/kg body weight (BW) interfered with ability to perform motor tasks; no evidence of cumulative effects (Idemudia and McMillan 1986b)
Domestic chicken, <i>Gallus</i> sp.	Single oral dose of 3 mg trimethyltin/kg BW produced tremors, convulsions, and death within 24 h (Stoner et al. 1955)
Pigeon	Triethyltin injections (4 intramuscular injections, 2 weeks apart) at 1.75 mg/kg BW resulted in total suppression of pecking behavior for 3 h; recovery underway by 27 h postinjection (Idemudia and McMillan 1986a)
Domestic chicken	Single oral dose of 3 mg triethyltin sulfate/kg BW resulted in immediate collapse, salivation, convulsions, and death in a few min; at 2 mg/kg, bird was unconscious for 1–1.5 h postadministration, with recovery beginning in 1 day (Stoner et al. 1955)
Domestic chicken	Feeding of 160 mg triethyltin hydroxide/kg diet for 15 weeks was not fatal, but caused muscular weakness and some diet avoidance (Stoner et al. 1955)
Japanese quail	Acute oral LD50 of tricyclohexyltin hydroxide varies between 255 and 390 mg/kg BW; dietary levels of 20 mg/kg had no measurable effect on growth, survival, or reproduction (Zuckerman et al. 1978)
Japanese quail; fed diets containing 0, 24, 60 or 150 mg tri- <i>n</i> -butyltin oxide for 6 weeks. Eggs produced and chicks hatched were observed	Food concentration normal with no overt adverse signs of TBTO exposure noted in adults. Decreased hatchability and increase in percent of chicks found dead in the shell were noted at 60 and 150 mg/kg food. Egg production and eggshell thickness normal. Abnormal blood chemistry and hepatic EROD noted in parent birds treated with TBTO (Coenen et al. 1992)
Domestic chicken	Acute oral LD50 of 654 mg of tricyclohexyltin hydroxide (Smith 1978a)
TETRAALKYLTINS	
Domestic chicken	Daily doses >0.0001 mg tetraethyltin/kg BW produced adverse effects on blood chemistry and CNS (Duncan 1980)

mulations, and rapid tissue excretion (Hiles 1974; Kimbrough 1976). Inorganic tin compounds accumulate mostly in liver and kidney, rarely in brain, in proportion to dose and regardless of the exposure route (Hassett et al. 1984). Noncyclic organotin compounds, by contrast, have produced adverse effects on the skin, eyes, gastrointestinal tract, liver, bile duct, kidney, hematopoietic system, central nervous system, reproduction, growth, and chromosomes of small laboratory animals (Table 8.11). Effects of diorganotin compounds can be distinguished from those of tri- and tetraorganotin compounds. The chief toxicological difference is that some trialkyltins have a specific effect on the central nervous system resulting in cerebral edema, whereas diorganotins do not produce this effect but are potent irritants that induce inflammatory reactions. The tetraorganotins resemble triorganotins, which are usually more toxic than either mono- or diorganotins (WHO 1980; Table 8.11).

Diorganotin compounds cause cerebral edema and inhibit mitochondrial respiration by preventing the oxidation of keto acids, presumably through inhibition of alpha-keto oxidase activity (Piver 1973; WHO 1980). Large interspecies variability exists in the capacity of diorganotins to induce lymphoid atrophy. For example, dioctyltins and dibutyltins were selectively cytotoxic to rat thymocytes after dietary exposures of 50 to 150 mg/kg diet for 2 weeks; in contrast, no lymphoid atrophy occurred in mice, guinea pig, or Japanese quail given similar dosages and exposures (Seinen et al. 1977a, 1977b). Route of exposure can also modify effects of diorganotins. Oral exposure to dibutyltin compounds, for example, produces inflammatory changes in bile duct of the rat and

necrotic changes in liver of mice and rats; dermal exposure causes bile duct injury in rats and rabbits; and intravenous administration produces pulmonary edema in rats (WHO 1980). Intratesticular administration of high doses of some dibutyltins produced marked degeneration in rat testes within 7 days, including atrophy of seminiferous tubules and complete arrest of spermatogenesis; however, similar results have been reported for cadmium, zinc, and copper salts (Saxena et al. 1985).

Trimethyltin, triethyltin, and tributyltin compounds are highly toxic to animals and man. Trimethyltin and triethyltin compounds are more toxic to mammals than the higher triorganotin homologues, probably because of poorer absorption of higher trialkyltin compounds from the gastrointestinal tract (Kimbrough 1976; WHO 1980). Trimethyltin and triethyltin compounds are potent inhibitors of oxidative phosphorylation in the mitochondria for which these compounds have a high binding affinity (WHO 1980). Different triorganotin compounds cause different neuronal patterns of toxicity in adult animals (Reiter and Ruppert 1984). Trimethyltins, for example, produce largely irreversible behavioral impairments, such as hyperactivity and impaired learning and performance, and these are consistent with reported neuronal cell death in limbic system structures. Triethyltins, with their direct effect on muscle — consistent with reports of myelin vacuolation and cerebral edema — produce largely reversible effects (Reiter and Ruppert 1984). Differences in chronic toxicity between triethyltins and trimethyltins have resulted in different strategies in assessment of hazard. Evaluations of triethyltin have focused on repeated testing throughout dosing, followed by a recovery period. However, evaluations of trimethyltin-induced behavioral impairments have generally focused on testing weeks to months after exposure (Reiter and Ruppert 1984).

Symptoms of trimethyltin intoxication in humans include irritability, headache, depression, aggressiveness, disorientation, appetite loss, memory deficits, and decreased libido; changes were largely reversible following cessation of exposure (Reiter and Ruppert 1984; Reuhl et al. 1985). At high doses, trimethyltins cause death in primates and humans, preceded by seizures, anorexia, and emotional lability (Brown et al. 1984). Trimethyltin produced adverse effects in laboratory animals over an unusually narrow dose range, with differences of tenfold or less between doses producing no observable effects and those producing 100% mortality in all species tested (McMillan and Wenger 1985). Trimethyltin effects in small laboratory animals are usually not reversible. Signs of trimethyltin poisoning include tremors, hyperexcitability, aggressive behavior, weight loss, neuronal destruction in hippocampus and other portions of the brain, seizures, learning and memory impairment, self-mutilation, altered sensitivity to stimuli, and disrupted patterns of drinking and eating (Aldridge et al. 1981; Brown et al. 1984; Hassett et al. 1984; Reiter and Ruppert 1984; Bushnell and Evans 1985; McMillan and Wenger 1985; Reuhl et al. 1985).

Trimethyltin-induced behavioral disruptions usually peak 3 to 5 days after exposure, but effects persist for extended periods and seem to be irreversible (Reiter and Ruppert 1984; McMillan and Wenger 1985). Rats sometimes survive the trimethyltin behavior syndrome and appear outwardly normal, although later neuropathological examination shows extensive bilateral damage, including hippocampus shrinkage and cell loss (Aldridge et al. 1981).

Triethyltins were the most potent organotins tested on mammals, although other organotins produced similar signs of poisoning (Table 8.11). Mammals poisoned by triethyltin compounds showed muscle weakness within hours of dosing; after a short period of recovery, tremors developed, leading to convulsions and death 2 to 5 days after dosing. Although toxicity produced by triethyltins becomes more pronounced with continued exposure, reversal of behavioral deficits occurs within weeks after dosing is terminated (Reiter and Ruppert 1984). Initial reaction to triethyltin exposure in rats was fluid accumulation in white matter of the central nervous system, which persisted for as long as the compound was administered; after administration the effects reversed (Piver 1973). There is general agreement that triethyltin-induced behavioral changes are accompanied by cerebral edema, neurodegenerative disorders, interference with oxidative phosphorylation, and disrupted metabolism of glucose and enzyme activity (Kimbrough 1976; Hassett et al. 1984; Reiter and Ruppert 1984; McMillan and Wenger 1985; Reuhl et al. 1985; Linee and Hennon 1986).

Triphenyltins are skin and eye irritants to rats and rabbits (WHO 1980). They do not accumulate in rats, dogs, and guinea pigs, although some triphenyltin acetate was partly absorbed by cattle and sheep — with most excreted in 6 to 8 weeks (Duncan 1980). Thymus atrophy was associated with a lymphocyte depletion in the thymic cortex and is the predominant effect of the intermediate trialkyltins. Intermediate trialkyltin homologues caused a dose-related reduction of thymus weight in male rats after 2 weeks on diets containing 150 mg organotin/kg; decreases were 19% for triphenyltin, 47% for tripropyltin, and 61% for tributyltin (Snoeij et al. 1985).

Phenyltin compounds significantly inhibit natural killer cell function and possible natural killer cell-mediated immunotoxic potential of these compounds in humans (Whalen et al. 1999). The toxic potential followed the order of triphenyltin > diphenyltin > monophenyltin; however, phenyltins were less toxic than butyltins to human natural killer cells (Whalen et al. 1999).

Tributyltins and other organotins induce chromosomal aberrations in mammals, although this was not observed in tests with aquatic invertebrates (Dixon and Prosser 1986). Studies with isolated rat hepatoma cells, TBT, and PCB 126, show that TBT inhibits cytochrome P-4501A activity, and PCB 126 induces EROD activity. However, PCB-induced EROD activity was potentiated by coexposure to low noncytotoxic concentrations of TBT (Kannan et al. 1998b). Authors concluded that TBT does not interfere with Ah receptor binding and that potentiation of EROD activity and cytotoxicity as a result of coexposure to PCB 126 and TBT is significant because they coaccumulated in a variety of marine organisms.

Tetraorganotin compounds produce muscular weakness, paralysis, respiratory failure, tremors, and hyperexcitability as acute effects in mice and dogs; latent effects are similar to those seen in triorganotin poisoning (WHO 1980). Tetramethyltin, for example, produces the same toxic syndrome as trimethyltin in rats because it is rapidly dealkylated *in vitro* to the latter compound (Aldridge et al. 1981). Signs of triorganotin poisoning in rabbits were evident shortly after administration of tetraorganotin compounds, suggesting that triorganotins were soon distributed to the site of action in amounts sufficient to produce signs of poisoning (Arakawa et al. 1981). The dealkylation and distribution of tetraorganotins are related to alkyl chain length and to their accumulations in tissues, including brain. In 3-hour studies with rabbits, at intravenous dosage rates of 2 to 3 mg/kg BW, tetraethyltin was quickly distributed to liver, but tetrapropyltin and tetrabutyltin were slowly distributed (Arakawa et al. 1981). Tetraethyltin was more readily converted into the corresponding trialkyltin than was tetrapropyltin. About 20% of the tetraethyltin, 4% of the tetrapropyltin, and 1% of the tetrabutyltin were converted to their corresponding trialkyltins. Thus, the extent of formation of triorganotins decreased as the size and stability of the ligand increased. There was poor distribution of tetraorganotins to brain, but the amounts of triorganotin metabolites found in brain increased over time. Particularly, the transfer of triethyltin to the brain was significant and compatible with the appearance of signs of toxicity. It was concluded that the extent of the dealkylation and the toxicity of organotin compounds depends on the length of their alkyl group, which was associated with their rate of absorption and ultimate distribution (Arakawa et al. 1981).

Organotin compounds are not mutagenic, teratogenic, or carcinogenic, as judged by largely negative but incomplete evidence (Duncan 1980; WHO 1980; Cardarelli et al. 1984b). It has been suggested that some organotins retard the onset and growth of cancer in laboratory animals and that the anticarcinogenic action is mediated through the thymus gland (Cardarelli et al. 1984b). The absence of tin in tissues may also be associated with tumor development (Cardarelli et al. 1984)). In one study, mice with cancer-prone mammary glands and transplanted mammary tumors had significantly reduced tumor growth rates after oral dosing with tributyltin fluoride (Cardarelli et al. 1984b). In another study, tumor growth rates were significantly reduced in mice continuously exposed to various diorganotin compounds in drinking water at 1 and 10 mg/L (Cardarelli et al. 1984a). It is hypothesized that the unknown thymic organotins are antagonistic to cancers in mice and possibly man (Cardarelli et al. 1984a, b). Additional research on potential anticarcinogenic properties of organotins is clearly indicated.

Table 8.11 Effects of Tin Compounds on Selected Species of Mammals

Tin Compound, Organism	Dose	Effect	Ref. ^a
INORGANIC TINS			
Rat, <i>Rattus</i> sp.	6.7 mg/kg body weight (BW)	Single intraperitoneal (ip) injection caused deficits in auditory startle habituation tests	1
Dog, <i>Canis familiaris</i>	54 mg/kg BW	LD100, single oral dose	2
Rat	20–30 mg/kg BW, or 1.0 g/kg diet	No observed effect level after 13 weeks	3
Rat	188 mg/kg BW	LD50, single oral dose of tin fluoride	4
Rat	700 mg/kg BW	LD50, single oral dose of tin chloride	4
Rat	2275 mg/kg BW	LD50, single oral dose of Sn ⁺²	3
Rat	10 g/kg diet	Normal growth after 4 weeks	3
Rat	>10 g/kg BW	LD50, single oral dose of SnO	4
Mouse, <i>Mus</i> sp.	Radiotin-113	50% clearance after 29 days following ip injection	5
METHYLTINS			
Rat	120 mg/L drinking water	Impaired learning of pups when dam consumed Sn-laced water throughout 21-day gestation	6
Rat	575 to 1370 mg/kg BW	LD50, single oral dose	7, 8
Rat	600 mg/L	LC50, aerosol dose for 1 h	7
ETHYLTINS			
Rat	200 mg/kg BW	LD50, single oral dose	7
BUTYLTINS			
Mouse	1400–>6000 mg/kg BW	LD50, single oral dose	3
Rat	2220–2300 mg/kg BW	LD50, single oral dose	7
OCTYLTINS			
Rat	2400–3800 mg/kg BW	LD50, single oral dose	7
Mouse	4600 mg/kg BW	LD50, single oral dose	3
DIMETHYLTINS			
Rat	74–237 mg/kg BW	LD50, single oral dose	7
Rat	1070 mg/L	LC50, aerosol dose for 1 h	7
DIETHYLTINS			
Rat	40–100 mg/kg BW	LD50, single oral dose	9
DIBUTYLTINS			
Rat	0.1 and 1.0 mg/kg BW	Kidney damage after 12-month dietary exposure	3
Mouse	1–10 mg/L drinking water	Reduction in tumor growth rates	10
Rat	2 mg/kg BW daily or 40 mg/kg diet	No observable effect level after 90 days	9
Rat, mouse	10 mg/kg BW	Dermal application daily for 10 days causes severe effect on skin and bile duct	3
Mouse	35–112 mg/kg BW	LD50, single oral exposure	9
Rat	80 mg/kg diet	Slight reduction in growth rate and food intake; mild anemia after 90 days	9
Rat	100–520 mg/kg BW	LD50, single oral dose	8

Table 8.11 (continued) Effects of Tin Compounds on Selected Species of Mammals

Tin Compound, Organism	Dose	Effect	Ref. ^a
DIOCTYLTINS			
Rat	50 or 150 mg/kg ration	After 6 weeks altered immune function as evidenced by inhibition of T-lymphocyte activity	11
Guinea pig, <i>Cavia</i> sp.; mouse	50 or 150 mg/kg diet	No evidence of altered immune function	11
Rat	945–7000 mg/kg BW	LD50, single oral exposure	7, 8, 9
Mouse	1140–4000 mg/kg BW	LD50, single oral exposure	9
TRIMETHYLTINS			
Rat	0.15–1.0 mg/L in drinking water	Dams consuming contaminated water throughout 21-day gestation produced pups with decreased learning ability at age 11 days	6
Rat	0.625 mg/kg BW	3 ip doses resulted in flavor aversion	12
Cynomolgus monkey, <i>Macaca fascicularis</i>	0.75 mg/kg BW	Single intravenous (iv) injection produced reduced appetite 7 days postexposure	13
Cynomolgus monkey	1.1 mg/kg BW	Single iv injection resulted in tremors, hyperactivity, ataxia, stupor, unconsciousness	13
Cynomolgus monkey	1.25 mg/kg BW	Single iv injection is fatal within 4 days	13
Cynomolgus monkey	1.5 mg/kg BW	Single iv injection is fatal within 2 days	13
Cynomolgus monkey	3.0 mg/kg BW	Single iv injection is fatal within 24 h	13
Hamster, <i>Cricetus</i> sp.	About 3.0 mg/kg BW	LD100, single oral dose	14, 15
Rat	3.0 mg/kg BW	Loss in body weight and disrupted diurnal pattern of drinking and in rearing young after single oral dose, 2-week observation period	16
Mouse	3.0 mg/kg BW	Single ip dose produced hypoactivity and impaired motor activity	12
Marmoset, <i>Callithrix jacchus</i>	About 3.0 mg/kg BW	LD50, single oral dose	14, 15
Gerbil, <i>Gerbillus</i> sp.	About 3.0 mg/kg BW	LD50, single oral dose	14, 15
Human, <i>Homo sapiens</i>	About 3.0 mg/kg BW	LD50, single oral dose	14, 15
Rat	<4 mg/kg BW	No effect following stomach gavage route of administration	1
Rat	5 mg/kg BW	Single oral dose produces hyperactivity	12
Rat	6 mg/kg BW	No significant effect on behavior	17
Rat	7 mg/kg BW	Significantly altered behavior	17
Rat	>8 mg/kg BW	Lethal within 4 days after stomach gavage	1
Rat	9.1–30 mg/kg BW	LD50, single oral dose	9, 18
Rat	15 mg/kg diet	Neuronal degradation in 2 weeks	19
Rat	16 mg/kg BW	LD50, single ip dose	2
Rat	30 mg/kg BW	LD100, single oral dose	7
TRIETHYLTINS			
Rat	0.25 mg/kg BW	Impaired response to pain after 14 subcutaneous (sc) injections	12
Rat	0.38 mg/kg BW	Flavor aversion after 2 ip doses	12
Rat	1.0 mg/kg BW	Reduced amplitude startle response after 3 oral doses	12
Rat	1.5 mg/kg BW	Hypoactivity, single sc injection	12
Mouse	2.0 mg/kg BW	Hypoactivity, 27 days after single ip injection	12
Rat	4.0–9.0 mg/kg BW	LD50, single oral dose	8

Table 8.11 (continued) Effects of Tin Compounds on Selected Species of Mammals

Tin Compound, Organism	Dose	Effect	Ref. ^a
Guinea pig	5–10 mg/kg BW	LD50, single oral dose	9
Rat	5 mg/L in drinking water for 15 days followed by 10 mg/L for 15 days	Brain edema	20
Rat	10 mg/kg BW	LD50, single ip dose	2
Rat	10 mg/kg BW	LD100, single oral dose	7
Rabbit, <i>Lepus</i> sp.	10 mg/kg BW	LD50, single ip dose	2
Rabbit	10 mg/kg BW	LD50, single oral dose	8
Rabbit, rat, guinea pig	10 mg/kg BW	LD100, single oral dose	21
Rat	15 mg/kg diet	Cerebral edema in 2 weeks	19
Rat	20 mg/kg diet	After 7 days, decreased food intake; after 3 to 4 weeks, hind limb weakness and some deaths; on return to normal diet, signs of poisoning gone in 7 days with normal weight in 4 weeks	21
Rabbit	40 mg/kg diet	Muscular weakness after chronic exposure	21
TRIPROPYLTINS			
Rat	44–120 mg/kg BW	LD50, single oral dose	4, 8
TRIBUTYLTINS			
Rabbit	0.04 mg/kg BW	After 16 weeks, central nervous system dysfunction	20
Rat	Isolated H411E hepatoma cells exposed to various concentrations of TBT	TBT was cytotoxic at >98 nM and inhibited EROD activity in a dose-dependent manner	26
Guinea pig	0.2 mg/L air	Ocular and nasal irritation, asphyxic convulsions, death within 1 h	20
Mouse	0.2 mg/kg BW	Reduces mammary tumor growth rate; adversely affects thymus gland growth	22
Rat	0.36–0.95 mg/kg BW	Single dermal application causes skin irritation	3
Rat	Pregnant females given oral doses of 8, 16, or 32 mg tributyltin chloride on days 0–3 of pregnancy or 8, 16, 32, or 65 mg/kg BW on days 4–7 of pregnancy	On day 20 of pregnancy, 16 mg/kg BW and higher produced increase in rate of implantation failure for both gestation periods. No increase in fetal malformations in any group	25
Rat	10 mg/kg BW	LD50, single ip dose	2
Rabbit	12 mg/kg BW	Daily doses for 6 months were not fatal; signs of intoxication disappeared within a few weeks after withdrawal	20
Guinea pig	20 mg/kg BW	LD50, single oral dose	9
Rat	32 mg/kg diet	Impaired growth after 30 days	20
Mouse	46–230 mg/kg BW	LD50, single oral dose. LD50 values were lowest for tributyltin acetate (46 mg/kg BW) followed by benzoate (108), chloride (117), laurate (180), and oleate (230)	9
Rat	50–380 mg/kg BW	LD50, single oral dose	7, 8, 9
Rabbit	60 mg/kg BW	LD50, single oral dose	9
Rat	150 mg/kg diet	61% reduction in thymus weight after 2 weeks	19
Rat	320 mg/kg diet	Some deaths in 30 days	20
TRIPHENYLTINS			
Rat	0.6 mg/kg BW daily	After 6 weeks, diminished exploratory behavior in maze and significantly more errors in maze learning	23

Table 8.11 (continued) Effects of Tin Compounds on Selected Species of Mammals

Tin Compound, Organism	Dose	Effect	Ref. ^a
Guinea pig	3.7 mg/kg BW	LD50, single ip dose	2
Guinea pig	10–24 mg/kg BW	LD50, single oral dose	2, 9
Guinea pig	25–50 mg/kg diet	At 25 mg/kg, 83% dead in 77 days; at 50 mg/kg, all dead by day 29	7
Rat	25–300 mg/kg diet	No measurable effect at 25 mg/kg in 170 days; some lesions at 50 mg/kg in 105 days; impaired growth at 200 mg/kg in 70 days; weight loss and some deaths at 300 mg/kg in 117 days	7
European hare, <i>Lepus europaeus</i>	Fed diets with 25, 50, or 100 mg triphenyltin acetate/kg ration for 15 days, then 5 days on clean feed, 15 days on test diet, 5 days on clean feed then 22 days on diets	Normal food consumption, blood chemistry, and growth in all groups. Tissue concentrations were elevated only in the 100 mg/kg group: 3.0 mg/kg DW in liver, 2.8 in kidney, and 2.4 in caecum (vs. <1–<2 in all other groups)	24
Rat	34 mg/kg BW	LD50, single ip dose	23
Mouse	81–245 mg/kg BW	LD50, single oral dose	3
Rat	118–268 mg/kg BW	LD50, single oral dose	7, 8
TRIHEXYLTINS			
Rat	1000 mg/kg BW	LD50, single oral dose	8
TRICYCLOHEXYLTINS			
Dogs, rats	6–12 mg/kg diet	Some weight loss in 2 years, but no other toxic effects	20
Rat	13 mg/kg BW	LD50, single ip dose	2
Sheep, <i>Ovis</i> sp.	15–150 mg/kg BW	No observed effect at injected dose of 15 mg/kg BW; adverse effects at 25 to 50 mg/kg; death at 150 mg/kg	8
Rat	25 mg/kg BW	Gastroenteritis after 19 days	3
Rat	235–650 mg/kg BW	LD50, single oral dose	20
Rabbit	500–1000 mg/kg BW	LD50, single oral dose	7
White-footed mice, <i>Peromyscus leucopus</i>	710 mg/kg BW	LD50, single oral dose	3
Guinea pig	780 mg/kg BW	LD50, single oral dose	7
Dogs, monkeys, cats (<i>Felis domesticus</i>)	>800 mg/kg BW	LD50, single oral dose	8
Mouse	1070 mg/kg BW	LD50, single oral dose	3
TRIOCTYLTINS			
Rat	29,200 mg/kg BW	LD50, single oral dose	7
TETRAMETHYLTINS			
Rat	195–331 mg/kg BW	LD50, single oral dose	7
TETRAETHYLTINS			
Rabbit	7 mg/kg BW	LD50, single oral dose	8
Rat	9–16 mg/kg BW	LD50, single oral dose	8
Mouse	40 mg/kg BW	LD50, single oral dose	3
Guinea pig	40 mg/kg BW	LD50, single oral dose	3
TETRABUTYLTINS			
Rat	6000 mg/kg BW	LD50, single oral dose	7

Table 8.11 (continued) Effects of Tin Compounds on Selected Species of Mammals

8.5.5 Terrestrial Invertebrates

Resistance to organotin acaricides has been reported in several populations of spider mites. After cyhexatin and fenbutatin oxide were used for 10 to 17 years on pears and apples to control mites, populations of McDaniel spider mite (*Tetranychus mcdanieli*), two-spotted spider mite (*T. urticae*), and European red mite (*Panonychus ulmi*) slowly began to develop strains that were resistant to these chemicals (Croft et al. 1987).

8.6 RECOMMENDATIONS

Proposed organotin criteria for the protection of aquatic life, domestic animals, and human health, vary substantially (Table 8.12). The most stringent criteria now proposed are for triorganotins and aquatic life; these vary from 0.002 to 0.008 µg/L (Table 8.12). But even these comparatively low concentrations will not protect certain species of gastropod molluscs or larvae of the sheep sturgeon (*Accipenser nudipectoralis*) from tributyltin impacts, as discussed earlier. No criteria are currently proposed for protection of mammals against trimethyltins and triethyltins, the most toxic organotins tested in this group. Trimethyltins, for example, produce nonreversible neurotoxicological effects to certain species of small laboratory animals at concentrations as low as 0.15 mg/L drinking water or 0.625 mg/kg BW and are fatal at 1.25 mg/kg BW.

Hazard evaluation posed by organotin compounds to natural resources is predicated partly on their chemical composition, partly on their concentration and persistence in abiotic materials and diet items, and partly on their availability to organisms. In each of these areas, key data are missing for promulgation of effective regulations. It seems that additional research is needed in eight areas to acquire these data:

1. The development of sensitive and rapid analytical schemes for the extraction and separation of inorganic tin and organic tin compounds and their chemical speciation products from water, sediments, and biological materials (WHO 1980; Reuhl and Cranmer 1984; Hall and Pinkney 1985; Laughlin and Linden 1985; Thompson et al. 1985; Blunden and Chapman 1986; USPHS 1992).
2. Elucidation of mechanisms and modes of toxicity for organotin compounds, especially those involving sublethal chronic exposures and cellular and subcellular impacts (WHO 1980; Reuhl and Cranmer 1984; Hall and Pinkney 1985; Thompson et al. 1985; Vrijhof 1985).
3. Acquisition of data on organotin toxicokinetics, including data on routes of exposure, uptake, retention, and translocation. Studies should emphasize whole organisms to determine if food chain biomagnification is a potential problem; reproductive organs, in which organotin burdens may affect proliferation; and edible tissue, especially muscle and liver, which are selectively consumed by humans and various animal species (WHO 1980; Reuhl and Cranmer 1984; Wilkinson 1984; Hall and Pinkney 1985; Thompson et al. 1985).
4. Determination of the persistence and mobility of organotin compounds — especially in aquatic abiotic materials, such as sediments, sediment interstitial waters, suspended particulates, and the water column — and on the partitioning of these compounds between the surface microlayer and subsurface waters (Wilkinson 1984; Thompson et al. 1985).
5. Determination of the extent of tin methylation and the biotransformation and pharmacodynamics of organotins (WHO 1980).

^a 1, Anonymous 1985; 2, Duncan 1980; 3, Cardwell and Sheldon 1986; 4, Side 1987; 5, USN 1984; 6, Hall et al. 1987; 7, Zuckerman et al. 1978; 8, Thompson et al. 1985; 9, Chliamovitch and Kuhn 1977; 10, WHO 1980; 11, Simmonds 1986; 12, Blunden and Chapman 1986; 13, Watanabe 1980; 14, CEC 1978; 15, Huggett et al. 1992; 16, Pinkney et al. 1990; 17, USPHS 1992; 18, Harrington 1991.

6. Measurement of biological interaction effects of organotins with other toxic chemicals under stressful environmental conditions of temperature, oxygen, and other variables (Thompson et al. 1985).
7. Development of quantitative structure activity relations for use in evaluating toxicity of organotin compounds (Hall and Pinkney 1985; Laughlin and Linden 1985; Laughlin et al. 1985; Laughlin 1987).
8. Initiation of long-term environmental monitoring studies in terrestrial and aquatic ecosystems to establish appropriate baseline concentrations and to separate these from contaminant effects (Kumplainen and Koivistoninen 1977; WHO 1980; Hall and Pinkney 1985; Thompson et al. 1985).

Antifouling paints containing organotin compounds have been associated with a number of adverse effects to marine biota, including reductions in natural bacterial assemblages (Prior and Riemann 1998), contamination of salmon farmed in sea cages with treated net panels (Side 1987), and reduced growth of oysters (Cleary and Stebbing 1985). The United States Navy, however, has implemented fleetwide use of organotin antifouling paints that contain tributyltin as a biocide. This procedure will result in a 15% fuel consumption reduction, and will increase the interval between cleaning ship hulls from 2 years (with cuprous oxide-based antifouling paints) to about 7 years, and will also increase ship speed up to 40% as a direct result of reduced drag (U.S. Navy [USN] 1984). Since naval vessels rarely remain moored for extended periods in coastal areas, hazard effects to the environment are minimal — despite the size of the vessel — when compared to boating practices at local marinas (USN 1984).

Accordingly, civilian use of marine paints containing organotin compounds has been severely restricted in recent years. France banned tributyltin compounds in antifouling paints in January 1982 for use on vessels under 25 m (82 feet) in length (Waldock and Thain 1983; Side 1987; Huggett et al. 1992). The State of Virginia enacted legislation that prohibits the use of tributyltin paints on nonaluminum vessels under 25 m (Anonymous 1987). Also in Virginia, tributyltin paints applied on large ships and aluminum craft should not exceed a daily leach rate of 4.0 µg/cm² (Huggett et al. 1992). Similar legislation is proposed in at least 12 coastal and Great Lakes states (Anonymous 1988). In April 1987, England banned the retail sale of antifouling paints containing organotin compounds at concentrations greater than 4 grams of total tin per liter (Side 1987). Because of their hazards, use of the more toxic triorganotin biocides should be curtailed to prevent their entry into the environment (Piver 1973). Continued monitoring of tributyltin levels is recommended, especially in areas of extensive boating activity (Simmonds 1986).

8.7 SUMMARY

Tin (Sn) has influenced our lives for the past 5000 years. Today we are exposed to tin on a daily basis: tin-plated baby food cans; alloys such as pewter, bronze, brass, and solder; and toothpaste containing stannous fluoride. These inorganic tin compounds are not highly toxic due to their low solubility, poor absorption, low accumulation, and rapid excretion. Synthetic organotin compounds, however, first manufactured commercially in the 1960s, may present a variety of problems to animals, including impaired behavior and reduced growth, survival, and reproduction. Some triorganotins (for example, in antifouling marine paints, in molluscicides, and in agricultural pesticides) can be harmful to sensitive species of nontarget biota at recommended application protocols.

Background concentrations of organotin compounds are frequently elevated — occasionally to dangerous levels — in aquatic organisms collected near marinas and other locales where organotin-based antifouling paints are used extensively. But more information is needed on background concentrations of organotins, especially those from terrestrial ecosystems.

Tributyltin compounds are especially toxic to aquatic organisms. Adverse effects were noted at concentrations of 0.001 to 0.06 µg/L on molluscs and at 0.1 to 1.0 µg/L on algae, fish, and crustaceans. In general, bioconcentration of organotins from seawater was high, especially by algae, but degradation was sufficiently rapid to preclude food chain biomagnification. In contrast, current

environmental concentrations of some organotins are not likely to be directly toxic to birds and mammals. Birds seem to be relatively resistant to organotins, although data are scarce. Preliminary studies of 75 days' duration suggest that diets containing 50 mg tin as trimethyltin chloride/kg were fatal to ducklings; 5 mg/kg killed 40%, and 0.5 mg/kg was not lethal. Trimethyltin compounds were lethal to other species of birds tested at doses of 1 to 3 mg/kg body weight. Other tests with ducklings and 11 other mono-, di-, tri-, and tetraalkyltin compounds at dietary levels equivalent to about 50 mg Sn/kg showed no adverse effects on survival. Small laboratory mammals were adversely affected by trimethyltin compounds at doses as low as 0.15 mg/L in drinking water (learning deficits), 0.63 mg/kg body weight (diet aversion), and 1.25 mg/kg body weight (death); neurotoxicological effects of trimethyltins were usually not reversible. Triethyltins were also toxic to small mammals, but effects (which were similar to those of trimethyltins) were usually reversible after cessation of exposure. All evidence to date indicates that organotin compounds are not carcinogenic.

Methodologies and data necessary for the promulgation of effective criteria and standards to protect natural resources seem to be deficient in eight key areas: (1) routine analytical chemical methodologies for extraction, separation, and identification of inorganic and organic tin compounds and their chemical speciation products in biological and other samples; (2) mechanisms of toxicity for organotin compounds; (3) rates of uptake, retention, and translocation of organotins in biota; (4) persistence and mobility rates of organotins in nonbiological materials; (5) rates of tin methylation and biotransformation in biological and abiotic samples; (6) organotin interactions with other toxic chemicals; (7) quantitative structure-activity relation for use in evaluating organotin toxicity; and (8) long-term environmental monitoring studies in terrestrial and aquatic ecosystems for establishment of baseline concentrations.

CHAPTER 9

Zinc

9.1 INTRODUCTION

Zinc is an essential trace element for all living organisms. As a constituent of more than 200 metalloenzymes and other metabolic compounds, zinc assures stability of biological molecules, such as DNA, and of biological structures, such as membranes and ribosomes (Vallee 1959; National Academy of Sciences [NAS] 1979; Casey and Hambidge 1980; Llobet et al. 1988b; Mason et al. 1988; Leonard and Gerber 1989). Plants do not grow well in zinc-depleted soils, and deficiency has resulted in large losses of citrus in California and pecans in Texas (Vallee 1959). Clinical manifestations of zinc deficiency in animals include growth retardation, testicular atrophy, skin changes, and poor appetite (Prasad 1979). The ubiquity of zinc in the environment would seem to make human deficiencies unlikely; however, reports of zinc-associated dwarfism and hypogonadism in adolescent males are now confirmed (Casey and Hambidge 1980) and reflect the fact that much of their dietary zinc is not bioavailable. Zinc deficiency was a major factor in the syndrome of nutritional dwarfism in adolescent males from rural areas of Iran and Egypt in 1961; about 3% of the population in these areas were affected, and a similar syndrome was found in Turkey, Tunisia, Morocco, Portugal, and Panama (Casey and Hambidge 1980). The use of unleavened bread as a major staple food contributed to severe zinc deficiency in the Middle East. Even though unleavened bread may contain adequate amounts of zinc for nutrition and intakes may exceed recommended allowances by a wide margin, zinc is largely unavailable for absorption due to the high levels of fiber and phytic acid esters in unleavened bread (Casey and Hambidge 1980). Marginal deficiency of zinc in man is probably widespread and common throughout the world, including the United States (Prasad 1979). Dietary zinc replacement usually will reverse the pathologic events of zinc depletion in humans and animals (NAS 1979). But zinc repletion seems to be of little value in rat offspring with congenital malfunctions or behavioral abnormalities associated with zinc depletion (NAS 1979).

Zinc poisoning has been documented in dogs, cats, ferrets, birds, cattle, sheep, and horses, usually as a result of ingesting galvanized metal objects, certain paints and fertilizers, zinc-containing coins, and skin and sunblock preparations containing zinc oxide (Wentink et al. 1985; Lu and Combs 1988a; Ogden et al. 1988; Binnerts 1989; Robinette 1990). Signs of acute poisoning include anorexia, depression, enteritis, diarrhea, decreased milk yield, excessive eating and drinking and, in severe cases, convulsions and death (Ogden et al. 1988). Emissions from zinc smelters at Palmerton, Pennsylvania, have destroyed wildlife habitat, reduced prey abundance, poisoned deer, songbirds, and shrews, and eliminated terrestrial amphibians from the mountainside at Lehigh Gap (Beyer et al. 1985; Sileo and Beyer 1985; Beyer 1988). Aquatic populations are frequently decimated in zinc-polluted waters (Solbe and Flook 1975; Everall et al. 1989a). Zinc in the aquatic

environment is of particular importance because the gills of fish are physically damaged by high concentrations of zinc (NAS 1979).

Zinc toxicosis in humans is not a common medical problem, although it may appear in some metal workers and others under special conditions (NAS 1979). Industrial processes, such as welding, smelting, or fabrication of molten metals can produce ultrafine metal oxides at harmful concentrations. Inhalation of these metal oxides, including oxides of zinc, causes the industrial malady known as *metal fume fever* (Lam et al. 1985; Llobet et al. 1988b; Lu and Combs 1988a). Symptoms occur several hours after exposure and include fever, chills, perspiration, tachycardia, dyspnea, and chest pains. Recovery is normally complete within 24 h, but susceptible workers can have persistent pulmonary impairment for several days after exposure (Lam et al. 1985). Most reports of human zinc intoxication have been in response to food poisoning incidents arising from lengthy storage of acidic foods or beverages in galvanized containers (Llobet et al. 1988b; Fosmire 1990).

Historically, zinc has been used for industrial, ornamental, or utilitarian purposes for nearly 2000 years, and may have been used as an ointment to treat skin lesions by the ancient Egyptians and other Mediterranean peoples (NAS 1979). In biblical times, the Romans were known to have produced brass by mixing copper with a zinc ore (Elinder 1986). In its isolated form, zinc was not recognized until the 15th century when smelting occurred accidentally (NAS 1979). The Chinese probably were the first to extract zinc metal, although its first description in 1597 by an occidental traveler, Liborius, related that the process was observed in India (Vallee 1959). Commercial smelting began in the 18th century, when it was realized that zinc could be obtained from the calamine ore used to make brass; no reports of zinc toxicosis in any form were recorded from these early accounts (NAS 1979). The first documented use of zinc administered orally was in 1826 to treat discharges from various body orifices (NAS 1979). Zinc was recognized as an essential nutrient for plants and animals in 1869. Its occurrence in biological matter, e.g., human liver, was first described in 1877 (Vallee 1959). In 1934, zinc was conclusively demonstrated to be essential to normal growth and development in animals (Prasad 1979).

Zinc composes 0.004% of the earth's crust and is 25th in order of abundance of the elements (Vallee 1959). Uses of zinc include production of noncorrosive alloys, galvanizing steel and iron products, and in the therapeutic treatment of zinc deficiency (Elinder 1986). Zinc is found in coal and many manufactured products such as motor oils, lubricants, tires, and fuel oil (NAS 1979). Ecological and toxicological aspects of zinc in the environment have been reviewed by many authorities, including Vallee (1959), Skidmore (1964), NAS (1979), Prasad (1979, 1980), U.S. Environmental Protection Agency [USEPA] (1980, 1987), Nriagu (1980), Weatherley et al. (1980), Eisler (1981, 1993, 1997), Spear (1981), Apgar (1985), Elinder (1986), Vymazal (1986), Greger (1989), U.S. Public Health Service [USPHS] (1989), and Sorensen (1991).

9.2 SOURCES AND USES

World production of zinc increased from 0.5 million metric tons in 1900 to 6.1 million tons in 1978 (Elinder 1986) to 7.1 million tons in 1987 (USPHS 1989). The principal ores of zinc are sulfides, such as sphalerite and wurtzite (Elinder 1986). The major world producers include Canada, the former Soviet Union, and Japan — which collectively account for about half the production — and, secondly, the United States, Australasia, Mexico, and Peru (Weatherley et al. 1980; Elinder 1986). Zinc is now available as ingots, lumps, sheets, wire, shot, strips, granules, and powder (USPHS 1989). The United States produced 240,000 tons of zinc in 1987 — mostly from Tennessee, Mississippi, and New York, but also 16 other states — and imported an additional 774,000 metric tons, thus consuming 14% of world zinc production while producing 3.4% (USPHS 1989).

Zinc is mainly used in the production of noncorrosive alloys, brass, and in galvanizing steel and iron products. Zinc undergoes oxidation on the surface, thus protecting the underlying metal from degradation. Galvanized products are widely used in construction materials, automobile parts, and

household appliances (Elinder 1986). Zinc oxide is used to form white pigments, in rubber processing, and to coat photocopy paper (USEPA 1987; USPHS 1989). Zinc sulfate is used as a cooperative agent in fungicides and as a protective agent against zinc deficiency in soils. When incorporated with copper compounds or arsenic-lead wettable powders and applied by spraying, it can minimize the toxic effects of these metals on fruits, such as plum, apple, and peach; in Japan alone, about 250 tons of zinc sulfate is sprayed in fields each year (Maita et al. 1981). Zinc is used therapeutically in human medicine in the treatment of zinc deficiency, various skin diseases, wound healing, and to reduce pain in sickle cell anemia patients (Prasad 1979; Spear 1981; USEPA 1987; Warner et al. 1988).

Zinc is discharged into the global environment at a yearly rate estimated at 8.8 million tons; 96% of the total is a result of human activities (Leonard and Gerber 1989). Major sources of anthropogenic zinc discharges to the environment include electroplaters, smelting and ore processors, drainage from active and inactive mining operations, domestic and industrial sewage, combustion of fossil fuels and solid wastes, road surface runoff, corrosion of zinc alloys and galvanized surfaces, and erosion of agricultural soils (Weatherley et al. 1980; Spear 1981; Mirenda 1986; Llobet et al. 1988a; Buhl and Hamilton 1990). During smelting, large amounts of zinc are emitted into the atmosphere. In the United States alone during 1969, about 50,000 metric tons of zinc were discharged into the atmosphere during smelting operations (Elinder 1986). Another 20,000 metric tons are discharged annually into U.S. estuaries (Table 9.1). Zinc is also dispersed from corroded galvanized electrical transmission towers for at least 10 km by runoff, and by wind-driven spray and water droplets from the towers (Jones and Burgess 1984). Discharges from placer mining activities usually contain 75 to 165 µg Zn/L, sometimes up to 882 µg Zn/L in active mines, and these concentrations may represent acute hazards to salmonids in areas downstream of placer mine effluents (Buhl and Hamilton 1990). In Maine, galvanized culverts significantly increased zinc concentrations in stream waters, particularly in newer culverts. Highest zinc concentrations in culverts were found during conditions of elevated temperatures and low flow; levels of zinc sometimes exceeded the avoidance threshold (0.05 mg/L) of Atlantic salmon (*Salmo salar*); invertebrates seemed unaffected, except for a freshwater sponge, *Spongilla* sp. (Gregory and Trial 1975). Zinc sources implicated in livestock poisonings include galvanized iron wire and troughs, and zinc-containing fertilizers and fungicides (Allen et al. 1983; Reece et al. 1986). Zinc toxicosis in man has been reported from consumption of milk stored in galvanized vessels, and from food contaminated with particles of zinc from a zinc pigment plant (Zee et al. 1985). Zinc toxicity will be discussed in greater detail later.

Table 9.1 Estimated Annual Zinc Inputs to United States Coastal Marine Ecosystems (study area comprised 116,000 km²)

Source	Metric Tons Per Year
Rivers	5950
Atmosphere	4300
Barged wastes	3490
Storm channels	3060
Municipal wastewater	2500
Direct industrial discharges	710
Vessel protection	360
Dredging release	10
Thermal discharges	2
Groundwater	1
Total	20,383

Data from Young, D.R., T.K. Jan, and G.P. Hershelman. 1980. Cycling of zinc in the nearshore marine environment. Pages 297-335 in J.O. Nriagu (ed.), *Zinc in the Environment. Part I: Ecological Cycling*. John Wiley, NY.

9.3 CHEMICAL AND BIOCHEMICAL PROPERTIES

9.3.1 General

Most of the zinc introduced into aquatic environments is eventually partitioned into the sediments. Zinc release from sediments is enhanced under conditions of high dissolved oxygen, low salinity, and low pH. Dissolved zinc usually consists of the toxic aquo ion ($Zn(H_2O)_6^{2+}$) and various organic and inorganic complexes. Aquo ions and other toxic species have their greatest biological impacts under conditions of comparatively low pH, low alkalinity, low dissolved oxygen, and elevated temperatures. Zinc has its primary metabolic effect on zinc-dependent enzymes that regulate RNA and DNA. Low-molecular-weight proteins, metallothioneins, play an important role in zinc homeostasis and in protection against zinc poisoning in animals; zinc is a potent inducer of metallothioneins. The pancreas seems to be a primary target organ of zinc intoxication in birds and mammals, followed by bone; in fish, gill epithelium is the primary target site. Biological effects of excess zinc are modified by numerous variables, especially by interactions with other chemicals. Interactions frequently produce radically altered patterns of accumulation, metabolism, and toxicity. Some are beneficial to the organism, while others are harmful.

9.3.2 Chemical Properties

Zinc is a bluish-white metal which dissolves readily in strong acids. In nature it occurs as a sulfide, oxide, or carbonate. In solution, it is divalent and can form hydrated Zn^{2+} cations in acids, and zinctated anions — probably $Zn(OH)_4^{2-}$ — in strong bases (USEPA 1980, 1987). Zinc dust and powder are sold commercially under a variety of trade names: Asarco, Blue powder, CI 77949, CI pigment metal 6, Emanay zinc dust, granular zinc, JASAD Merrillite, L15, and PASCO (USPHS 1989). Selected physical and chemical properties of zinc, zinc chloride, and zinc sulfate are listed in [Table 9.2](#).

Zinc ligands are soluble in neutral and acidic solutions, so that zinc is readily transported in most natural waters (USEPA 1980, 1987), but zinc oxide, the compound most commonly used in industry, has a low solubility in most solvents (Elinder 1986). Zinc mobility in aquatic ecosystems is a function of the composition of suspended and bed sediments, dissolved and particulate iron and manganese concentrations, pH, salinity, concentrations of complexing ligands, and the concentration of zinc (USEPA 1980). In freshwater, zinc is most soluble at low pH and low alkalinity: 10 mg Zn/L of solution at pH 6 that declines to 6.5 at pH 7, 0.65 at pH 8, and 0.01 mg/L at pH 9 (Spear 1981). Dissolved zinc rarely exceeds 40 $\mu\text{g}/\text{L}$ in Canadian rivers and lakes; higher concentrations are usually associated with zinc-enriched ore deposits and anthropogenic activities. Marine

Table 9.2 Some Properties of Zinc, Zinc Chloride, and Zinc Sulfate

Property	Zinc	Zinc chloride	Zinc sulfate
Formula	Zn	$ZnCl_2$	$ZnSO_4$
CAS number	7440-66-6	7646-85-7	7733-02-0
Molecular weight	65.38	136.29	161.44
Melting point, °C	419.5	290	Decomposes at 600
Boiling point, °C	908	732	—
Density	7.14	2.907	3.54
Physical state	Bluish-white lustrous solid	Solid white granules	Colorless solid
Solubility	Insoluble in water, soluble in acetic acid and alkali	61.4 g/L water, 769 g/L alcohol, 500 g/L glycerol	Soluble in water, slightly soluble in alcohol

From U.S. Public Health Service (USPHS). 1989. Toxicological profile for zinc. U.S. Publ. Health Serv., *Agen. Toxic Subst. Dis. Regis.*, Atlanta, GA. 121 pp.

waters usually contain <10 µg Zn/L, most adhering to suspended solids; however, saturated seawater may contain 1.2 to 2.5 mg Zn/L (Spear 1981).

In water, the free zinc ion is thought to coordinate with six water molecules to form the octahedral aquo ion ($Zn(H_2O)_6^{2+}$) in the absence of other complexing or adsorbing agents (Spear 1981). In freshwater, zinc exists almost exclusively as the aquo ion at pH >4 and <7 (Campbell and Stokes 1985). In freshwater at pH 6, the dominant forms of dissolved zinc are the free ion (98%) and zinc sulfate (2%); at pH 9 the dominant forms are the monohydroxide ion (78%), zinc carbonate (16%), and the free ion (6%; USEPA 1987). In typical river waters, 90% of the zinc is present as aquo ion, and the remainder consists of $ZnHCO_3^+$, $ZnCO_3$, and $ZnSO_4$ (Spear 1981).

Zinc bioavailability and toxicity to aquatic organisms are highest under conditions of low pH, low alkalinity, low dissolved oxygen, and elevated temperatures (Weatherley et al. 1980). Soluble chemical species of zinc are the most bioavailable and most toxic (Spear 1981). The aquo ion predominates over other dissolved species and is suspected of being most toxic; however, aquo ion concentrations decrease under conditions of high alkalinity, at pH >7.5, and increasing salinity (Spear 1981). Under conditions of high alkalinity and pH 6.5, the most abundant species are $ZnHCO_3^+$, Zn^{2+} , and $ZnCO_3$; at low alkalinity and an elevated pH of 8.0, the order of abundance was $Zn^{2+} > ZnCO_3 >$ zinc humic acid $> ZnOH^+ > ZnHCO_3^+$ (Spear 1981). Water hardness is the principal modifier of acute zinc toxicity. Increased alkalinity or water hardness results in decreased toxicity to freshwater organisms when all zinc is dissolved; this effect is associated with decreased concentration of aquo ions and is heightened by increased pH. Increased water hardness at pH <8.5 when zinc is in suspension results in increased toxicity associated with increased suspended $ZnCO_3$. Increased water hardness at pH >8.5 when zinc is in suspension produces decreased toxicity and increased suspended $Zn(OH)_2$. Suspended zinc carbonate may also be toxic, although its toxicity decreases under conditions suitable to zinc hydroxide formation; suspended $Zn(OH)_2$ is relatively nontoxic. Thus, $ZnCO_3$ composes <1% of the dissolved zinc at low pH and low alkalinity but is the predominant chemical species at high pH and high alkalinity. Organozinc complexes are not stable and may dissociate under reducing conditions, liberating Zn^{2+} (Spear 1981).

In seawater, zinc exists in a dissolved state, as a solid precipitate, or is adsorbed to particle surfaces. Soluble zinc in seawater exists as uncomplexed free (hydrated) ions, as inorganic complexes (the primary form in the open sea), or as organic complexes (Young et al. 1980). In seawater at pH 8.1, the dominant species of soluble zinc are zinc hydroxide (62%), the free ion (17%), the monochloride ion (6.4%), and zinc carbonate (5.8%). At pH 7, the percentage of dissolved zinc present as the free ion increases to 50% (USEPA 1987). In the presence of dissolved organic materials, most of the dissolved zinc is present as organozinc-complexes (USEPA 1987). In estuaries and other marine environments, the relative abundance of zinc species changes with increasing salinity. At low salinities, $ZnSO_4$ and $ZnCl^+$ predominate; at higher salinities, the aquo ion predominates (Spear 1981). But as salinity decreases, the concentration of free zinc ion increases and the concentration of zinc-chloro complexes decreases, resulting in increased bioavailability of the free metal ion and increased bioconcentration by resident organisms (Nugegoda and Rainbow 1989b).

In solution, zinc is adsorbed by organic agents such as humic materials and biogenic structures (i.e., cell walls of plankton), and by inorganic adsorbing agents, such as mineral particles, clays, and hydrous oxides of manganese, iron, and silicon (Spear 1981). Particulate materials in the medium may contain as little as 2% and as much as 100% of the total zinc (Sprague 1986). Formation of zinc-ligand complexes increases the solubility of zinc and probably increases the tendency for zinc to be adsorbed (USEPA 1980). Sorption to particulates was lower at higher salinities due to displacement of sorbed zinc ions by alkali and alkaline earth cations (USEPA 1987). Increased pH increases zinc sorption to particulates, and seems to be independent of water salinity or hardness (USEPA 1987).

Most of the zinc introduced into aquatic environments is sorbed onto hydrous iron and manganese oxides, clay minerals, and organic materials, and eventually is partitioned into the sediments (USEPA 1987). Zinc is present in sediments as precipitated zinc hydroxide, ferric and manganic

oxyhydroxide precipitates, insoluble organic complexes, insoluble sulfides, and other forms. As the sediments change from a reduced to an oxidized state, soluble zinc is mobilized and released; however, the bioavailability of different forms of sediment zinc varies substantially, and the mechanisms of transfer are poorly understood (USEPA 1987). Sorption to sediments was complete at pH >7, but was negligible at pH <6 (USEPA 1987). Zinc is dissolved from sediments at low salinities due to displacement of adsorbed zinc ions by alkali and alkaline earth cations, which are abundant in brackish waters (USEPA 1980). Sulfide precipitation in sediments is an important control on zinc mobility in reducing environments, and precipitation of the hydroxide, carbonate or sulfate may occur when zinc is present in high concentrations (USEPA 1980).

Extractable concentrations of sediment-bound zinc were positively correlated with zinc concentrations in deposit feeding clams (Luoma and Bryan 1979). Availability of sediment zinc to bivalve molluscs was higher at increased sediment concentrations of amorphous inorganic oxides or humic substances, and lower at increased concentrations of organic carbon and ammonium acetate-soluble manganese. Zinc uptake by euryhaline organisms was enhanced at low water salinity (Luoma and Bryan 1979).

9.3.3 Metabolism

Zinc is ubiquitous in the tissues of plants and animals (Rosser and George 1986) and is essential for normal growth, reproduction, and wound healing (Prasad 1979; Stahl et al. 1989a). More than 200 different enzymes require zinc for maximum catalytic activity, including carbonic anhydrase, alkaline phosphatase, alcohol dehydrogenase, acid phosphatase, lactic dehydrogenase, carboxypeptidase, and superoxide dismutase (Prasad 1979, 1980; Casey and Hambidge 1980; Rosser and George 1986; Blesbois and Mauger 1989; Thompson et al. 1989). Zinc has its primary effect on zinc-dependent enzymes that regulate the biosynthesis and catabolic rate of RNA and DNA (Prasad 1979; Casey and Hambidge 1980; Gipouloux et al. 1986; Sternlieb 1988). Zinc exerts a protective effect on liver by inhibiting lipid peroxidation and stabilizing lysosomal membranes (Sternlieb 1988); aids neurotransmission in brain of fish, birds, reptiles, and mammals (Smeets et al. 1989); prolongs muscular contractions, increases oxygen affinity of myoglobin, and is necessary for the growth and differentiation of muscle fiber types (Rosser and George 1986); increases numbers and birth weights of lambs of zinc-supplemented ewes; is essential for wound healing in most organisms studied (Ireland 1986); and is used therapeutically in treating patients with skin diseases, zinc deficiency, and other symptoms (Mooradian et al. 1988; Sternlieb 1988).

Zinc enters the gastrointestinal tract as a component of low-molecular-weight proteins secreted by the salivary glands, intestinal mucosa, pancreas, and liver (Goyer 1986). Usually, only dissolved zinc is sorbed or bound, but zinc dissolution probably occurs in the alimentary tract of animals after ingestion of particulates containing undissolved zinc (USEPA 1987). After ingestion, zinc is absorbed across several physiologically active membranes: gut mucosa, alveocapillary membranes, and tissue and organ membranes. The exact transport mechanisms are unknown but may be associated with formation of a tetrahedral quadradentate ligand with a small organic molecule (NAS 1979). Some of the zinc taken up by the intestinal epithelial cells is rapidly transferred to the portal plasma where it associates with albumin, α_2 macroglobulin, and amino acids. About 67% of the zinc in plasma is bound to albumin, and about 3% is stored in liver (Sternlieb 1988). Soluble organozinc complexes are passively absorbed across the plasma membrane of the mucosa of the intestinal villi; the soluble, nondiffusible complexes are transported in the intestinal products and excreted in feces (NAS 1979). Zinc loss from urine and sweat is usually small (Casey and Hambidge 1980). In a normal human adult, about 2 g of zinc is filtered by the kidneys daily and about 0.3 to 0.6 mg is actually excreted each day (Goyer 1986). Zinc homeostasis in rats, unlike most mammals, is maintained by zinc secretion from the intestines rather than by regulation of zinc absorption (Elinder 1986). Initial uptake of zinc from the rat gastrointestinal tract involves binding to albumin and transport of the zinc-albumin complex from intestine to liver (Hoadley and Cousins 1988).

Foods rich in zinc include red meat, milk, gelatin, egg yolks, shellfish, liver, whole grain cereals, lentils, peas, beans, and rice (Sternlieb 1988). About 20 to 30% of zinc in the diet is absorbed, but this is highly variable and ranges from <10% to >90% (Prasad 1979; Casey and Hambridge 1980; Elinder 1986). Increased zinc absorption, for example, was associated with low body weight, poor zinc status, and various prostaglandins; decreased absorption was caused by excess dietary calcium or phytate, and by a deficiency of pyridoxine or tryptophan (Elinder 1986; Goyer 1986). The half-time persistence of zinc in most mammalian tissues ranges between 100 and 500 days; it is longer in bone and muscle, and shorter in liver (Elinder 1986).

Metallothioneins play an important role in metal homeostasis and in protection against heavy-metal toxicity in vertebrates and invertebrates (Engel 1987; Overnell et al. 1987a; Andersen et al. 1989; Olsson et al. 1989; Richards 1989a; Eriksen et al. 1990). Metallothioneins are cysteine-rich (>20%), low (about 6000)-molecular-weight proteins, with high affinity for copper, silver, gold, zinc, copper, and mercury. These heat-stable, metal-binding proteins are found in all vertebrate tissues and are readily inducible by a variety of agents, to which they bind through thiolate linkages. Zinc is a potent inducer of metallothioneins, and a redistribution of zinc from enzymes to metallothioneins is one way to maintain low intracellular zinc concentrations. Metallothioneins also serve as temporary storage proteins for zinc and other metals during early development and may function by maintaining the pool of available zinc at an appropriate concentration. Metallothioneins are quite similar among organisms; that is, all metallothioneins are small proteins of molecular weight 6000 to 10,000, rich in sulfur and cysteine, and lacking aromatic amino acids (Sprague 1986). Metallothioneins isolated from cattle, sheep, horses, pigs, and other livestock, contain 61 amino acids; thioneine, the metal-free protein, is a single-chain polypeptide with a molecular weight of about 6000 (Richards 1989a). Chicken thioneine consists of 63 amino acids, including histidine, an amino acid not present in mammalian metallothioneins. The unusually high cysteine content enables metallothioneins to selectively bind up to 7 zinc and 12 copper atoms per mole of protein (Richards 1989a).

Metallothioneins are involved in zinc homeostasis in chick, rat, and calf. When zinc is present at high dietary concentrations, a temporary zinc storage protein aids in counteracting zinc toxicity (Oh et al. 1979). Zinc absorption in mice is directly proportional to intestinal metallothionein levels and implies a significant role for metallothionein in zinc absorption (Starcher et al. 1980). Chick embryo hepatic metallothionein is highly responsive to exogenous zinc introduced into the yolk, and increases in a dose-dependent manner; a similar pattern is evident in turkey development (Fleet and McCormick 1988). Zinc protects against subsequent exposure to zinc insult, and protection is believed to be mediated by metallothioneins (Woodall et al. 1988). For example, preexposure of South African clawed frog (*Xenopus laevis*) tadpoles to 5 mg ZnSO₄ (7H₂O)/L for 96 h resulted in no deaths during subsequent exposure to 15 mg Zn/L for 90 h vs. 45% dead in the nontreated group. At 20 mg Zn/L, 15% died in the pretreated group vs. 50% in the nontreated group (Woodall et al. 1988). Metallothioneins are an important factor in zinc regulation during the period of exogenous vitellogenesis in rainbow trout (*Oncorhynchus mykiss*). In female rainbow trout, for example, metallothioneins maintain homeostasis of hepatic zinc during egg formation (Olsson et al. 1989). In plaice (*Pleuronectes platessa*), a marine fish, intraperitoneal injection of zinc raised hepatic metallothionein-like species by a factor of 15; metallothionein levels remained elevated for the next 4 weeks (Overnell et al. 1987a).

In marine molluscs and crustaceans, excess zinc is usually sequestered by metal-binding proteins and subsequently transported to storage or detoxification sites; soluble proteins and amino acids may contain 20 to 70% zinc (Sprague 1986). Metallothioneins are actively involved in zinc regulation during normal growth processes in blue crab (*Callinectes sapidus*), as judged by a decrease in zinc content in hemolymph and digestive gland during molting (Engel 1987).

Elevated metallothionein levels are not necessarily indicative of heavy-metal insult. Starcher et al. (1980) show that liver metallothionein levels in mice are elevated following acute stress or starvation, and that this effect is blocked by actinomycin D, a protein synthesis inhibitor. It is further emphasized that not all zinc-binding proteins are metallothioneins (Webb et al. 1985;

Andersen et al. 1989; Richards 1989; Eriksen et al. 1990). Low-molecular-weight metal-binding proteins — not metallothioneins — were induced in snails and polychaete annelids in metals-contaminated environments (Andersen et al. 1989). A high-molecular-weight protein fraction was detected in the plasma of laying turkey (*Meleagris gallopavo*) hens, which bound significant amounts of zinc and which coeluted with vitellogenin; vitellogenin, a metalloprotein, from laying hens contained 0.54 mg Zn/kg protein (Richards 1989). In rock oysters (*Saccostrea cucullata*) collected near an iron-ore shipping terminal, some of the tissue zinc was bound to a high molecular weight (around 550,000) iron-binding protein called ferritin (Webb et al. 1985). Ferritin accounts for about 40% of the protein-bound zinc in rock oysters, and most probably in other bivalves containing elevated tissue levels of zinc (Webb et al. 1985). This requires verification, however. In four species of sediment-feeding marine polychaete annelids, zinc was mainly associated with high-molecular-weight proteins, suggesting that metallothionein-like proteins may not be satisfactory for monitoring purposes and that other cytosolic components should be studied (Eriksen et al. 1990).

High zinc levels induce copper deficiency in rats and interfere with metabolism of calcium and iron (Goyer 1986). Excess zinc interferes with normal metabolism of pancreas, bone, gall bladder, and kidney in mammals, and gill in fishes. The pancreas is a target organ for zinc toxicity in birds and mammals. Pancreatic alterations are documented from experimentally produced zinc toxicosis in cats, sheep, dogs, calves, chickens, and ducklings, and naturally in sheep and calves. Pancreatic changes were limited to acinar cells, specifically cytoplasmic vacuolation, cellular atrophy, and eventually cell death (Lu and Combs 1988a; Kazacos and Van Vleet 1989). Zinc excess may cause stimulation of bone resorption and inhibition of bone formation in chicks, dogs, monkeys, and rats (Kaji et al. 1988). By preferentially accumulating in bone, zinc induces osteomalacia — a softening of the bone caused by deficiency of calcium, phosphorus, and other minerals (Kaji et al. 1988). Zinc plays a role in bone metabolism of aging rats (Yamaguchi et al. 1989a). Normally, the femoral zinc diaphysis content in rats increases from 50 to 150 mg/kg FW during the first three weeks of life and remains constant thereafter. Oral administration of zinc (5 to 20 mg/kg body weight [BW] daily for 3 days to 28-week-old rats) increased alkaline phosphatase activity and calcium content in femur, and delayed bone deterioration in aging rats (Yamaguchi et al. 1989a). Its high affinity for electrons causes zinc to bind covalently to proteins, mostly at imidazole and cysteine residues. In mud puppy (*Necturus maculosus*), zinc blocks apical membrane anion exchange in gallbladder epithelium and blocks chloride channels in nerve and muscle cells. The slow onset and reversal of the effects suggest a covalent modification of the exchanger, or an effect requiring Zn²⁺ transport to the cell interior (Kitchens et al. 1990).

Zinc toxicity to aquatic organisms depends on the physical and chemical forms of zinc, the toxicity of each form, and the degree of interconversion among them. Aquatic plants and fish are relatively unaffected by suspended zinc, but many aquatic invertebrates and some fishes may be adversely affected if they ingest enough zinc-containing particulates (USEPA 1987). Zinc toxicosis affects freshwater fishes by destruction of gill epithelium and consequent tissue hypoxia. Signs of acute zinc toxicosis in freshwater fishes includes osmoregulatory failure, acidosis and low oxygen tensions in arterial blood, and disrupted gas exchange at the gill surface and at internal tissue sites (Spear 1981). Zinc exerts a critical influence on mammalian and piscine immune systems (Ghanmi et al. 1989). Lymphocytes from the pronephros of common carp (*Cyprinus carpio*) were transformed by various mitogenetic agents; zinc added to lymphocyte cultures enhanced thymidine incorporation, and inhibited the response of the mitogenetic agents — although Zn²⁺ was in itself toxic at these concentrations (650 µg Zn²⁺/L; Ghanmi et al. 1989).

9.3.4 Interactions

Zinc interacts with numerous chemicals, sometimes producing greatly different patterns of accumulation, metabolism, and toxicity when compared to zinc alone. Recognition of these interactions is essential to the understanding of zinc kinetics in the environment.

Cadmium

Cadmium-zinc interactions are typical in that sometimes they act to the organism's advantage and sometimes not, depending on the organism, its nutritional status, and other variables.

Dietary cadmium accentuates signs of zinc deficiency in turkeys, chicks, rodents, and pigs (NAS 1979). Chicks on a zinc-deficient diet showed an increased frequency of muscle and feather abnormalities when 40 mg of cadmium/kg of diet was added; however, supplementing the diet with 200 mg Zn/kg for 14 to 15 days lessened or reversed the adverse effects of cadmium (Supplee 1963). Cadmium promotes the growth of zinc-limited phytoplankton (Price and Morel 1990). Substitution of trace metals or metalloenzymes could be a common strategy for phytoplankton in trace-metal impoverished environments, such as the ocean, and could result in an effective colimitation of phytoplankton growth by several bioactive elements (Price and Morel 1990). Zinc-deficient marine diatoms (*Thalassiosira weissflogii*), for example, can grow at 90% of their maximum rate when supplied with cadmium (which substitutes for Zn in certain macromolecules); cobalt can also substitute for zinc, although less efficiently than cadmium (Price and Morel 1990).

Zinc diminishes or negates the toxic effects of cadmium. Specifically, zinc protected embryos of the toad (*Bufo arenarum*) and other amphibian embryos against cadmium-induced developmental malformations (Herkovits et al. 1989; Herkovits and Perez-Coll 1990; Rivera et al. 1990). Zinc counteracted adverse effects of cadmium on limb regeneration and growth of the fiddler crab (*Uca pugilator*; Weis 1980). Preexposure of a freshwater amphipod (*Gammarus pulex*) to 10 µg Zn/L for 2 weeks increased whole-body zinc content from 74 to 142 mg/kg DW and protected against the toxic effects of subsequent cadmium exposure of 500 µg Cd/L for 96 h (Howell 1985). In crickets (*Acheta domesticus*), excess zinc in diets of larvae protected against cadmium toxicity (Migula et al. 1989). Zinc protected rats (*Rattus* sp.) against the toxic effects of cadmium, such as testicular lesions, reduced sperm counts, hepatotoxicity, and lung damage (Sato and Nagai 1989; Saxena et al. 1989a). Zinc also protected mouse (*Mus* sp.) embryos against cadmium toxicity (Yu and Chan 1988). An effective protection ratio was 1 Cd: 1 Zn for mouse embryos, but for free-living embryos of the toads (*B. arenarum*), this ratio was 1 Cd: 8 Zn (Belmonte et al. 1989). Zinc reversed the toxic action of cadmium on natural killer cells of mice: 500 mg Zn/L drinking water negated the toxic action of 50 mg Cd/L (Chowdhury and Chandra 1989). The mechanisms of zinc protection against cadmium were variously attributed to metallothionein induction (Sato and Nagai 1989), enhanced detoxification rates of cadmium (Rivera et al. 1990), and competition with cadmium for the same metalloenzyme sites (Yu and Chan 1988; Rivera et al. 1990).

Waterborne solutions of zinc–cadmium mixtures were usually additive in toxicity to aquatic organisms, including freshwater fishes (Skidmore 1964) and amphipods (de March 1988), and to marine fishes (Eisler and Gardner 1973), copepods (Verriopoulos and Dimas 1988), and amphipods (Ahsanullah et al. 1988). However, mixtures of zinc and cadmium were less toxic than expected to *Daphnia magna*, as judged by acute lethality studies (Attar and Maly 1982).

Zinc exerted antagonistic effects on the uptake of cadmium by gills of the freshwater clam (*Anodonta cygea*), but accelerated cadmium transport from gills toward internal organs (Hemelraad et al. 1987). Cadmium uptake in tissues of *Anodonta* was reduced by about 50% during exposure for 16 weeks to water containing 25 µg Cd/L and 2.5 mg Zn/L (Hemelraad et al. 1987). In a marine prawn (*Pandalus montagui*), cadmium exposure had no effect on tissue zinc levels, but zinc enhanced cadmium uptake in hepatopancreas at the expense of carcass (Ray et al. 1980). In marine fishes, cadmium was taken up more rapidly at elevated seawater zinc levels; however, zinc concentrations in fish tissues decreased with increasing tissue cadmium burdens, suggesting competition between these two metals for the same physiologically active site (Eisler 1981). Zinc concentrations in larval shrimp (*Palaemon serratus*), within its threshold regulation range of 75 to 525 µg Zn/L, were not affected by the addition of 100 µg of cadmium/L (Devineau and Amiard Triquet 1985). In zebrafish (*Brachydanio rerio*), zinc did not affect cadmium uptake by whole body or gills, but did inhibit intestinal uptake and tended to increase gill cadmium elimination rates (Wicklund et al. 1988).

Among marine vertebrates, cadmium is selectively accumulated over zinc (Eisler 1984). In ducks, zinc selectively competes with cadmium on high- and low-molecular-weight protein pools in kidney and liver. Once the high-molecular-weight protein pool is Zn-saturated, excess Zn is stored on metal-binding proteins, with serious implications for waterfowl simultaneously stressed with cadmium and zinc (Brown et al. 1977). On the other hand, a cadmium-induced disease in bone collagen of chicks was prevented by zinc because of preferential accumulation of Zn (Kaji et al. 1988).

Copper

Mixtures of zinc and copper are generally acknowledged to be more-than-additive in toxicity to a wide variety of aquatic organisms, including oyster larvae (Sprague 1986), marine fishes (Eisler and Gardner 1973; Eisler 1984), freshwater fishes (Skidmore 1964; Hilmy et al. 1987b) and amphipods (de March 1988), and marine copepods (Sunda et al. 1987; Verriopoulos and Dimas 1988). But Zn–Cu mixtures were less-than-additive in toxicity to marine amphipods (*Allorchestes compressa*; Ahsanullah et al. 1988).

Zinc added to the ambient water depressed copper accumulations in tissues of juvenile catfish (*Clarias lazera*), but copper added to the medium depressed zinc uptake (Hilmy et al. 1987b). A similar situation was reported in barnacles (*Elminius modestus*); however, simultaneous exposure to copper and zinc resulted in enhanced uptake of both metals (Elliott et al. 1985).

In higher organisms zinc is a copper antagonist and potentiates the effects of nutritional copper deficiency in rats and chicks. This effect only occurs at extremely high Zn:Cu dietary ratios. The addition of copper to the diet of chicks or rats in physiological amounts counteracted all observed signs of zinc intoxication (Tom et al. 1977). No antagonism was evident between dietary copper and zinc fed to channel catfish (*Ictalurus punctatus*) fingerlings; therefore, the high levels of supplemental zinc required in practical feeds should not impair copper status, provided that normal dietary copper levels are present (Gatlin et al. 1989).

High levels of administered zinc limits copper uptake in humans and certain animals (Sammon and Roberts 1988) and provides protection against toxicosis produced by copper in pigs and sheep (Allen et al. 1983). Excessive zinc in humans interferes with copper absorption from the intestine, resulting in copper deficiency and eventually cardiovascular diseases; high zinc intakes also decrease iron bioavailability, leading to a 67% reduction in erythrocyte life span (Saxena et al. 1989b). Copper deficiency induced by excess dietary zinc is associated with lameness in horses, donkeys, and mules (NAS 1979; Bridges 1990; Ostrowski et al. 1990).

Lead

Lead–zinc mixtures were more-than-additive in toxicity to marine copepods (Verriopoulos and Dimas 1988) and significantly delayed development of mud crab (*Rithropanopeus harrissii*) larvae (USEPA 1987). Lead is accumulated up to 10 times more rapidly by marine fishes at elevated zinc concentrations in seawater (Eisler 1981).

Among terrestrial animals, zinc protects against lead toxicosis. Dietary zinc reduced the toxic effects of dietary lead to larvae of the house cricket (*Acheta domesticus*) by inhibiting assimilation and stimulating fecal excretion (Migula et al. 1989). Zinc at 100 to 200 µg/egg (1 mg Zn/kg egg) significantly protected developing white leghorn chicks against lead (50 µg/egg)-induced deformities and death when injected into the yolk sac on the 7th day of incubation (Anwer et al. 1988). Zinc also protects against lead toxicity in horses (Anwer et al. 1988), and against testicular injury induced by lead in rats (Saxena et al. 1989a).

Nickel

Nickel–zinc mixtures were additive in toxicity to marine copepods (Verriopoulos and Dimas 1988) and to the three-spined stickleback (*Gasterosteus aculeatus*; Skidmore 1964).

Oral nickel toxicity in chicks was prevented by increased dietary zinc (Warner et al. 1988).

Nickel is a leading cause of allergic contact dermatitis (ACD) in many industrial nations; about 6% of the general public is sensitive to nickel and about 11% of dermatology clinic patients (Warner et al. 1988). Zinc prevents nickel sulfate-induced ACD in guinea pigs (*Cavia* spp.) through addition of 100 to 200 mg Zn/L drinking water for 4 weeks prior to nickel insult (Warner et al. 1988). Nickel and other metals that cause ACD penetrate the skin, complex with selected ligands, and stimulate a delayed hypersensitivity. Zinc is thought to block the sites where nickel complexes to the protein (Warner et al. 1988).

Other Chemicals

Zinc interacts with a wide variety of inorganic, organic, and biological agents, but in most cases the available information is fragmentary, and the mechanisms of action are unknown. Mice pre-treated with zinc at 6.5 mg Zn/kg BW for 9 days showed increased resistance to arsenic toxicosis over a 30-day observation period (Kreppel et al. 1988). Oral zinc therapy was effective in treating biological agents, such as infectious pododermatitis in cattle, ovine foot rot in sheep, sporidesmin in sheep, cattle, and rodents, and the toxins of the fungus *Phomopsis leptostromiformis* in sheep (Allen et al. 1983). However, juvenile channel catfish (*Ictalurus punctatus*) fed zinc in the diet for 16 weeks at concentrations as high as 60 mg Zn/kg ration as zinc methionine or zinc sulfate were not protected against bacterial infections of *Edwardsiella ictaluri* (Lim et al. 1996). Elevated testicular zinc concentrations in bank voles (*Clethrionomys glareolus*) protect the testes from fluoride-induced histopathology caused by 200 mg F/L drinking water for 4 months (Krasowska and Wlostowski 1996). Calcium modifies zinc toxicity to freshwater aquatic organisms, with increased calcium associated with decreased acute toxicity (Everall et al. 1989a; Handy et al. 1989). Zinc absorption in rat gut is decreased after ingestion of phosphorus as polyphosphate or orthophosphate plus high levels of calcium (Greger 1989). Zinc cytotoxicity is blocked by increased calcium or iron, but not magnesium (Borovansky and Riley 1989). Zinc reportedly protects rats against carbon tetrachloride poisoning (Allen et al. 1983).

Various chelating agents protect mice against zinc acetate poisoning, including disodium ethylene diamine tetraacetic acid (EDTA), disodium calcium cyclohexanediamine tetraacetate, D-penicillamine, 2,3-dimercapto-1-propane sulfonic acid, and 2,3-dimercaptosuccinic acid (Llobet et al. 1988b). Zinc protects toad embryos against agents known to produce malformations, including excess Vitamin A, acetazolamide, calcium-EDTA, and acetaminophen (Herkovits et al. 1989). Venom of the jararaca (*Bothrops jararaca*), a venomous Brazilian serpent, contains a zinc metalloprotease called J protease; the proteolytic activity of J protease is inactivated by EDTA and other sequestering agents (Tanizaki et al. 1989).

Chromium-zinc mixtures were more-than-additive in toxicity to *Tisbe holothuriae*, a marine copepod. Zinc in combination with chromium was more toxic to copepods than were mixtures of zinc with copper, lead, nickel, or cadmium (Verriopoulos and Dimas 1988).

Renal tubular absorption of zinc in mice was impaired by certain diuretics and was further influenced by dietary proteins (Goyer 1986). Zinc absorption in rats was depressed after consumption of high levels of inorganic iron; absorption was normal with organoiron (Greger 1989).

Mercury-zinc mixtures were more-than-additive in toxicity to oyster larvae (Sprague 1986). Preexposure of mussels (*Mytilus edulis*) to 50 µg Zn/L for 28 days conferred increased tolerance to 75 µg inorganic mercury/L (Roesijadi and Fellingham 1987). Zinc inhibited the accumulation of mercury in marine snails and crustaceans (Andersen et al. 1989).

Zinc deficiency places an increased demand on selenium (Se) pools in daphnids. As little as 5 µg Se/L in zinc-free water eliminated overt cuticle damage and substantially increased reproduction, but did not alter the shortened life span. Cladocerans at the threshold of Se deficiency will become overtly Se deficient when zinc supplies are lacking (Keating and Caffrey 1989). Insufficient copper introduces cuticle problems in daphnids similar to those introduced by insufficient zinc or

selenium, increasing the likelihood of a proposed relation between glutathione peroxidase (which contains Se), and copper-zinc superoxide dismutase (Keating and Caffrey 1989).

High levels of dietary tin increased zinc loss from rats (Greger 1989). Zinc prevented toxic effects of vanadium (10 mg/kg BW) on bone metabolism of weanling rats (Yamaguchi et al. 1989).

9.4 CARCINOGENICITY, MUTAGENICITY, AND TERATOGENICITY

9.4.1 General

Zinc can induce testicular sarcomas in birds and rats when injected directly into the testes, but zinc has not been shown to be tumorogenic by any other route. Zinc promotes tumor growth after conditions of zinc deficiency, but excess zinc may suppress or inhibit tumor proliferation, although the mechanisms of action are imperfectly understood. Chromosomal aberrations were observed under conditions of zinc deficiency, but excess zinc was not mutagenic in most tests. Organozinc compounds are effective mutagens when presented to susceptible cell populations in an appropriate form, but the evidence for inorganic zinc is incomplete. Zinc is teratogenic to frog and fish embryos, but conclusive evidence of teratogenicity in mammals is lacking. Zinc may protect against the effects of some mammalian teratogens. Under conditions of mild zinc deficiency, however, diabetes and effects of various teratogens are exacerbated.

9.4.2 Carcinogenicity

Carbamate esters of zinc, zineb, and ziram are carcinogenic and teratogenic in animals, but this is attributed to the action of the carbamate esters and not to zinc (Elinder 1986). Results of studies with small mammals showed zinc to be cocarcinogenic with 4-nitroquinoline-N-oxide on oral cancer, and with N-ethyl-N-nitrosourea on brain cancer (Leonard and Gerber 1989).

There is conclusive evidence that repeated intratesticular injections of zinc salts can induce testicular sarcomas in birds and rats (NAS 1979; Elinder 1986; Goyer 1986; USPHS 1989). Testicular teratomas in roosters were first produced experimentally in 1926 when zinc salts were injected into the testes as a method of practical castration; tumors could be induced only by intratesticular injection during the spring period of gonadal growth (Guthrie 1971). Teratomas of the testes were observed in fowl given testicular injections of 2 mL of 10% ZnSO₄ solution (USPHS 1989). Teratomas were induced in Japanese quail (*Coturnix coturnix japonica*) by intratesticular injections of 3% zinc chloride solutions during a period of testicular growth stimulated by increased photoperiod. Tumors were similar to those of domestic fowl and had histological features in common with spontaneous testicular teratomas in humans (Guthrie 1971). Testicular tumors in rats were produced by direct intratesticular injection of zinc; no other carcinogenic effects were produced by any other route, regardless of dose (Goyer 1986). It is emphasized that zinc and zinc compounds are not conclusively carcinogenic except when injected directly into the testes; no field or experimental evidence exists showing zinc to be tumorogenic through any other route (NAS 1979; Phillips and Kindred 1980; Elinder 1986; Leonard and Gerber 1989; USPHS 1989).

Zinc is essential for the growth of rapidly proliferating cells, such as tumors. The high zinc requirements of these cells in tumor disease can result in latent zinc deficiency. Accordingly, growth of animal tumors is stimulated by zinc and retarded by zinc deficiency (Prasad 1979; Leonard and Gerber 1989). In mouse fibrosarcoma cells, zinc inhibits endonucleases, subsequently blocking DNA fragmentation and tumor cell lysis, allowing tumors to grow (Flieger et al. 1989). There is no evidence that zinc deficiency causes cancer (NAS 1979), although deficiency was associated with decreasing tumor growth (Prasad 1979; Phillips and Kindred 1980). Malignant human tissues, for example, frequently contained less zinc than normal tissue, i.e., 78 mg/kg FW normal liver vs. 18 in cancerous liver (Phillips and Kindred 1980).

Zinc can also inhibit tumor growth (NAS 1979), although the mechanisms of zinc suppression of carcinomas are imperfectly understood (Phillips and Kindred 1980). Zinc inhibits the growth of mouse melanoma cells at concentrations between 8.2 and 9.9 mg Zn/L culture medium (Borovansky and Riley 1989). The addition of 100 mg ZnSO₄/L to drinking water of hamsters inhibited formation of dimethylbenzanthracene-induced carcinomas (Phillips and Kindred 1980). Rats fed high zinc diets of 500 mg/kg ration had reduced growth of a chemically induced hepatoma (Phillips and Kindred 1980). Intramuscular injections of zinc oxide or zinc acetate administered together with nickel sulfide — a potent muscle carcinogen — delayed, but did not prevent, 100% tumor incidence in rats over a 66-week observation period (Kasprzak et al. 1988). Administration of zinc slows the carcinogenic process induced by nickel due to the production of water-soluble and water-insoluble zinc compounds, despite markedly different retention times in muscle of zinc compounds (T_b 1/2 of ZnO = 24 days; Zn acetate = 2.5 days; Ni₃S₂ = 21 days). Zinc in either form exerted no measurable influence on nickel retention at the injection site or early local cellular reactions to nickel (Kasprzak et al. 1988). Testicular tumors in rats caused by injection of cadmium were suppressed by zinc injection (Leonard and Gerber 1989), provided that the Zn:Cd molar ratio was about 100:1 (Phillips and Kindred 1980). Zinc inhibition of cadmium carcinogenesis is a complex phenomenon, depending on dose, route, and target site (Waalkes et al. 1989). For example, the number of cadmium-induced testicular tumors in rats was reduced by 50% over a 2-year period after three subcutaneous injections of 65.4 mg Zn/kg BW given within 18 h of initial cadmium insult, even though this group had a marked elevation in prostatic tumors when compared to controls. Tumor number was reduced by 92% when rats were given 100 mg Zn/L in drinking water (Waalkes et al. 1989).

9.4.3 Mutagenicity

Results of mutagenicity studies with whole organisms were usually negative because homeostatic controls of absorption and protein binding preclude the likelihood of zinc being genotoxic under standard feeding conditions (Thompson et al. 1989). However, zinc is an effective mutagen and clastogen when presented to a susceptible cell population in an appropriate form (Thompson et al. 1989). Zinc acetate produced dose-related positive responses in the mouse lymphoma assay, and also in a cytogenetic assay with Chinese hamster ovary cells; however, results of mutagenicity assays with inorganic zinc were negative in the *Salmonella* mutation assay, and in unscheduled DNA synthesis on primary cultures of rat hepatocytes (Thompson et al. 1989). Organozinc compounds have mutagenic potential, as judged by the positive responses with zinc 2,4-pentanedione and *Salmonella* (Thompson et al. 1989).

Structural chromosome aberrations, particularly chromatid gaps and increased frequency of fragment exchange, were observed in rat bone marrow cells after 14 days of exposure to 240 mg Zn/L drinking water (Kowalska-Wochna et al. 1988). Chromosomal aberrations were observed in bone marrow cells of mice fed diets equivalent to 650 mg Zn/kg BW daily, in mice exposed to zinc oxide by inhalation, and in mice maintained on a low-calcium diet (USPHS 1989). Aberrations in bone marrow of mice given 5000 mg Zn/kg diet may be associated with calcium deficiency (Leonard and Gerber 1989). Calcium is displaced by zinc in calcium-depleted conditions, leading to chromosomal breaks and interference in the repair process (USPHS 1989).

Zinc chloride induces chromosomal aberrations in human lymphocytes *in vitro* (Elinder 1986). A higher incidence of chromosome anomalies in leukocytes occurs among workers exposed to zinc (Elinder 1986), but these aberrations are likely due to other (unspecified) mutagenic factors in the work environment (Leonard and Gerber 1989).

Zinc inhibits the mutagenic action of some carcinogens because it is a constituent of mutagen detoxifying enzymes, or because it acts directly on the microsomal monooxygenases forming the ultimate carcinogen (Leonard and Gerber 1989). Zinc significantly reduced a genotoxic effect of lead in rat bone marrow cells (500 mg Pb/L drinking water followed by 240 mg Zn/L for 2 weeks), and also protected against lead accumulations in erythrocytes and Pb-induced inhibition of delta-amino

levulinic acid dehydratase (Kowalska-Wochna et al. 1988). Zinc deficiency can lead to chromosomal aberrations, but excess zinc was not mutagenic in the majority of tests for DNA damage — except for zinc-containing fungicides wherein the organic dithiocarbamate constituents were the mutagenic agents, and for zinc chromate wherein the chromate ion was the active agent (Leonard and Gerber 1989). Frequencies of sister chromatid exchanges (SCE) in calves with hereditary zinc deficiency, also known as lethal trait A46, are lower than in healthy normal cows, suggesting a fundamental association between disturbed zinc metabolism and the low incidence of SCE in A46 cattle (Bosma et al. 1988).

9.4.4 Teratogenicity

Excess zinc is teratogenic to frog and fish embryos, possibly by inhibition of DNA synthesis (Dawson et al. 1988; Fort et al. 1989). Zinc at 150 mg/kg in rat diets was associated with inhibited fetal implantation, but this needs confirmation (Elinder 1986). No conclusive evidence now exists demonstrating that excessive zinc produces any teratogenic effect in mammals (NAS 1979; Dawson et al. 1988; Leonard and Gerber 1989). Excess zinc may protect against some teratogens, such as calcium EDTA (Leonard and Gerber 1989). Also, teratogenic effects of cadmium salts in golden hamsters was reduced by simultaneous administration of zinc salts (NAS 1979).

Zinc deficiency is clearly teratogenic in mammals (Dawson et al. 1988; Leonard and Gerber 1989). Severe maternal zinc deficiency is known to be teratogenic in rats. Fetal malformations — especially calcification defects — due to maternal zinc deficiency affect almost every tissue (Ferreira et al. 1989). Skeletal malformations are most common, possibly due to a reduction in cellular proliferation and in activity of bone alkaline phosphatase (Leonard and Gerber 1989). Human zinc deficiency may act teratogenically, either directly or indirectly via other toxic agents (Jameson 1980). Zinc deficiency may exacerbate effects of several teratogenic agents, such as thalidomide; there is also the possibility that zinc deficiency may increase the incidence of spina bifida and anencephaly, but this needs verification (Leonard and Gerber 1989). Diabetes during pregnancy can amplify the effects of a mild maternal zinc deficiency. In one study, diabetic and nondiabetic rat strains were fed a low-zinc diet (4.5 mg Zn/kg diet), an adequate-zinc diet (24.5 mg/kg) or a high-zinc diet (500 mg/kg) throughout gestation. Fetuses from diabetic dams were smaller, weighed less, and had less calcified skeletons and more malformations than did fetuses from control dams. In controls, maternal dietary zinc had a minor effect on fetal malformation frequency. In diabetic strains, however, the low-zinc diet had a strong teratogenic effect (Uriu-Hare et al. 1989).

9.5 CONCENTRATIONS IN FIELD COLLECTIONS

9.5.1 General

Total zinc concentrations in nonbiological samples seldom exceed 40 µg/L in water, 200 mg/kg in soils and sediments, or 0.5 µg/m³ in air. Environments heavily contaminated by anthropogenic activities may contain up to 99 mg Zn/L in water, 118 g/kg in sediments, 5 g/kg in soil, and 0.84 µg/m³ in the atmosphere. Zinc measurements in field collections of plants and animals (Table 9.4) show several trends: (1) zinc is present in all tissues of all organisms measured; (2) concentrations are elevated in organisms near anthropogenic point sources of zinc contamination; (3) concentrations are normally grossly elevated (>4 g/kg FW soft parts) in some species of bivalve molluscs and barnacles; (4) zinc-specific sites of accumulation include the frond in algae; kidney in molluscs; hepatopancreas in crustaceans; jaws in polychaete annelids; viscera, gonad, and brain in fishes; liver, kidney, and bone in birds; and serum, pancreas, feces, liver, kidney, and bone in mammals; (5) interspecies variations in zinc content are considerable, even among species closely related taxonomically; (6) intraspecies differences in zinc content vary with age, size, sex,

season, and other modifiers; and (7) many species regulate zinc within a threshold range of concentrations. Additional information on background concentrations of zinc is given in Vallee (1959), NAS (1979), Young et al. (1980), and Eisler (1980, 1981, 1993).

9.5.2 Nonbiological

Zinc concentrations in freshwater, seawater, groundwater, sewage sludge, sediments, and soils are listed in [Table 9.3](#). These data are considered reliable, although clean-laboratory techniques suggest that dissolved Zn concentrations in nonpolluted rivers may be 10 to 100 times lower than previously reported (Shiller and Boyle 1985).

Zinc concentrations in water seldom exceed 40 µg/L except near mining, electroplating, and similar activities, where concentrations between 260 and 954 µg/L have frequently been recorded. Drinking water usually contains <10 µg Zn/L, although concentrations >2 mg/L may occur after passage through galvanized pipes (Goyer 1986). Zinc-contaminated streams within the Platt River Basin sometimes contain up to 99 mg Zn/L, and in Arkansas up to 79 mg/L (Mirenda 1986). Zinc concentrations in water downstream of placer mining activities in Alaska sometimes exceed the concentrations found to be toxic to Arctic grayling, *Thymallus arcticus* (Buhl and Hamilton 1990). The disappearance of stone loach (*Noemacheilus barbatulus*) in the U.K. from streams receiving industrial wastes was attributed directly to zinc concentrations in the stream rising from 1 mg/L to a lethal 5 mg/L (Solbe and Flook 1975).

Concentrations of zinc in sediments and soils usually do not exceed 200 mg/kg, but can range between 3 and 118 g/kg as a result of human activities ([Table 9.3](#)). Atmospheric zinc levels were almost always <1 µg/m³, although they tended to be higher over industrialized areas (Goyer 1986). Average zinc concentrations, in µg/m³ atmosphere, were <0.001 at the South Pole, 0.01 to 0.02 in rural areas of the United States, <0.01 to 0.84 in U.S. cities, and 0.06 to 0.35 at various locations in the United Kingdom (Elinder 1986).

Table 9.3 Zinc Concentrations in Representative Nonbiological Materials (Concentrations are in mg Zn/kg fresh weight [FW], or dry weight [DW].)

Material	Concentration ^a (mg/kg or mg/L)	Reference ^b
EARTH'S CRUST	40 DW	11
FRESHWATER		
Canada		
Normal	<0.04 FW	1
Acidic mine tailings wastes, Sudbury, Ontario	0.9 FW, Max. 3.3 FW	2
United States		
Alaska		
Contaminated streams	0.029–0.882 FW	3
Downstream of placer mining activities	0.125 (0.075–0.165) FW	3
Nationwide	0.0005–0.010 FW	4
Worldwide, rivers	0.021 FW	2, 5
Groundwater, near Lake Erie	Max. 0.954 FW	1
SEAWATER		
Australia (polluted)	0.134 FW	6

9.5.3 Terrestrial Plants and Invertebrates

Zinc concentrations in forest plants vary considerably. In oaks (*Quercus* spp.), for example, some species are accumulators, whereas others may be termed discriminators. For individual species, zinc concentrations tend to follow the pattern of roots > foliage > branch > trunk (Van Hook et al. 1980). Small lateral roots accumulate Zn to much greater levels than other vegetation components and are probably most sensitive to changes in zinc inputs. Half-time persistence of zinc in forest ecosystems varies from about 3 years in organic matter components to >200 years for large soil pools (Van Hook et al. 1980).

Terrestrial plants growing beneath corroded galvanized fencing have been poisoned by zinc (Jones and Burgess 1984). Vegetables are relatively low in zinc, but growing plants can accumulate zinc applied to soils (Goyer 1986). High soil level of zinc is the primary cause of vegetation damage near zinc smelters (Buchauer 1971; Leonard and Gerber 1989). Elevated zinc concentrations in soils near zinc smelters inhibit seedling root elongation and probably prevent establishment of invader species in denuded areas (Buchauer 1971). Lichen species richness and abundance were reduced by about 90% in lichen communities near a Pennsylvania zinc smelter; elevated zinc concentrations were the probable cause of the impoverished lichen flora (Nash 1975). Soils and vegetation surrounding zinc smelters in Palmerton, Pennsylvania, were grossly contaminated with zinc, cadmium, and lead. Zinc was primarily responsible for the destruction of trees and subsequent erosion of the soil, reductions in moss and lichen flora, reductions in litter arthropod populations, and reductions in species diversity of soil fungi and bacteria; zinc residues were elevated in slugs and millipedes (Sileo and Beyer 1985; Beyer 1988). Soil litter invertebrates were rare or absent 2 km downwind of the smelter. Invertebrates collected up to 10 km upwind of the smelters had significantly elevated zinc concentrations when compared to soil litter invertebrates from more distant sites (Beyer et al. 1985).

The maximum zinc concentration in earthworms collected from a contaminated site was 1600 mg/kg DW whole animal; for uncontaminated sites it was 650 mg/kg (Beyer and Cromartie 1987). Whole-body zinc concentrations in earthworms (*Dendrodrilus rubidus*, *Lumbricus rubellus*) tended to reflect zinc concentrations in soil, although zinc accumulations in both species seem to be physiologically regulated when soil zinc values exceeded 1000 mg/kg DW (Morgan and Morgan 1988).

Whole-body zinc content of terrestrial isopods seems to reflect soil zinc levels and may be a useful indicator of soil contamination (Hopkin et al. 1989). *Porcellio scaber*, a terrestrial isopod known as a woodlouse, is recommended as a biological indicator of zinc contamination because of the positive correlation between zinc content in soil or leaf litter and woodlouse hepatopancreas. Zinc content in *Porcellio*, litter, and soil near a zinc smelter, in mg/kg DW, was >1000 in whole isopod, >9000 in hepatopancreas, >10,000 in litter, and >50,000 in soil (Hopkin et al. 1986).

Interspecies variability in zinc content of terrestrial invertebrates is large and governed by numerous modifiers. For example, whole-body zinc content in closely related species of terrestrial gastropods collected from a single contaminated site ranged between 600 and 1200 mg/kg DW (Greville and Morgan 1989). Zinc was highest in grey field slugs (*Deroferas reticulatum*) in late spring, lowest in summer, and positively correlated with tissue cadmium concentrations. Starvation for 16 days had no effect on body zinc concentrations (Greville and Morgan 1989a). Zinc tends to concentrate in mechanical structures of various invertebrates, such as mandibular teeth. High concentrations of zinc are reported in jaws of polychaete worms, the cutting edge of the mandibles of herbivorous insects, mandibles of various species of beetles, copepod mandibles, chaetognath teeth and spines, mandibular teeth of ants, and fangs of spiders (Schofield and Lefevre 1989). Honeybees (*Apis mellifera*) collected near a lead smelting complex at East Helena, Montana, had depressed whole-body zinc concentrations despite increased ambient air Zn values. However, whole-body burdens of arsenic, cadmium, copper, and lead were significantly elevated, and this may have influenced zinc kinetics (Bromenshenk et al. 1988). Also, pollen was usually the most indicative source of zinc and other heavy metals in bees (Veleminsky et al. 1990).

9.5.4 Aquatic Organisms

Concentrations of zinc in tissues of aquatic organisms are usually far in excess of that required for normal metabolism. Much of the excess zinc is bound to macromolecules or present as insoluble metal inclusions in tissues (Eisler 1981, 1984, 1993; USEPA 1987). Diet is the most significant source of zinc for aquatic organisms and is substantially more important than uptake from seawater (Eisler 1981, 1984). In general, zinc concentrations in sediments and tissues of aquatic organisms are elevated in the vicinity of smelters and other point sources of zinc, and decrease with increasing distance (Ward et al. 1986; [Table 9.4](#)).

Freshwater algae in Canadian mine tailing environments heavily concentrate zinc and other metals and may retard metal dispersion through the water column (Mann and Fyfe 1988). Zinc levels in field collections of marine algae and macrophytes are usually at least several orders of magnitude higher than zinc concentrations in the surrounding seawater (Eisler 1981). In general, concentrations in marine aquatic flora were high when seawater zinc concentrations were elevated, although the relationship was not linear. Marine flora, especially red and brown algae, are among the most effective marine zinc accumulators. Increasing accumulations of Zn in marine algae were associated with decreasing light intensity, decreasing pH, increasing temperature, decreasing levels of DDT, and increasing oxygen. Ionic zinc was accumulated more rapidly than other forms (Eisler 1981). Many species of marine algae had zinc concentrations >1 g/kg DW (Eisler 1980). These grossly elevated levels were usually associated with nearby industrial or domestic outfalls containing substantial amounts of zinc (Eisler 1981). In eelgrass, *Zostera marina*, zinc concentrations increased with age of the leaf (Brix and Lyngby 1982).

In the Fal estuary, England, long-term metal pollution over the past 120 years has resulted in zinc sediment levels between 679 and 1780 mg/kg DW, producing benthic communities that favor zinc-tolerant organisms, such as oysters and nereid polychaetes, and a general impoverishment of mussels, cockles, other polychaetes, and gastropods (Bryan et al. 1987).

Zinc in molluscs is usually associated with high-molecular-weight proteins, with diet (as opposed to ambient water zinc concentrations), with elevated sediment zinc burdens, and with particulate matter resulting from dredging and storm perturbations (Eisler 1981). Zinc levels in molluscs were highest in animals collected near anthropogenic point sources of zinc. Excess zinc accumulations do not seem to affect normal molluscan life processes, and zinc is frequently accumulated far in excess of the organism's immediate needs (Eisler 1981). American oysters (*Crassostrea virginica*), for example, may naturally contain up to 4 g Zn/kg FW soft parts. This is comparable to accumulations observed in oysters exposed to 0.2 mg Zn/L for 20 weeks (NAS 1979). In general, zinc concentrations in American oysters were highest in summer and lowest in winter and spring (Jiann and Presley 1997). Zinc tends to accumulate in molluscan digestive gland and stomach as excretory granules, and in kidney as concretions (Eisler 1981; Sprague 1986; Sullivan et al. 1988). Kidney is the preferred storage site in mussels and scallops, and digestive gland in oysters (Sprague 1986). In oysters, granules may contain up to 60% of the total body zinc, explaining, in part, how some shellfish can exist with such high body burdens (Sprague 1986).

Zinc in molluscan tissues is usually elevated under conditions of increasing water temperature and pH, and decreasing salinity (Eisler 1981); however, zinc accumulation kinetics in molluscs vary considerably among species (Chu et al. 1990). Variations in zinc content of clam tissues were associated with seasonal changes in tissue weights (Cain and Luoma 1986). Gastropods nearest a ferro-nickel smelter had elevated zinc concentrations in hepatopancreas when compared to those collected at more distant sites; however, there were no consistent seasonal variations (Nicolaidu and Nott 1990). Fluctuations in zinc content of mussels (*Mytilus edulis*) related to size or season of collection were sufficient to conceal low chronic or short-term pollution (Amiard et al. 1986). Diet (the primary route of zinc accumulation in most molluscs) had no significant effect on whole-body zinc content of certain predatory marine gastropods. Whole-body zinc concentration of gastropod oyster drills (*Ocenebra erinacea*) ranged between 1451 and 2169 mg/kg DW, and remained

unchanged after feeding for 6 weeks on Pacific oysters (*Crassostrea gigas*) containing 1577 mg Zn/kg DW or mussels (*Mytilus edulis*) containing 63 mg Zn/kg DW (Amiard-Triquet et al. 1988).

High zinc concentrations in crustaceans are usually associated with industrial contamination. In the case of barnacles (*Balanus* spp.), high (>3.3 g/kg DW soft parts) levels are attributed to inorganic granules that contain up to 38% zinc and which accumulate in tissue surrounding the midgut (Eisler 1980, 1981). The granules consist of phosphorus, zinc, potassium, sulfur, and chlorine, in that order (Thomas and Ritz 1986). These insoluble, membrane-limited, spheres form in response to high zinc levels in the ambient seawater within 12 days of exposure, and concentrate in specialized cells around the gut: the stratum peritestinale (Walker et al. 1975; Sprague 1986; Thomas and Ritz 1986). Zinc granules in barnacles represent a detoxification mechanism for surplus zinc (Thomas and Ritz 1986). Older barnacles have greater whole-body zinc accumulations than younger stages, and accumulations change seasonally (Anil and Wagh 1988). Zinc concentrations in marine crustacean tissues are usually <75 mg/kg FW or <100 mg/kg DW; exceptions include hepatopancreas, molts, eggs, fecal pellets, and barnacles (Table 9.4). In crustaceans, zinc is slightly elevated in hepatopancreas, but most tissues are only 2 to 3 times higher than muscle (Sprague 1986). For marine crustaceans, the highest concentration recorded in muscle was 57 mg Zn/kg FW in king crab, *Paralithodes camtschaticus* (NAS 1979), and was associated with two metal-binding proteins of molecular weight 11,500 and 27,000 (Eisler 1981). In crustacean tissues, zinc levels were higher in summer, at lower salinities, and in young animals (Eisler 1981), although young amphipods had higher zinc residues than older stages (Rainbow 1989). Seasonal accumulations of whole-body zinc in the shrimp (*Palaemon serratus*) during spring and summer and loss in winter seem to reflect water zinc concentrations in the range 0.0 to 9.0 µg/L (Alliot and Frenet-Piron 1990). Zinc is present in crustacean serum at concentrations >1000 times higher than ambient seawater; in serum, it serves primarily as a cofactor of carbonic anhydrase — the principal enzyme involved in calcification. Serum zinc concentrations in crustaceans seem to be independent of season, water temperature, or salinity (Sprague 1986).

Molting results in a 33 to 50% loss of total zinc in marine crustaceans; molts, together with fecal pellets, constitute an important vehicle of zinc transfer in marine ecosystems (Eisler 1981). The freshwater opossum shrimp (*Mysis relicta*) can transport zinc from sediments into the water column, and the reverse, during their migratory cycle. *Mysis relicta* and other benthic invertebrates play an important role in determining the concentration of zinc and other metals in lake sediments (Van Duyn-Henderson and Lasenby 1986). Unlike decapod crustaceans, marine amphipods do not regulate body zinc concentrations; amphipod body burdens of zinc may reflect sediment total zinc levels and suggest that certain groups may be suitable bioindicators (Rainbow et al. 1989). Molting had no effect on body zinc concentration in four species of adult marine amphipods (Weeks and Moore 1991), and this forces a reexamination of the role of cast exuviae in zinc transport.

In annelids, zinc content was highest in nonselective deposit feeders, omnivores, and carnivores, and from animals collected from sediments with elevated zinc levels (Eisler 1981). Freshwater tubificid worms have the potential to increase zinc concentrations in the water column, particularly during short episodes of high burrowing activity (Krantzberg and Stokes 1985). A high zinc content appears to be a structural characteristic of jaws of marine nereid worms (Table 9.4). In the marine polychaete worm *Nereis diversicolor*, zinc is localized in the gut wall, epidermis, nephridia, and blood vessels; most of the body zinc is present in wandering amoebocytic cells of excretory organs. Zinc in *Nereis* may be present as insoluble granules in membrane-bound vesicles. Excretion is via exocytosis with the aid of amoebocytes (Fernandez and Jones 1989). Unlike the insoluble zinc phosphate granules of molluscs and crustaceans, zinc granules in *Nereis* were very soluble and retained only by sulfide precipitation (Pirie et al. 1985).

Marine vertebrates, including fishes and elasmobranchs, have low zinc concentrations in tissues (i.e., 6 to 400 mg/kg DW) when compared to marine plants and invertebrates (Eisler 1980, 1981, 1984). Highest concentrations in muscle of marine fishes (20.1 to 25.0 mg/kg FW) were recorded in northern anchovy (*Engraulis mordax*) and Atlantic menhaden (*Brevoortia tyrannus*; NAS 1979).

The highest zinc concentrations measured in whole freshwater fishes in the conterminous United States in 1978/79 were in common carp (*Cyprinus carpio*) from Utah; concentrations in carp from Utah ranged between 70 and 168 mg Zn/kg FW vs. an average of 63 mg Zn/kg FW for this species collected elsewhere (Lowe et al. 1985). Zinc concentrations in fishes tend to be higher near urban areas (Peterson et al. 1989); highest in eggs, viscera, and liver (Eisler and LaRoche 1972; Eisler 1981); lowest in muscle (Eisler 1981); positively correlated with metallothionein concentrations (Overnell et al. 1987); lower in all tissues with increasing age and growth (Eisler and LaRoche 1972; Eisler 1981, 1984; Grady et al. 1989); and relatively unaffected by water salinity, temperature, or copper concentrations (Eisler and LaRoche 1972; Eisler 1981). Zinc residue data from marine fishes that were dead on collection are of limited worth because dead fish accumulate zinc from seawater at a substantially higher rate than living teleosts (Eisler 1981).

Zinc concentrations in fishes and other aquatic vertebrates are modified by diet, age of the organism, reproductive state, and other variables. In fish, diet is the major route of zinc uptake and juveniles accumulate zinc from the medium more rapidly than embryos or larvae (Cutshall et al. 1977; Eisler 1981). Because the diet of many teleost carnivores changes dramatically with age, and because upper trophic level vertebrates are frequently used as indicators of water quality, it seems that more research is needed on zinc burdens in prey organisms (Eisler 1984). A reduction in serum zinc during egg formation in a flatfish (*Pleuronectes platessa*) may represent a transfer of zinc to eggs (Overnell et al. 1987). High (>35 mg/kg FW) zinc concentrations in eggs of Atlantic salmon (*Salmo salar*) are sometimes associated with increasing mortality, although low (14 mg/kg FW) concentrations seem to have no adverse effect on survival (Craik and Harvey 1988). Zinc concentrations in Atlantic salmon milt ranged from 0.5 to 5.5 mg Zn/kg and was linearly proportional to spermatozoan abundance (Poston and Ketola 1989). In lakes containing 1150 mg Zn/kg sediment and 209 to 253 µg Zn/L water column, white sucker (*Catostomus commersoni*) females did not grow after sexual maturity and had increased incidences of spawning failure. Alterations in growth and reproduction were related, in part, to nutritional deficiencies as a result of chronic effects of elevated sediment zinc on the food base of the sucker. That is, invertebrate fauna were absent in the uppermost 7 m (Munkittrick and Dixon 1988). Eggs of the white sucker incubated at a metals-contaminated site (400 µg Zn/L) produced larvae with a decreased tolerance to copper and with elevated zinc body burdens when compared to a noncontaminated (2.7 µg Zn/L) site; larval size and fertilization rate were the same at both sites (Munkittrick and Dixon 1989).

9.5.5 Birds

Zinc residues were elevated in birds collected near zinc smelters (Beyer 1988). In general, the highest concentrations of zinc in birds are in liver and kidney, and the lowest in muscle (Eisler 1981, 1984). In the giant Canada goose (*Branta canadensis maxima*), red muscle contains more zinc than does white muscle, and slow contracting muscle more than fast muscle (Rosser and George 1986). In nestling kittiwakes (*Rissa tridactyla*), zinc concentrations increased in liver and feathers throughout chick growth (Wenzel et al. 1996). Zinc concentrations in marine birds normally range between 12 mg/kg FW in eggs and 88 mg/kg FW in liver. The highest concentration of zinc recorded in a marine bird was 541 mg/kg DW in the liver of a booby (*Sula* sp.) that died from polychlorinated biphenyl poisoning. Elevated zinc levels in these birds may have been a manifestation of toxicant-induced stress (i.e., breakdown in osmoregulatory processes), as is the case for other taxonomic groups (Eisler 1981). Seabirds with high zinc concentrations in liver and kidney tend to have high cadmium levels in these tissues (Muirhead and Furness 1988). In flamingos, zinc in liver was positively correlated with copper levels in liver and kidney, and with metallothionein levels in kidney (Cosson 1989). In egrets, zinc was positively correlated with metallothionein protein levels in liver (Cosson 1989). In blue-winged teal (*Anas discors*), zinc concentrations were higher in liver than muscle, higher in males than females, and higher in autumn than in the spring (Warren et al. 1990). Zinc concentrations in liver of black-crowned night heron (*Nycticorax nycticorax*)

were usually higher in younger birds, although weight and sex had no direct effect on zinc content (Custer and Mulhern 1983). Zinc concentrations in tissues and feathers of California condors (*Gymnogyps californianus*) found dead from a variety of causes (Table 9.4) were similar to those found in turkey vultures (*Cathartes aura*), common ravens (*Corvus corax*), and ospreys (*Pandion haliaetus*) and are considered normal (Wiemeyer et al. 1988). The highest concentration recorded in condor liver (250 mg/kg FW) approaches those in livers of mallards (*Anas platyrhynchos*) that died from high dietary loadings of zinc (Wiemeyer et al. 1988). Zinc concentrations in liver of osprey were similar between age groups and sexes (Wiemeyer et al. 1987). With the onset of egg production in turkeys (*Meleagris gallopavo*), serum zinc in hens increased from 1.6 to 6.9 mg/L and remained significantly elevated throughout egg laying; during this same period, liver zinc concentration declined from 75 to 39 mg/kg DW, although total liver zinc increased because of an increase in liver weight (Richards 1989).

Zinc concentrations in the sediments of the Rhine River increased about sixfold between 1900 and 1950, and have remained stable since then. However, migratory waterfowl from this collection locale do not have elevated zinc concentrations in their primary feathers (Goede 1985). Zinc content in feathers of the hoopoe (*Upupa epops*) increased from 200 mg/kg DW at age 7 days to 1000 mg/kg DW at age 35 days (Kaur 1989). Hoopoe populations are declining in India, and this is said to be associated with increasing zinc concentrations in feathers (Kaur 1989). Feathers of the greater flamingo (*Phoenicopterus ruber*) have been proposed as indicators of atmospheric zinc contamination: outer barbs of the black primary feathers — exposed to air pollution — contained 53% more zinc, on average, than did inner barbs (Cosson et al. 1988). More research seems needed on the use of feathers as indicators of Zn contamination.

Zinc concentrations in seminal plasma of domestic chickens (*Gallus* sp.) are about 100 times lower than those for humans and most other mammals, except sheep. Concentrations of zinc in fowl seminal plasma after *in vitro* storage of spermatozoa for 24 h at 4°C were near the threshold values toxic to spermatozoa (Blesbois and Mauger 1989), suggesting that poultry spermatozoa normally function near their lower lethal zinc threshold.

9.5.6 Mammals

White-tailed deer (*Odocoileus virginianus*) collected near a zinc smelter had elevated tissue zinc concentrations when compared to those from more distant sites. Deer with zinc concentrations of 150 mg/kg FW (750 mg/kg DW) in the renal cortex of the kidney had swollen joints, lameness, and joint lesions similar to those seen in zinc-poisoned horses from the same area (Sileo and Beyer 1985). Zinc was elevated in kidney cortex of red deer (*Cervus elephas*), and older deer tended to have higher concentrations (up to 184 mg/kg DW) than did younger deer (as low as 20 mg/kg FW); in the case of older deer, zinc was associated with the metallothionein fraction (Holterman et al. 1984). Zinc residues were usually elevated in rodents near smelters (Beyer et al. 1985). Rodents from metals-contaminated forests had zinc loadings in tissues similar to those from control locations, although lead and cadmium were significantly elevated in the contaminated zone (Sawicka-Kapusta et al. 1987). Elevated zinc concentrations in mine tailings reportedly do not represent a notable contamination hazard to the invading mammalian fauna, although zinc concentrations in invertebrates (especially earthworms) and vegetation were elevated (Andrews et al. 1989; Table 9.4).

Otters (*Lutra lutra*) were found only on a single unpolluted tributary of a river system contaminated by zinc mine drainage waste, suggesting that a contaminated food supply may be responsible for avoiding otherwise suitable habitat (Mason and Macdonald 1988).

Marine mammals collected near heavily urbanized or industrialized areas or near zinc pollution point sources usually had elevated zinc concentrations when compared to individuals of the same species and of similar age from relatively pristine environments (Eisler 1984). Zinc concentrations in tissues of the ringed seal (*Phoca hispida*) were essentially the same in animals near a lead-zinc mine and in those of a distant reference site, although lead and selenium burdens were elevated in the vicinity

of the mine (Wagemann 1989). Concentrations of zinc in tissues of Steller sea lion (*Eumetopias jubata*) were highest in liver and pancreas, followed by kidney, muscle, heart, spleen, and lung; this rank order is comparable to that in human tissues (Hamanaka et al. 1982). There is considerable variation among species in tissue zinc concentrations; threefold differences are not uncommon for the same tissue in different species of marine mammals (Muir et al. 1988). In bottlenose dolphins (*Tursiops truncatus*), zinc concentrations were higher in juveniles than in adults (Beck et al. 1997). Marine mammals contained the lowest zinc concentrations (2 to 505 mg/kg DW, elevated in liver) of all groups of marine organisms examined. Because zinc is usually available in sufficient quantity in the marine environment and is usually accumulated in excess of the organism's immediate needs, it remains unclear why zinc is comparatively depressed in tissues of marine mammals (Eisler 1981).

Zinc toxicosis in horses near a zinc smelter was characterized by lameness, swollen joints, and unkempt appearance, particularly in foals. Zinc concentrations in afflicted foals were elevated in pancreas, liver, kidney, and serum when compared to foals at more distant sites (Gunson et al. 1982). Foals born near the smelter had joint swellings that were attributable to generalized osteochondrosis; lesions were similar to those induced experimentally in animals fed high-zinc diets, and may have been the result of a zinc-induced abnormal copper metabolism (Gunson et al. 1982). Concentrations of zinc in tissues of horses from farms near the Palmerton smelter were extremely high, in some cases approaching lethal thresholds; zinc poisoning was a cause of debility and death of foals (Sileo and Beyer 1985). Grazing mares managed with standard husbandry had significant monthly variations in plasma zinc due, in part, to dietary factors such as nutritional supplementation and to seasonal variations in the quality of grazing pasture (Auer et al. 1988). Peak plasma zinc levels in horses are positively related to age (in weanlings age 22 to 52 weeks) and to summer diets (Cymbaluk and Christison 1989).

Dairy cattle near a lead and zinc ore processing facility did not have elevated blood or hair zinc levels, although daily zinc intake was 5.6 mg/kg body weight vs. 1.2 mg/kg BW daily for a control area (Milhaud and Mehannaoui 1988). In cattle, proximity to zinc refineries did not result in significant elevation of liver or kidney zinc concentrations (Spierenburg et al. 1988). However, cows living within 6 km of a power plant in Czechoslovakia had elevated zinc loadings in hair and poor reproduction when compared to a herd 26 km distant (Pisa and Cibulka 1989). In adult bovines, zinc reserves are usually small and located primarily in the skeleton and muscle, although appreciable hepatic accumulations can occur in the fetus. At 270 days of gestation, for example, 30% of fetal zinc in cattle is present in liver; fetal zinc concentration is about 4 times higher than that in maternal liver (Gooneratne and Christensen 1989). Liver concentrations >120 mg Zn/kg DW in cattle are frequently associated with elevated dietary zinc loadings (Binnerts 1989). Concentrations of zinc in milk of cows and goats varied significantly between breeds, with zinc level in diet, and declined markedly after parturition (Park and Chukwu 1989).

A normal 70 kg human male contains 1.5 to 2.0 grams of zinc, or about 21 to 29 mg Zn/kg BW; normal zinc uptake is 12 to 15 mg daily, equivalent to 0.17 to 0.21 mg/kg BW (Prasad 1979). Foods rich in zinc are seafoods, meats, grains, dairy products, nuts, and legumes (Goyer 1986). About 90% of the total body zinc is in the musculoskeletal system (Rosser and George 1986). Highest zinc concentrations of 100 to 200 mg/kg occur in prostate, eye, brain, hair, bone, and reproductive organs; intermediate concentrations of 40 to 50 mg/kg occur in liver, kidney, and muscle (NAS 1979; Casey and Hambidge 1980). In blood, about 80% of the total zinc is in red cells, where it is associated with carbonic anhydrase. The mean plasma zinc level is about 0.9 mg/L; about half is in a freely exchangeable form loosely bound to albumin. Most of the remainder is tightly bound to macroglobulins and amino acids, especially histidine and cysteine (Casey and Hambidge 1980; Goyer 1986). The greatest zinc concentration in the human body is in the prostate and may be related to the elevated levels of acid phosphatase, a zinc-containing enzyme, in that organ (Goyer 1986). The prostate gland contributes zinc to spermatozoa in dogs — a necessary process for canine fertility and fecundity; in rats, however, the prostate does not contribute to zinc in spermatozoa, and its function is not essential for rat reproduction (Saito et al. 1967).

Table 9.4 Zinc Concentrations in Field Collections of Representative Plants and Animals (Concentrations are in mg Zn/kg fresh weight [FW], or dry weight [DW].)

Taxonomic Group, Organism, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
AQUATIC PLANTS		
<i>Euglena</i> sp.		
From acidic mine tailings waste discharges (0.9 mg Zn/L, Max. 3.3 mg/L)	143 DW; Max. 410 DW	1
Aquatic moss, <i>Fontinalis squamosa</i>		
Contaminated river, Wales, 1985	Max. 2810 DW	2
Uncontaminated site	<400 DW	2
Marine plants		
Phytoplankton	38 DW	3
Seaweeds	90 DW	3
Eelgrass, <i>Zostera marina</i>		
Leaf	Max. 195 DW	4
Rhizome	Max. 70 DW	4
Root	Max. 155 DW	4
Stem	Max. 85 DW	4
TERRESTRIAL PLANTS AND INVERTEBRATES		
Honey bee, <i>Apis mellifera</i> , Czechoslovakia, 1986–1987		
Drones	77–89 DW	5
Honey	0.6–4.5 DW	5
Pollen in combs	39–55 DW	5
Wax	11–249 DW	5
Workers, whole		
Foragers, spring	116–204 DW	5
Dead overwintering	8–13 DW	5
Young	83–160 DW	5
Grey field slug, <i>Deroceras reticulatum</i> , near lead-zinc mine		
Digestive gland	3968 DW	6
Foot/head	308 DW	6
Gonads	118 DW	6
Intestine	380 DW	6
Whole	800 DW	7
Earthworms, northeastern United States, whole		
From uncontaminated soils (23–200 mg Zn/kg DW), 6 species	120–650 DW	8
From mining sites (100–2500 mg Zn/kg DW), 5 species	200–950 DW	8
From industrial sites (24–320 mg Zn/kg DW soil), 6 species	320–1600 DW	8
Near galvanized towers (28–270 mg Zn/kg DW soil), 1 species	340–690 DW	8
Earthworms, whole, gut empty		
<i>Dendrodrilus rubidus</i>	(308–1683) DW	9
<i>Lumbricus rubellus</i>	(394–3873) DW	9
Gastropods, whole, near abandoned mine, soil contained 1377 mg Zn/kg DW		
<i>Arion ater</i>	900 DW	7
<i>Arion hortensis</i>	600 DW	7
<i>Arion subfuscus</i>	1200 DW	7
<i>Deroceras caruanae</i>	1000 DW	7
Lichen, <i>Lasallia papulosa</i>		
Near zinc smelter	2560 DW	10

12 km	154 DW	35
30 km	100 DW	35
150 km	111 DW	35

Table 9.4 (continued) Zinc Concentrations in Field Collections of Representative Plants and Animals
(Concentrations are in mg Zn/kg fresh weight [FW], or dry weight [DW].)

Taxonomic Group, Organism, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
Muscle		
12 km	93 DW	35
30 km	97 DW	35
150 km	80 DW	35
Grass shrimp, <i>Palaemonetes pugio</i>		
From sediments containing 627 mg Zn/kg DW		
Exoskeleton	58 FW	36
Muscle	55 FW	36
From sediments containing 8 mg Zn/kg DW		
Exoskeleton	18 FW	36
Muscle	30 FW	36
Prawn, <i>Pandalus montagui</i>		
Cuticle	57 DW	37
Eye	70 DW	37
Gill	106 DW	37
Hepatopancreas	30 DW	37
Muscle	57 DW	37
Whole	58 DW	37
Pink shrimp, <i>Penaeus brasiliensis</i> , adults, whole	(47–75) DW; (181–290) FW	38
INSECTS, MARINE, WHOLE	110–197 DW	13
CHAETOGNATHS, WHOLE	76–90 DW	13
ANNELIDS, AQUATIC		
Annelids, marine		
Jaws		
Total	5000–24,000 DW	13
Basal section	1790 DW	13
Distal section	34,950 DW	13
Whole body	22–1564 DW	13
Lugworm, <i>Arenicola marina</i> , whole	1.8 FW	14
Freshwater leech, <i>Erpobdella octoculata</i> , adults, whole body	Upstream (18 µg Zn/L) from zinc-polluted mine waste discharge, whole body content of 1439–1559 DW; reproduction normal. Downstream (180 µg Zn/L), concentration after 19-month exposure was 1932–2432 DW; reproduction impaired	116
Sandworm, <i>Nereis diversicolor</i>		
Head	(843–995) DW	39
Parapodia	(216–413) DW	39
Trunk	(158–218) DW	39
ECHINODERMS		
Various species, whole	Usually 100 DW or lower, frequently >100 DW; Max. 245 FW, 1500 DW	3, 13
TUNICATES, WHOLE	200 DW; Max. 64 FW, 370 DW	3, 13
FISH		
Catostomids, 3 species, Missouri, blood		
Site contaminated with mine tailings	10.9–13.4 FW, 94–119 DW	40
Uncontaminated site	8.7–11.2 FW, 76–86 DW	40

Table 9.4 (continued) Zinc Concentrations in Field Collections of Representative Plants and Animals
(Concentrations are in mg Zn/kg fresh weight [FW], or dry weight [DW].)

Taxonomic Group, Organism, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
White sucker, <i>Catostomus commersoni</i>		
From metals-contaminated lake (400 µg Zn/L)		
Eggs	83–158 DW	41
Larvae	511 DW	41
Ovaries		
Prespawning	114 DW	41
Postspawning	290 DW	41
Testes, postspawning	89 DW	41
From control lake (2.7 µg Zn/L)		
Eggs	69–108 DW	41
Larvae	163 DW	41
Ovaries		
Prespawning	84 DW	41
Postspawning	317 DW	41
Testes, postspawning	163 DW	41
New Brunswick, whole	92–93 DW	42
Nova Scotia, whole	98–122 DW	42
African sharptooth catfish, <i>Clarias gariepinus</i> , age 4–8 years, South Africa, 1988–1989, lake sediments contained 1104 mg Zn/kg DW (595–2189)		
Brain	335 DW	43
Fat	50 DW	43
Gill	177 DW	43
Gonad	126 DW	43
Heart	196 DW	43
Intestine	143 DW	43
Kidney	143 DW	43
Liver	143 DW	43
Muscle	59 DW	43
Spleen	163 DW	43
Vertebrae	75 DW	43
Baltic herring, <i>Clupea harengus</i> , liver	23 FW	14
Freshwater fishes, various species		
Great Lakes		
Whole, less intestines, 4 species	12–20 FW	19
Liver, 10 species	11–48 FW	19
Greece, 1987–1988, muscle, 11 species	7 (3–37) FW	44
United States, nationwide, whole		
1978–1979	25 (8–168) FW	45
1980–1981	24 (9–109) FW	45
1984		
Geometric mean	21.7 FW	121
85th percentile	34.2 FW	121
Maximum	118.4 FW	121
From metals-contaminated (636 µg dissolved Zn/L) Lake, Indiana, whole		
Bowfin, <i>Amia calva</i>	93 DW	46
White sucker, <i>Catostomus commersoni</i>	102 DW; Max. 152 DW	46
Brown bullhead, <i>Ictalurus nebulosus</i>	127 DW; Max. 139 DW	46
Warmouth, <i>Lepomis gulosus</i>	140 DW; Max. 166 DW	46
Orangespot sunfish, <i>Lepomis humilis</i>	248 DW	46
Redear sunfish, <i>Lepomis microlophus</i>	477 DW; Max. 820 DW	46
Largemouth bass, <i>Micropterus salmoides</i>	119 DW; Max. 207 DW	46
Golden shiner, <i>Notemigonus crysoleucas</i>	160 DW; Max. 171 DW	46
Yellow perch, <i>Perca flavescens</i>	160 DW; Max. 171 DW	46
Black crappie, <i>Pomoxis nigromaculatus</i>	123 DW	46

Table 9.4 (continued) Zinc Concentrations in Field Collections of Representative Plants and Animals
 (Concentrations are in mg Zn/kg fresh weight [FW], or dry weight [DW].)

Taxonomic Group, Organism, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
From metals-contaminated stream, Missouri, muscle, 5 species	3.1–24 FW	47, 115
Shortfin mako, <i>Isurus oxyrinchus</i> , vertebrae	36 (5–127) DW	48
Marine fishes, various species		
Muscle		
54 species	0–5 FW	19
32 species	5.1–10 FW	19
7 species	10.1–15 FW	19
4 species	15.1–20 FW	19
2 species	20.1–25 FW	19
Whole	80 DW	3
Red Sea, 1980–1982		
Triggerfish, <i>Balistoides viridiscens</i>		
Muscle	66 DW	49
Liver	154 (81–227) DW	49
Ovaries	291 (287–792) DW	49
Surgeonfish, <i>Ctenochaetus strigosus</i> , muscle	29 (11–43) DW	49
Halfbeak, <i>Hemiramphus marginatus</i> , muscle	32 DW	49
Labrids, 3 species, muscle	33 (19–51) DW	49
Lethrinids, <i>Lethrinus</i> spp.		
Muscle	33 (13–112) DW	49
Liver	95 (43–146) DW	49
Ovaries	146 (72–259) DW	49
Testes	152 (141–164) DW	49
Snapper, <i>Lutjanus fulviflamma</i> , muscle	48 (25–70) DW	49
Parrotfish, <i>Scarys gyttatus</i>		
Liver	17 DW	49
Muscle	62 DW	49
Serranids, 4 species		
Muscle	51 (8–112) DW	49
Liver	130 (78–183) DW	49
Rabbitfish, <i>Siganus oramin</i>		
Muscle	55 (18–195) DW	49
Liver	179 (68–611) DW	49
Sparids, 2 species, muscle	56 (34–76) DW	49
Goatfish, <i>Upeneus tragula</i> , muscle	51 (37–68) DW	49
Pacific hake, <i>Merluccius productus</i>		
Muscle	4 (3–6) FW	33
Whole	12 FW	33
Catfish, <i>Mystus gulio</i> , juveniles, whole, India		
From contaminated estuary (100–120 µg Zn/L, 120–145 mg Zn/kg sediment DW)	160–180 DW	50
From uncontaminated estuary (10 µg Zn/L, 30 mg Zn/kg sediment)	15 DW	50
Yellow perch, <i>Perca flavescens</i> , whole		
New Brunswick	81–103 DW	42
Nova Scotia	68–85 DW	42
Blue shark, <i>Prionace glauca</i> , vertebrae	95 (32–210) DW	48
Atlantic salmon, <i>Salmo salar</i>		
Eggs		
Hatchery	20–35 FW	51
Native	19–28 FW	51
Liver, juveniles		
Hatchery	29–41 FW	51
Native	34 FW	51
Muscle	13 DW	52

Table 9.4 (continued) Zinc Concentrations in Field Collections of Representative Plants and Animals
 (Concentrations are in mg Zn/kg fresh weight [FW], or dry weight [DW].)

Taxonomic Group, Organism, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
Ovaries	166 DW	52
Spines	79–219 DW	52
Stomach contents	78 DW	52
Brook trout, <i>Salvelinus fontinalis</i> , whole		
New Brunswick	87–158 DW	42
Nova Scotia	90–110 DW	42
Atlantic mackerel, <i>Scomber scombrus</i> , liver	31 FW	14
King mackerel, <i>Scomberomorus cavalla</i> , otolith		
Age <1 year	16 DW; Max. 50 DW	53
Age 2 years	11 DW	53
Age 10 years	8 DW	53
Lesser spotted dogfish, <i>Scyliorhinus caniculus</i> , liver	8.7 FW	14
Monkfish, <i>Squatina squatina</i> , liver	8 FW	14
REPTILES		
American alligator, <i>Alligator mississippiensis</i> , eggs (less shell), Florida, 1984	4.9–9.2 FW	54
Leatherback turtle, <i>Dermochelys coriacea</i> ; Mexico; 1992–93; eggshells from eggs incubated in sand containing 58.9 mg Zn/kg DW	11.9 DW; Max. 60.0 DW	124
BIRDS		
Blue-winged teal, <i>Anas discors</i> , Texas, 1983		
Muscle		
Males	13.8 FW	55
Females	11.3 FW	55
Liver		
Autumn	41.4 FW	55
Spring	33.7 FW	55
Mallard, <i>Anas platyrhynchos</i> , liver	54 FW	56
Canvasback, <i>Aythya valisineria</i> , Chesapeake Bay, liver	41 FW	56
Nicobar pigeon, <i>Caloenas nicobarica</i> , zinc-poisoned		
Kidney	2107 DW	57
Liver	3575 DW	57
Ovary	654 DW	57
Cory's shearwater, <i>Calonectris diomedea</i> ; Azores, Portugal; 1992–93; fledglings age 12 weeks		
Kidney	111 (40–194) DW	128
Liver	199 (39–389) DW	128
Turkey vulture, <i>Cathartes aura</i> , California, 1980–81		
Liver	21–44 FW	58
Kidney	16–24 FW	58
Feather	81–110 DW	58
Willet, <i>Catoptrophorus semipalmatus</i> ; 1994; San Diego Bay; sediments vs. stomach contents		
Naval Air Station	22 DW vs. 79 DW	134
Tijuana Slough National Wildlife Refuge	57 DW vs. 170 DW	134
Common raven, <i>Corvus corax</i> , California, 1980–1981		
Liver	14–45 FW	58
Kidney	17–33 FW	58
Feather	110–160 DW	58

Table 9.4 (continued) Zinc Concentrations in Field Collections of Representative Plants and Animals
 (Concentrations are in mg Zn/kg fresh weight [FW], or dry weight [DW].)

Taxonomic Group, Organism, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
Trumpeter swan, <i>Cygnus buccinator</i> , USA, 7 western states, 1976–87, found dead		
Liver, kidney, femur	96 (61–160) FW	118
Blood	5.2 (3.7–8.8) FW	118
Dutch Wadden Sea		
Knots, 3 species, recently-formed primary feathers		
Juveniles	100–400 DW	59
Adults	Max. 977 DW	59
Geese, 3 species, feather vane	93–164 DW; Max. 330 DW	59
Little egret, <i>Egretta garzetta</i> , France, found dead		
Bone	100 DW	60
Feather	80 DW	60
Gizzard	140 DW	60
Kidney	70 DW	60
Liver	120 DW	60
Lung	50 DW	60
Muscle	70 DW	60
Stomach	65 DW	60
Chicken, <i>Gallus</i> sp.		
Egg yolk	64 DW	61
Kidney	70 DW	61
Liver	69 DW	61
Liver	32 (25–56) FW	62
Pancreas	88 DW	61
Seminal plasma		
Age 30 weeks	9.8 FW	63
Age 60 weeks	9.8–25 FW	63
California condor, <i>Gymnogyps californianus</i> ,		
Dead on collection, 1980–1986		
Nestlings (death from handling shock)		
Liver	22 FW	64
Kidney	17 FW	64
Juveniles (died of cyanide poisoning)		
Liver	33 FW	64
Feather	99–100 DW	64
Subadults (death from lead poisoning)		
Liver	30 FW	64
Kidney	33 FW	64
Feather	85 DW	64
Adults (death from lead poisoning)		
Liver	27–250 FW	64
California, 1980–81, feather	(46–130) DW	58
Kern County, California, 1976		
Liver	49 FW	65
Kidney	16 FW	65
White-tailed eagle, <i>Haliaeetus albicilla</i>		
Blood, clotted	7.5 FW	66
Brain	20 FW	66
Feather	88 DW	66
Femur	284 (175–390) DW	66
Heart	28 (21–39) FW	66
Intestine	50 (27–76) FW	66
Kidney	43 (35–60) FW	66
Liver	68 (38–100) FW	66
Lung	14 (11–17) FW	66

Table 9.4 (continued) Zinc Concentrations in Field Collections of Representative Plants and Animals
 (Concentrations are in mg Zn/kg fresh weight [FW], or dry weight [DW].)

Taxonomic Group, Organism, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
Muscle	55 (42–80) FW	66
Stomach	25 (20–30) FW	66
Bald eagle, <i>Haliaeetus leucocephalus</i> , egg, 1968		
Wisconsin	30–56 DW; 4–8 FW	67
Maine	32–52 DW; 4–7 FW	67
Florida	36–65 DW; 5–8 FW	67
Glaucous gull, <i>Larus hyperboreus</i>		
Liver	32 (26–47) FW	68
Kidney	46 (37–57) FW	68
Turkey, <i>Meleagris gallopavo</i>		
Laying hens		
Serum	6.9 FW	117
Liver	75 DW	117
Nonlaying hens		
Serum	1.6 FW	117
Liver	39 DW	117
Red-breasted merganser, <i>Mergus serrator</i> , egg, Lake Michigan, 1978	15 (12–20) FW	69
Norway; October–March 1992–95; passerines; liver; adults vs. juveniles		
Greenfinch, <i>Carduelis chloris</i>	67 DW vs. 56 DW	132
Great tit, <i>Parus major</i>	72 DW vs. 69 DW	132
Willow tit, <i>Parus montanus</i>	70 DW vs. 68 DW	132
Marsh tit, <i>Parus palustris</i>	74 DW vs. 68 DW	132
Bullfinch, <i>Pyrrhula</i>	79 DW vs. 66 DW	132
Norway; as above; industrial area vs. subalpine forest		
Tits	68.8 DW vs. 66.8 DW	132
Finches	77.2 DW vs. 65.1 DW	132
Black-crowned night-heron, <i>Nycticorax nycticorax</i> , liver, pre fledglings, 1979		
Massachusetts	602 (482–784) DW	70
North Carolina	649 (479–857) DW	70
Rhode Island	503 (246–885) DW	70
Osprey, <i>Pandion haliaetus</i>		
Eastern United States, 1975–1982, liver		
Iowa	98 FW	71
Maryland	19–34 FW	71
Massachusetts	89 FW	71
New Jersey	63–120 FW	71
North Carolina	69 FW	71
South Carolina	73 FW	71
Wisconsin	59 FW	71
Virginia	27–150 FW	71
Eastern United States, 1964–1973, liver		
Florida	(27–36) FW	56
Maryland	(18–93) FW	56
New Jersey	22 FW	56
Ohio	60–80 FW	56
All ospreys, liver		
Immature	67 FW	56
Adults	38 FW	56
Brown pelican, <i>Pelecanus occidentalis</i>		
Egg contents		
South Carolina, 1971–72	6.4 (5.5–8.0) FW	119
Florida, 1969–70	6.4 (4.3–8.3) FW	119

Table 9.4 (continued) Zinc Concentrations in Field Collections of Representative Plants and Animals
 (Concentrations are in mg Zn/kg fresh weight [FW], or dry weight [DW].)

Taxonomic Group, Organism, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
Liver		
Found dead		
South Carolina, 1973	26 FW	119
Florida, 1972–73	41–50 FW	119
Georgia, 1972	33 FW	119
Shot		
Florida, 1970	32–55 FW	119
South Carolina, 1973	31–38 FW	119
Greater flamingo, <i>Phoenicopterus ruber</i>		
Bone	123 (103–145) DW	60, 72
Feather		
Inner barbs	66 (38–105) DW	60, 72
Outer barbs	101 (45–190) DW	60, 72
Kidney	115 (90–167) DW	60, 72
Liver	758 (525–963) DW	60, 72, 73
Lung	43 (33–56) DW	60, 72
Muscle	53 (38–78) DW	60, 72
Kittiwake, <i>Rissa tridactyla</i> ; nestlings; Germany; 1992–94; age 1 day vs. age 21–40 days		
Brain	69 DW vs. 66 DW	122
Feather	79 DW vs. 116 DW	122
Kidney	104 DW vs. 120 DW	122
Liver	66 DW vs. 111 DW	122
Seabirds		
Albatrosses, 3 species		
Liver	(29–86) FW	68
Kidney	(31–65) FW	68
Fulmars, 2 species		
Liver	36–95 FW	68
Kidney	32–96 FW	68
Penguins, 4 species		
Liver	(27–73) FW	68
Kidney	(25–71) FW	68
Petrels, 7 species		
Liver	(28–81) FW	68
Kidney	(15–78) FW	68
Seabirds		
Liver, 11 species	Means 108–186 DW	135
3 species		
Brain, lung, heart, gonad, muscle, skin, gall bladder, uropygial gland, stomach, feather, trachea, esophagus	<100 DW	135
Intestine, liver, spleen, kidney, bone, eyeball	101–200 DW	135
Pancreas	208 DW	135
Shearwaters, 2 species		
Liver	(28–54) FW	68
Kidney	(27–88) FW	68
Skuas, 3 species		
Liver	(21–51) FW	68
Kidney	(22–53) FW	68
South Atlantic Ocean, adults, 15 species		
Kidney	28–63 (15–88) FW	74
Liver	22–67 (18–86) FW	74
Spain, infertile eggs, 1985–1986		
Golden eagle, <i>Aquila chrysaetos</i>	8.4 (5.5–11.9) FW	75
Buzzard, <i>Buteo buteo</i>	14 FW	75

9.6 ZINC DEFICIENCY EFFECTS

9.6.1 General

Zinc is important in the metabolism of proteins and nucleic acids and is essential for the synthesis of DNA and RNA. Zinc deficiency has been reported in humans and a wide variety of plants and animals — with severe effects on all stages of reproduction, growth, and tissue proliferation in the young. In early gestation, zinc deficiency may cause severe congenital abnormalities. Later in gestation, deficiency can cause growth inhibition and brain growth impairment, leading to altered behavioral development after birth. Feeding a low-zinc diet to lactating dams produces signs of zinc deficiency in suckling pups. In humans, zinc deficiency is associated with delayed sexual maturation in adolescent males; poor growth in young children; impaired growth of hair, skin, and bone; disrupted Vitamin A metabolism; and abnormal taste acuity, hormone metabolism, and immune function.

9.6.2 Terrestrial Plants

Zinc deficiencies in citrus groves in California, pecan trees in Texas, and various crops in Australia, have resulted in large crop losses (Vallee 1959). Applications of zinc salts were effective under acidic soil conditions, but neutral or alkaline soils rendered zinc salts insoluble and zinc therapy ineffective. Sprays of zinc salts applied to leaves, or injections into tree trunks overcame the problems of soil solubility and have generally been successful (Vallee 1959). Zinc is usually bound strongly in plants, particularly in grains, markedly decreasing its availability to animal consumers. Binding is attributed mainly to high content of phytate, and also to high levels of fiber, hemicelluloses, and amino acid-carbohydrate complexes (Casey and Hambidge 1980). Whole-grain cereals and legumes are considered rich sources of zinc (Casey and Hambidge 1980).

9.6.3 Aquatic Organisms

Nutritional zinc deficiency is rare in aquatic organisms (Spear 1981), although reports are available of experimentally induced zinc deficiency in algae, sponges, daphnids, echinoderms, fish, and amphibians.

Experimental zinc deficiency in euglenoids (*Euglena gracilis*) was associated with arrested growth and abnormal cell differentiation and development, leading to extensive teratological abnormalities. Zinc-deprived *Euglena* survived for extended periods through decreased metabolism (Falchuk et al. 1985; Falchuk 1988). Marine algae stopped growing when ambient zinc concentrations fell below 0.7 µg/L; also, zinc-deficient cultures of freshwater algae were unable to metabolize silicon (Vymazal 1986).

A freshwater sponge (*Ephydatia fluviatilis*) grew normally at a concentration of 0.65 µg Zn/L, but growth was reduced at lower concentrations tested (Francis and Harrison 1988). Daphnids (*Daphnia pulex*, *Daphnia magna*) reared for six brood cycles in zinc-free water showed reduced survival, inhibited reproduction, and cuticle damage (Keating and Caffrey 1989). Zinc is important

in pH regulation of sperm of marine invertebrates. Zinc reduction in semen to <6.5 µg/L adversely affected sperm pH and motility in sea urchins (*Strongylocentrotus purpuratus*, *Lytechinus pictus*), horseshoe crab (*Limulus polyphemus*), and starfish (Clapper et al. 1985a, 1985b).

Rainbow trout (*Oncorhynchus mykiss*) fry fed diets containing 1 to 4 mg Zn/kg ration have poor growth, increased mortality, cataracts, and fin erosion; supplementing the diet to 15 to 30 mg Zn/kg alleviates these signs (Spry et al. 1988). Spry et al. (1988) also fed rainbow trout fry diets containing 1, 90, or 590 mg Zn/kg ration and simultaneously exposed them to a range of waterborne zinc concentrations of 7, 39, 148, or 529 µg Zn/L. After 16 weeks, the 7 µg Zn/L plus 1 mg/kg diet group showed clear signs of deficiency, including a significantly reduced plasma zinc concentration (which was evident as early as the first week of exposure), reduced growth (with no growth after week 12), decreased hematocrit, and reduced plasma protein and whole-body zinc concentration. Elevating waterborne zinc to 39 or 148 µg Zn/L partially corrected the deficiency, but did not restore plasma or whole-body zinc to levels seen initially or in fish raised for 16 weeks on a zinc-adequate diet of 90 mg Zn/kg ration. There were no toxic effects at any other dietary–waterborne zinc mixture. It was concluded that zinc uptake from water was independent of uptake from diet, since at any dietary zinc level an increase in the waterborne zinc resulted in an increase in whole-body zinc. In freshwater, where waterborne concentrations of <10 µg Zn/L are most commonly encountered, waterborne zinc contributions to whole-body zinc loadings are likely to be insignificant. In cases where dietary zinc was adequate (i.e., 90 mg Zn/kg ration), the contribution of waterborne zinc was significant in the case of rainbow trout (Spry et al. 1988). In marine teleosts, diet is the major zinc source when seawater contained <15 µg Zn/L; at higher ambient concentrations of 600 µg Zn/L, waterborne zinc contributed up to 50% of the total body zinc burden (as quoted in Spry et al. 1988).

Experimentally produced zinc deficiency in toad (*Bufo arenarum*) embryos resulted in adults with abnormal ovarian development, altered meiotic and ovulation processes, and embryos with a high incidence of congenital malformations (Herkovits et al. 1989).

9.6.4 Birds

Zinc deficiency in chickens, turkeys, and Japanese quail is characterized by low survival, reduced growth rate and food intake, poor feathering, shortening and thickening of the long bones of legs and wings, reduced egg production and hatchability, skeletal deformities in embryos, an uncoordinated gait, reduced bone alkaline phosphatase activity, and increased susceptibility to infection (Blamberg et al. 1960; NAS 1979; Prasad 1979; Apgar 1985; O'Dell et al. 1989; Stahl et al. 1989a).

Laying hens (*Gallus* sp.) had low egg hatchability on diets that contained 6 mg Zn/kg, and produced chicks that were weak and poorly feathered; these chicks usually died within a few days on 8 to 9 mg Zn/kg diets (Blamberg et al. 1960). Zinc-deficient chicks (13 to 16 mg Zn/kg DW diet for 4 weeks) had pathological defects in epiphyseal cartilage; no interference with calcification was noted in controls fed diets containing 93 to 96 mg Zn/kg feed (Westmoreland and Hoekstra 1969). Pullets fed diets containing 28 mg Zn/kg for 4 months, then 4 mg Zn/kg ration for 4.5 months produced few hatchable eggs after 4 months. Prevalent malformations included faulty trunk and limb development, missing vertebrae, missing limbs and toes, abnormal brain morphology, small eyes, and skeletal malformations (Blamberg et al. 1960). Most zinc deficiency effects were reversed by increasing dietary zinc concentrations to 96 to 120 mg/kg (Blamberg et al. 1960).

Japanese quail fed an excess of zinc (25 to 30 mg Zn/kg diet) during their first week of life were protected during a subsequent period of zinc deprivation (1 mg Zn/kg diet for 1 week). Birds that received an initial intake of zinc in excess of requirements grew significantly better than those receiving a minimal amount of zinc. Japanese quail may store excess zinc in bones; this zinc store may become available during a subsequent period of zinc deprivation, especially during a period of rapid bone growth (Harland et al. 1975), but this requires verification.

Egg production constitutes a major loss of zinc and other trace metals by the laying hen. Vitellogenin mediates the transfer of zinc from liver to the maturing oocyte, ultimately resulting in deposition into yolk of the newly formed egg (Richards 1989). More research seems needed on the role of zinc in avian reproduction.

9.6.5 Mammals

Compared with zinc toxicity, zinc deficiency is a much more frequent risk to mammals (Leonard and Gerber 1989). Zinc is required in all stages of the cell cycle, and deficiency adversely affects metabolism of DNA, RNA, proteins, and activity of carbonic anhydrase, lactic dehydrogenase,mannosidase, and other enzymes (NAS 1979; Prasad 1979, 1980; Apgar and Everett 1988). In zinc deficiency, the activity of various zinc-dependent enzymes is reduced in testes, bone, esophagus, and kidney of rats, and alkaline phosphatase activity is reduced in bone and plasma from zinc-deficient rats, pigs, and cows (Prasad 1979; Vergnes et al. 1990). Deficiency leads to loss of appetite and taste, skin disturbances, slow wound healing, impaired brain development, deficient immune system, and disrupted water metabolism (Binnerts 1989). Zinc deficiency adversely affects testicular function in humans and animals and seems to be essential for spermatogenesis and testosterone metabolism (Prasad 1980). Zinc deficiency in young men with very low zinc intakes resulted in testicular lesions and reduced accessory gland weights, due primarily to reduced food intake and growth (Apgar 1985). Zinc deficiency during pregnancy has produced low birth weight, malformations, and poor survival in rat, lamb, and pig; the role of zinc in human reproductive problems is still unclear (Apgar 1985). Zinc-deficient diets for ruminants and small laboratory animals usually contain <1 mg Zn/kg ration, although rats show deficiency at <12 mg Zn/kg ration (Elinder 1986). Zinc deficiency has been documented in humans, small laboratory animals, domestic livestock, mink, and monkeys. Signs of severe zinc deficiency in mammals include decreased food intake, growth cessation, fetal malformations, testicular atrophy, swelling of feet, excessive salivation, dermal lesions, parakeratosis of the esophagus, impaired reproduction, hair loss, unkempt appearance, stiffness, abnormal gait, skin and organ histopathology, and hypersensitivity to touch (NAS 1979; Jameson 1980; Gupta et al. 1988; Elinder 1986; O'Dell et al. 1989). Selected examples of zinc deficiency in various species follow.

Zinc deficiency in humans is rare and is usually associated with severe malabsorption, parenteral alimentation lacking zinc, or geophagia (Sternlieb 1988). Symptoms of zinc deficiency depend, in part, on age, acuteness of onset, duration and severity of the zinc depletion, and the circumstances in which deficiency occurs. Many of the features of zinc deficiency observed in humans are similar to those seen in zinc-deficient animals (Casey and Hambidge 1980). Simple nutritional deficiency due to marginal zinc intake may be common, even in the United States (Casey and Hambidge 1980). Factors contributing to zinc deficiency include inadequate dietary intake (protein-calorie malnutrition), decreased availability (high fiber/phytate diets), decreased absorption, excessive losses (increased sweating, burns), increased requirements (rapid growth, pregnancy, lactation), as well as old age, alcoholism, and possible genetic defects (Casey and Hambidge 1980). Zinc deficiency may also occur as a result of liver or kidney disease, gastrointestinal disorders, skin disorders, parasitic infections, diabetes, and genetic disorders such as sickle cell disease (Prasad 1979). Clinical disorders aggravated by zinc deficiency include ulcerative colitis, chronic renal disease, and hemolytic anemia (Goyer 1986). In the 40 years since human zinc deficiency was demonstrated, it has been observed in a wide variety of geographic areas and economic circumstances. Severe zinc deficiency occurs in some areas of the Middle East and North Africa, and is frequently associated with the consumption of unrefined cereals as a major part of the diet (Casey and Hambidge 1980). Chronic zinc deficiency in humans is associated with dwarfism, infantile testes, delayed sexual maturity, birth defects, poor appetite, mental lethargy, immunodeficiency, skin disorders, night blindness, impotence, spleen and liver enlargement, defective mobilization of Vitamin A, delayed wound healing, impaired taste acuity, abnormal glucose tolerance, impaired

secretion of luteinizing hormone, and iron and folate deficiency (Prasad 1979, 1980; Casey and Hambidge 1980; Elinder 1986; Goyer 1986; Sternlieb 1988; Mackay-Sim and Dreosti 1989). A deficiency of zinc in the growing age period results in growth retardation; a severe zinc deficiency may be fatal if untreated (Prasad 1980). Zinc-deficient humans excrete <100 µg Zn daily in urine compared to a normal >300 µg Zn daily (Goyer 1986). Zinc deficiency may exacerbate impaired copper nutrition; interactions with cadmium and lead may modify the toxicity of these metals (Goyer 1986).

Acrodermatitis enteropathica is a disease characterized by skin eruptions, gastrointestinal disorders, and low serum zinc levels. One causative factor is poor intestinal absorption of zinc; a complete cure was accomplished by oral administration of 135 mg Zn daily as 600 mg of zinc sulfate (Elinder 1986). Using radiozinc-65, it was shown that afflicted individuals had a greater turnover of plasma zinc, a smaller pool of exchangeable zinc, and a reduced excretion of zinc in stool and urine (Prasad 1979). Zinc deficiency in humans is usually treated by oral administration of 1 mg Zn/kg BW daily (Casey and Hambidge 1980). However, zinc-deficient humans given daily intravenous injections of 23 mg of zinc experienced profuse sweating, blurred vision, and hypothermia (Saxena et al. 1989b).

An endemic zinc deficiency syndrome among young men has been reported from Iran and Egypt, and is characterized by retarded growth, infantile testes, delayed sexual maturation, mental lethargy, anemia, reduced concentration of zinc in plasma and red cells, enlarged liver and spleen, and hyperpigmentation; oral supplementation of 30 mg Zn daily had a prompt beneficial effect (Prasad 1979; Elinder 1986).

A zinc deficiency syndrome during human pregnancy includes increased maternal morbidity, abnormal taste sensations, prolonged gestation, inefficient labor, atonic bleeding, and increased risks to the fetus (Jameson 1980). Pregnant women with initially low and subsequently decreasing serum zinc levels had a high frequency of complications at delivery, including congenital malformations in infants (Jameson 1980). Multiple severe skeletal abnormalities and organ malformations in human fetuses have been attributed to zinc deficiency (Casey and Hambidge 1980). In newborns, zinc deficiency is manifested by growth retardation, dermatitis, hair loss, impaired healing, susceptibility to infections, and neuropsychologic abnormalities (Casey and Hambidge 1980; Goyer 1986).

Hereditary zinc deficiency occurs in certain strains of cattle (*Bos* spp.) and affects the skin and mucous membranes of the gastrointestinal tract. The disease — also known as Lethal Trait A46 — is caused by failure of a single autosomal recessive gene regulating zinc absorption from the intestine. Affected animals will die within a few months from secondary bacterial infections unless treated daily with high oral doses of zinc compounds (Bosma et al. 1988). Certain imported breeds of cattle in the western Sudan with low zinc serum levels (i.e., <0.6 mg/L) showed signs of zinc deficiency, including stunted growth, weakness, skin lesions, and loss of hair pigment (Damir et al. 1988). Cows fed a low (25 mg/kg ration) but adequate zinc diet had liver zinc concentrations below the expected 125 mg Zn/kg DW; increasing the total zinc dietary loading to 45 or 50 mg/kg DW is recommended for counteracting reduced zinc absorption in diets with soybean products (Binnerts 1989). Cows and calves fed low-zinc diets of 25 mg Zn/kg ration showed a decrease in plasma zinc from 1.02 mg/L at start to 0.66 mg/L at day 90; cows fed 65 mg Zn/kg diet had a significantly elevated (1.5 mg Zn/L) plasma zinc level and increased blood urea and plasma proteins (Ramachandra and Prasad 1989). Biomarkers used to identify zinc deficiency in bovines include zinc concentrations in plasma, unsaturated zinc-binding capacity, ratio of copper to zinc in plasma, and zinc concentrations in other blood factors; indirect biomarkers include enzyme activities, red cell uptake, and metallothionein content in plasma and liver (Binnerts 1989).

Domestic goats (*Capra* sp.) fed a zinc-deficient diet (15 mg Zn/kg) developed skin histopathology and alopecia (hair loss) after 177 days; zinc-deficient diets lacking Vitamin A hastened the process, with signs evident between 46 and 68 days (Chhabra and Arora 1989). No signs were evident in goats fed Vitamin A-adequate diets containing 80 mg Zn/kg ration (Chhabra and Arora 1989).

Guinea pigs (*Cavia* spp.) fed a zinc-deficient diet (1.25 mg Zn/kg FW) for 60 days, had significant reductions in zinc concentration of serum (0.5 mg/L), kidney (10 mg/kg FW), testes (9.5 mg/kg FW), and liver (9.4 mg/kg FW). Guinea pigs fed 1.25 mg Zn/kg FW diet for 45 days followed by a zinc-replete diet of 100 mg/kg FW for 15 days had normal concentrations of zinc (mg/kg FW) in serum (1.6 to 2.0), kidney (18 to 20), testes (19 to 27), and liver (15 to 17; Gupta et al. 1988). Zinc-deficient guinea pigs (<3 mg Zn/kg diet, 1 mg Zn/L drinking water) exposed from day 30 of gestation to term on day 68, when compared to zinc-adequate animals (<3 mg Zn/kg diet, 15 mg Zn/L) produced young of low birth weight, with severe skin lesions, sensitive to handling, slow in recovering balance when turned on their side, and a peculiar stance; fetal Zn concentrations were depressed 15 to 33% in liver and placenta (Apgar and Everett 1988). Disrupted immunocompetence responses and disordered protein metabolism were found in guinea pigs fed a zinc-deficient diet of 1.25 mg/kg FW ration for 45 days; marked, though incomplete, restoration occurred when this group was switched to 100 mg Zn/kg ration for 15 days (Verma et al. 1988). Neuromuscular pathology was evident in weanling guinea pigs fed a zinc-deficient diet (<1 mg Zn/kg) for 4 weeks, as judged by abnormal posture, skin lesions, and disrupted vocalizations; signs became severe after 5 to 6 weeks, but a single intraperitoneal injection of 1.3 mg Zn/kg BW (as ZnSO₄) caused remission within 7 days (O'Dell et al. 1989). Acute experimental allergic encephalomyelitis (EAE) was induced in guinea pigs maintained on low (6 mg/kg), normal (20 mg/kg), and high (200 mg/kg) levels of zinc in the diet. Acute EAE is usually a fatal disease of the central nervous system (CNS) induced by inoculation with protein found in myelin of the CNS. Those on the zinc-deficient diet exhibited the expected signs of zinc deficiency, but unlike other groups did not develop neurological signs of acute EAE (Scelsi et al. 1989). EAE suppression observed in the Zn-deficient guinea pigs is ascribed to the influence of zinc deficiency of the T-cell function. A model of autoimmune CNS disease, such as EAE, that requires a prominent T-lymphocyte sensitization, can be altered or suppressed when the immunoregulatory mechanisms are impaired by Zn deficiency (Scelsi et al. 1989).

Rhesus monkeys (*Macaca mulatta*) fed a marginally deficient zinc diet (4 mg Zn/kg diet) between age 5.5 and 30 months had lower plasma Zn levels, delayed onset of accelerated weight gain and linear growth, and no loss of subcutaneous fat — typical of early adolescence — when compared to those fed diets containing 100 mg Zn/kg (Golub et al. 1988). Marginal dietary zinc deprivation also depressed immune function in rhesus monkeys by about 30%, and impaired both learning and reversal of a visual discrimination task by 33 to 66% (Golub et al. 1988). When pregnant rhesus monkeys are fed a diet marginally deficient in zinc (4 mg/kg), perturbations in the mothers' immune system can occur. Their infants have reduced immune responsiveness despite the absence of marked differences in plasma or soft tissue zinc concentrations from control (100 mg Zn/kg diet) infants (Keen et al. 1989). Infant rhesus monkeys from zinc-deprived (4 mg Zn/kg ration) pregnant dams and subsequently fed the same low-zinc diet showed delayed skeletal maturation during their first year. The condition was most severe at age 6 months but began to return to normal despite continuation of the marginally deficient zinc diet (Leek et al. 1988).

Mice (*Mus* sp.) fed a zinc-deficient diet of 0.7 mg Zn/kg ration for 40 days, when compared to mice fed a zinc-adequate diet of 36.5 mg Zn/kg, had a reduced growth rate, impaired phagocytic function, increased susceptibility to lead poisoning, and reduced zinc content in blood (0.7 mg/L vs. 1.0–1.1) and liver (12 mg Zn/kg FW vs. 17–19; Tone et al. 1988). Zinc deficiency during early development affects neural tube development through arrested cell growth (Mackay-Sim and Dreosti 1989). Zinc deficiency in mice may disrupt olfactory function through interference with zinc-containing neurones in higher olfactory centers. Adult mice fed a zinc-deficient diet of 5 mg Zn/kg ration for 42 days, when compared to mice given 100 mg Zn/kg diet, could not distinguish odors, although olfactory epithelia seemed normal (Mackay-Sim and Dreosti 1989).

Mink (*Mustela vison*) kits fed a zinc-deficient diet of 4.1 mg Zn/kg FW ration for 4 days retained 0.49 mg Zn/kit and lost weight. Kits fed a zinc-adequate diet (35 to 45 mg Zn/kg FW, 100 to 150 mg/kg DW) retained 2.5 mg Zn/kit, and those fed 83 mg Zn/kg FW diet retained 7.8 mg Zn/kit.

Low-dose kits ate less than other groups. Urine was the most important excretory route in the zinc-deficient group, compared to feces in higher-dose groups (Mejborn 1989).

Domestic sheep (*Ovis aries*) fed a low-zinc diet (2.2 mg Zn/kg DW diet) for 50 days, when compared to those fed a zinc-adequate diet (33 mg Zn/kg DW diet), excreted less zinc (<4 mg daily vs. 23 to 25), consumed less food (409 g daily vs. 898), and had lower plasma zinc concentrations (0.18 mg/L vs. 0.53 to 0.58); a reduction in plasma alkaline phosphatase activity and an increase in plasma zinc binding capacity were also noted (Khandaker and Telfer 1990). Sensitive indicators of zinc deficiency in lambs include significant reductions in plasma alkaline phosphatase activity and plasma zinc concentrations; signs were clearly evident in lambs fed 10.8 mg Zn/kg DW diet for 50 to 180 days (Vergnes et al. 1990). A normal diet for lambs contains 124 to 130 mg Zn/kg DW ration vs. 33 for adults (Vergnes et al. 1990). One recommended treatment for zinc-deficient sheep is ruminal insertion of zinc-containing boluses every 40 days; bolus zinc release is about 107 mg daily (Khandaker and Telfer 1990).

Zinc-deficient pregnant laboratory white rats (*Rattus sp.*) have reduced litter size, a high frequency of fetal deformities, low birth weight, and a prolonged parturition; dams are inactive and behavior toward young seems indifferent (Harland et al. 1975). Fetal skeletal defects are prominent in rats fed zinc-deficient diets of 10 mg/kg ration during a 21-day gestation period. About 91% of zinc-deficient fetuses had multiple skeletal malformations vs. none in controls fed 76 mg Zn/kg diet (Ferreira et al. 1989). Zinc-deficient (1.5 mg Zn/kg diet) pregnant rats also had increased iron levels in liver, kidney, and spleen, depleted liver glycogen, and reduced levels of zinc in pancreas and duodenum (Mamba et al. 1989). Zinc deficiency causes testicular atrophy and hypogonadism in rats; the effects include spermatic arrest, histopathology of seminiferous tubules and interstitial cells, reduced serum testicular testosterone levels, and reduced testicular zinc concentrations (Hafiez et al. 1990). Zinc is required in Leydig cells for normal testosterone activity. Calcitonin inhibits transmembrane influx of zinc in the isolated rat Leydig cell, but these effects usually take >2 days and are critical only in states of borderline zinc deficiency (Chausmer et al. 1989). Zinc deficiency during pubertal development of rats depresses the activity of dipeptidyl carboxypeptidase in the testes and epididymis; this enzyme is required for maturation and development of sperm cells, and reduced activity may cause suppression of sexual maturity (Reeves 1990). Laboratory white rats fed zinc-deficient diets for 20 days show an aversion to the zinc-deficient diet. They readily consumed a familiar zinc-adequate diet for 15 days, but the previously deficient animals continued to avoid zinc-deficient diets when given a choice (Cannon et al. 1988). Zinc deficiency in rats (<1 mg Zn/kg diet for 26 days) significantly reduced blood pressure, and this correlated positively with serum angiotensin converting enzyme activity; increasing the dietary intake of calcium had no effect on these responses (Reeves and O'Dell 1988). During zinc deficiency, zinc is mobilized from bone in immature animals and may be available for metabolic processes including growth (Calhoun et al. 1978). Diabetic rats are at risk of developing zinc deficiency, owing to zinc's role in modulating immune system dysfunction in diabetes mellitus (Morradian et al. 1988). Cadmium toxicity is related to the zinc status of the body. Zinc-deficient rats (<1 mg Zn/kg diet) and zinc-adequate rats (40 mg/kg) were both challenged with cadmium. The zinc-deficient group had accelerated zinc loss from kidney; enlarged liver, kidney, spleen, and lungs; and increased distribution of cadmium in tissues (Sato and Nagai 1989). Other signs noted in zinc-deficient laboratory white rats include the following: decreased food intake and loss of body weight (Vallee 1959; Cannon et al. 1988; Dib et al. 1989; Reeves and O'Dell 1988; Ferreira et al. 1989; Mamba et al. 1989; Mansour et al. 1989; Sato and Nagai 1989), reduction in serum zinc (Calhoun et al. 1978; Reeves and O'Dell 1988), altered cholesterol metabolism (Sammon and Roberts 1988), increased serum magnesium (Reeves and O'Dell 1988), low bone (femur) zinc concentrations (Calhoun et al. 1978), degeneration of olfactory epithelium (Mackay-Sim and Dreosti 1989), reduction in serum total proteins (Mansour et al. 1989), decreases in activity of glutamate, glycine, methionine, arginine, lysine, and proline (Bettger 1989), and increased dental caries (Goldberg et al. 1990).

Zinc deficiency in domestic pig (*Sus* spp.) is associated with a condition known as porcine parakeratosis, characterized by dermatitis, diarrhea, vomiting, anorexia, severe weight loss, and eventually death. The condition is exacerbated by high calcium levels (Vallee 1959).

9.7 LETHAL AND SUBLETHAL EFFECTS

9.7.1 General

Significant adverse effects on growth, reproduction, and survival are documented for sensitive marine and freshwater species of aquatic plants, invertebrates, and vertebrates at nominal water concentrations between 10 and 25 µg Zn/L. Sensitive terrestrial plants died when soil zinc concentrations were >100 mg/kg, and showed decreased photosynthesis when total plant contained >178 mg Zn/kg DW. Representative soil invertebrates showed reduced growth at 300 to 1000 mg Zn/kg diet, and reduced survival at 470 to 6400 mg Zn/kg soil. Domestic poultry and avian wildlife had reduced growth at >2000 mg Zn/kg diet, and reduced survival at >3000 mg Zn/kg diet or at a single oral dose >742 mg Zn/kg BW; younger stages (i.e., chicks, ducklings) were least resistant. Sensitive species of livestock and small laboratory animals were adversely affected at >0.8 mg Zn/m³ air, 90 to 300 mg Zn/kg diet, >90 mg Zn/kg BW daily, >300 mg Zn/L drinking water, and >350 mg Zn/kg BW single oral dose.

9.7.2 Terrestrial Plants and Invertebrates

Sensitive terrestrial plants die when soil zinc levels exceed 100 mg/kg or when plant zinc content exceeds 178 mg/kg DW (Table 9.5). The phytotoxic zinc level for barley (*Hordeum vulgare*) is not known, but zinc content of barley leaf rarely exceeds 100 mg/kg DW (Chang et al. 1983). Uptake of zinc from soils by plants depends on soil type; for example, uptake is lower in coarse loamy soils than in fine loamy soils (Chang et al. 1983). Zinc uptake by barley leaf is greater with increasing rate of sludge application, but the relation is not proportional (Table 9.5).

Among terrestrial invertebrates, adverse effects on earthworm survival were documented at 470 to 662 mg/kg soil; slugs had reduced food consumption at 300 mg Zn/kg diet and reduced growth at 1000 mg Zn/kg diet; and woodlouse had impaired reproduction at 1600 mg Zn/kg soil, and reduced survival at 5000 mg Zn/kg diet or 6400 mg Zn/kg soil (Table 9.5). Woodlouse (*Porcellio scaber*) fed diets containing sublethal concentrations of zinc for 22 weeks at air temperatures of 12, 16, 20, or 24°C had decreased growth and increased accumulations at high dietary loadings and low temperatures; however, the interaction between temperature and zinc toxicity is not attributed to increased accumulations, but to a physiological interaction with energy metabolism (Donker et al. 1998).

High zinc concentrations in soils are responsible for reductions in populations of soil invertebrates near brass mills and zinc smelters (Beyer 1990). Soils in the vicinity of zinc smelters contained up to 35 g Zn/kg and had decreased populations of arthropods; experimentally, 20 grams of total zinc per kg of soil could account for the decreased survival (Beyer et al. 1984). Zinc concentrations exceeding 1600 mg/kg soil litter are associated with reduced natural populations of decomposer organisms in contaminated forest soil litter, and this has been verified experimentally (Beyer and Anderson 1985). Poisoning decomposer organisms, such as the woodlouse, may disrupt nutrient cycling and reduce the number of invertebrates available as wildlife food (Beyer and Anderson 1985). The woodlouse contains higher concentrations of zinc than other terrestrial invertebrates: up to 152 mg Zn/kg DW whole organism (Hopkin and Martin 1985). It is speculated that the large zinc stores in *P. scaber* repels predators that find zinc distasteful (Hopkin and Martin 1985).

Table 9.5 Effects of Zinc on Representative Terrestrial Plants and Invertebrates

Organism, Dose, and Other Variables	Effect	Reference ^a
PLANTS		
Fir, <i>Abies pindrow</i> , wooden stakes coated with 10% zinc oxide	Protects wood against termite damage for 5 years, compared to 4 years for copper sulfate, 2 years for calcium carbonate, and <6 months for untreated wood	1
Red maple, <i>Acer rubrum</i> , 100 mg Zn/kg culture medium	Lethal to seedlings	2
Lichen, <i>Cladonia uncialis</i> , whole plant zinc content	Depressed photosynthesis when whole lichen burden is >178 mg Zn/kg DW; decreased respiration at >3550 mg Zn/kg DW	3
Barley, <i>Hordeum vulgare</i> , leaf, from soil treated with sludge for 3 years		
No sludge	21–25 mg/kg DW	4
80 kg Zn/ha per year	26–47 mg/kg DW	4
160 kg Zn/ha per year	29–56 mg/kg DW	4
320 kg Zn/ha per year	41–57 mg/kg DW	4
Lichen, <i>Lasallia papulosa</i> , whole plant zinc content	Significant depression in photosynthesis at >308 mg Zn/kg DW and in respiration at >3300 mg Zn/kg DW	3
Oak, <i>Quercus rubra</i> , culture medium contained 100 mg Zn/kg	Lethal to seedlings	2
Corn, <i>Zea mays</i> , grown on sludge amended loam plots; soil contains a maximum of 460 mg Zn/kg DW	Leaf contains a maximum of 293 mg Zn/kg DW vs. 60 for controls; grain contains a maximum of 65 mg Zn/kg DW vs. 32 for controls	5
INVERTEBRATES		
Earthworm, <i>Aporrectodea tuberculata</i> ; concentrations of zinc in soil, in mg/kg DW, ranged from 28 to 470 vs. concentrations in whole worms (less gut contents), in mg/kg DW	At soil Zn concentration of 28 mg/kg DW (control), worms contained 320 mg Zn/kg DW. At soil Zn levels of 97, 110, 190, and 320 mg/kg DW, whole worms contained 810, 1300, 1100 and 650 mg Zn/kg DW, respectively. No worms were found at soil Zn levels of 470 mg/kg DW	6
Slug, <i>Arion ater</i> , fed diets containing 10, 25, 50, 100, 300 or 1000 mg Zn/kg ration for 27 days	No deaths in any group. Significantly reduced food consumption in 300 and 1000 mg/kg diets. All groups weighed less than controls at day 27, but growth was statistically impaired only in the 1000 mg/kg group	7
Slug, <i>Arion ater</i> , fed diets containing up to 1000 mg/kg feed for 30 days	No adverse effects except for glycogen depression at 1000 mg/kg diet	8, 9
Spider, <i>Dysdera crocata</i> , fed woodlice, <i>Porcellio scaber</i> at rate of 1 every 3 days for 36 days		
Woodlice from uncontaminated site (87 mg Zn/kg DW whole organism)	Whole spider contains 182 mg Zn/kg DW	10
Woodlice from contaminated site (152 mg Zn/kg DW whole organism)	Whole spider contains 118 mg Zn/kg DW vs. 116 mg Zn/kg DW in starved spiders	10
Earthworm, <i>Eisenia fetida</i>		
10–12 µg Zn/cm ² applied to epidermis	LC50 (48 h)	11
662 mg Zn/kg artificial soil (95% confidence interval: 574–674)	LC50 (2 weeks)	11
Springtail, <i>Folsomia candida</i>		
Soil		
1.5–34 mg pore water zinc/kg DW vs. 28–113 mg pore water zinc/kg DW	10% reduction in growth, survival, and reproduction vs. 50% reduction	14
6–34 mg water soluble zinc/kg DW vs. 36–97 mg water soluble zinc/kg DW	10% vs. 50% inhibition of growth, survival, and reproduction	14
Body residues; 59–149 mg Zn/kg DW whole springtail vs. 198–479 mg Zn/kg DW	10% vs. 50% effect level on growth, survival, and reproduction	14

Table 9.5 (continued) Effects of Zinc on Representative Terrestrial Plants and Invertebrates

Organism, Dose, and Other Variables	Effect	Reference ^a
Woodlouse, <i>Porcellio scaber</i> , fed soil litter containing up to 12,800 mg Zn/kg for 64 weeks	Soil litter containing 1600 mg Zn/kg or more had adverse effects on reproduction; adult survival was reduced at 6400 mg Zn/kg litter and higher	12
<i>P. scaber</i> , fed diets containing up to 20,000 mg Zn/kg feed for 8 weeks	Decreased survival at 5000 mg/kg and higher	13

^a 1, Roomi et al. 1990; 2, Buchauer 1971; 3, Nash 1975; 4, Chang et al. 1983; 5, Hinesly et al. 1977; 6, Beyer et al. 1987; 7, Marigomez et al. 1986; 8, Recio et al. 1988a; 9, Recio et al. 1988b; 10, Hopkin and Martin 1985; 11, Neuhauser et al. 1985; 12, Beyer and Anderson 1985; 13, Beyer et al. 1984; 14, Smit and Van Gestel 1998.

Slugs (*Arion ater*) are resistant to high dietary zinc intakes (1000 mg/kg feed) for 30 days, although zinc accumulations occur in excretory and calcium cells of the digestive gland (Recio et al. 1988a, 1988b). Histochemical detection of zinc in digestive gland of *Arion* is an indication of high levels of zinc in the environment (Recio et al. 1988a). Zinc elimination in *Arion* occurs directly from lipofuscin material of excretory cells and from spherules of calcium cells; excretion of lipofuscin material via feces is the major excretory route (Recio et al. 1988b).

Zinc normally aids wound healing in terrestrial invertebrates. Wounding of the optic tentacle, foot tissue, and partial shell removal in *Helix aspersa*, a terrestrial gastropod, resulted in deposition of zinc in the wound area after 2 to 5 days. Increased zinc in *Helix* wound areas may be necessary to promote protein synthesis, collagen formation, and mitotic cell division (Ireland 1986).

9.7.3 Aquatic Organisms

Significant adverse effects of zinc on growth, survival, and reproduction occur in representative sensitive species of aquatic plants, protozoans, sponges, molluscs, crustaceans, echinoderms, fishes, and amphibians at nominal water concentrations between 10 and 25 µg Zn/L (Table 9.6). Latent effects of zinc intoxication after brief exposures are poorly documented. One study showed that sensitive species of freshwater crustaceans exposed to zinc concentrations as low as 150 µg/L for as little as 30 minutes had delayed effects that included increasing immobility for up to 172 hours after exposure (Brent and Herricks 1998).

Acute LC50 (96 h) values for freshwater invertebrates ranged between 32 and 40,930 µg Zn/L; for fish, this range was 66 to 40,900 µg/L (USEPA 1987). For marine invertebrates, the LC50 (96 h) range was 195 µg/L for embryos of the hard-shelled clam (*Mercenaria mercenaria*) to >320 mg/L for adults of the Baltic clam (*Macoma balthica*). For marine teleosts LC50 (96 h) values ranged between 191 µg/L for larvae of the cabezon (*Scorpaenichthys marmoratus*) to 38 mg/L for juvenile spot, *Leiostomus xanthurus* (USEPA 1987). Many factors are known to modify the biocidal properties of zinc in aquatic environments. In general, zinc was more toxic to embryos and juveniles than to adults or to starved animals, at elevated temperatures, in the presence of cadmium and mercury, in the absence of chelating agents, at reduced salinities, under conditions of marked oscillations in ambient zinc concentrations, at decreased water hardness and alkalinity, and at low dissolved oxygen concentrations (Skidmore 1964; Weatherley et al. 1980; Spear 1981; USEPA 1987; Paulauskis and Winner 1988; Table 9.6).

Bioconcentration factors (BCF) for zinc accumulation from the medium varied widely between and within species of aquatic organisms. For representative freshwater organisms BCF values ranged from 107 to 1130 for insects, and 51 to 432 for fish (USEPA 1980). In marine environments the most effective zinc accumulators included red and brown algae, ostreid and crassostreid oysters, and scallops. The ranges of BCF values for representative marine groups were 370 to 64,000 for algae, 85 to 1,500,000 for crustaceans, 15 to 500 for echinoderms, up to 4,000,000 in scallop kidney, and 1900 to 6900 for fishes (Eisler 1980). Significant zinc accumulations were reported

after death in algae and fish, suggesting that residue data from these and other organisms found dead on collection are of limited worth (Eisler 1980). Maximum net daily accumulation rates recorded for various whole marine organisms, in mg Zn/kg FW, were 1.3 for the alga *Ascophyllum nodosum*, 7.7 for mussel *Mytilus edulis*, 19.8 for oyster *Crassostrea virginica*, 32 for the killifish *Fundulus heteroclitus*, 32 for softshell clam *Mya arenaria*, and 223 for sandworm *Nereis diversicolor*; in general, accumulation rates and total accumulations were higher at elevated water temperatures, and at higher ambient zinc water concentrations (Eisler 1980).

Algae and Macrophytes

Blue-green algae are among the most zinc-resistant aquatic plants (Vymazal 1986). Algae are classified by Vymazal (1986) as very resistant (>10 mg Zn/L), resistant (2 to 10 mg/L), moderately resistant (0.5 to 2 mg/L), having low resistance (0.1 to 0.5 mg/L; *Navicula*, *Synedra*), and having very low resistance (<0.1 mg Zn/L; *Diatoma*, *Tabellaria*, *Microspora*, *Ulothrix*).

The most sensitive aquatic plant was *Schroederella schroederi*, a diatom; 19 µg Zn/L was sufficient to inhibit growth 50% in 48 h (USEPA 1987). Freshwater aquatic plants are usually absent from areas containing >2.0 mg Zn/L; in the hard waters of artificial streams containing 170 mg CaCO₃/L, a water concentration of 1.1 mg Zn/L caused a 50% decrease in the number of algal species (Spear 1981). Most freshwater diatom populations decreased in the range of 175 to 380 µg Zn/L; this sensitivity may be useful as an indicator of zinc contamination (Spear 1981). Zinc and cadmium are strongly synergistic in their toxic action to plants. Any level of cadmium >10 µg/L should be suspected of producing a significant increase in the toxicity of available zinc to freshwater plants (Whitton 1980).

In heavily-contaminated zinc environments (i.e., 130 to 6500 µg Zn/L), zinc-tolerant species are dominant (Spear 1981). Highly tolerant strains of algae require 1.5 to 1.65 mg Zn/L for normal growth; at least three species of some tolerant strains can live in water containing 3 g Zn/L (Vymazal 1986). Highly tolerant mutant strains of *Anacystis nidulans* required 1.5 to 16.5 mg Zn/L. In France, at least 17 species of freshwater algae seemed to be flourishing at 42.5 mg Zn/L and pH 4.2 (Vymazal 1986). Zinc-tolerant strains of aquatic algae tolerate high zinc concentrations with little bioconcentration. A zinc-tolerant strain of *Euglena gracilis*, for example, tolerates >700 mg Zn/L, but contains <500 mg Zn/kg DW whole organism vs. 50 mg Zn/L and 5000 mg/kg DW for nontolerant strains (Fukami et al. 1988a). Another zinc-tolerant strain of *Euglena* had normal growth at 300 mg Zn/L and residues of about 7000 mg Zn/kg DW vs. population decline of nontolerant strains at 300 mg Zn/L (Fukami et al. 1988).

Algae are effective accumulators of zinc. Three species of marine algae had a mean bioconcentration factor (BCF) of 1530 in 12 days, 4680 in 34 days, and 16,600 in 140 days (USEPA 1980). Bioconcentration factors for zinc and various species of algae are quite variable and usually range between 76 and 163,750 (Vymazal 1986; USEPA 1987). Many species of aquatic plants contain 150 mg Zn/kg DW, and higher. In one case, algae (*Mougeotia* spp.) from northern England in Zn-contaminated waters contained a spectacular 219 g Zn/kg DW (Vymazal 1986); it is likely that most of the Zn in *Mougeotia* was not biologically incorporated. Algal accumulations of zinc are modified significantly by physicochemical variables. Zinc concentrations in algae were higher under conditions of decreasing light intensity, water pH, DDT levels, copper, cadmium, phosphate, suspended sediments, organic chelators and other complexing agents, calcium, and magnesium, and under conditions of increasing water temperature, dissolved oxygen, duration of exposure, and ambient zinc concentrations (Eisler 1980; Whitton 1980; Vymazal 1986).

Unlike algae, submerged aquatic macrophytes play a minor role in cycling zinc (Lyngby et al. 1982). Rooted aquatic macrophytes may participate in heavy-metal cycling in the aquatic environment either as a source or as a sink, but studies with eelgrass (*Zostera marina*) show that zinc exchange between the sediment and the water is insignificant (Lyngby et al. 1982).

Table 9.6 Effects of Zinc on Representative Aquatic Plants and Animals (Concentrations are in micrograms of zinc per liter of medium.)

Taxonomic Group, Organism, and Other Variables	Concentration (ppb)	Effects	Reference ^a
PLANTS			
Alga, <i>Amphidinium carteri</i>	400	Growth inhibition	1
Aquatic plants, various	30->200,000	Adverse effects	2
Brown alga, <i>Ascophyllum nodosum</i>	100	No effect on growth in 10 days	2
<i>A. nodosum</i>	250	Decreased growth in 10 days	2
Coccolithophorid, <i>Cricospaera carterae</i>	77	Growth reduced 50% in 4 days	2
Freshwater algae, 11 species	140–800	Growth inhibition	3
Freshwater algae, most species	>1000	Growth inhibition	1
Brown macroalgae, <i>Fucus serratus</i>	9.5	BCF of 10,770 in 140 days	2
<i>F. serratus</i>	8.8	Altered lipid metabolism	2
Marine macroalgae, <i>Fucus vesiculosus</i>	3500	No adverse effects	2
<i>F. vesiculosus</i>	7000	Growth retardation	2
Dinoflagellate, <i>Glenodinium halli</i>	20	Chlorophyll reduced 65% in 2 days	2
Dinoflagellate, <i>Gymnodinium splendens</i>	110–392	Chlorophyll reduced about 65% in 2 days in temperature range 16–30°C	2
<i>G. splendens</i>	100	Growth inhibition in 38 days	3
Alga, <i>Isochrysis galbana</i>	74	Chlorophyll reduced 65% in 48 h at 16 ppt salinity, 20°C	2
<i>I. galbana</i>	430	Chlorophyll reduced 65% in 48 h at 16°C, 16 ppt salinity	2
Kelp, <i>Laminaria digitata</i>	100	Growth inhibition in 24 days	1
Brown macroalga, <i>Laminaria hyperborea</i>	250	Reduced growth of sporophytes in 8–10 days	2
Marine algae, 4 species	50–500	Decrease in cell numbers	1
Marine algae, 5 species	100	Growth inhibited in 48 h	2
Marine macroalgae, 4 species	100	No adverse effects	2
Marine macroalgae, 4 species	1400	Growth reduction	2
Diatom, <i>Nitzschia closterium</i>	271–300	50% growth inhibition in 4 days	2
Diatom, <i>Nitzschia longissima</i>	100	Growth stimulated during exposure for 1–5 days	2
Dinoflagellate, <i>Procentrum micans</i>	319	50% growth inhibition in 4 days	2
Diatom, <i>Phaeodactylum tricornutum</i>	250	BCF of 1800 in 3 days	2
<i>P. tricornutum</i>	4800	6.7% increase in growth during 12-day exposure	2
Phytoplankton	15	Primary productivity reduced in 14 days	2
Marine alga, <i>Rhizosolenia</i> sp.	15–25	Photosynthesis reduction	3
Alga, <i>Scenedesmus quadricauda</i>	2	Adverse effects	4
<i>S. quadricauda</i>	64	Growth inhibition in 14 days	2
<i>S. quadricauda</i>	300	Lethal	4

Table 9.6 (continued) Effects of Zinc on Representative Aquatic Plants and Animals (Concentrations are in micrograms of zinc per liter of medium.)

Taxonomic Group, Organism, and Other Variables	Concentration (ppb)	Effects	Reference ^a
Diatom, <i>Schroederella schroederi</i>	19	Growth inhibited 50% in 48–96 h	2
Freshwater alga, <i>Selenastrum capricornutum</i>	30	Some growth inhibition in 7 days	1
<i>S. capricornutum</i>	40–68	95% growth inhibition in 14 days	1
<i>S. capricornutum</i>	100	100% growth inhibition in 7 days	1
Diatom, <i>Skeletonema costatum</i>	19.6	Adverse effects	4
<i>S. costatum</i>	50–100	Growth reduced 20–23% in 10–15 days	2
<i>S. costatum</i>	200	Growth stimulated in 1–5 days	2
<i>S. costatum</i>	265	Metabolic disruption in 3 days	2
Diatom, <i>Thalassiosira pseudonana</i>	65	Adverse effects	4
<i>T. pseudonana</i>	500	Growth reduced 41% in 11–15 days	2
<i>T. pseudonana</i>	823	Growth reduced 50% in 72 h	2
Green macroalga, <i>Ulva lactuca</i>	65	BCF of 255 in 6 days	2
PROTISTS			
Protozoan, <i>Cristigera</i> sp.	50–125	Growth reduced in 5 h exposure	1, 2
Bacterium, <i>Escherichia coli</i>	650–1400	Growth inhibition	3
Microorganisms, various	650–1100	Growth inhibition, usually	3
Paramecium, <i>Paramecium multimicronucleatum</i>	560–10,000	LC50 (3 h)	3
Bacterium, <i>Pseudomonas</i> sp.	1000–10,000	Growth inhibition	3
Protozoan, <i>Vorticella convallaria</i>	50	LC50 (48 h)	3
PORIFERA			
Freshwater sponge, <i>Ephydatia fluviatilis</i>			
Adults	6.5	No effect on growth; no tolerance developed with long-term exposure	5
Adults	26	After exposure for 10 days, tissue deterioration and death during 3-week postexposure period	5
ROTIFERS			
Rotifer, <i>Philodena acutiformis</i>			
Adults	500	LC50 (48 h), 25°C	2
Adults	1550	LC50 (48 h), 5°C	2
MOLLUSCS			
Freshwater snail, <i>Ancylus fluviatilis</i>			
Juvenile	80	LC50 (100 days), shell length <2 mm	6
Adult	100	No adverse effect on reproduction in 100 days	6
Juvenile	130	LC50 (100 days), shell length >3 mm	6
Adult	180	Reproduction reduced in 100 days	6

Table 9.6 (continued) Effects of Zinc on Representative Aquatic Plants and Animals (Concentrations are in micrograms of zinc per liter of medium.)

Taxonomic Group, Organism, and Other Variables	Concentration (ppb)	Effects	Reference ^a
Bay scallop, <i>Argopecten irradians</i>			
Larvae	50	Growth rate reduced 22% in 9 days	7
Larvae	109	Growth reduced 50% in 9 days	7
Larvae	120	LC50 (9 days), increased shell deformities	7
Larvae	150–200	All dead at metamorphosis	7
Juvenile	2250	LC50 (96 h)	8
Freshwater snail, <i>Biomphalaria glabrata</i>	500	By day 33 of exposure embryo survival was reduced 50% and adult growth and reproduction inhibited	9
Asiatic clam, <i>Corbicula fluminea</i>	<20	Residues were 169 mg/kg DW soft parts after feeding on periphyton containing 393–1327 mg/kg DW for 30 days	11
<i>C. fluminea</i>	25	Normal growth during exposure for 30 days	10
<i>C. fluminea</i>	34	Residues were 433 mg/kg DW soft parts in 30 days after feeding on periphyton containing 956–4369 mg Zn/kg DW; growth reduced; cellulase enzyme activity reduced	11
<i>C. fluminea</i>	50–500	Growth inhibited between days 20 and 30 of exposure	10
<i>C. fluminea</i>	218	BCF of 126 in 28 days	2
<i>C. fluminea</i>	1000	After exposure for 30 days, about 30% dead. Survivors had osmoregulatory impairment and residues, in mg Zn/kg DW soft parts, of 2000 vs. 200 in controls. Depuration complete by day 17 post-exposure, and growth rate returns to normal	10
Pacific oyster, <i>Crassostrea gigas</i>			
Larvae	10–20	Reduced larval settlement in 20 days	2
Larvae	30–35	Reduced larval settlement in 6 days	2
Larvae	50	Normal growth and development in 5 days	12
Larvae	70	Abnormal shell development in 48 h	1
Larvae	75	No deaths in 48 h	1
Larvae	80–95	Growth reduced 50% in 4 days	2
Larvae	119–310	LC50 (48 h)	1, 3
Larvae	125	Substrate attachment inhibited in 5 days	1, 2
Larvae	200	No growth in 5 days	12
Embryo	233	LC50 (96 h)	2
Larvae	250	Increasing incidence of abnormal development and mortality	12
Sperm	444	Fertilization success reduced 50% in 60 min	2
Larvae	500	All dead in 48 h	1
American oyster, <i>Crassostrea virginica</i>			
Adult	100	Whole body concentration of 2560–2708 mg Zn/kg FW soft parts after 20-week exposure vs. 1036–1708 for controls	14
Adult	200	After exposure for 20 weeks, residues were 3185–3813 mg Zn/kg FW soft parts	14

Table 9.6 (continued) Effects of Zinc on Representative Aquatic Plants and Animals (Concentrations are in micrograms of zinc per liter of medium.)

Taxonomic Group, Organism, and Other Variables	Concentration (ppb)	Effects	Reference ^a
Embryo	230	LC50 (96 h)	2
Larvae	340	LC50 (48 h)	13
Red abalone, <i>Haliotis rufescens</i>			
Larvae	19	No adverse affects after 9-day exposure	13
Larvae	41	Normal development during 48-h exposure	13
Larvae	50	50% abnormal development during exposure for 9 days	13
Larvae	68	50% abnormal development in 48 h exposure	13
Marine gastropod, <i>Littorina littorea</i>			
Adult	0.2 (controls)	Zinc concentrations in all tissues were <185 mg/kg DW, except kidney which was 372 mg/kg DW	15
Adult	10	After exposure for 42 days tissue Zn residues, in mg/kg DW, were: head/foot 120, gills 255, whole soft parts 605, viscera 1322, stomach 1918, and kidney 2153	15
Freshwater pond snail, <i>Lymnaea luteola</i>			
Adult	1680	LC50 (96h)	85
Hard shell clam, <i>Mercenaria mercenaria</i>			
Larvae	50	5% dead in 12 days	1
Larvae	166	50% dead or abnormal in 48 h	1
Embryo	195	LC50 (96 h)	2
Larvae	195–341	LC50 (10–12 days)	1
Larvae	279	All dead in 48 h	1
Softshell clam, <i>Mya arenaria</i>			
Adult	10	Soft parts contained 9.5 mg Zn/kg FW after 16 weeks at 0–10°C, and 11 mg/kg after 2 weeks at 16–22°C	14
Adult	200	BCF of 85–135 in 50 days	2
Adult	500	Soft parts contained 31–48 mg Zn/kg FW after exposure for 6–16 weeks at 0–10°C, and 59–82 mg/kg after 1–2 week exposure at 16–22°C	14
Adult	900	No deaths in 7 days at 22°C	16
Adult	1550	LC50 (7 days) at 22°C	16
Adult	25,000	All dead after 70-day exposure at 0–10°C; at exposure temperature of 16–22°C, all dead by day 14	17
Common mussel, <i>Mytilus edulis</i>			
Adult	25	Maximum kidney zinc residue after 18 days was 14.1 g/kg DW vs. 4.9 g/kg in controls	18
Adult	60	Shell growth rate reduced 50% in 2–6 day exposure	2
Embryo	96–314	Development inhibited 50% in 72 h	2
Adult	100	No accumulations in tissues after 4-day exposure	19

Table 9.6 (continued) Effects of Zinc on Representative Aquatic Plants and Animals (Concentrations are in micrograms of zinc per liter of medium.)

Taxonomic Group, Organism, and Other Variables	Concentration (ppb)	Effects	Reference ^a
Adult	230–860	In 7-h exposure, pumping rate decreased with increasing Zn, and was completely stopped at >470 µg/L; recovery on return to background levels	20
Adult	1000	After exposure for 24 h, zinc concentration in soft parts rose from 150 mg/kg DW to 252 mg/kg DW and remained elevated for at least 6 weeks postexposure	21
Larvae	1752	LC50 (48 h)	13
Adult	1800	Reduced byssal thread production	2
Adult	5000	LC50 (7 days)	2
Adult	5000	LC 100 (16 days)	19
Adult	20,800	LC50 (24 h exposure plus 6 weeks post-exposure); none dead during exposure	22
Sperm	65,400	Respiration inhibited 50% in 20 min	23
Mud snail, <i>Nassarius obsoletus</i>			
Adult	200	Decreased oxygen consumption in 72 h	1
Egg	650	Abnormal veliger development	24
Adult	5000	No deaths in 168 h	25
Green-lipped mussel, <i>Perna viridis</i>			
Adult	<178–362	Maintains constant body concentration over 21-day exposure period	26
Adult	>362	Accumulation in tissue	26
Adult	6090	LC50 (96 h)	26
Freshwater snail, <i>Physa heterostropha</i> , juvenile	241	LC50 (96 h)	2
Surf clam, <i>Spisula solidissima</i> , juvenile	2950	LC50 (96 h)	8
BRYOZOANS			
Bryozoan, <i>Bugula neritina</i> , larvae	200	LC50 (5 h)	3
Bryozoan, <i>Watersipora cucullata</i> , larvae	650	LC50 (5 h)	3
CRUSTACEANS AND ARACHNOIDS			
Copepod, <i>Acartia tonsa</i>	290	50% immobilized in 48 h	1
<i>A. tonsa</i>	294	LC50 (96 h)	2
Amphipod, <i>Allorchestes compressa</i>	580–2000	LC50 (96 h)	3, 27
Brine shrimp, <i>Artemia</i> sp.	14–1360	Egg hatching significantly reduced in dose-dependent manner; no effect on survival of prenauplii larvae	28
Cladoceran, <i>Ceriodaphnia reticulata</i>	51	LC50 (96 h)	2
Hermit crab, <i>Clibanarius olivaceus</i>			
Larvae	1–90	Molting delayed in dose-dependent manner	29
Larvae	100	LC50 (96 h)	29
Larvae	125	LC 100 (96 h)	29
Daphnia, <i>Daphnia galeata mendotae</i>	15	BCF of 9400 in 2 weeks	2

Table 9.6 (continued) Effects of Zinc on Representative Aquatic Plants and Animals (Concentrations are in micrograms of zinc per liter of medium.)

Taxonomic Group, Organism, and Other Variables	Concentration (ppb)	Effects	Reference ^a
<i>D. g. mendotae</i>	30	BCF of 5833 in 2 weeks	2
<i>D. g. mendotae</i>	60	BCF of 6333 in 2 weeks	2
Daphnid, <i>Daphnia magna</i>	5–14	LC50 (72 h) at 30°C	2
<i>D. magna</i>	25	No effect in soft water (50 mg CaCO ₃ /L) in 50 days	30
<i>D. magna</i>	42–52	MATC ^b ; water contains 104–211 mg CaCO ₃ /L	1, 2
<i>D. magna</i>	68–655	LC50 (96 h)	31
<i>D. magna</i>	70	Reproduction reduced 16% in 21 days	2
<i>D. magna</i>	100	LC50 (48 h), starved	84
<i>D. magna</i>	250	Nonlethal in 6 weeks when sediments present in test container. Final sediment value of 13,400 mg/kg DW vs. 600 in controls. Organisms had whole body residues of 450 mg/kg DW	32
<i>D. magna</i>	280	LC50 (48 h), fed	3
<i>D. magna</i>	560	LC50 (24 h) at 25°C	84
<i>D. magna</i>	560	50% immobilized in 48 h	33
<i>D. magna</i>	2300	LC50 (24 h) at 5°C	3
Daphnid, <i>Daphnia pulex</i>	253	LC50 (96 h)	2
<i>D. pulex</i>	280	LC50 (48 h)	1
<i>D. pulex</i>	500	LC50 (24 h) at 25°C	3
<i>D. pulex</i>	1550	LC50 (24 h) at 5°C	3
Copepod, <i>Eudiaptomus padanus</i>	500	LC50 (48 h)	31
Amphipod, <i>Gammarus duebeni</i>			
Natural population	>100	Survival reduced in 7 days	34
Natural population	1000	All dead in 7 days at 10 ppt salinity, 84% dead at 30 ppt	34
Zinc-tolerant population	1000	50% dead in 14 days at 10 ppt salinity, 33% dead at 30 ppt	34
American lobster, <i>Homarus americanus</i>			
Larvae	130	LC50 (17 days)	3
Larvae	381	LC50 (96 h)	2
Adult	13,000	LC50 (11 days)	3
Horseshoe crab, <i>Limulus polyphemus</i>			
Embryos	<100	LC50 (72 h), Sandy Hook Bay, NJ	86
Larvae	100,000	Normal survival and molting	86
Embryos	715,000	LC50 (72 h), Delaware Bay, Delaware	86
Mysid, <i>Mysidopsis bahia</i>	120–231	MATC ^b	1, 2
<i>M. bahia</i>	499	LC50 (96 h)	2, 13
Crayfish, <i>Orconectes virilis</i>	130,000	No deaths in 10 days	35
Hermit crab, <i>Pagurus longicarpus</i>			
Adult	200	LC50 (168 h)	25
Adult	400	LC50 (96 h)	1, 2
Prawn, <i>Palaemon elegans</i>	562	LC 67 (21 days)	36
Shrimp, <i>Pandalus montagui</i>	65	BCF of 3.7 in 14 days	2
Mysid, <i>Praunus flexuosus</i>	2000	LC50 (192 h), 5°C, 4.5 ppt salinity	37

Table 9.6 (continued) Effects of Zinc on Representative Aquatic Plants and Animals (Concentrations are in micrograms of zinc per liter of medium.)

Mudcrab, <i>Rithropanopeus</i> <i>harrissii</i> , larvae	50	Delayed development in 16-day exposure	1
Copepod, <i>Tisbe holothuriae</i>			
Life cycle	7	No effect on population size after exposure for 4 generations	38
Life cycle	10	Some deaths in fourth generation	38
Life cycle	70	All dead by end of first generation	38
Copepodid	421	LC50 (48 h)	39
Adults	620–700	LC50 (48 h)	38, 40
Females with egg sacs	713	LC50 (48 h)	39
Copepod, <i>Tropocyclops prasinus mexicanus</i> , Quebec lakes, uncontaminated	52–264	LC50 (48 h) in soft water	41
<i>T. p. mexicanus</i> Quebec lakes, contaminated	2934	LC50 (48 h) in hard water lake; metal preexposure protective effect hypothesized	41
AQUATIC INSECTS			
Mayfly, <i>Epeorus latifolium</i>			
Larvae	30	Gradual decrease in growth rate in 4-week exposure; some deaths prior to emergence	42
Larvae	100–300	Growth inhibited after 2 weeks; all dead before emergence	42
Midge, <i>Tanytarsus dissimilis</i> , embryo through third instar	37	LC50 (10 days)	1,2
ANNELIDS			
Polychaete worm, <i>Capitella capitata</i>			
Larvae	50–100	Abnormal development during 16-day exposure	2
Adult	1250	LC50 (28 days)	2
Adult	10,700	LC50 (48 h)	13
Leech, <i>Erpobdella octoculata</i>			
Juveniles	60	LC50 (70 days)	43
Adults	100	LC50 (70 days)	43
Adults	180	High frequency of abnormal eggs produced in 60-day exposure	43
Adults	320	Inhibited reproduction in 60-day exposure	43
Juveniles	390	LC50 (40 days)	43
Juveniles	2100	LC50 (96 h)	43
Adults	4800	LC50 (40 days)	43
Adults	8800	LC50 (96 h)	43
Polychaete, <i>Neanthes arenaceodentata</i> , juveniles	900	LC50 (28 days)	3
Sandworm, <i>Nereis diversicolor</i>			
Adults	1500	No deaths in 168 h	25
Adults	2600	LC50 (168 h)	25

Table 9.6 (continued) Effects of Zinc on Representative Aquatic Plants and Animals (Concentrations are in micrograms of zinc per liter of medium.)

Taxonomic Group, Organism, and Other Variables	Concentration (ppb)	Effects	Reference ^a
Adults	10,000	Whole body zinc concentration, in mg/kg DW, in survivors after exposure for 34 days was 2500 vs. 180 in controls	14
Adults	10,000	After 96 h exposure at 6°C, zinc residues (mg/kg DW) were 1031 in head vs. 843 for controls, 366 vs. 158 in trunk, and 455 vs. 275 in parapodia; uptake higher at 12° and 20°C	44
Adults	20,000	No deaths in 96 h	44
Adults	40,000	LC50 (47 h) for nontolerant strains; LC50 (70 h) for zinc-tolerant strains	45
Worm, <i>Spirorbis lamellora</i> , larvae	350	LC50 (3 h)	3
ECHINODERMS			
Sea urchin, <i>Anthocidarius crassispina</i>			
Egg	65	No effect on fertilization membrane formation or development in eggs transferred 1 min after insemination	46
Egg	326	Irreversible inhibition of fertilization membrane formation in eggs transferred 10 sec. after insemination	46
Starfish, <i>Asterias rubens</i>			
Adult females	240	Increased steroid metabolism in pyloric caeca after 21 days	47
Adults	1000	No deaths in 168 h	25
Adults	2300	LC50 (168 h)	25
Sand dollar, <i>Dendraster excentricus</i> , sperm	28	Fertilization success reduced 50% in 60 min	2
Echinoderms, 3 species, embryos	60–200	Embryonic development inhibited	48
Red sea urchin, <i>Strongylocentrotus franciscanus</i> , sperm	313	Fertilization success reduced 50% in 60 min	2
Purple sea urchin, <i>Strongylocentrotus purpuratus</i> , embryos	23	Development inhibited 50% in 5 days	2
Embryos; field populations vs. laboratory-raised populations	97 vs. 107	50% inhibition of larval development in 96 h	87
FISH			
Longfin dace, <i>Agosia chrysogaster</i> , larvae	228	LC50 (96 h)	2
Murrel, <i>Channa punctatus</i> , fingerlings, 31-day exposure	12,000	Growth rate reduced by day 19; liver RNA and proteins decreased by day 20; muscle RNA and proteins reduced by day 30	49, 50
Texas cichlid, <i>Cichlasoma cyanoguttatum</i> , adults, exposure for 4 weeks	40 (control), 65, or 90	Residues in mg Zn/kg FW, were 0.8, 28, and 34 in muscle; 6, 56, and 25 for viscera; 6, 59, and 98 for gills; and 12, 66, and 92 for bone	51

Table 9.6 (continued) Effects of Zinc on Representative Aquatic Plants and Animals (Concentrations are in micrograms of zinc per liter of medium.)

Taxonomic Group, Organism, and Other Variables	Concentration (ppb)	Effects	Reference ^a
Air-breathing catfish, <i>Clarias lazera</i> , juveniles	26,000–52,000	LC50 (96 h) at 25.1°C (26,000) through 9.3°C (52,000); at 38,000 µg/L and 18.5°C, 50% died and survivors had BCF values of 544 in gill, 425 in liver, and 250 in muscle	52
Baltic herring, <i>Clupea harengus</i> , eggs exposed from fertilization through hatching	500, 2000, 6000, or 12,000	Histopathology of epidermis and kidney in larvae at 6000 µg/L and higher; no measurable effects at 2000 µg/L and lower	53, 54
Atlantic herring, <i>Clupea harengus harengus</i> , embryos and larvae	50	Significant increase in incidence of jaw and branchial abnormalities	2
Freshwater fishes, 4 species, adults	4600–17,300	LC50 (5 days)	55
Mummichog, <i>Fundulus heteroclitus</i>			
Adults	810	Bioconcentration factor (BCF) of 16 in whole fish after 56 days	2
Adults	10,000	Zinc concentration, in mg/kg DW scale, rose from 229 at start to 746 after 45 days and to 1608 after 94 days	56
Adults	10,000	Zinc content in scale, in mg/kg DW, after 45 days exposure and 21 to 49 days in uncontaminated water fell from 746 to 422–498	56
Adults	43,000	No deaths in 8 days; no significant increase in tissue Zn levels	57
Adults	52,000–66,000	LC50 (8 days)	25, 57
Adults	71,000–153,000	LC50 (48 h)	58
Mosquitofish, <i>Gambusia affinis</i> , adults, muscle	18,000	After 24 h, Zn increased from 82 to 134 µg/kg FW; significant increases in glycogen, total lipids, phospholipids, and cholesterol; decreases in RNA and proteins	59
Flagfish, <i>Jordanella floridae</i>			
Life cycle	26–51	MATC ^b	2
Larvae	85	LC80 (30 days)	3
Adults	139	BCF of 417 in whole fish in 100 days	2
Cypriniform freshwater fish, <i>Labeo rohita</i>			
Juveniles and adults	20,000	No deaths in 96 h	60
Juveniles	65,000	LC50 (96 h); liver glycogen reduced; BCF of 22 in whole fish	60
Adults	77,000	LC50 (96 h); survivors had disrupted respiration and decreased liver glycogen	60
Spangled perch, <i>Leiopotherapon unicolor</i> , adults, exposed for 2 h	5000, 10,000, or 20,000	Temporary decrease in ventilation rate at 5 mg/L; significant increase in ventilation rate at 10 and 20 mg/L; bradycardia at 20 mg/L	61
Spot, <i>Leiostomus xanthurus</i>	38,000	LC50 (96 h)	62
Bluegill, <i>Lepomis macrochirus</i>			
Adults	76–235	Reproduction inhibition	3
Adults	100	Hyperactivity	3

Table 9.6 (continued) Effects of Zinc on Representative Aquatic Plants and Animals (Concentrations are in micrograms of zinc per liter of medium.)

Taxonomic Group, Organism, and Other Variables	Concentration (ppb)	Effects	Reference ^a
Fry	235	Lethal in 3 days	1, 2
Adults, exposed for 7 days, then placed in a lethal NaCl salinity (1.46%) for 60 h	2350	Exposed fish all dead in 60 h vs. 8 h for controls; plasma chloride declined in Zn-exposed fish, suggesting that Zn reduces permeability of gills to chloride influx	63
Adults	5400	LC50 (96 h) at 20 mg CaCO ₃ /L	3
Adults	40,900	LC50 (96 h) at 360 mg CaCO ₃ /L	3
Marine fishes, most species	>1000	LC50 (96 h)	1
Tidewater silverside, <i>Menidia peninsulae</i>	5600	LC50 (96 h)	62
Striped bass, <i>Morone saxatilis</i>			
Larvae	100–119	LC50 (96 h)	1, 2
Fry	430–1180	LC50 (96 h)	1, 2
Adults	6700	LC50 (96 h)	1
Stone loach, <i>Noemacheilus barbatulus</i> , adults	1900–2000	LC50 (25 days)	3, 55
<i>N. barbatulus</i>	3500	LC50 (96 h)	55
Loach, <i>Noemacheilus</i> sp.	25,000	LC50 (96 h)	64
Cutthroat trout, <i>Oncorhynchus clarki</i>	61–600	LC50 (96 h)	1, 65
<i>O. clarki</i>	360	None dead in 14 days	66
<i>O. clarki</i>	670	LC50 (14 days)	3, 66
Coho salmon, <i>Oncorhynchus kisutch</i>			
Water hardness <50 mg CaCO ₃ /L	280	LC50 (96 h)	3
Juveniles	500–10,700	Decreased white blood cell count in 24 h	3
0.5–0.9 g body weight	820–1810	LC50 (96 h)	67
Rainbow trout, <i>Oncorhynchus mykiss</i>			
Immatures	5.6	Avoidance, 10 to 20 min tests	1, 2
Larvae and alevins	10	LC54 (28 days)	3
Immatures	47	94% avoidance, 40-min tests	2
Early life stages	70–140	LC50 (25 days)	3
Juveniles	81	Hyperglycemia in 24 h	3
Fry	90–93	LC50 (96 h)	1, 2
Life cycle	140–547	MATC ^b	1, 2
Weight 0.6 grams	169	LC50 (96 h)	67
Juveniles	210–1120	Increased blood glucose in 7–63 days	3
Parr	240–830	LC50 (96 h) at 30 mg CaCO ₃ /L	1
Juveniles	310	LC 20 (14 days)	66
Immatures	352	Hyperglycemia in 9 days	2
Larvae and alevins	400–2800	LC50 (120 h)	3
Juveniles	410	LC50 (14 days)	66
Juveniles	430	LC59 (96 h) at 26 mg CaCO ₃ /L	3
Juveniles	520	LC50 (96 h) at 47 mg CaCO ₃ /L	3
Fry	689	LC50 (96 h)	2
Juveniles	690	Increased respiration in 24 h	3
Immatures	1030	LC50 (96 h) value for group acclimatized to 80 µg Zn/L for 28 days (vs. 469 µg Zn/L for controls)	68
Adults	1120	Reduced growth in 85 days	3

Table 9.6 (continued) Effects of Zinc on Representative Aquatic Plants and Animals (Concentrations are in micrograms of zinc per liter of medium.)

Taxonomic Group, Organism, and Other Variables	Concentration (ppb)	Effects	Reference ^a
Parr	1190–4520	LC50 (96 h) at 350 mg CaCO ₃ /L	1
Juveniles	2960	LC50 (96 h) at 179 mg CaCO ₃ /L	3
Parr	4700	LC50 (96 h) at 500 mg CaCO ₃ /L	1
Juveniles	4800–7200	LC50 (96 h) at 333–504 mg CaCO ₃ /L	3
Fry	10,000	16% dead in 90 h vs. none dead in group pretreated with 5 mg Zn/L for 96 h	69
Fry	15,000	79% dead in 90 h vs. 20% dead in group pretreated with 5 mg Zn/L for 96 h	69
Sockeye salmon, <i>Oncorhynchus nerka</i>			
Embryo through smolt	242	No measurable effects in 18-month exposure	1
Immatures	447	LC50 (115 h)	1
Immatures	750	LC50 (96 h)	3
Chinook salmon, <i>Oncorhynchus tshawytscha</i>			
Swim up	97	LC50 (96 h)	1
Chronic exposure	270–510	MATC ^b	1, 2
Smolts	446	LC50 (96 h)	2
Minnow, <i>Phoxinus phoxinus</i>			
Yearlings	50–130	Reduced growth during exposure for 150 days; no deaths	70
Larvae	60	Decreased swimming ability after exposure for 108 days	3
Larvae	80	LC37 (40 days)	3
Adults	130	Reduced growth during 150-day exposure; some deaths	70
Juveniles	160	Decreased swimming ability after 109 days	3
Adults	200	Decreased swimming ability after 100 days	3
Adults	200	Reduced growth during 30-day exposure; some deaths	70
Adults	250	LC50 (150 days)	3
Fathead minnow, <i>Pimephales promelas</i>			
Life cycle	78–145	MATC ^b	1, 2
Juveniles	125	Reduced growth in 7 days	2
Larvae	152–294	LC84 (8 weeks)	3
Adults	180	65 to 83% reduction in fecundity in 10-month exposure	1, 2
Adults	480	Reduced growth in 30 days	3
Embryo/larvae	500–1400	50% developmental malformations in 96 h	71
Larvae	600	LC50 (96 h)	3
Adults	600	Preexposure for 14 days increased resistance 28% over controls in 96-h zinc toxicity assays	72
Adults	800	LC50 (30 days)	3
Adults	870	LC50 (96 h) at 20 mg CaCO ₃ /L	3
Adults	1800	Exposure for 7 days decreased tolerance 63% in 96-h Zn toxicity assays; tolerance decreased 74% after exposure for 14 days	72

Table 9.6 (continued) Effects of Zinc on Representative Aquatic Plants and Animals (Concentrations are in micrograms of zinc per liter of medium.)

Taxonomic Group, Organism, and Other Variables	Concentration (ppb)	Effects	Reference ^a
Adults	2800	LC 15 (10 months), no eggs deposited	73
Embryo/larvae	3600	LC50 (6 days)	71
Adults	4700–6100	LC50 (96 h) at 50 mg CaCO ₃ /L	3
Adults	6400–10,900	LC50 (96 h) at 100 mg CaCO ₃ /L	3
Adults	7100	LC50 (96 h) at 166 mg CaCO ₃ /L	3
Adults	8200–21,000	LC50 (96 h) at 200 mg CaCO ₃ /L	3
Adults	33,400	LC50 (96 h) at 360 mg CaCO ₃ /L	3
Guppy, <i>Poecilia reticulata</i>			
Age 5 days	125	After 134 days, whole body Zn content of 0.6 mg/kg DW vs. 0.3 in controls; growth reduced	74
Adults	173	Whole body BCF of 466–965 in 30 days	2
Age 5 days	250	Delayed sexual maturation after 134 days	74
Age 5 days	500	Reproduction inhibited	74
Age 5 days	1350–1500	LC50 (96 h)	74
Adult males	4400–5700	LC50 (96 h)	74
Adult females	5600–7300	LC50 (96 h)	74
Atlantic salmon, <i>Salmo salar</i>			
Parr	50	50% avoidance in 4 h	2
Parr	100	Avoidance within 20 min	3
Immatures	100–500	LC50 (21 days)	1
Water hardness, in mg CaCO ₃ /L			
14	420	LC50 (96 h)	1
20	600	LC50 (96 h)	1
Brown trout, <i>Salmo trutta</i>			
Yolk-sac fry	4.9	40% with noncalcified vertebrae center; all dead in 18 days at pH 4.5 and soft water	75
Yolk-sac fry	9.8–19.6	60% to 75% dead in 20–30 days; 6% to 21% with abnormal vertebrae in pH 4.5 and soft water	75
Yearlings	<140	LC50 (96 h) at pH 8, 10 mg CaCO ₃ /L	76
Adults	570	LC 17 (14 days)	66
Adults	640	LC50 (14 days)	66
Yearlings	3200	LC50 (96 h) at pH 5, 204 mg CaCO ₃ /L	76
Brook trout, <i>Salvelinus fontinalis</i>			
Chronic exposure	534–1360	MATC ^b	1, 2
Adults	630	LC 17 (14 days)	66
Adults	960	LC50 (14 days)	3, 66
Cabezon, <i>Scorpaenichthys marmoratus</i> , larvae	192	LC50 (96 h)	2
Dogfish, <i>Scyliorhinus</i> sp., exposure for 25 days	15,000	No significant accumulations in kidney and muscle, but elevated levels (as judged by BCF values) in gill filament (1.6), spleen (1.7), pancreas (2.7), and liver (5.2)	77, 78
Arctic grayling, <i>Thymallus arcticus</i>			
Body weight 0.2–1.8 g	112–168	LC50 (96 h)	67
Fry	315	LC50 (96 h)	67
Alevins	1580–2920	LC50 (96 h)	67

Table 9.6 (continued) Effects of Zinc on Representative Aquatic Plants and Animals (Concentrations are in micrograms of zinc per liter of medium.)

Taxonomic Group, Organism, and Other Variables	Concentration (ppb)	Effects	Reference ^a
Tilapia, <i>Tilapia sparrmanii</i> , adults, exposure for 72 h	98,000	Decreased oxygen consumption, mucus precipitation on gills, histopathology of gill epithelium	79
Bolti, <i>Tilapia zilli</i>			
Adults	13,000	LC50 (96 h) at 25°C	52
Adults	21,000	LC50 (96 h) at 21°C; residues in survivors were 38,000 mg/kg DW vs. 70 in controls for gill; 23,000 vs. 50 for liver; and 2000 vs. 10 for muscle, blood, serum, and liver chemistry	52, 80
Adults	27,000	LC50 (96 h) at 15.3°C	52
Adults	33,000	LC50 (96 h) at 9.3°C	52
AMPHIBIANS			
Marbled salamander, <i>Ambystoma opacum</i> , embryos	2380	50% dead or deformed in 8 days	2
Narrow-mouthed toad, <i>Gastrophryne carolinensis</i> , embryos	10	50% dead or deformed in 7 days	2
Leapfrog, <i>Rana dalmatina</i> , larvae, exposed during formation of gonadal structures	9000	Toxic effect on larval gonad, especially on germ cells of ovarian structure	81
Columbia spotted frog, <i>Rana luteiventris</i> ; tadpoles	28,400	LC50 (96 h)	88
Newt, <i>Triturus cristatus</i> , adults, held in tank with a zinc-plated base	200 to 3000 over a 7-day period	Zinc-poisoned newts were lethargic, ate poorly, and had skin darkening prior to death. Zinc residues were elevated in kidney, brain, liver, and intestine, when compared to controls. The hippocampus region of the brain of poisoned newts contained zinc-rich cells	82
South African clawed frog, <i>Xenopus laevis</i>			
Embryos	>1500	At 96 h, some midgut malformations and pericardial edema	83
Embryos	2700	50% malformations in 96 h	83
Embryos	3600	50% developmental malformations in 6 days	71
Embryos	>4000	Severe edema of the pericardium and eye, gut miscoiling, head and mouth malformations. At high sublethal concentrations, severe skeletal kinking, microphthalmia, and microencephaly	83
Tadpoles, pretreated with 5 mg Zn/L for 96 h	15,000–20,000	At 15 mg/L, none died in pretreated group vs. 45% dead in controls at 90 h; at 20 mg/L, 15% died in pretreated group vs. 50% in untreated controls	69
Embryos	34,500	LC50 (96 h)	71, 83

^b MATC = Maximum acceptable toxicant concentration. Lower value in each MATC pair indicates highest concentration tested producing no measurable effect on growth, survival, reproduction, and metabolism during chronic exposure; higher value indicates lowest concentration tested producing a measurable effect.

Molluscs

Zinc was most toxic to representative molluscs at elevated temperatures (Eisler 1977a; Sprague 1986; Khangarot and Ray 1987), in comparatively soft water or, in the case of marine molluscs, low salinity (Sprague 1986; Khangarot and Ray 1987), at earlier developmental stages (Munzinger and Guarducci 1988), at low dissolved oxygen concentrations (Khangarot and Ray 1987), and with increasing exposure to high zinc concentrations (Amiard-Triquet et al. 1986).

High zinc accumulations in molluscs are usually linked to high levels of calcium in tissues, low ambient concentrations of iron or cobalt, exposure to organochlorine or organophosphorus insecticides, low salinity, elevated temperatures, increased particulate loadings in medium, increasing length of exposure to higher doses of zinc, increasing age of the organism, and, especially, proximity to heavily carbonized and industrialized areas (Eisler 1980). Radiozinc-65 was rapidly accumulated in southern quahog (*Mercenaria campechiensis*) over a 10-day period; accumulation in kidney was linear over time and was enhanced at elevated phosphate loadings in the medium (Miller et al. 1985). Large variations in daily zinc accumulation rates by marine bivalve molluscs are typical. For example, softshell clams (*Mya arenaria*) immersed in 500 µg Zn/L at 16 to 22°C had daily accumulation rates, in mg/kg FW soft parts, of 2 on the first day of exposure, 7.7 between days 1 and 7, and 3.3 between days 7 and 14. At a lower temperature regimen of 0 to 10°C, immersion in 500 µg/L produced daily accumulation rates of 9.9 mg/kg FW soft parts for the first 42 days, but clams lost zinc at a rate of 0.24 mg/kg daily between days 42 and 112 (Eisler 1981). At 2500 µg/L and 16 to 22°C, daily accumulation rates in surviving *Mya* were 32.0 mg Zn/kg FW soft parts on the first day of exposure, and 11.7 between days 1 and 7. Changes in accumulation rates of zinc by *Mya* reflect, at least partially, complex interactions between water temperature, ambient zinc concentrations, duration and season of exposure, and physiological saturation and detoxification mechanisms (Eisler 1977a, 1977b).

The half-time persistence (T_b 1/2) of zinc in whole molluscs is extremely variable, and reported to range from 4 days in the common mussel (*Mytilus edulis*) to 650 days in the duck mussel (*Anodonta nuttalliana*); intermediate values were 23 to 40 days in limpet (*Littorina irrorata*), 76 days in the California mussel (*Mytilus californianus*), and 300 days in the Pacific oyster (NAS 1979). Zinc persistence in selected organs also shows considerable variability and may be significantly different from T_b 1/2 values seen in whole animal. For example, the T_b 1/2 of zinc in

Mytilus edulis kidney was estimated at 2 to 3 months (Lobel and Marshall 1988) vs. 4 days for whole animal (NAS 1979).

Mytilus edulis has been used extensively as a model for molluscan zinc kinetics. Results of selected studies follow. In mussels, zinc is taken up by the digestive gland, gills, and mantle and rapidly transported via hemolymph to kidney where it is stored in insoluble granules (Lobel and Marshall 1988). There is a high degree of variability in soft tissues of *M. edulis* due entirely to an unusually high degree of variability in kidney zinc of 97 to 7864 mg/kg DW (Lobel 1987). This variability in kidney zinc content is due largely to a low-molecular-weight zinc complex (MW 700 to 1300), that showed a high degree of variability and a positive correlation with kidney zinc concentration (Lobel and Marshall 1988). However, at low ambient concentrations of 50 µg Zn/L, the most sensitive bioindicators of zinc exposure were gills and labial palps (Amiard-Triquet et al. 1986). Food composition had little effect on tissue distribution of radiozinc-65 in mussels as judged by 5-day feeding studies of radiolabeled diatoms (*Thalassiosira pseudonana*), green alga (*Dunaliella tertiolecta*), glass beads, and egg albumin particles (Fisher and Teyssie 1986). Soft part BCF values ranged between 12 and 35 times and was probably due to a rapid desorption of radiozinc from the food particles into the acidic gut, followed by binding to specific ligands or molecules. The Tb 1/2 in mussel soft parts ranged from 42 to 80 days for all food items — including glass beads — and about 20 days in shell (Fisher and Teyssie 1986; Wang et al. 1996). Zinc concentrations in mussels are proportionately related to zinc loadings in the water column and the assimilation efficiency from ingested particles, which in *Mytilus edulis* ranges from 32 to 41% (Wang et al. 1996). Elevated temperatures in the range 10 to 25°C were associated with increased uptake rates of zinc from seawater by mussels (Watkins and Simkiss 1988). If the temperature is oscillated through this range over a 6-hour period, there is a further enhancement of zinc uptake. This effect parallels decreases in zinc content of cytosol fractions and increases in granular fractions (Watkins and Simkiss 1988). Mussels were more sensitive to zinc than were other bivalve molluscs tested. The pumping rate of mussels completely stopped for up to 7 h on exposure to 470 to 860 µg Zn/L; however, other bivalves tested showed only a 50% reduction in filtration rates in the range 750 to 2000 µg Zn/L (Redpath and Davenport 1988). *Mytilus edulis* accumulates zinc under natural conditions, but under some conditions does not depurate (Luten et al. 1986). This conclusion was based on results of a study wherein mussels were transferred from a pristine environment in the Netherlands to a polluted estuary for 70 days, then back again for 77 days. At the start, zinc concentration was 106 mg/kg DW soft parts. By day 70, it had risen to 265 mg/kg DW, at a linear daily uptake of 0.47 mg/kg, but mussels contained 248 mg/kg DW on day 147, indicating that elimination was negligible (Luten et al. 1986). In another study, zinc depressed sperm motility through respiratory inhibition at 6.5 mg/L, a concentration much higher than those normally found environmentally (Earnshaw et al. 1986). In mussel spermatozoa, zinc caused reductions of bound calcium and phosphorus in both acrosomes and mitochondria, suggesting increased permeability of organelle membranes to both elements (Earnshaw et al. 1986).

Arthropods

Arthropods were the most zinc-sensitive group of invertebrates tested (Table 9.6). Toxicity was usually greatest to marine crustaceans (Eisler 1981), to larvae (Eisler 1980), at elevated temperatures (Spear 1981; Sprague 1986; McLusky and Hagerman 1987), during extended exposures (USEPA 1980, 1987), in soft water (Winner and Gauss 1986; Paulauskis and Winner 1988), under conditions of starvation (NAS 1979; Verriopoulos and Moraitou-Apostolopoulou 1989), at salinity extremes above and below the isosmotic point (McLusky and Hagerman 1987), in summer (Eisler 1980), at low concentrations of humic acid (Winner and Gauss 1986; Paulauskis and Winner 1988), in proximity to anthropogenic discharges (Eisler 1980), and at low sediment particulate loadings (Memmert 1987). Acquired zinc tolerance is reported in amphipods collected from zinc-contaminated

sewage wastes (Johnson and Jones 1989) and in fiddler crabs (*Uca* spp.) from a metals-contaminated area. *Uca* from zinc-contaminated areas were more resistant to zinc than were crabs from pristine areas, as judged by increased survival and lower tissue zinc concentrations (Devi 1987; Devi and Rao 1989, 1989a). More research seems warranted on acquired zinc tolerance.

Adverse effects of zinc insult to crustaceans include gill histopathology in prawns, *Macrobrachium hendersdyanum* (Patel and Kaliwal 1989); increased tissue total proteins, decreased glycogen, and decreased acid phosphatase activity in crabs, *Portunus pelagicus* (Hilmy et al. 1988); retardation of limb regeneration of fiddler crab, *Uca pugilator* (Weis 1980); and elevated tissue residues in American lobster, *Homarus americanus* (Waiwood et al. 1987). For example, tissue zinc residues in *Homarus americanus* exposed for 4 days to 25 mg Zn/L were especially high in gill (2570 mg Zn/kg DW vs. 126 at start), hepatopancreas (734 vs. 135), and green gland (1032 vs. 148). After 7 days in uncontaminated media, tissue zinc residues remained elevated in gill (675 mg Zn/kg DW), hepatopancreas (603), green gland (286), and other tissues (Waiwood et al. 1987). Zinc concentrations in crustacean soft tissues usually range between 50 and 208 mg/kg DW, and exceed soft tissue zinc enzymatic requirements by factors of 1.4 to 6.0 (Depledge 1989).

Half-time persistence of zinc in the prawn (*Palaemon elegans*) is about 17 days (Nugegoda and Rainbow 1988b), and between 30 and 270 days for five other crustacean species (NAS 1979). Differences in half-time persistence are linked to differences in excretion rates of ionic zinc and complexed zinc. In general, ionic zinc in crustaceans is excreted first, then complexed zinc; surface-adsorbed zinc is turned over faster than internally adsorbed zinc; molting accounts for 33 to 50% loss of the total body burden in crabs (Eisler 1981).

Crustaceans can accumulate zinc from both water and food (USEPA 1987). In uncontaminated waters, the diet is probably the major source of zinc. Absorption from the stomach is efficient and occurs, in part, via the hepatopancreas. When a large pulse of zinc reaches the blood from the stomach, some is excreted, but much is resorbed and stored in the hepatopancreas in a relatively nonlabile form. Ultimately, stored zinc is also excreted, although removal via the gut is unimportant (Bryan et al. 1986). Zinc absorption occurs initially at the gill surface, followed by transport on a saturable carrier in the cell wall, and is most efficient at low dissolved ambient zinc concentrations. Urinary excretion is an important body removal pathway, especially at high dissolved ambient concentrations when it can account for 70 to 80% of total zinc excretion (Bryan et al. 1986).

Barnacles (*Elminius modestus*) usually accumulate zinc to high body concentrations with no significant excretion. Barnacle detoxification mechanisms of the stored zinc includes production of metabolically inert zinc phosphate granules (Rainbow and White 1989). However, *Elminius modestus* transplanted from an area of high ambient zinc (101 µg/L) to a low ambient zinc (4 µg/L) environment lost zinc slowly (0.3% body burden daily) over an 11-week period. Whole-body zinc burdens declined from 1554 mg/kg DW to 125 mg/kg DW, or about 4.1 mg/kg DW daily (Thomas and Ritz 1986). In the case of *Balanus balanoides*, another barnacle, high BCF values were attributed to inorganic granules that contained up to 38% zinc and accumulated in tissues surrounding the midgut (Eisler 1980).

Crustaceans — and other groups — can regulate body concentration of zinc against fluctuations in intake, although the ways in which regulation is achieved vary among species (Bryan et al. 1986). Regulation of whole body zinc to a constant level is reported for many crustaceans, including intertidal prawns (*Palaemon* spp.), sublittoral prawns (*Pandalus montagui*), green crab (*Carcinus maenus*), lobster (*Homarus gammarus*), amphipods (*Gammarus duebeni*), isopods (*Asellus communis*), and crayfish (*Austropotamobius pallipes*) (Devineau and Amiard-Triquet 1985; Bryan et al. 1986; Lewis and McIntosh 1986; Nugegoda and Rainbow 1988b; Johnson and Jones 1989; Rainbow and White 1989). The body zinc concentration at which zinc is regulated in crustaceans usually increases with temperature, salinity, molting frequency, bioavailability of the uncomplexed free metal ions, and chelators in the medium (Nugegoda and Rainbow 1987, 1988a, 1989a, 1989b). Lobsters (*Homarus gammarus*) are able to equilibrate over a 30-day period with seawater containing

between 2 and 505 µg/L. In response to a 100-fold rise in seawater concentrations (from 5 to 500 µg/L), zinc levels in whole body, blood, hepatopancreas, excretory organs, and gills approximately doubled but changed little in muscle. Shell zinc concentrations increased about 12 times, largely through adsorption (Bryan et al. 1986). Regulation of zinc in lobster blood is achieved by balancing uptake through the gills against urinary excretion and loss over the body surface including the gills (Bryan et al. 1986). The sublittoral prawn, *Pandalus montagui*, can regulate total body zinc concentration to a constant level (75 mg/kg DW) in dissolved zinc concentrations up to 22 µg/L, beyond which there is net accumulation of body zinc. This threshold of zinc regulation breakdown is lower than that in *Palaemon elegans* (93 µg Zn/L) and *Palaemonetes varians* (190 µg Zn/L) under the same physicochemical conditions (Nugegoda and Rainbow 1987; 1988a, 1988b, 1989a, 1989b, 1989c; Rainbow and White 1989). The authors conclude that regulation of body zinc concentration is most efficient in decapods adapted to the fluctuating environments of littoral habitats, possibly as a result of changes in permeability of uptake surfaces in combination with improved zinc excretion systems.

Freshwater crayfish (*Orconectes virilis*) are among the more resistant crustaceans (LC50 value of 84 mg Zn/L in two weeks), and can easily tolerate the recommended water-quality criteria of 50 to 180 µg/L; nevertheless, some streams in Arkansas and Colorado contain 79 to 99 mg Zn/L (Mirenda 1986). *Orconectes virilis* exposed to very high sublethal ambient zinc concentrations of 63 mg/L for 2 weeks show whole-body BCF values of only 2; a similar pattern was observed at other concentrations tested. In all cases, zinc tended to concentrate in gill and hepatopancreas at the expense of muscle, carapace, and intestine (Mirenda 1986). In freshwater crayfish (*Procambarus acutus*), the major uptake route was the ambient medium when compared to diet, although retention time was greater for dietary zinc (Giesy et al. 1980). When dietary zinc was the only zinc source, crayfish rapidly reached a steady state; when water was the only zinc source, crayfish did not reach a steady state (Giesy et al. 1980). Freshwater mysidaceans and their particulate wastes may play an important role in zinc cycling. The freshwater opossum shrimp (*Mysis relicta*) feeding on sediments ingested two to four times more zinc than did mysids feeding on zooplankton. However, sediment-feeding mysids excreted three to five times more zinc than did zooplankton consumers; zinc concentrations in fecal pellets of sediment feeders were up to 24 times higher than in food (Van Duyn-Henderson and Lasenby 1986). In the freshwater crayfish, *Austropotamobius pallipes*, fecal excretion is a major zinc removal pathway; a similar case is made for green crab (*Carcinus maenus*; Bryan et al. 1986). Marine copepods (*Anomalocera*, *Acartia*, *Temora*) excreted 52% of the ingested zinc in fecal pellets that subsequently leached all zinc to seawater within 24 h (Fisher et al. 1991).

Freshwater insects, including many species of mayflies, damselflies, stoneflies, and caddisflies, are relatively tolerant to zinc, with LC50 values usually >1.33 mg/L — although some species were adversely affected at concentrations between 30 and 37 µg Zn/L (USEPA 1987; Table 9.6). Mayfly (*Epeorus latifolium*) larvae were adversely affected at ambient water concentrations of 30 µg Zn/L, but could tolerate dietary loadings of 600 mg Zn/kg DW ration without measurable effects on growth or emergence (Hatakeyama 1989). Chironomid insect populations were reduced or missing immediately downstream from coal mine drainage containing 5 to 10 mg Zn/L. Populations further downstream recovered numerically, but diversity was reduced when compared to upstream communities (Wilson 1988).

Annelids

Populations of freshwater oligochaetes and leeches were reduced in numbers of individuals and numbers of taxa in mine tailing effluents containing 146 to 213 µg Zn/L or sediments containing >20 g Zn/kg DW (Willis 1985b). Leeches (*Erpobdella octoculata*) experienced a reduction in density and reproductive capacity in streams containing 25 to 310 µg Zn/L from mine wastes and did not avoid these harmful concentrations (Willis 1989).

The highest rate of net zinc absorption reported for any group of invertebrates was 2230 mg Zn/kg BW daily in sandworms (*Nereis diversicolor*) from sediments with low zinc levels during exposure for 34 days in 250 mg Zn/L. At 10 mg Zn/L, the rate decreased to 55 mg Zn/kg BW daily (Eisler 1981). Zinc uptake in *Nereis* increased with increasing sediment zinc levels, at lower salinities (Eisler 1980) and elevated temperatures (Fernandez and Jones 1987, 1989). Zinc had no significant effect on burrowing behavior of *Nereis*, even at acutely lethal concentrations (Fernandez and Jones 1987). Sandworms from zinc-contaminated sediments were more resistant to waterborne zinc insult by 10 to 100 times than those from clean sediments (USEPA 1987). Tolerance to zinc in sandworms may be a result of acclimatization or genetic adaptation. In either event, the degree of metal tolerance decreases rapidly as the level of zinc contamination declines, suggesting that some zinc-tolerant worms may be competitively inferior to normal individuals in clean environments (Grant et al. 1989). More research on zinc-tolerant populations seems merited.

Unlike other major groups of marine benthic organisms, the polychaete *Neanthes arenaceodentata* has a limited capacity to regulate zinc (Mason et al. 1988). Uptake in *Neanthes* occurs from the free ionic pool of zinc, whereas EDTA and EDTA-zinc complexes are largely excluded. Zinc accumulates linearly over time (350 h), and the rate decreases with increasing temperature in the range 4 to 21°C. Mason et al. (1988) conclude that uptake and accumulation of zinc is passive in *Neanthes* and does not require metabolic energy. Zinc transfer across the plasma membrane is by way of diffusion. Within the cell, zinc binds to a variety of existing ligands which maintain an inwardly directed diffusion gradient, preventing zinc efflux. Accumulation rate is determined by the number and binding characteristics of the available ligands and their accessibility to zinc. After 50 h of exposure, worms selectively accumulate zinc over cadmium from the medium by a process requiring metabolic energy, and this is attributed to a change in the turnover rate and to the size and nature of the pool of zinc-binding ligands (Mason et al. 1988).

Echinoderms

In echinoderms, zinc concentrations are usually higher in detrital feeders than in carnivores, higher in surface feeders than in sediment feeders, and higher in specimens collected inshore than those collected offshore in deeper waters (Eisler 1980). Sea cucumbers, *Stichopus tremulus*, accumulate radiozinc-65 from seawater by a factor of 1400; however, radiozinc accumulation data should be viewed with caution because addition of stable zinc can reduce zinc-65 accumulations in echinoderm viscera up to tenfold (Eisler 1981). Zinc inhibits the formation of the fertilization membrane in sea urchin eggs, possibly by interfering with cortical granule-derived proteases and proteins (Nakamura et al. 1989).

Fish

Several trends are evident from Table 9.6: (1) freshwater fishes are more sensitive to zinc than marine species; (2) embryos and larvae are the most sensitive developmental stages; (3) lethal and sublethal effects occur in the range 50 to 235 µg Zn/L for most species, and 4.9 to 9.8 µg Zn/L for brown trout (*Salmo trutta*); and (4) behavioral modifications, such as avoidance, occur at concentrations as low as 5.6 µg Zn/L.

Signs of zinc poisoning in fish included hyperactivity followed by sluggishness. Prior to death, fish swam at the surface, were lethargic and uncoordinated, showed hemorrhaging at the gills and base of the fins, shed scales, and had extensive body and gill mucus (Bengeri and Patil 1986). Zinc is most toxic to yearlings of brown trout in soft water at pH 4 to 6 and pH 8 to 9; toxicity at alkaline pH is attributed to the formation of $ZnOH^+$, $Zn(OH)_2$, and $ZnCO_3$ in both hard and soft water — suggesting increased entrapment of metal precipitates within mucous and epithelial layers of the gill (Everall et al. 1989). Acute zinc poisoning in fish is generally attributed to blockade of gas exchange across the gills, causing hypoxia at the tissue level. Tissue hypoxia in fish is a major

physiological change before death once the gas exchange process at the gills is no longer sufficient to meet its oxygen requirements (Burton et al. 1972; NAS 1979; Everall et al. 1989b; Grobler et al. 1989). Cardiorespiratory responses to zinc in the spangled perch (*Leiopotherapon unicolor*) are similar to those induced by hypoxia; zinc-poisoned perch had damaged gill epithelia, resulting in impaired gas exchange and lowered oxygen tension in arterial blood (Gehrke 1988). Acute exposures to high lethal concentrations of zinc also caused histopathology of epithelia lining the oral cavity (Eisler and Gardner 1973).

Many factors modify the lethal properties of zinc in fish. Zinc is more toxic under conditions of comparatively low dissolved oxygen concentrations, high sodium concentrations, decreased loadings of organic complexing agents (Spear 1981), and low pH (NAS 1979). In guppies (*Poecilia reticulata*), females were more resistant than males to acute zinc insult; adults of both sexes were more resistant than were 5-day-old fry (Pierson 1981). Dominant bluegills (*Lepomis macrochirus*) survived exposure to 32 mg Zn/L longer than did submissive fish (NAS 1979). Water temperature is also an important modifier, and it is generally agreed that zinc is more toxic at elevated temperatures (NAS 1979; Spear 1981; Hilmy et al. 1987), provided that acclimatization temperature is considered. For example, cold-acclimatized (3°C) Atlantic salmon (*Salmo salar*) survived longer than warm-acclimatized (19°C) salmon when exposed to lethal concentrations of zinc at their respective acclimatization temperatures. However, at test temperatures lower than their prior acclimatization temperatures, salmon were less tolerant of zinc (Hodson and Sprague 1975). Fish surviving high sublethal concentrations of zinc had significant alterations in blood and serum chemistry, liver enzyme activity (Hilmy et al. 1987a), and muscle glycogen, total lipids, phospholipids, cholesterol, RNA, and proteins (Taneja et al. 1988).

Reproductive impairment seems to be one of the more sensitive indicators of zinc stress in freshwater teleosts, with effects evident in the range 50 to 340 µg Zn/L (Spear 1981). In some cases, reproduction was almost totally inhibited at zinc concentrations that had no effect on survival, growth, or maturation of these same fish (Brungs 1969). Zinc-induced developmental abnormalities were documented in marine teleosts, but concentrations tested were grossly elevated. Eggs of the Baltic herring (*Clupea harengus*), for example, exposed to >6 mg Zn/L have an altered rate of development and produce deformed larvae with cellular disruptions in the brain, muscle, and epidermis (Somasundaram 1985; Somasundaram et al. 1985).

Avoidance tests with fathead minnows (*Pimephales promelas*) show that almost all fatheads, except males with established territories, will avoid 284 µg Zn/L when given a choice; however, avoidance thresholds were 6.4 times higher for established males (Korver and Sprague 1989).

Limited tolerance to zinc was observed in freshwater fishes preexposed to sublethal levels of zinc (Spear 1981; Heath 1987; Woodall et al. 1988; Anadu et al. 1989; Hobson and Birge 1989). In one case, rainbow trout acclimatized to 50 µg Zn/L for 21 days were up to five times more tolerant to subsequent zinc exposures than were nonacclimatized trout. This was not evident at 100 µg Zn/L; also, acclimatization to zinc produced tolerances to copper and cadmium in trout (Anadu et al. 1989). The mechanisms to account for this phenomenon are unknown, but several theories are proposed: increased metallothionein synthesis (Woodall et al. 1988), although this is disputed by Hobson and Birge (1989); high mortality during preexposure may have caused the selection of more zinc-tolerant individuals (Spear 1981); and tolerance may be limited to strains capable of increased zinc excretion, although no evidence now exists linking genetic mechanisms to zinc resistance (Spear 1981).

The half-time persistence (T_b 1/2) of zinc in whole mosquitofish (*Gambusia affinis*) was estimated at 215 days (Newman and Mitz 1988). The half-time persistence of zinc in whole marine fishes ranged from 35 to 75 days in mummichog (*Fundulus heteroclitus*) to 295 to 313 days in a flatfish (*Pleuronectes platessa*); T_b 1/2 in mummichog was shortest at 30°C, longest at 10°C, and intermediate at 20°C (NAS 1979).

Fish can accumulate zinc from both the surrounding medium and from their diet (USEPA 1987). The freshwater zebra danio (*Brachydanio rerio*) accumulated zinc from the medium, but there was

no additional zinc enrichment from a *Daphnia* diet (Memmert 1987). In marine fishes, however, diet was considered to be the major route of zinc intake, and significantly more important than water zinc levels (Eisler 1980).

In freshwater fishes, bioconcentration factors for whole individuals range between 51 and 500 times (USEPA 1987), but are strongly influenced by dose, duration of exposure, water chemistry, and other variables. In mosquitofish, uptake rate from water and zinc elimination rate decreased with increasing age of the fish (Newman and Mitz 1988). In three-spined stickleback (*Gasterosteus aculeatus*), uptake was greater in hard water than in soft water and higher in larger fish, suggesting a surface adsorption mechanism (Matthiessen and Brafield 1977). In brown trout, however, uptake was lower and excretion greater in hardwater of 220 mg CaCO₃/L than in soft water of 9 mg CaCO₃/L, thereby reducing tissue burdens (Everall et al. 1989b). Starved rainbow trout accumulated zinc more rapidly than did fed fish, due to an increased contribution of waterborne zinc to total body zinc levels (Handy and Eddy 1990). Rapidly growing chinook salmon (*Oncorhynchus tshawytscha*) fingerlings removed radiozinc-65 from the medium and retained nearly all of it for 63 days after transfer to uncontaminated media. Most of the zinc-65 was translocated to vertebral column, head, and visceral mass (Joyner and Eisler 1961). The outer surface of the bone seems to be an ion exchange medium capable of taking up large quantities of metal ions whether natural or foreign to the system. Metals thus exchanged from serum proteins may be prevented from undergoing further exchange by the overlaying action of growing bone (Joyner and Eisler 1961). Channel catfish (*Ictalurus punctatus*) fingerlings fed diets containing up to 200 mg Zn/kg FW ration for 12 weeks had elevated bone zinc levels (359 mg/kg DW vs. 254 in controls) and reduced hematocrit, but survival and feed conversion efficiency was the same as in controls (Gatlin et al. 1989). Plasma zinc levels in four species of freshwater fishes consuming diets containing 100 to 200 mg Zn/kg ration ranged between 9.3 and 15.1 mg Zn/L FW; in rainbow trout, zinc tended to concentrate in the erythrocyte membrane (Bettger et al. 1987).

In marine fishes, zinc residues were usually higher in dead fish than in live or moribund animals, higher in smaller fish, higher in liver and viscera, and higher with decreasing water cadmium levels (Eisler 1980). Uptake from the medium by adult mummichogs was inversely related to zinc concentration in the water (USEPA 1987). In mummichogs, zinc accumulates in scales during exposure to 10 mg Zn/L, significantly elevating the zinc:calcium ratio; ratios remained elevated for at least 4 months after transfer to low zinc media, and this phenomenon might have application for environmental monitoring (Sauer and Watabe 1989a). Scale osteoblasts of zinc-exposed mummichogs showed an increase in the number of lysosome-like structures contained by cytoplasm, and suggests that osteoblast lysosomes are involved in zinc accumulation in fish scales via enzymatic degradation of metallothioneins or other metal-binding proteins (Sauer and Watabe 1989). Dietary zinc is not well assimilated in marine flatfish. Turbot (*Scophthalmus maximus*) fed diets containing 100 (control) or 1000 mg Zn/kg DW for 200 days were not different in renal and hepatic metallothionein levels, or in zinc concentrations in liver, kidney, muscle, skin, or bone; a similar case is made for other marine flatfish (Overnell et al. 1988). However, turbot injected intraperitoneally (2 mg Zn/kg BW) had an 18-fold increase in liver metallothionein content, and a threefold increase in liver zinc, confirming the ability of this species to synthesize metallothionein rapidly to a high concentration (Overnell et al. 1988).

Amphibians

Amphibian embryos are more sensitive to zinc than older stages; developmental abnormalities were evident in most species at concentrations >1.5 mg Zn/L (Table 9.6). Embryos of the narrow-mouthed toad (*Gastrophryne carolinensis*) seem to be especially sensitive, with adverse effects reported at 10 µg Zn/L (USEPA 1987), but this requires verification. Amphibians, along with other taxonomic groups, were rare or absent in the vicinity of zinc smelters when compared to more distant sites (Beyer et al. 1985).

In tests with isolated skin of frogs (*Rana* spp.), Zn^{2+} stimulates sodium transport and inhibits chloride-related tissue conductance; however, skin of toads (*Bufo* spp.) is relatively insensitive to zinc (Nagel et al. 1988). In early stages of embryonic development, Zn^{2+} stimulates multiplication of germ cells, but long-term treatment with $ZnSO_4$ has a toxic effect upon the larval gonad and especially on the germ cells of the ovarian structure that is developed in frog larvae (Gipouloux et al. 1986).

9.7.4 Birds

Ducks (*Anas* spp.) had reduced survival when fed diets containing 2500 to 3000 mg Zn/kg ration or when force-fed zinc metal shot equivalent to 742 mg Zn/kg BW (Table 9.7). Domestic chickens (*Gallus* sp.) were more resistant: 8000 mg Zn/kg ration was fatal to chicks, although higher doses were routinely fed to laying hens to induce molting; 2000 to 3000 mg Zn/kg ration inhibited chick growth; 178 mg Zn/kg feed caused immunosuppression in chicks; and dietary concentrations as low as 100 mg Zn/kg caused pancreas histopathology in chicks under conditions of selenium deficiency (Table 9.7). Excessive zinc (2000 mg/kg diet for 21 days) fed to chicks (*Gallus* sp.) caused zinc accumulations in tissues, reduced tissue turnover of zinc, reduced liver turnover of iron, and reduced copper content in liver and pancreas, and of iron in tibia (Stahl et al. 1989b). However, hens were less sensitive and when fed diets containing 2000 mg Zn/kg for 44 weeks produced chicks that had no apparent alteration in tissue zinc, copper, or iron metabolism (Stahl et al. 1990).

Zinc-poisoned mallards (*Anas platyrhynchos*) force fed zinc shot pellets developed ataxia, paresis, and total loss of muscular control in their legs, including the ability to swim (Wobeser 1981). The muscular weakness associated with zinc intoxication would probably make ducks highly susceptible to predation and argues against the use of zinc shot as a substitute for lead shot (Grandy et al. 1968). Mallards fed 3000 mg Zn/kg DW ration for 60 days had diarrhea after 15 days, leg paralysis in 20 days, high mortality after 30 days, and zinc residues at day 60 that were 14 times higher in pancreas than in controls, 7 times higher in liver, 15 times higher in kidney, and 2 to 4 times higher in adrenals, muscle, testes, and ovary (Gasaway and Buss 1972).

In Australia, almost all aviary birds are held in cages made of galvanized wire mesh, resulting in sporadic cases of “new wire disease” caused by the ingestion of galvanized metal used in cage construction. In one case, peach-faced lovebirds (*Agapornis roseicollis*) died within 5 weeks of being placed in a newly erected wire cage; dead birds had elevated liver zinc concentrations of 75 to 156 mg/kg DW vs. normal values of 21 to 33 mg/kg DW (Reece et al. 1986). Zinc poisoning in a captive Nicobar pigeon (*Caloenas nicobarica*) was attributed to plated zinc metal fragments found in the gizzard — presumably ingested from the galvanized cage bars. In addition to elevated tissue zinc concentrations, this pigeon had a swollen liver and kidneys, and extensive kidney histopathology (Zee et al. 1985). A zinc-poisoned blue and gold macaw (*Ara ararauna*) showed weakness, ataxia, extreme thirst, diarrhea, cyanosis, and a plasma zinc concentration of 15.5 mg/L after ingesting galvanized hardware cloth that was 24% zinc by weight and 0.2% lead. The bird was treated with 35 mg/kg BW calcium versenate intramuscularly (im) and 30 mg thiamine hydrochloride kg BW/im; recovery following chelation therapy took 2 months, at which time plasma zinc was 0.6 to 0.8 mg/L vs. 1.3 to 2.0 mg/L for normal birds (Morris et al. 1986). New galvanized wire used in aviary construction should weather for 1 to 2 months, then be scrubbed with a mild acidic solution, such as vinegar, and rinsed; flakes of galvanized metal — which contain up to 2.4 g Zn/kg — should be removed before birds are put in cages (Reece et al. 1986). Zinc toxicosis was diagnosed in a gray-headed chachalaca (*Ortalis cinereiceps*) after it ingested a copper-plated zinc penny; necropsy showed pancreas histopathology and severe gizzard erosion; liver contained 1910 mg Zn/kg FW (Droual et al. 1991).

Zinc phosphide — a rodenticide — is relatively toxic when compared to elemental zinc or zinc oxide; most of the biocidal action is attributed to the phosphide fraction. Acute oral LD₅₀s for zinc

Table 9.7 Effects of Zinc on Representative Birds

Species, Dose, and Other Variables	Effects (reference)
Mallard, <i>Anas platyrhynchos</i>	
Fed diets containing 3000 mg Zn/kg feed, and higher, for 30 days	At 3000 mg/kg ration, ducks had leg paralysis and decreased food consumption; at >3000 mg/kg diet, many deaths occurred (NAS 1979).
Age 7 weeks. Fed diets containing 3000, 6000, 9000 or 12,000 mg Zn/kg dry weight (DW) diet for 60 days; zinc in form of zinc carbonate	Food intake reduced for all groups; the 9000 and 12,000 mg/kg groups had almost zero intake. High mortality after 30 days in all groups; only 17% of 3000 mg/kg group alive at day 60. Zinc residues, in mg/kg fresh weight (FW) at time of death or at day 60 for the 3000 mg/kg group were: 1252 in pancreas vs. 89 for controls; 401 vs. 54 in liver; 88 vs. 45 in adrenals; 413 vs. 27 in kidney; 32 v. 14 in muscle; 78 vs. 17 in testes; and 71 vs. 31 in ovary (Gasaway and Buss 1972).
Age one year. Single oral dose of five Number 6 zinc shot in gelatin capsules, equivalent to 0.40 g Zn or 495 mg Zn/kg body weight (BW)	All shot retained in gizzard after 14 days; no adverse effects after 28 days. Residues at 28 days, in mg/kg DW, were 217 in liver, 79 in kidney, and 126 in feather (French et al. 1987).
Drakes, 18 months old, force-fed eight Number 6 zinc shot pellets	By day 30 posttreatment, 20% had died. The mean weight loss was 33% in dead birds and 22% in survivors. About 83% of survivors developed signs of zinc poisoning (Grandy et al. 1968).
Age one year. Single oral dose of ten Number 6 zinc shot in gelatin capsules, equivalent to 0.80 g Zn or 990 mg Zn/kg BW	Two to 4 shot voided in first 48 h, but no further loss for 28 days. Residues, in mg Zn/kg DW, at 28 days were 211 in liver vs. 171 for control birds, 72 vs. 61 in kidney, and 143 vs. 128 in feather (French et al. 1987).
Pekin duck, <i>Anas platyrhynchos</i>	
3-day-old male white ducklings fed diet containing 2500 mg Zn/kg, as $\text{ZnSO}_4 \cdot \text{H}_2\text{O}$, for 56 days	Progressive ultrastructural degeneration of pancreatic acinar cells evident as early as day 5 (Kazacos and Van Vleet 1989).
Japanese quail, <i>Coturnix coturnix japonica</i>	
Intratesticular injection of 3% zinc chloride equivalent to 1 mg Zn/kg testes or 0.02 mg/kg BW	Testicular teratomas produced during a period of testicular growth stimulated by increased photoperiod (Guthrie 1971).
Hens fed diet containing 15,000 mg Zn/kg ration, as zinc oxide, for 7 days	Significant reduction in body weight, egg production approached zero at day 3, eggshell breaking strength reduced, molting induced (Hussein et al. 1988).
<i>Coturnix, Coturnix japonica</i>	
14-day-old quail fed diets containing various concentrations of zinc, as zinc phosphide (a rodenticide) for 5 days followed by 3 days of untreated fed.	At 600 mg Zn/kg ration, 7% died and all had reduced food intake. At 990 mg Zn/kg diet, 53% died; at 1634 mg/kg, 93% died (Hill and Camardese 1986).
Domestic chicken, <i>Gallus sp.</i>	
Developing embryos, 1-day-old, with 0.76 mg Zn/yolk at start, supplemented with 0.2, 0.4, or 0.6 mg zinc	Hepatic metallothionein levels increased by factors of 3.9 (0.2 mg), 4.7 (0.4 mg) and 7.1 (0.6 mg) (Fleet and McCormick 1988).
Femurs from 9-day-old chick embryos cultivated for 6 days at 3.26 mg Zn/L As above, 6.5 mg Zn/L	Inhibited calcium accumulations in bone and increased alkaline phosphatase activity of medium (Kaji et al. 1988). Decrease in calcified tissues (Kaji et al. 1988).
Domestic breeding hens fed diets containing 28, 38, 48, 68, 94, or 178 mg Zn/kg ration for up to 9 months	Progeny growth after 3 weeks was not affected by maternal zinc feeding levels. A minimum of 38 mg Zn/kg diet was considered necessary for minimal feather fraying and maximal immune response in chicks. Diets containing 178 mg Zn/kg may be excessive and cause immunosuppression of young progeny without affecting growth (Stahl et al. 1989a).

Table 9.7 (continued) Effects of Zinc on Representative Birds

Species, Dose, and Other Variables	Effects (reference)
Fed 28 (control), 48, 228, or 2028 mg Zn/kg diets for 12 or 44 weeks. Hens were 56-weeks old at start of short-term study and 24-weeks old at start of long-term study	Zinc treatments had no effect on overall egg production, feed conversion, feed consumption, hatchability, or progeny growth to age 3 weeks. Zinc was elevated in eggs from hens fed the 2000 mg/kg diet, but chick performance and tissue zinc content were unaffected by maternal zinc nutritional status (Stahl et al. 1990)
Chicks fed diets containing 37 (control), 100, or 2000 mg Zn/kg feed for 21 days	No accumulations in 100 mg/kg group; zinc excretion rate about twice that of controls. No deaths in 2000 mg/kg group, but growth rate was decreased, anemia evident, tissue copper and iron decreased, and tissue zinc increased (Stahl et al. 1989b).
Day-old chicks fed selenium-deficient diets plus 100 mg Zn/kg FW, as zinc oxide, purified ration for 9 days	Elevated zinc concentrations in pancreas, and pancreas histopathology (Lu and Combs 1988a).
Hens fed diets containing 218, 257, 1762, or 1861 mg Zn/kg diet for up to 40 weeks	Eggs from hens fed 218 or 257 mg Zn/kg diet containing a maximum of 14 mg/kg FW, equivalent to about 25% more zinc than eggs produced by control hens. Eggs from the two higher-dose diets had a maximum of 19 mg/kg FW or 57–90% more zinc than eggs produced by hens fed a control diet of 26–28 mg Zn/kg (Stahl et al. 1988).
9-day-old chicks fed purified diet containing 500 mg Zn/kg ration for 2 weeks	Plasma alpha-tocopherol reduced 64%; plasma and pancreas zinc concentrations elevated (Lu and Combs 1988b).
Day-old chicks fed selenium-adequate diet plus 2000 mg Zn/kg FW, as zinc oxide, nonpurified ration for 9 days	Negligible effects on pancreas zinc concentration and on pancreas exocrine function (Lu and Combs 1988a).
9-day-old chicks fed nonpurified diet containing 2000 mg Zn/kg ration for 30 days	No effect on plasma alpha-tocopherol or plasma and pancreas zinc content (Lu and Combs 1988b).
Chicks fed diets containing 2000 or 3000 mg Zn/kg ration for 30 days	Slight reduction in growth at 2000 mg/kg; significant growth reduction at 3000 mg/kg (NAS 1979).
Day-old chicks fed diets containing up to 4000 mg Zn/kg ration for 4 weeks	No effect on growth, survival, or feed conversion. Zinc accumulated in tissue metallothioneins, especially in liver and kidney; levels normal after 5 days on zinc-deficient diet (Oh et al. 1979).
Day-old chicks fed diets containing 4000, 8000 or 16,000 mg Zn/kg for 5 weeks	All dead at 16,000 mg/kg diet. The 8000 mg/kg group had 80% mortality; survivors had significantly reduced growth and feed conversion. At 4000 mg/kg, no significant effect on growth or survival; zinc concentrations elevated in kidney, liver, intestinal mucosa, and pancreas — but values normal after 10 days on basal diet (Oh et al. 1979).
Age 71 weeks, laying hens. Fed diet containing 10,000 mg Zn/kg feed for 2 days, then 5000 mg/kg diet for 4 days	Hens started to molt and ceased laying. Feed intake decreased about 90%. Zinc concentrations in pancreas increased 7-fold, in liver 6-fold, kidney 3-fold, and were elevated in shell gland and yolk. High Zn levels in kidney reflect high Zn excretion rates; high pancreatic Zn (410 mg Zn/kg FW) may suppress the release of insulin by calmodulin inhibition, and could account for the rapid cessation of lay (Verheyen et al. 1990).
White leghorns and brown layers were fed diets containing 10,000, 20,000, or 30,000 mg Zn/kg feed, as zinc oxide, for up to 3 weeks to induce molting	Cessation of egg laying in all treatments. On resumption of egg production, zinc levels in albumin or eggshell were not affected by the treatment or strain; Zn levels in yolk increased and depended on feed intake rather than dose. No increase in zinc content in eggs laid after egg production resumed, regardless of dose or duration of zinc treatment (Decuyper et al. 1988).
White leghorn laying pullets and hens fed diet containing 20,000 mg Zn/kg feed for 5 days	Reduced body weight on day 5, and significantly lowered egg production for 4 weeks. Eggs collected 14–28 days after the 5-day study period had reduced fertility and hatchability. Normal growth, egg production, fertility, and hatchability during weeks 4–12 posttreatment (Palafox and Ho-A 1980).
Laying hens fed diet containing 20,000 mg Zn/kg, as zinc oxide, for 4 days followed by 18 days on basal (35 mg Zn/kg) diet	At day 4, liver zinc concentrations increased 10-fold, kidney 3-fold, egg yolk 3-fold, and pancreas 25-fold; liver and kidney values returned to normal by day 22, but pancreas concentration (1673 mg/kg DW) remained elevated when compared to controls (88 mg/kg DW). At day 10, reduced weight of ovary and oviduct (Williams et al. 1989).
Turkey, <i>Meleagris gallopavo</i>	
Zinc concentration of sperm storage medium increased from 25 to 90 mg/L	Fertilizing ability of stored sperm significantly reduced (Blesbois and Mauger 1989).

phosphide ranged between 16 and 47 mg/kg BW for ring-necked pheasant (*Phasianus colchicus*), golden eagle (*Aquila chrysaetos*), mallard, and horned lark (*Eremophila alpestris*; Hudson et al. 1984). Signs of zinc phosphide poisoning include excessive drinking, regurgitation, muscular incoordination, appetite loss, sluggishness, rapid breathing, and eyelid droop. Signs appeared as soon as 15 min after dosing, and death usually occurred between 2 and 21 h; remission took up to 1 month (Hudson et al. 1984).

Large amounts of zinc are crucial for new feather growth. Zinc deficiency during this period results in stunted, frayed, easily broken feathers. Studies with the giant Canada goose (*Branta canadensis maxima*) show that zinc was released from the pectoralis muscle during molt-induced atrophy and used for growth of feathers and leg muscles during this period (Rosser and George 1986). High dietary levels of zinc are frequently fed to poultry to force molting and reduce egg deposition (Decuyper et al. 1988; Hussein et al. 1988). Extremely high dietary levels of 20 g Zn/kg ration have been used as a commercial management technique to force the molting of laying hens and the subsequent improvement of long-term egg production that molting produces (Lu and Combs 1988a). Laying hens (*Gallus* sp.) given high zinc diets increased their zinc uptakes five- to 40-fold in a dose-dependent pattern despite the decreased food intake associated with high zinc dietary levels. Zinc preferentially accumulated in chicken kidney, liver, pancreas, and gizzard; significant increases in egg zinc occurred at dietary levels of 10 and 20 g Zn/kg (Verheyen et al. 1990). Unlike adults, high dietary levels of zinc adversely affected pancreatic exocrine function in the chick. Effects were exacerbated under conditions of selenium deficiency and feeding of purified diets (Lu and Combs 1988a). Impaired enteric absorption and transport of Vitamin E as a consequence of zinc-induced pancreatic insufficiency is a major cause of reduced tissue concentrations of alpha-tocopherol produced in chicks by excess dietary zinc; these effects were magnified by diets low in corn, soybean meals, and other materials known to chelate zinc, and thus reduce its biological availability (Lu and Combs 1988b). Excess dietary zinc causes pancreatic damage in the chick, including reduced activities of major digestive enzymes, elevated plasma amylase activities, reduced digestibility of starch, and reduced Vitamin A activity. These changes were associated directly with elevated tissue zinc concentrations, especially in the pancreas (Lu et al. 1990).

Zinc sulfate-treated homing pigeons had impaired navigational ability when released approximately 60 km from their roosts. Homing pigeons made anosmic by treating their olfactory mucosa with zinc sulfate solution had significantly poorer homing behavior than did unmanipulated or treated control pigeons, as judged by homeward initial orientation and homing performance (Benvenuti and Gagliardo 1996).

9.7.5 Mammals

Livestock and small laboratory animals are comparatively resistant to zinc, as judged by their tolerance for extended periods to dietary loadings >100 times the minimum recommended daily zinc requirement (Table 9.8). Nevertheless, excessive zinc intake through inhalation or oral exposure can have dramatic effects on survival, metabolism, and well being. Sensitive species of mammals were affected at 90 to 300 mg Zn/kg diet, >300 mg Zn/L drinking water, >90 mg/kg BW daily, >350 mg Zn/kg BW as a single oral dose, and >0.8 mg Zn/m³ air (Table 9.8).

Zinc is relatively nontoxic in mammals. A wide margin of safety exists between normal intakes and those producing deleterious effects. In most cases, dietary levels up to 100 times the daily requirement for extended periods show no discernible effects (NAS 1979; Wentink et al. 1985; Goyer 1986; Leonard and Gerber 1989). The possibility of oral zinc intoxication in adult humans is unusually low, as judged by the low (40%) bioavailability of zinc from the gastrointestinal tract and the high tolerances to zinc reported in domestic livestock and small laboratory animals (Llobet et al. 1988). Humans ingesting up to 12 g of elemental zinc over a 2-day period, equivalent to 33 mg/kg BW for a 60 kg adult, show no evidence of hematologic, hepatic, or renal toxicity (Goyer 1986).

Excessive zinc intake adversely affects survival of all mammals tested (including humans) and produces a wide variety of neurological, hematological, immunological, hepatic, renal, cardiovascular, developmental, and genotoxic effects (USPHS 1989). The most sensitive species of mammals tested showed adverse effects at dietary levels of 80 to 90 mg Zn/kg in humans, 300 mg Zn/kg ration in domestic cats, and 500 mg Zn/kg feed in rats; drinking water concentrations of 300 mg/L in domestic mice, and 800 mg Zn/L in laboratory white rats; daily whole-body intakes >90 mg Zn/kg in horses; acute oral LD₅₀ doses of 350 to 800 mg Zn/kg BW in rats; intraperitoneal injections of 13 mg Zn/kg BW in mice; and 0.8 mg Zn/m³ air in guinea pigs ([Table 9.8](#)).

Metal fume fever is commonly encountered among industrial workers exposed to zinc fumes and is characterized by pulmonary irritation, fever, chills, and gastroenteritis (Saxena et al. 1989b). Attacks begin 4 to 8 h after exposure, and recovery is in 24 to 48 h. The pathogenesis of metal fume fever is unknown but may be associated with endogenous pyrogens released by cell lysis (Goyer 1986). Rabbits, rats, and cats exposed to zinc oxide fumes for 3.5 hours at concentrations of 110 to 600 mg/m³ reacted with a transient fall in body temperature followed by leucocytosis; heavily-exposed animals had signs of bronchopneumonia (Elinder 1986). The atmospheric threshold limit value (TLV) for zinc is 5 mg/m³; however, results of studies with guinea pigs suggest that the TLV value for zinc oxide should be lowered (Lam et al. 1985; [Table 9.8](#)).

Excessive zinc uptake is associated with lameness, unthrifty appearance, and osteochondrosis in foals and pigs, nephrosis in ferrets, and pancreatic fibrosis in sheep (Gunson et al. 1982). Zinc-poisoned mammals are usually characterized by a decreased growth rate, subcutaneous hematomas, ulcerative gastritis, hemorrhagic enteritis, lesions of major limb joints, renal lesions, elevated serum and tissue zinc concentrations, acute diarrhea, copper deficiency, impaired reproduction, and decreased activity of cardiac and hepatic cytochrome oxidase (Saxena et al. 1989b). In severe cases histopathological changes in liver and especially pancreas are evident, as are degenerative changes in kidney and gastrointestinal tract, followed by life-threatening hemolytic anemia (Straube et al. 1980; Allen et al. 1983; Robinette 1990). The pancreas is key in the diagnosis of zinc toxicity and in estimating the period of exposure; in sheep, it takes about four weeks of continued ingestion of toxic amounts of zinc before the pancreas is affected (Allen et al. 1983). More research is needed on the role of the pancreas in zinc toxicokinetics.

Zinc is important to the normal functioning of the central nervous system (CNS). At low concentrations, zinc protects mammalian brain neurons by blocking N-methyl-D-aspartate receptor-mediated toxicity. At high concentrations, zinc is a potent, rapidly acting neurotoxicant in the mammalian brain, as judged by zinc-induced neuronal injury of *in vitro* mature cortical cell cultures (Choi et al. 1988). Increased brain levels of zinc are associated with Pick's disease in certain strains of rodents with inherited epileptic seizures. Intravenous injection of zinc in rats with genetically inherited epilepsy produces seizures; a similar response occurs with intracranial injection of zinc in rabbits with inherited audiogenic seizures (Choi et al. 1988).

Zinc fed to adult male rats at 500 mg/kg diet for 3 weeks or longer negatively impacts the testes and other male accessory organs; effects are a direct result of zinc cytotoxicity from transfer across the blood-testes barrier (Saxena et al. 1989a). Elevated dietary zinc also depresses bone calcium levels and increases fecal calcium loss in rats (Greger 1989). Increases in serum zinc levels of rats after acute zinc overload is due mainly to increases in the zinc bound to the albumin fraction, and secondarily to that bound to the globulin fraction (Castellano et al. 1988). Albumin may play a new physiological role by fitting its binding capacity to serum zinc levels, essentially binding all excess zinc that arrives in the blood (Castellano et al. 1988).

Zinc toxicosis has been observed in humans and livestock after ingestion of acidic foods or drink prepared and stored in galvanized containers (Latimer et al. 1989). Symptoms appear within 24 hours and include nausea, vomiting, diarrhea and abdominal cramps. The emetic dose for zinc in humans was estimated at 225 to 450 mg (3.2 to 6.4 mg Zn/kg BW), equivalent to 1 to 2 g of zinc sulfate (Elinder 1986). Zinc poisoning in dogs is well documented as a result of ingestion of galvanized metal objects, calamine lotion, skin and sunblock preparations containing zinc oxide, staples, nails,

fertilizers, some paints, products containing zinc undecylenate, metallic hardware items with a high zinc content, nuts found on certain types of animal transport cages, and pennies (Latimer et al. 1989; Robinette 1990). The propensity of some individuals to throw pennies (U.S. coinage) into animal cages while visiting zoos and animal parks should be considered a potential source of zinc poisoning in captive animals. Pennies minted prior to 1982 contain 95% copper and 5% zinc; however, copper-clad pennies minted after 1981 contain 97.6% zinc and 2.4% copper (Ogden et al. 1988).

Humans given zinc supplements should be aware of possible complications (Fosmire 1990). Low intakes of 100 to 300 mg of zinc daily in excess of the recommended dietary allowance of 15 mg Zn daily may produce induced copper deficiency, impaired immune function, and disrupted blood lipid profiles. Patients treated with zinc supplements (150 mg daily) to control sickle cell anemia and nonresponsive celiac disease developed a severe copper deficiency in 13 to 23 months; normal copper status was restored by cessation of zinc supplements and increased dietary copper (Fosmire 1990).

Due to false positives, zinc may confound interpretation of the paralytic shellfish poisoning (PSP) mouse bioassay, one of the routine tests used to measure shellfish safety for human consumption. For example, mice injected intraperitoneally with extracts of healthy oyster tissues showed extreme weakness, a drop in body temperature, cyanosis, and some deaths (McCulloch et al. 1989). The threshold for a toxic PSP response corresponds to a drained tissue zinc level >900 mg/kg FW, and this overlaps the zinc concentration range of 230 to 1650 mg/kg FW (1900 to 9400 mg/kg DW) recorded in healthy oyster soft tissues (McCulloch et al. 1989).

Table 9.8 Effects of Zinc on Representative Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect	Reference ^a
Cows, cattle, <i>Bos spp.</i>		
Dairy cows fed control diet (310 mg Zn/kg DW feed) or control diet supplemented with 1000 or 2000 mg Zn/kg DW ration (as $\text{ZnSO}_4 \cdot \text{H}_2\text{O}$)	The 1000 mg/kg supplement had no adverse effects on milk production, feed intake, body weight, general health, or reproduction; there was a moderate increase in Zn content of plasma and milk. Cows fed the 2000 mg Zn/kg diet, however, had decreased milk yield and feed intake after several weeks; calf weights were lower; adverse effects reversed when excess zinc was removed from diet.	1
Calves fed diets containing 600 mg Zn/kg for 21 days	Appeared normal, although zinc levels were elevated in pancreas, liver, and kidney.	2
Lactating dairy cows fed diets containing 700 or 1000 mg Zn/kg feed for 6 weeks	No change in general health or milk production; no increase in milk zinc content.	2
Lactating cows fed diets containing up to 1386 mg Zn/kg feed for 5 weeks	No significant change in food intake, weight gain, milk production or in zinc concentrations in plasma (1.15–1.3 mg/kg FW) or milk (3.7–4.3 mg/kg FW).	3
Calves and young female cattle fed roughage harvested in vicinity of a factory galvanizing steel tubes, and containing 3000–7300 mg Zn/kg DW roughage	Signs of chronic zinc poisoning evident after 12–14 months. Signs included reduced appetite, emaciation, submandibular edema, diarrhea, moderate anemia, elevated serum zinc (4.3–6.0 mg/L vs. normal 1.8–2.1), liver Zn (420–1600 mg/kg DW vs. normal 72–248), kidney Zn (910–1680 mg/kg DW vs. normal 40–114), and low serum calcium and magnesium.	4
Dog, <i>Canis familiaris</i>		
Fed diets containing up to 1000 mg Zn/kg ration for up to 1 year	No measurable signs of damage.	2
Pomeranian, 2.2 kg, 4-months old, ingested four copper-clad zinc pennies	Hemolytic anemia, vomiting, salivation, serum zinc dropped from 29 mg/L to 4.4 mg/L 15 days after coins were surgically removed (normal dog serum Zn values range between 0.6 and 2.0 mg/L).	5

Table 9.8 (continued) Effects of Zinc on Representative Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect	Reference ^a
Zinc-poisoned oral route, (lethal) dose unspecified	Tissue zinc concentrations (in mg/L or mg/kg FW) were 32 in serum, 16–32 in plasma, 20–25 in urine, 369 in liver, and 295 in kidney. Normal values were 0.7–1.1 in serum, 0.6–1.0 in plasma, 1.3–2.0 in urine, 17–32 in liver, and 9–23 in kidney.	6
Died from ingestion of 34 copper-clad zinc pennies	Elevated zinc levels in serum, liver, and kidney; jaundice, anoxemia, anemia, vomiting, dark red urine.	7
Guinea pig, <i>Cavia</i> sp.		
Inhalation of 0.8 mg Zn/m ³ for 1 h	Difficulty in breathing.	8
Inhalation of 4 mg Zn/m ³ , 3 h daily for 6 days	Temporary lung damage.	8
Inhalation of 5 mg Zn/m ³ , as ultrafine zinc oxide, 3 h daily for 6 days	Decrease in lung capacity, alveolar volume, and diffusing capacity for carbon monoxide; values remained depressed for at least 72 h after last exposure. Persistent inflammation of proximal portion of alveolar ducts and adjacent alveoli.	9, 10
Horse, <i>Equus caballus</i>		
Weanling foals, age 3 months, fed diets containing 7.7 mg copper/kg plus 29, 250, 1000, or 2000 mg Zn/kg ration for 15 weeks. At start, serum zinc level was 0.6 mg/L and serum copper level 1.4 mg/L	Foals fed 29 or 250 mg Zn/kg diets had normal serum copper and zinc concentrations. Those fed 1000 or 2000 mg Zn/kg diet became hypocupremic in 5 to 6 weeks and developed lameness owing to cartilaginous disease similar to osteochondritis dessicans. Foals fed high zinc diets became lame when serum copper fell to 0.3 mg/L for >1 week; at end of study arthritic foals had <0.2 mg copper/L serum. Serum zinc concentrations rose to >2 mg/L within 2 weeks at 1000 or 2000 mg Zn/kg diet; liver zinc was <333 mg/kg DW at diets of <250 mg Zn/kg, 2728–3511 mg/kg DW at 1000 mg Zn/kg diet, and 4364–4524 mg/kg DW at the highest dietary loading of 2000 mg Zn/kg in 15 weeks	2
Adults, vicinity of lead-zinc smelter, ingesting >90 mg Zn/kg BW daily	Decreased growth, lameness, bone deformities, death.	2
Cat, <i>Felis domesticus</i>		
Fed diet containing 300 mg Zn/kg ration for 16 weeks	Weight loss and pancreas histopathology.	2
Fed diets containing >600 mg Zn/kg ration	Diets rejected.	2
Fed diet containing 9000 mg Zn/kg ration for 3–53 weeks	Pancreas histopathology.	8
Human, <i>Homo sapiens</i>		
Dietary route		
80 mg/kg ration for 6 weeks	Digestive problems.	8
90 mg Zn/kg ration for 5 weeks	Decreased serum cholesterol levels.	8
153 mg Zn/kg ration for 6 weeks	Altered immune system.	8
<150 mg Zn daily	No effect on male plasma cholesterol; females have decreased cholesterol.	12
>160 mg Zn daily	Increased plasma cholesterol level in both sexes; increased risk of heart disease in males.	12
Inhalation route		
600 mg Zn/m ³ for 10 min	Metal fume fever; i.e., difficulty in breathing, flu-like symptoms.	8

Table 9.8 (continued) Effects of Zinc on Representative Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect	Reference ^a
Oral route		
15-year-old girl who consumed 220 mg of zinc sulfate twice daily "for some time"	Acute gastrointestinal bleeding ulcers.	13
Boy who consumed 12 g of elemental zinc	Headache and lethargy.	13
Single oral dose of 45 grams of zinc as ZnSO_4 (normal is 15–20 mg daily)	Death, preceded by dehydration, electrolyte imbalance, abdominal pain, nausea, vomiting, dizziness, muscular incoordination, and acute renal failure.	14
Celebes ape, <i>Macaca nigra</i>; male; age 16 years; zoo animal; serum		
Routine examination showed stomach containing 4 zinc-clad US pennies	8.0 mg/L FW	24
36 h after unaided passage of last penny	6.15 mg/L FW	24
6 months after above	1.3 mg/L FW	24
Control animal	2.3 mg/L FW	24
Domestic mouse, <i>Mus sp.</i>		
Dietary route		
68, 682, or 6820 mg Zn/kg ration for 13 weeks (fed as 300, 3000, or 30,000 mg $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$ /kg ration)	No observed effects at 682 mg/kg diet (and lower), equivalent to 104–109 mg Zn/kg BW daily. At 6820 mg Zn/kg ration, however, adverse effects were documented on survival, growth, food and water intake, and blood chemistry; lesions noted in pancreas, stomach, intestine, spleen, and kidney.	15
500 mg/kg for 3 months	Anemia.	8
30,000 mg/kg ration for 13 weeks	Some deaths, liver and kidney histopathology.	8
Drinking water		
300 mg/L for 5–14 months	Pancreas histopathology.	8
Intraperitoneal injection		
4 injections over 9-day period totalling 13 mg Zn/kg BW	Toxic. Severe weight loss, some deaths.	23
European ferret, <i>Mustela putorius furo</i>		
Fed basal diet (27 mg Zn/kg feed) or basal diet plus 500, 1500, or 3000 mg Zn/kg ration for up to 197 days; four animals per group	Ferrets fed 500 mg/kg all survived with no significant histopathology; zinc concentrations, in mg/kg DW, were 148 in liver vs. 115 in controls, and 383 in kidney vs. 180 in controls. At 1500 mg/kg, all 4 ferrets were <i>in extremis</i> or dead by day 21. At death, liver zinc was 859 mg/kg DW and kidney zinc 1000 mg/kg DW; ferrets had 40–50% loss in body weight; food intake had decreased 80%; and erythrocyte number, hemoglobin, and hematocrit had significantly decreased. Ferrets fed the 3000 mg/kg diet died between days 9 and 13, lost up to 40% of initial body weight, and food intake decreased 77%; postmortem examination showed blood in intestine, orange-colored liver, and kidney histopathology. Elevated zinc content in liver of 1273 mg/kg DW and in kidney of 1138 mg/kg DW.	8, 16, 17
Rabbit, <i>Oryctolagus sp.</i>		
Single oral dose of 65 mg Zn/kg BW, as ZnSO_4	Half-time persistence of 713 min.	8

Table 9.8 (continued) Effects of Zinc on Representative Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect	Reference^a
Intravenous injection of 0.325 mg Zn/kg BW, as ZnSO ₄	Half-time persistence of 268 min.	8
Intraperitoneal injection of 3.4 mg Zn daily	Associated with lowered plasma cholesterol levels.	12
<i>Domestic sheep, Ovis aries</i>		
Domestic ewe, age 5 years, found moribund, suspected zinc poisoning	Elevated zinc levels (mg/kg DW) in liver of 650 vs. 144 in controls, and in kidney 760 vs. 84 in controls; muscle residues same as controls, i.e., 154 vs. 158; generalized jaundice; liver degeneration and blockage of bile ducts.	18
Found dead, zinc-poisoned naturally	Zinc concentrations, in mg/kg DW, were 463 in liver (vs. 165 in controls), 274 in kidney (vs. 150 in controls), and 752 in pancreas (vs. 88 in controls).	19
Zinc-poisoned experimentally, oral route	Zinc concentrations, in mg/kg DW, were 1125–1671 in liver, 2130–2442 in kidney, 1440–1932 in pancreas, and 4900 in feces (vs. 158 in controls).	19
Lambs fed diets containing 1000 mg Zn/kg	Food intake reduced; approaching toxic level.	2,7
<i>Laboratory white rat, Rattus sp.</i>		
Dietary route		
Adult males given 500 mg Zn/kg ration, as ZnSO ₄ , for 6 weeks	After 3 weeks, spermatogenesis was arrested at the primary spermatocyte stage. After 4 weeks, food consumption declined, forelimb lameness, and swelling in cervical lymph nodes. At 6 weeks, testes showed enlarged lumen and abnormal germinal epithelium.	20
682 mg Zn/kg ration, as ZnSO ₄ · 7H ₂ O, for 13 weeks	No observable effect level, equivalent to 53–55 mg Zn/kg BW daily.	15
2000 mg Zn/kg ration, chronic exposure	“Tolerated.”	2
4000–5000 Zn/kg ration for 18 days	Fetotoxic dose, poor reproduction.	8, 2
5000–10,000 mg Zn/kg ration	Reduced growth, anemia, poor reproduction, disrupted liver catalase and cytochrome oxidase activity, copper deficiency.	14
6820 mg Zn/kg ration for 13 weeks	Retarded growth, low food intake, abnormal blood chemistry, regressive changes in pancreas.	15
Drinking water route		
Doses equivalent to zero, 160, 320, and 640 mg Zn/kg BW daily for 3 months	No significant effect of any dose on organ weight, hematocrit, hemoglobin, glucose, and enzyme activity. Effects noted only at 640 mg Zn/kg BW daily: some deaths, less drinking water ingested, decreased volume of urine, significant increase in urea and decrease in creatinine. Tissue residues, in mg Zn/kg FW, were significantly elevated over controls in high dose group at 3 months: 60 vs. 20 in liver, 38 vs. 16 in kidney, 330 vs. 92 in bone, 21 vs. 3 in blood, 36 vs. 16 in spleen. Residues were the same as controls in brain (9), lung (13), and muscle. Liver alterations.	21
800 mg Zn/L for 30 days		8
Intragastric administration		
180 g adults given single dose of 500 mg, equivalent to 2777 mg/kg BW	Serum zinc reached a maximum of 3.5 mg Zn/L after 60 min, and returned to normal (1.6 mg/L) within 24 h.	22
165 g adults given 500 mg daily for up to 30 days, equivalent to 3030 mg Zn/kg BW daily	Serum zinc, in mg/L, after 7, 14, or 30 days was 1.9, 2.2, and 2.1, respectively; 10 days after last dose, serum zinc was normal.	22

Table 9.8 (continued) Effects of Zinc on Representative Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect	Reference ^a
Single oral dose 350–800 mg Zn/kg BW	Acute oral LD50.	2, 21
Domestic pig, <i>Sus spp.</i>		
Weanlings fed diet containing 1000 mg Zn/kg feed for 30 days	Decreased growth rate and food intake, arthritis, lameness, and inflammation of the gastrointestinal tract.	13

9.8 RECOMMENDATIONS

For growing agricultural crops: (1) sewage sludge may be applied to soils provided that total zinc content does not exceed 150 to 560 kg per surface hectare ([Table 9.9](#)); (2) a maximum permissible extractable soil zinc concentration of 23 mg/kg DW is recommended, according to Soviet agronomists (Beyer 1990); and (3) seedlings of oak (*Quercus spp.*) and red maple (*Acer rubrum*) will eventually die in culture medium containing >100 mg Zn/kg (Buchauer 1971), although total zinc concentrations for global crop production routinely exceed 100 mg/kg DW soil ([Table 9.9](#)). Research is needed in standardized methodology for measuring bioavailable (i.e., extractable) soil zinc and on its relation to other soil measurements, such as total zinc and depth of cultivation, in the case of surface application.

Data are limited on zinc hazards to terrestrial invertebrates; however, sensitive species are adversely affected at dietary concentrations >300 mg Zn/kg, or at soil concentrations >400 mg/kg ([Table 9.9](#)).

Water-quality criteria protection of aquatic life should include both total recoverable zinc and acid-soluble zinc (USEPA 1980, 1987). For example, if total recoverable zinc is substantially above the proposed criteria and acid-soluble zinc is below the limit, there is cause for concern (USEPA 1987). To protect approximately 95% of freshwater animal genera, the U.S. Environmental Protection Agency recommends water concentrations that average <47 µg total recoverable zinc per liter, not to exceed 180 µg/L at any time in soft water (i.e., <50 mg CaCO₃/L), or a mean concentration of 59 µg acid soluble zinc per liter, not to exceed 65 µg/L at any time in soft water ([Table 9.9](#)). These criteria are unsatisfactory because lower ambient zinc concentrations between 5 and 51 µg/L clearly have significant negative effects on growth, survival, and reproduction of important species of freshwater fishes, amphibians, insects, sponges, and crustaceans ([Table 9.9](#)). Some downward modification seems necessary in the current proposed zinc criteria for freshwater aquatic life protection.

To protect important species of marine animals, the U.S. Environmental Protection Agency recommends that total recoverable zinc in seawater should average <58 µg/L and never exceed 170 µg/L; for acid-soluble zinc, these values are <86 and 95 µg/L ([Table 9.9](#)). As was the case for freshwater biota, there is a growing body of evidence ([Table 9.9](#)) demonstrating that many species of marine plants, crustaceans, molluscs, echinoderms, and fish are adversely affected at ambient zinc concentrations between 9 and 50 µg/L, or significantly below the current proposed criteria for marine life protection.

Zinc deficiency effects have been produced experimentally in freshwater sponges at <0.65 µg Zn/L (Francis and Harrison 1988), in rainbow trout fed diets containing <15 mg Zn/kg FW (Spry et al. 1988), in certain species of marine algae at <0.7 µg Zn/L (Vymazal 1986), and in certain species of marine invertebrates at <6.5 µg Zn/L (Clapper et al. 1985a, 1985b) or <34 mg Zn/kg DW whole organism (White and Rainbow 1985). Zinc deficiency in natural aquatic ecosystems has not yet been credibly documented.

In aquatic environments, Spear (1981) spotlights three research needs: (1) development of analytical procedures for measurement of individual dissolved zinc species, notably the aquo ion and zinc chloride, and for nondissolved species that occur in natural waters; (2) separation of natural from anthropogenic influences of sediment-water interactions on flux rates, with emphasis on anoxic conditions, the role of microorganisms, and the stability of organozinc complexes; and (3) establishment of toxicity thresholds for aquatic organisms based on bioaccumulation and survival to determine the critical dose and the critical dose rate, with emphasis on aquatic communities inhabiting locales where zinc is deposited in sediments. These research needs are still valid.

Bird diets, in mg Zn/kg DW feed, should contain 25 to 38 to prevent zinc deficiency effects, 93 to 120 for adequate to optimal growth, <178 to prevent marginal sublethal effects, and <2000 to prevent the death of chicks and ducklings (Table 9.9). Extremely high dietary levels of 20 g Zn/kg ration are fed routinely to laying hens by poultry managers to force molting and to improve long-term egg production (Lu and Combs 1988a); in these cases zinc preferentially accumulates in kidney, liver, pancreas, and eggs (Verheyen et al. 1990). Much additional work now seems warranted on the role of zinc in avian nutrition, and on the significance of tissue concentrations as an indicator of zinc stress.

The normal daily intake for all human age groups ranges between 8 and 14 mg (Casey and Hambidge 1980), but pregnant women require an additional 350 to 375 mg of zinc during the course of their pregnancy (Jameson 1980). Zinc used therapeutically in humans at >160 mg daily may have deleterious effects on copper status (Sammon and Roberts 1988). Lower levels — close to the recommended daily allowance of 15 mg — are reported to interfere with iron metabolism and with high-density lipoprotein cholesterol concentrations (Fosmire 1990), but this requires verification. The proposed air quality criterion for human health protection is 5 mg Zn/m³, although this is demonstrably harmful to guinea pigs (Table 9.9). It is not yet known if guinea pigs are more sensitive than man to atmospheric zinc, or if some downward modification is needed in the current zinc air quality criterion for protection of human health, and presumably wildlife.

Single oral doses >350 mg Zn/kg BW were fatal to rats, although doses of 320 mg/kg BW were tolerated (Table 9.9), suggesting a rapid breakdown in ability to regulate zinc in a relatively narrow critical threshold range. More research seems needed on zinc regulation of massive doses.

Data are scarce in mammals that link zinc concentrations in tissues with environmental zinc perturbations. In harbor porpoises, impaired homeostasis reportedly occurs when zinc exceeds 100 mg/kg FW liver; however, livers of many species of marine mammals routinely exceed this value (Wood and Van Vleet 1996). Elevated zinc concentrations, in mg Zn/kg DW tissue, were >120 in cattle liver, >180 in sheep kidney, and >250 in sheep liver (Table 9.9), but their significance is unclear. No international regulations or guidelines applicable to zinc are available (USPHS 1989). No U.S. Food and Drug Administration “action level” or other maximum acceptable concentration exists for zinc, and therefore no Final Residue Value can be calculated (USEPA 1987). This seems to be a high priority research need.

Eating seafoods that contain high concentrations of zinc does not seem to present a threat to human health. However, oysters from Tasmania allegedly caused nausea and vomiting in some people who ate them; these oysters contained about 20 grams of zinc per kg soft parts FW, or about 500 times more than the Australian food regulation of 40 mg/kg FW (Eisler 1981).

In mammals, large differences are evident between and within species in resistance to zinc poisoning and in sensitivity to zinc nutritional needs (Table 9.9). Adverse effects of excess dietary

zinc occurred in sensitive species at 80 (human) and 300 (cat) mg Zn/kg DW; other species tested were significantly more resistant. Daily intake rates considered harmful over long periods ranged from about 2.3 mg/kg BW in man to >90 mg/kg BW in horses. Dietary loadings that optimally prevented zinc deficiency, in mg Zn/kg DW diet, were 30 for bank voles, 33 for adult sheep (124 to 130 for lambs), 37 for mice, 45 to 60 for cattle, 76 for rat, 80 for goat, 100 for monkey, and 150 for mink; recommended daily intake rates in mg/kg BW, ranged from about 0.2 in man to 110 to 140 in cattle (Table 9.9). More research is needed on the interaction effects of zinc with proteins, calcium, chloride, and other trace elements, and on the long-term consequences of nutrient interactions using animals of various age and nutrient status (Greger 1989).

Table 9.9 Proposed Zinc Criteria for the Protection of Natural Resources and Human Health

Resource, Criterion, and Other Variables	Effective Zinc Concentration	Reference ^a
CROP PLANTS		
<i>Sewage sludge applied to agricultural soils</i>		
Europe, acceptable	150–<300 kg/ha at pH 6.0–7.0	1
Florida		
Maximum permissible	205 kg/ha	1
Unacceptable	>10,000 mg/kg dry weight (DW)	1
Oregon ^b , Wisconsin ^b , acceptable	250–<1000 kg/ha	1
Vermont ^b , acceptable	280–<1120 kg/ha	1
Maryland ^b , Massachusetts ^b , acceptable	280–<560 kg/hg	1
Minnesota ^b , Missouri ^b , acceptable	280–<1120 kg/ha	1
Illinois, maximum	560 kg/ha	1
<i>Soils</i>		
Soviet Union		
Maximum permissible	23 mg/kg DW, extractable by ammonium acetate buffer at pH 4.8	1
Alberta, Canada		
For growing livestock forage	<100 mg/kg DW	1
Quebec, Canada		
Background	200 mg/kg DW	1
Marginal	500 mg/kg DW	1
Unacceptable	>3000 mg/kg DW	1
Netherlands		
Background	200 mg/kg DW	1
Marginal	500 mg/kg DW	1
Unacceptable	>3000 mg/kg DW	1
Ontario, Canada, acceptable	<220 mg/kg DW	1
Germany, acceptable	<300 mg/kg DW	2
New Jersey, goal	<350 mg/kg DW	1
New York, acceptable		
Agricultural soils	168–<250 kg/ha DW	1
Forest soils	<560 kg/ha DW	1
TERRESTRIAL INVERTEBRATES		
<i>Earthworms</i>		
Soil		
High accumulations, but otherwise safe	97 mg/kg DW	3
Adverse effects	>400 mg/kg DW	3
<i>Slugs</i>		
Diet, adverse effects	>300 mg/kg DW	4

FRESHWATER AQUATIC LIFE		
Water		
Total recoverable zinc		
50 mg CaCO ₃ /L	47 µg/L, 24 h average; not to exceed 180 µg/L at any time	5
100 mg CaCO ₃ /L	47 µg/L, 24 h average; not to exceed 320 µg/L at any time	5
200 mg CaCO ₃ /L	47 µg/L, 24 h average; not to exceed 570 µg/L at any time	5
Acid-soluble zinc ^c	4-day average concentration not to exceed the numerical value $e^{((0.8473 \ln \text{hardness})+0.7614)}$ more than once every 3 years on average; 1-h concentration not to exceed $e^{((0.8473 \ln \text{hardness})+0.8604)}$ more than once every 3 years on average. See below for examples.	6
50 mg CaCO ₃ /L	4-day average not to exceed 59 µg/L; 1-h average not to exceed 65 µg/L	6
100 mg CaCO ₃ /L	4-day average not to exceed 110 µg/L; 1-h average not to exceed 120 µg/L	6
200 mg CaCO ₃ /L	4-day average not to exceed 190 µg/L; 1-h average not to exceed 210 µg/L	6
Adverse effects, most sensitive species		
Brown trout, <i>Salmo trutta</i> , embryos and fry	4.9–19.6 µg/L	7
Daphnid, <i>Daphnia magna</i>	5–14 µg/L	6
Rainbow trout, <i>Oncorhynchus mykiss</i>	5.6–10 µg/L	5, 6, 8
Narrow-mouthed toad, <i>Gastrothryne carolinensis</i> , embryos	10 µg/L	6
Daphnid, <i>Daphnia galeata mendotae</i>	15–30 µg/L	6
Freshwater sponge, <i>Ephydatia fluviatilis</i>	26 µg/L	9
Mayfly, <i>Epeorus latifolium</i>	30 µg/L	10
Midge, <i>Tanytarsus dissimilis</i>	37 µg/L	5, 6
Atlantic salmon, <i>Salmo salar</i>	50 µg/L	6
Cladoceran, <i>Ceriodaphnia reticulata</i>	51 µg/L	6
Flagfish, <i>Jordanella floridae</i>	51 µg/L	6
Diet		
Channel catfish, <i>Ictalurus punctatus</i>		
Minimum	20 mg/kg DW	11
Recommended ^d	150–200 mg/kg DW	11
Rainbow trout, <i>Oncorhynchus mykiss</i>		
Minimum	10–30 mg/kg DW; 15–30 mg/kg fresh weight (FW)	12, 13
Adequate	90 mg/kg FW	13
Sediments		
Great Lakes		
Safe	<90 mg/kg DW	1
Marginal	90–200 mg/kg DW	1
Unacceptable	>200 mg/kg DW	1
Wisconsin and Ontario, for Great Lakes sediments dredged from harbors and for disposal in water	<100 mg/kg DW	1
MARINE AQUATIC LIFE		
Seawater		
Total recoverable zinc	58 µg/L, 24-h average; not to exceed 170 µg/L at any time	5

Zinc oxides	600 mg/m ³ for 10 min	38
Daily intake		
Recommended dietary intake, assuming availability of 20%		
Children		
To age 1 year	3–6 mg	48
1–10 years	8–10 mg	48
No age specified	10 mg	2, 20
Males		
Age 11–17	14–15 mg	48
Age 18+	11–15 mg	48
No age specified	15 mg	2, 20, 26, 47, 49, 50
Females		
Age 10–13	13–15 mg	48
Age 14+	11–15 mg	48
No age specified	12 mg	
Pregnant	15–20 mg	48
Lactating	25–27 mg	47, 48

Table 9.9 (continued) Proposed Zinc Criteria for the Protection of Natural Resources and Human Health

Resource, Criterion, and Other Variables	Effective Zinc Concentration	Reference ^a
Maximum safe total, adults		
Not zinc deficient	0.3–1.0 mg/kg BW	2
Zinc deficient	1 mg Zn/kg BW, oral administration	48
Adverse effects level	>160 mg (>2.3 mg/kg BW)	51
Diet		
Seafoods, safe level, Australia	<40 mg/kg fresh weight (FW)	14
Adverse effects		
Gastrointestinal disorders	>80 mg/kg DW diet for 6 weeks	38
Severe copper deficiency	150 mg Zn daily for 13–23 months	49
Vomiting	Single dose of 225–450 mg Zn or 1–2 grams of ZnSO ₄	49
Drinking water		
Safe level	5 mg/L	2, 20, 38
Adverse effects		
Acute GI distress	>280 mg/L	20
Intravenous injection		
Adverse effects	23 mg/kg BW daily	52
Soils		
Canada, nonhazardous to human health		
Ontario		
Residential, parkland, commercial, industrial	<800 mg/kg DW	1
Alberta		
Noncrop uses	<700 mg/kg DW	1
Tissue residues		
Serum		
Normal	0.5–1.29 mg/L	38
No toxic effects	1.92 mg/L	38
Plasma		
Zinc-deficient	0.4–0.6 mg/L	45
Normal	0.7–1.1 mg/L	48
GI disturbances	1.51 mg/L	38
Rhesus monkey, <i>Macaca mulatta</i>		
Diet		
Deficient	4 mg/kg DW	52
Adequate	100 mg/kg DW	53
Mouse, <i>Mus</i> spp.		
Diet		
Zinc-deficient	<5 mg/kg DW	54
Zinc-adequate	36.5 mg/kg DW	54
Tolerated	100 mg/kg DW	54
Tolerated	682 mg/kg DW for 13 weeks (107 mg/kg BW)	55
Harmful	500 mg/kg DW for 3 months	38
Harmful	6820 mg/kg DW	55
Fatal	30,000 mg/kg DW for 13 weeks	38
Drinking water		
Adverse effects	300 mg/L	38
Tissue residues		
Blood		
Deficient	0.7 mg/L	56
Normal	1.0–1.1 mg/L	56
Liver		
Deficient	12 mg/kg FW	56
Normal	17–19 mg/kg FW	56

^b Higher values permissible for soils with higher cation exchange capacity (Beyer 1990).

^c Zinc that passes through a 0.45 µm membrane filter after acidification to pH 1.5–2.0 with nitric acid (USEPA 1987).

^d Higher concentrations recommended to compensate for reduced bioavailability caused by excess calcium and phytate in diet (Gatlin et al. 1989).

9.9 SUMMARY

Ecological and toxicological aspects of zinc (Zn) in the environment are reviewed, with emphasis on natural resources. Subtopics include: sources and uses; chemical and biochemical properties; carcinogenicity, mutagenicity, and teratogenicity; background concentrations in biological and nonbiological compartments; zinc deficiency effects; toxic and sublethal effects to terrestrial plants and invertebrates, aquatic organisms, birds, and mammals; and recommendations for protection of sensitive resources.

World production of zinc is estimated at 7.1 million tons; the United States produces about 4% of the total and consumes 14%. Zinc is used primarily in the production of brass, noncorrosive alloys, and white pigments; in galvanizing iron and steel products; in agriculture as a fungicide, and as a protective agent against soil zinc deficiency; and therapeutically in human medicine. Major sources of anthropogenic zinc in the environment include electroplaters, smelting and ore processors, mine drainage, domestic and industrial sewage, combustion of solid wastes and fossil fuels, road surface runoff, corrosion of zinc alloys and galvanized surfaces, and erosion of agricultural soils.

Zinc has its primary effect on zinc-dependent enzymes that regulate RNA and DNA. The pancreas is a primary target organ in birds and mammals, followed by bone; in fish, gill epithelium is a primary target site. Dietary zinc absorption is highly variable in animals; in general, it increases with low body weight and low zinc status, and decreases with excess calcium or phytate and by deficiency of pyridoxine or tryptophan. Low molecular weight proteins called metallothioneins

play an important role in zinc homeostasis and in protection against zinc poisoning; zinc is a potent inducer of metallothioneins. Zinc interacts with many chemicals to produce altered patterns of accumulation, metabolism, and toxicity. Some interactions are beneficial to the organism, while others are not, depending on the organism, its nutritional status, and other variables. Knowledge of these interactions is essential to understanding zinc toxicokinetics.

In natural waters, dissolved zinc speciates into the toxic aquo ion $[Zn(H_2O)_6]^{2+}$, other dissolved chemical species, and various inorganic and organic complexes; zinc complexes are readily transported. Aquo ions and other toxic species are most harmful to aquatic life under conditions of low pH, low alkalinity, low dissolved oxygen, and elevated temperatures. Most of the zinc introduced into aquatic environments is eventually partitioned into the sediments. Zinc bioavailability from sediments is enhanced under conditions of high dissolved oxygen, low salinity, low pH, and high levels of inorganic oxides and humic substances.

Zinc and its compounds induce testicular sarcomas in birds and rodents when injected directly into the testes; however, zinc is not carcinogenic by any other route. Growth of animal tumors is stimulated by zinc, and retarded by zinc deficiency. Under some conditions excess zinc can suppress carcinoma growth, although the mechanisms are imperfectly understood. Organozinc compounds are effective mutagens when presented to susceptible cell populations in an appropriate form; the evidence for mutagenic potential of inorganic zinc compounds is incomplete. Zinc deficiency can lead to chromosomal aberrations, but excess zinc was not mutagenic in the majority of tests. Excess zinc is teratogenic to frog and fish embryos, but conclusive evidence of teratogenicity in higher vertebrates is lacking. In mammals, excess zinc may protect against some teratogens. Zinc deficiency may exacerbate the teratogenic effects of known teratogens, especially in diabetic animals.

Background concentrations of zinc seldom exceed 40 $\mu\text{g/L}$ in water, 200 mg/kg in soils and sediments, or 0.5 $\mu\text{g/m}^3$ in air. Environments heavily contaminated by anthropogenic activities may contain up to 99 mg Zn/L in water, 118 g/kg in sediments, 5 g/kg in soil, and 0.84 $\mu\text{g/m}^3$ in air. Zinc concentrations in field collections of plants and animals are extremely variable and difficult to interpret. Most authorities agree on six points: (1) elevated concentrations (i.e., >2 g Zn/kg fresh weight = FW) are normally encountered in some species of oysters, scallops, barnacles, red and brown algae, and terrestrial arthropods; (2) concentrations, in mg Zn/kg dry weight (DW) tissue, are usually <700 in fish, <210 in birds, and <210 in mammals; (3) concentrations are higher in animals and plants collected near zinc-contaminated sites than in the same species collected from more distant sites; (4) zinc content in tissue is not proportionate to that of the organism's immediate surroundings; (5) for individual species, zinc concentration varies with age, sex, season, tissue or organ, and other variables; and (6) many species contain zinc loadings far in excess of immediate needs, suggesting active zinc regulation.

The balance between excess and insufficient zinc is important. Zinc deficiency occurs in many species of plants and animals, with severe adverse effects on all stages of growth, development, reproduction, and survival. In humans, zinc deficiency is associated with delayed sexual maturation in adolescent males; poor growth in children; impaired growth of hair, skin, and bones; disrupted Vitamin A metabolism; and abnormal taste acuity, hormone metabolism, and immune function. Severe zinc deficiency effects in mammals are usually prevented by diets containing >30 mg Zn/kg DW ration. Zinc deficiency effects are reported in aquatic organisms at nominal concentrations between 0.65 and 6.5 $\mu\text{g Zn/L}$ of medium, and in piscine diets at <15 mg Zn/kg FW ration. Avian diets should contain >25 mg Zn/kg DW ration for prevention of zinc deficiency effects, and <178 mg Zn/kg DW for prevention of marginal sublethal effects.

Sensitive terrestrial plants die when soil zinc levels exceed 100 mg/kg (oak and maple seedlings), and photosynthesis is inhibited in lichens at >178 mg Zn/kg DW whole plant. Sensitive terrestrial invertebrates have reduced survival when soil levels exceed 470 mg Zn/kg (earthworms), reduced growth at >300 mg Zn/kg diet (slugs), and inhibited reproduction at >1600 mg Zn/kg soil (woodlouse). The most sensitive aquatic species were adversely affected at nominal water concentrations between 10 and 25 $\mu\text{g Zn/L}$, including representative species of plants, protozoans, sponges,

molluscs, crustaceans, echinoderms, fishes, and amphibians. Acute LC50 (96 h) values ranged between 32 and 40,930 µg/L for freshwater invertebrates, 66 and 40,900 µg/L for freshwater teleosts, 195 and >320,000 µg/L for marine invertebrates, and 191 and 38,000 µg/L for marine teleosts. Acute toxicity values were markedly affected by the age and nutrient status of the organism, by changes in the physicochemical regimen, and by interactions with other chemicals, especially copper salts. Pancreatic degeneration occurred in ducks fed diets containing 2500 mg Zn/kg ration. Ducks died when fed diets containing 3000 mg Zn/kg feed, or when given single oral doses >742 mg Zn/kg body weight (BW). Domestic poultry are routinely fed extremely high dietary levels of 20 g Zn/kg ration as a commercial management technique to force the molting of laying hens and the subsequent improvement of long term egg production that molting produces. However, poultry chicks died at 8 g Zn/kg diet, had reduced growth at 2 to 3 g Zn/kg diet, and experienced pancreas histopathology when fed selenium-deficient but zinc-adequate (100 mg Zn/kg) diets. Mammals are comparatively resistant to zinc, as judged by their tolerance for extended periods to diets containing >100 times the minimum daily zinc requirement. But excessive zinc through inhalation or orally will negatively impact mammalian survival, metabolism, and well-being. The most sensitive species of mammals were adversely affected at dietary concentrations of 90 to 300 mg Zn/kg, drinking water concentrations >300 mg Zn/L, daily intakes >90 mg Zn/kg BW, single oral doses >350 mg Zn/kg BW, and air concentrations >0.8 mg Zn/m³. Humans are comparatively sensitive to excess zinc. Adverse effects occur in man at >80 mg Zn/kg diet, or at daily intakes >2.3 mg/kg BW.

Proposed criteria for protection of aquatic life include mean zinc concentrations of <47 to <59 µg/L in freshwater, and <58 to <86 µg Zn/L in seawater. Results of recent studies, however, show significant adverse effects to a growing number of freshwater organisms in the range of 5 to 51 µg Zn/L, and to saltwater biota between 9 and 50 µg Zn/L, suggesting that some downward modification in the proposed criteria is necessary.

Although tissue residues are not yet reliable indicators of zinc contamination, zinc poisoning usually occurs in birds when liver or kidney contains >2.1 g Zn/kg DW, and in mammals when concentrations, in mg Zn/kg DW, exceed 274 in kidney, 465 in liver, or 752 in pancreas. The proposed air quality criterion for human health protection is <5 mg Zn/m³, but guinea pigs were more sensitive with adverse effects evident at >0.8 to 4.0 mg/m³.

Current research needs include the development of protocols to: (1) separate, quantitate, and verify the different chemical species of zinc; (2) identify natural from anthropogenic sources of zinc; (3) establish toxicity thresholds based on accumulation; (4) evaluate the significance of tissue concentrations in target organs as indicators of zinc stress; and (5) measure the long term consequences of zinc interactions with other nutrients using animals of various age and nutrient status.

CHAPTER 10

Acrolein

10.1 INTRODUCTION

Acrolein ($\text{CH}_2=\text{CHCHO}$) is an aldehyde that was first isolated in 1843 from the dry distillation of fats and glycerol (Beauchamp et al. 1985). It is now known that acrolein is ubiquitous in the environment; it is often present in trace amounts in foods and as a component of smog, fuel combustion products such as wood smoke, exhaust emissions from internal combustion engines, and cigarette smoke (Smith 1962; U.S. Environmental Protection Agency [USEPA] 1980; Beauchamp et al. 1985). Atmospheric concentrations of acrolein over urban areas are between 2 and 7 $\mu\text{g/L}$. Cigarette smoke, however, contains about 10,000 μg of acrolein/L (Beauchamp et al. 1985). Acrolein is classified as a hazardous chemical because of its reactivity and flammability (USEPA 1980). At low, sublethal concentrations, acrolein is widely known for its acrid pungent odor and strong irritating effects on mucous membranes of the eyes and upper respiratory tract, its toxicity to cilia in all organisms, and its interference with nucleic acid synthesis in bacteria (Marano and Puiseux-Dao 1982; Beauchamp et al. 1985). In bulk, acrolein during storage or transfer is potentially hazardous if it becomes overheated or contaminated with water. For example, in 1982, 17,000 residents of Toft, Louisiana, were evacuated when two large tanks of acrolein began to burn (Bowmer and Smith 1984).

Acrolein enters the aquatic environment from its use as an aquatic herbicide, from industrial discharges, and as a by-product of the chlorination of organic compounds in wastewater and drinking water treatment (USEPA 1980). Dilute solutions of acrolein kill undesirable plant life in irrigation streams and ditches (National Research Council [NRC] 1977) and have been used routinely in about 4000 km of irrigation canals in southeastern Australia to control submerged weeds, including *Potamogeton tricarinatus*, *Elodea canadensis*, and *Vallisneria gigantia* (Bowmer and Smith 1984). Acrolein has also been used for many years in channel maintenance in the United States (especially in the western states), Canada, Egypt, Argentina, Mexico, and Turkey (Bowmer and Smith 1984). Unlike most other aquatic herbicides, acrolein rapidly dissipates from the water by volatilization and degradation without leaving phytotoxic residues (Bowmer and Smith 1984; Parent et al. 1992; Joyce 1993). However, acrolein provides only temporary control of submerged weeds and also kills fish and other aquatic life at recommended treatment concentrations (Bowmer and Smith 1984). In one Montana stream, acrolein killed all fish in a 4-km stretch after application to control submerged weeds; some fish deaths were recorded as far as 6.4 km downstream (Fritz-Sheridan 1982). Useful reviews on ecological and toxicological aspects of acrolein are presented by Smith (1962), USEPA (1980), Beauchamp et al. (1985), Agency for Toxic Substances and Disease Registry [ATSDR] (1990), and Eisler (1994).

10.2 SOURCES AND USES

10.2.1 General

Acrolein enters the environment as a result of normal metabolic processes; incomplete combustion of coal, wood, plastics, tobacco, and oil fuels; and industrial emissions. Acrolein has been detected in smog, foods, and water. It is used extensively in chemical manufacture, for control of fouling organisms, and as an herbicide to control submerged weeds in irrigation canals.

10.2.2 Sources

Acrolein is ubiquitous in the environment as a result of natural and anthropogenic sources. Sources of atmospheric acrolein include smog; incomplete combustion of coal, wood, gasoline, plastics, and fats; tobacco smoke; and industrial emissions. The total amount of acrolein released into the atmosphere is unknown. In 1978, production losses of acrolein by emission from the four main U.S. plant locations were estimated at 34,682 kg; however, the gaseous emission streams are now either burned on emergence from the exhaust stack or sent to a furnace to destroy residual material (Beauchamp et al. 1985). Acrolein is found in photochemical smog and contributes to the smog's irritant capacity to the eye and respiratory pathways (Beauchamp et al. 1985; Leikauf et al. 1989). Recorded maximum acrolein concentrations in smog ranged from 12 to 14 µg/L (0.025 to 0.032 mg/m³) in Los Angeles between 1961 and 1963, and were 13 µg/L in Hudson County, New Jersey (USEPA 1980). For humans, exposure to atmospheric acrolein is greatest in the vicinity of incompletely combusted organic materials such as coal, wood, and petrol; highest acrolein concentrations are reported near forest fires and urban area fires (Beauchamp et al. 1985; Srivastava et al. 1992). The burning of southern pine (*Pinus* sp.), for example, generates 22 to 121 mg of acrolein/kg of wood burned (USEPA 1980). Acrolein is also in the smoke of burning plastic materials. Air samples from more than 200 fires in Boston, Massachusetts, contained greater than 3000 µg acrolein/L (greater than 6.8 mg/m³) in more than 10% of all samples; greater than 3000 µg acrolein/L air is an immediately hazardous concentration for human life and health (Beauchamp et al. 1985). Cigarette smoke in some enclosed areas may account for as much as 12,400 µg of acrolein/L air (Feron et al. 1978; Astry and Jakab 1983; Beauchamp et al. 1985; Leikauf et al. 1989; Cohen et al. 1992). In the case of an enclosed room of 30 m³ capacity, smoking five cigarettes raises the air concentration to about 50 µg acrolein/L and 30 cigarettes to 380 µg/L (USEPA 1980).

Acrolein is also generated when animal or vegetable fats are subjected to high temperatures (Feron et al. 1978; USEPA 1980). Acrolein was detected aboard submarines in trace concentrations as a degradation product during the heating of lubrication oils and edible fats (Lyon et al. 1970). Large amounts of acrolein are generated from exhausts of internal combustion engines (Astry and Jakab 1983; Heck et al. 1986; Ballantyne et al. 1989). Acrolein concentrations of 10,000 µg/L (23 mg/m³) have been measured in non-diesel automobile exhausts, 2900 µg/L in diesel engine emissions, and 2600 to 9600 µg/L in other internal combustion engines (USEPA 1980). Acrolein concentrations in air from several U.S. urban areas ranged from a maximum of 10 µg/L in 1960 to 1.8 to 3.4 µg/L in 1968; air in Tokyo during this period had an average acrolein concentration of 7.2 µg/L (Beauchamp et al. 1985). Urban acrolein pollution is derived mainly from automobile exhaust and incomplete burning of refuse (Beauchamp et al. 1985). Acrolein is formed during normal metabolic degradation of spermine and spermidine, glycerol, allyl formate, allyl alcohol, and cyclophosphamide (USEPA 1980; Marano and Puiseux-Dao 1982; Leach et al. 1987). Acrolein was also found in spores from the wheat stem fungus (*Puccinia graminis*) of infected wheat (*Triticum aestivum*); and acrolein was the major chemical factor that normally induced infection structure formation in *Puccinia* (Macko et al. 1978).

Acrolein has been detected in effluent water streams from industrial and municipal sources. Municipal effluents from Dayton, Ohio, for example, contained between 20 and 200 µg acrolein/L in 6 of 11 analyzed samples (USEPA 1980; Beauchamp et al. 1985). Acrolein is also a component of many foods, and processing may increase the acrolein content (USEPA 1980). Acrolein has been identified in raw turkey, potatoes, onions, coffee grounds, raw cocoa beans, alcoholic beverages, hops (USEPA 1980), white bread, sugarcane molasses, souring salted pork, and cooked bluefin tuna (*Thunnus thynnus*) (Beauchamp et al. 1985).

Occupational exposure to acrolein can occur during its production and isolation as a chemical intermediate or during the manufacture of acrylic acid, acrylic acid esters, and methionine (Beauchamp et al. 1985). Other sources of acrolein in the workplace include emissions from rubber vulcanization plants, welding of metals treated with anticorrosion primers, and pitch-cooking plants; skin contact during herbicidal applications for aquatic weed control; and its use as a slimicide in paper and paperboard manufacture. Acute acrolein poisoning from occupational exposure is improbable. However, the risks of poisoning are significant in certain industries, including welding of fat and oil cauldrons, smelting work and foundry operations, printing plants, linoleum and oil cloth factories, manufacture of insulators, tin plating of sheet iron, and processing of linseed oil (Beauchamp et al. 1985).

10.2.3 Uses

Since its discovery in 1843, acrolein has been known to polymerize readily in the presence of many chemicals, and since 1947 it has been used safely in a wide variety of commercial applications (Albin 1962; Fischer 1962). Acrolein is presently produced by the catalytic oxidation of propylene for the manufacture of methionine, glutaraldehyde, 1,2,6-hexane thiol, and other chemicals. The largest quantity of acrolein produced by this process is converted directly to acrylic acid and acrylic acid esters (Beauchamp et al. 1985). In 1975, global production of acrolein was 59,000 metric tons; in 1980, this value was 102,000 tons — including 47,600 tons produced by the United States (USEPA 1980). In 1983, about 250,000 tons (about 550 million pounds) of acrolein were produced, and 92% was converted to acrylic acid, 5% to methionine, and 3% was used as an aquatic herbicide (Beauchamp et al. 1985; Heck et al. 1986). Acrolein copolymers are used in photography, in textile treatment, in the paper industry, as builders in laundry and dishwasher detergents, and as coatings for aluminum and steel panels (USEPA 1980). Acrolein is used to scavenge sulfides from oilfield floodwater systems (Kissel et al. 1981), to crosslink protein collagen in the leather tanning industry, and to fixate tissue of histological samples (USEPA 1980). The use of acrolein as a military poison gas has been advocated because of its lacrimatory and blistering properties. During World War I, the French used acrolein under the name of Papite in hand grenades because of its irritating effect on the respiratory airways and the ocular mucosa (Beauchamp et al. 1985).

Acrolein has been used since 1960 to control submerged aquatic weeds in irrigation systems in the United States, Australia, and other countries where open channels distribute water for crop production (Hill 1960; Bartley and Hattrup 1975; Bowmer and Higgins 1976; USEPA 1980; Reinert and Rodgers 1987). Acrolein — as Magnacide H herbicide — is applied directly into agricultural irrigation systems at 1 to 15 mg/L. Water in treated canals is required by the Magnacide H label to be held for 6 days before discharge into receiving waters (Nordone et al. 1998). Acrolein is preferable to sodium arsenite for herbicidal control of submerged weeds because arsenicals are persistent (up to 1 year) and the high arsenic concentrations that are attained in water may be hazardous to humans and livestock (Hill 1960). Acrolein is extremely effective in killing submerged weeds that are difficult to control with other herbicides (Hill 1960). Acrolein has also been used as an herbicide in ponds, drains, and other bodies of water (Donohue et al. 1966). In Australia, the concentration of acrolein in irrigation canals to control various species of *Elodea*, *Potamogeton*,

and *Vallisneria* is usually less than 15,000 µg/L (Bowmer and Higgins 1976). In general, acrolein has a low order of toxicity to terrestrial plants (Donohue et al. 1966). Most field and garden crops can tolerate water with as much as 15,000 µg acrolein/L without serious adverse effects (Bartley and Hattrup 1975). Acrolein, as discussed later, has comparatively low persistence and low accumulation in aquatic ecosystems. One disadvantage to its use as an herbicide is its pungent, irritating odor (Hill 1960). At recommended treatment concentrations, however, acrolein kills fish and other aquatic organisms; therefore, acrolein should be used only in aquatic systems where these resources are considered expendable (Reinert and Rodgers 1987).

Acrolein has been used to control bacteria, fungi, algae, and molluscs in cooling water systems: 1500 µg/L killed as much as 95% of the target species in a once-through treatment (Donohue et al. 1966). Acrolein has been applied directly to the marine environment to control the growth and settlement of mussels (*Mytilus edulis*) and other fouling organisms in cooling water systems of coastal steam electric station power plants (USEPA 1980; Rijstenbil and van Galen 1981). Mussels in marine cooling water systems are controlled with 600 µg acrolein/L for 8 h daily for 3 days or with 700 µg/L for 3 h daily for 2 weeks (Rijstenbil and van Galen 1981). Acrolein prevents growth of microorganisms in liquid fuels such as jet fuels, in feed lines of subsurface wastewater injectors, and in water conduits of paper manufacturing plants (USEPA 1980; Beauchamp et al. 1985).

10.3 ENVIRONMENTAL CHEMISTRY

10.3.1 General

Acrolein, the simplest member of the class of unsaturated aldehydes, has a pungent, irritating odor. It is volatile, flammable, and explosive and requires elaborate and specific conditions for storage and use. The half-time persistence of acrolein in freshwater is usually less than 50 h; in seawater, it is less than 20 h; and in the atmosphere, less than 3 h. Biochemical and toxic effects of acrolein are caused by its rapid and essentially irreversible reaction with sulphydryl compounds to form a stable thiol ether; however, many compounds can mitigate or block its toxicity. Acrolein is eventually metabolized to acrylic acid and glyceraldehyde; glycidaldehyde — an intermediate metabolite with mutagenic and carcinogenic properties — has been produced *in vitro* but not *in vivo*.

10.3.2 Chemical Properties

Acrolein is soluble in water and in many organic solvents, including ethanol, acetone, and ether (Table 10.1) (Beauchamp et al. 1985). Acrolein is a highly reactive molecule with two reactive centers: one at the carbon–carbon double bond and the other at the aldehydic group. Typical reactions involving acrolein are shown in detailed figures in Beauchamp et al. (1985). Acrolein is extremely volatile, flammable, and explosive (Table 10.1) (Reinert and Rodgers 1987), especially in sunlight or in the presence of alkali or strong acid (Albin 1962; USEPA 1980). A potential hazard in handling acrolein is its rapid exothermic polymerization caused by the use of insufficient hydroquinone inhibitor or lack of strict control of pH (Beauchamp et al. 1985). Commercial acrolein should be maintained at pH 6.0 and contain less than 3% water and 0.1 to 0.25% hydroquinone as a polymerization inhibitor. A typical commercial sample contains about 97% acrolein, 0.5% other carbonyls, and 2.5% water. The addition of hydroquinone (0.1 to 0.25%) prevents the vinyl polymerization of acrolein, and controlling the pH between 5 and 6 by acetic acid increases stability of commercial acrolein by preventing aldol condensation. Elaborate and specific conditions are now prescribed for the storage of acrolein and include vents and safety valves, construction materials, fire control, spills, and waste disposal (Beauchamp et al. 1985). Commercial acrolein is stored and shipped under a blanket of oxygen-free inert gas (Albin 1962).

Table 10.1 Chemical and Other Properties of Acrolein

Variable	Data
Chemical name	2-Propenal
Alternate names	Acraldehyde Acraldehyde Acrolein Acryladehyde Acrylaldehyde Acrylic aldehyde Allyl aldehyde Aqualin Aquilin, Magnacide H Propenal
CAS Number	107-02-8
Structural formula	$\text{CH}_2 = \text{CHCHO}$
Molecular weight	56.06
Specific gravity	0.8427–0.8442
Physical state	Colorless or yellow liquid at 25°C
Odor	Pungent, irritating
Boiling point	52.5–53.5°C
Melting point	–86.95°C
Solubility	
Water	206–208 g/L
Organic solvents	Miscible
Log K_{ow}	0.01
Vapor pressure	215–220 mmHg at 20°C
Explosive limits of vapor and air	
Upper limit	31% acrolein
Lower limit	2.8% acrolein

Data from Hill 1960; Anderson and Hood 1962; Folmar 1977; USEPA 1980; Hudson et al. 1984; Beauchamp et al. 1985; Mayer 1987; Reinert and Rodgers 1987; Ballantyne et al. 1989; Sine 1991; Agency for Toxic Substances and Disease Registry [ATSDR] 1990; and National Institute for Safety and Health [NIOSH] 1990.

Spectrophotometric determination with 4-hexylresorcinol and a fluorometric method with *m*-aminophenol are the most commonly used procedures for the determination of acrolein. However, gas chromatography and high-performance liquid chromatography procedures are also used (USEPA 1980; Kissel et al. 1981; Nishikawa and Hayakawa 1986). Acrolein concentrations in rainwater between 4 and 200 µg/L can be measured rapidly (less than 80 min) without interference from related compounds; the method involves acrolein bromination and analysis by gas chromatography with electron capture detection (Nishikawa and Hayakawa 1986). Kissel et al. (1981) emphasize that water samples from potential acrolein treatment systems require the use of water from that system in preparing blanks, controls, and standards and that acrolein measurements should be made at the anticipated use concentrations.

10.3.3 Persistence

Degradation and evaporation seem to be the major pathways for acrolein loss in water; smaller amounts are lost through absorption and uptake by aquatic organisms and sediments (USEPA 1980; Reinert and Rodgers 1987). The half-time persistence of acrolein in freshwater is 38 h at pH 8.6 and 50 h at pH 6.6; degradation is more rapid when initial acrolein concentrations are less than 3000 µg/L (Bowmer and Higgins 1976). Nordone et al. (1998) show a half-time persistence of 2.9 to 11.3 h at initial nominal concentrations of 20 µg/L, and 27.1 to 27.8 h at 101 µg/L. At pH 5, acrolein reacts by reversible hydrolysis to produce an equilibrium mixture with 92% beta-hydroxy-

propionaldehyde and 8% acrolein. In alkali, the primary reaction is consistent with a polycondensation reaction (USEPA 1980). In natural waters, acrolein degradation proceeds to carboxylic acid via a microbial pathway (USEPA 1980); beta-hydroxypropionaldehyde is readily biotransformed in about 17.4 days (Reinert and Rodgers 1987). Microbial degradation plays a major role in the transformation of acrolein in aquatic systems (Nordone et al. 1998).

Acrolein is applied to irrigation canals to control submerged aquatic weeds at greatly different time-concentration treatments. Regardless of time-concentration regimens — which vary from 100 µg/L for 48 h in the United States to 15,000 µg/L for several hours in Australia — the daily decay rate constants are remarkably similar, ranging from 0.14 to 0.21, and are probably affected by variations in weed density (O'Loughlin and Bowmer 1975; Parent et al. 1992). In one case, acrolein applied to the Columbia River at an average initial concentration of 125 µg/L degraded to 25 µg/L after 48 h in samples greater than 65 km from the application point — a loss of 80% (USEPA 1980). High initial concentrations (50,000 to 160,000 µg/L) of acrolein in natural waters degraded 57 to 80% in 192 h, suggesting that high concentrations can alter the rate of hydrolysis (Kissel et al. 1981). In seawater, the half-time persistence of acrolein was less than 20 h (Rijstenbil and van Galen 1981). In photochemical smog, acrolein is comparatively unstable and not likely to persist; the dominant removal mechanism involves hydroxide attack on acrolein, and the atmospheric half-life persistence is 2 to 3 h under these conditions (Beauchamp et al. 1985).

10.3.4 Metabolism

Biochemical and toxic effects of acrolein are probably caused by its reaction with critical protein and nonprotein sulfhydryl groups (USEPA 1980; Beauchamp et al. 1985; Heck et al. 1986). The reaction of acrolein with sulfhydryl compounds is rapid and essentially irreversible, resulting in the formation of a stable thiol ether (Beauchamp et al. 1985; Heck et al. 1986). Metabolism of acrolein is believed to result in the formation of acrylic acid and glyceraldehyde (Figure 10.1). The postulated metabolites of acrolein can be oxidized to carbon dioxide (Beauchamp et al. 1985). Acrylic acid does not seem to represent a significant toxic hazard when compared to the parent acrolein because at low airborne concentrations of less than 1000 µg acrolein/L, the quantity of acrylic acid produced by metabolism is negligible. Thus, metabolism to acrylic acid after inhalation should be regarded as a detoxification pathway. Conjugation of acrylic acid with glutathione represents another elimination and detoxification pathway (Beauchamp et al. 1985). *In vitro* studies of acrolein metabolism in mammals suggest that acrolein exposures might result in exposure to glycidaldehyde, an intermediate in acrolein metabolism (Figure 10.1). The major toxic effects of acrolein exposure — including irritation, ciliastasis, and hypersensitivity — are probably due either

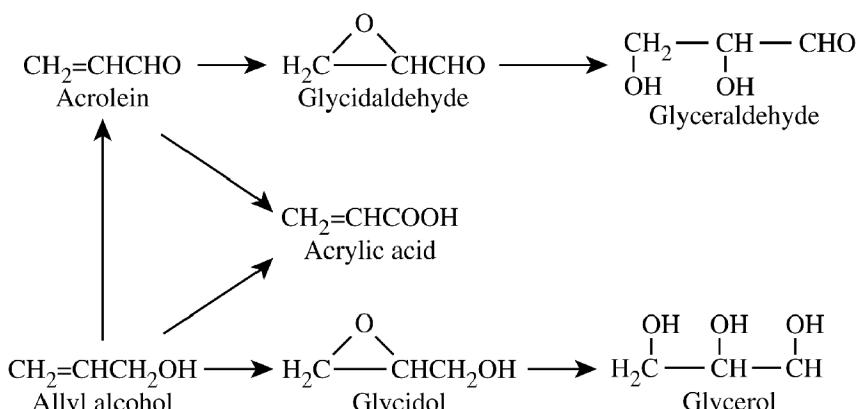

Figure 10.1 Proposed scheme for *in vitro* mammalian metabolism of acrolein and allyl alcohol, a precursor of acrolein. (Adapted from Beauchamp et al. 1985; ATSDR 1990; Eisler 1994.)

to the parent acrolein or to the reaction of glyceraldehyde with cell proteins. Glyceraldehyde is a potent mutagen and carcinogen; however, no evidence is available showing that acrolein can produce glyceraldehyde *in vivo* (Beauchamp et al. 1985). Acrolein is more toxic when inhaled than when taken orally (USEPA 1980). Inhalation of acrolein decreased the concentrations of protein and nonprotein sulphydryl groups in nasal mucosal tissue (Heck et al. 1986). Acrolein is highly reactive toward thiol groups and rapidly conjugates with glutathione and cysteine (USEPA 1980). When glutathione is depleted, acrolein potentiates the nasal toxicity of formaldehyde to rats (Heck et al. 1986).

Acrolein is a metabolite of allyl alcohol and cyclophosphamide, and these compounds should be considered in acrolein metabolism schemes (Beauchamp et al. 1985; Cohen et al. 1992). Allyl alcohol in the presence of NADPH and liver or lung microsomes degrades to acrolein, acrylic acid, and glycidol (Figure 10.1).

When added to water as an aquatic herbicide, acrolein undergoes rapid decomposition, especially in sunlight. At the same time, it reacts rapidly with amines, alcohols, and mercaptans of aquatic plants, destroying cell structure and killing the plants (Parent et al. 1992). Mammals drinking acrolein-contaminated water rapidly convert acrolein to saturated alcohol compounds because of the low pH in the upper portion of their GI tracts; the primary breakdown product is beta-propionaldehyde (USEPA 1980).

Many compounds, including glutathione, 2-mercaptoethanol, beta-dimethylcysteamine, penicillamide, gamma-mercaptopropionylglycine, and *N*-acetylcysteine, mitigate or block the toxic effects of acrolein (USEPA 1980; Beauchamp et al. 1985; Heck et al. 1986). In frogs (*Rana japonica*), sulphydryl compounds reduce the effects of acrolein on excitation-contraction uncoupling in skeletal muscle (Fujino et al. 1985). In mice, cysteine reduced the cytotoxic effects of acrolein on tumor cells; in rabbits, cysteine mitigated acrolein-induced alveolar macrophage calcium-dependent ATP-ase, phagocytosis, and adhesiveness (USEPA 1980). In male rats, cysteine and ascorbic acid antagonized the acute lethal effects of orally administered acrolein, and 2-mercaptoethanol antagonized the inhibitory effect of acrolein on liver DNA-polymerase (USEPA 1980).

10.4 LETHAL AND SUBLETHAL EFFECTS

10.4.1 General

Acrolein degrades quickly in soils and in plant tissues, regardless of mode of administration. Most terrestrial crop plants easily tolerate 25,000 µg acrolein/L of irrigation water, and some can tolerate 70,000 to 80,000 µg/L without adverse effects. Terrestrial plants were adversely affected at atmospheric concentrations of 500 µg acrolein/L air, but this concentration exceeds the recommended value of 110 µg/L (0.25 mg/m³) air for protection of human health in occupational settings.

Adult fruitflies (*Drosophila* sp.) were comparatively resistant to acrolein and had lowered survival when reared in culture media with greater than 3,700,000 µg acrolein/L. At recommended concentrations for control of nuisance submerged aquatic weeds (frequently 100 to 1000 µg/L, and often greater than 9600 µg/L), acrolein was lethal or harmful to almost all aquatic vertebrates and invertebrates tested in short-term exposures. The most sensitive groups of tested aquatic organisms in short-term assays were frog tadpoles (dead at 7 µg/L) and representative species of fish (reduced survival at 14 to 62 µg/L) and crustaceans (death or immobilization at 34 to 80 µg/L). Adverse effects of acrolein on birds were observed at acute oral doses of 9100 µg/kg BW (reduced survival), concentrations greater than 51 µg/kg egg for egg injection (abnormal development and reduced survival), and at greater than 50,000 µg/L air (respiratory tract histopathology). In mammals, acrolein is a strong cytotoxic and ciliostatic agent that is irritating to mucous membranes of dermal, ocular, gastrointestinal, and respiratory systems, and is systemically toxic by all routes of exposure. Adverse effects of acrolein are documented in sensitive species of mammals under the following

regimens: 50 µg/L air for 1 min (increased blood pressure and heart rate); 300 µg/L air for 10 min (ocular and nasal irritation); 500 to 1000 µg/L air (repelled by odor); 660 µg/L air for 24 days (reduced survival); 8000 to 11,000 µg/L air for 4 to 6 h, or 875,000 µg/L air for 1 min (death); dietary concentrations equivalent to 500 µg/kg BW for 102 weeks (decreased survival); 850 to 6000 µg/kg BW by way of intravenous injection (liver necrosis, embryo resorption); and single oral doses between 4000 and 28,000 µg/kg BW (death).

Acrolein was mutagenic to certain microorganisms and to the fruitfly; mutagenicity may be due, in part, to glyceraldehyde, an acrolein metabolite. Injected into the amniotic fluid, acrolein is teratogenic to rats. Teratogenicity may be due to acrylic acid, an acrolein metabolite. There is limited evidence that acrolein acts as a weak carcinogen and tumor promoter. Acrolein interacts with other chemicals, sometimes synergistically, additively, or antagonistically. Also, some chemicals normally contain acrolein as an impurity or yield acrolein as a metabolite.

10.4.2 Terrestrial Plants and Invertebrates

Most crop plants easily tolerate irrigation water with 25,000 µg of acrolein/L and many tolerate 70,000 to 80,000 µg/L without adverse effects — including corn (*Zea mays*), cotton (*Gossypium hirsutum*), milo (*Sorghum* spp.), squash (*Cucurbita* spp.), castor bean (*Ricinus communis*), tomato (*Lycopersicon esculentum*), alfalfa (*Medicago sativa*), and sugarcane (*Saccharum officinarum*) (Ferguson et al. 1961). Acrolein degrades quickly in soils and plant tissues, regardless of mode of administration (Ferguson et al. 1961). Atmospheric concentrations of 500 µg acrolein/L and higher were harmful to certain plants (Beauchamp et al. 1985). Leaves of the pinto bean (*Phaseolus* spp.) and morning glory (*Ipomoea* spp.) developed brown foliar lesions after exposure to 500 µg/L air for 4 to 7 h; damage was more severe if the plants were moist during exposure. Leaves of the radish (*Raphanus* spp.) developed lesions after exposure to 1500 µg acrolein/L air for 6 to 7 h. However, leaves of the geranium (*Geranium* spp.) and the tomato showed no adverse effects after exposure to 1500 µg/L air for 7 h (Beauchamp et al. 1985).

Acrolein inhibits DNA, RNA, and protein synthesis in the bacterium *Escherichia coli*, and this inhibition probably accounts for its cytotoxic and inhibitory effects on *E. coli* cell division (USEPA 1980; Beauchamp et al. 1985). Acrolein is demonstrably mutagenic to microorganisms and to larvae of the fruitfly (*Drosophila melanogaster*). Acrolein-induced mutagenicity — including point mutations, sister chromatid exchanges, and chromosome breakages — has been observed in selected strains of bacteria (*E. coli*, *Salmonella typhimurium*), yeast (*Saccharomyces cerevisiae*), fruitfly larvae, and cultured Chinese hamster ovary cells (USEPA 1980; Beauchamp et al. 1985; Sierra et al. 1991; Cohen et al. 1992). Acrolein's mutagenicity may be due to the metabolite glyceraldehyde. Glyceraldehyde was mutagenic to bacteria and yeast under controlled conditions (Beauchamp et al. 1985; Sierra et al. 1991). Studies with *D. melanogaster* show that acrolein is mutagenic in the sex-linked recessive lethal test when injected but not when fed (Sierra et al. 1991). Acrolein caused 2.2% sex-linked mutations in *D. melanogaster* — the highest percentage recorded among several tested aldehydes (USEPA 1980). In studies by Comendador (1984), early embryonic stages of fruitflies were most sensitive to the mutagenic properties of acrolein, and sensitivity decreased with increasing development to the point that adults showed negligible mutagenic responses. Adult fruitflies were generally resistant to acrolein; mortality was 25% when the culture medium contained 3,700,000 µg of acrolein/L, 50% at 8,600,000 µg/L, and 75% at 22,100,000 µg/L (Comendador 1984).

10.4.3 Aquatic Organisms

Adverse effects of acrolein on sensitive groups of aquatic organisms are documented (Table 10.2) at concentrations (in µg acrolein/L medium) as low as 7 for frog tadpoles (death), 14 to 62 for fish (death), 34 to 80 for crustaceans (death, immobilization), 50 for oysters (reduction

in shell growth rate), 100 to 200 for freshwater algae (DNA and RNA reduction, photosynthesis inhibition), 151 for gastropods (death), >151 for insects (death), 500 to 2000 for macrophytes (leaf cell deterioration, death), 1250 for trematodes (death of miracidia in 20 min), and 62,000 for bacteria (growth reduction). Aquatic vertebrates were more sensitive than invertebrates (Holcombe et al. 1987), and younger fish were more sensitive than older fish (Burdick et al. 1964). Aquatic insects do not avoid acrolein at concentrations that repel fish (Folmar 1978). Freshwater fishes and macroinvertebrates, when exposed under static conditions to sublethal concentrations of ¹⁴C-labeled acrolein, metabolize acrolein so rapidly that neither acrolein nor its major oxidative and reductive metabolites (acrylic acid, allyl alcohol) were detected in edible tissues within 24 h after dosing (Nordone et al. 1998).

As an herbicide, acrolein is most effective in controlling dense accumulations of submerged weeds in habitats where waterflow is rapid and uniform, such as irrigation canals and rapidly flowing streams (Ferguson et al. 1961). Acrolein is lethal to various genera of submerged plants (*Hydrodictyon*, *Spirogyra*, *Potamogeton*, *Zannichellia*, *Cladophora*, *Ceratophyllum*, *Elodea*, *Chara*, *Najas*) at 1500 to 7500 µg/L (Ferguson et al. 1961; Beauchamp et al. 1985), but some floating plants (*Pistia*, *Eichhornia*, *Jussiaea*) are more resistant to acrolein than submerged plants and require concentrations that are at least double those necessary for submerged forms (Ferguson et al. 1961). Also, acrolein has little effect on emergent aquatic macrophytes and should not be used to control emergents (Ferguson et al. 1961). Acrolein is the only herbicide now used in Australia for control of submerged aquatic weeds in larger irrigation canals (Bowmer et al. 1979); effective plant control was obtained at 9.6 to 28.8 mg/L for 3 h (Bowmer and Smith 1984). In the United States, the U.S. Bureau of Reclamation controls aquatic algae and weeds at lower concentrations (0.1 mg/L) and longer exposures (48 h; Folmar 1980). In the Columbia River Basin in the state of Washington, acrolein is used to control submerged aquatic macrophytes at concentrations of 0.1 mg/L for 48 h or 1.0 mg/L for 4 to 8 h with applications every 3 to 5 weeks (Bartley and Hattrup 1975). Vegetation destruction by acrolein is maximal 1 week after application, and green filamentous algae are usually the first plants to return after 1 month (Ferguson et al. 1961). Biomass and species diversity were altered in acrolein-treated phytoplankton populations in Egyptian irrigation canals 1 year after treatment (Kobbia 1982). Although acrolein is a powerful cytotoxic agent, its inhibitory effects at sublethal concentrations on plant mitosis, nucleic acid synthesis, and protein synthesis are considered completely reversible (Marano and Puiseux-Dao 1982).

Acrolein in concentrations sufficient to control nuisance submerged aquatic weeds may also kill snails, crayfish, shrimp, fish, and toads (Ferguson et al. 1961). In one case, acrolein was used to control *Potamogeton* and *Chara* in an Ohio farm pond during June 1960 (Hill 1960). Acrolein was applied at 16,100 µg/L to a 0.1-ha portion of the 0.7-ha pond. Within 1 h of application, many dead amphibian tadpoles and small bluegills (*Lepomis macrochirus*) were recovered. In 24 h, *Chara* had turned white and *Potamogeton* brown; both plant species seemed dead; fish were swimming in the treated area. In 72 to 96 h, several large dead walleyes (*Stizostedium vitreum vitreum*) were found. One week posttreatment, all algae and weeds in the treated area were dead; weeds were present in the untreated areas. The treated section remained weed-free for 4 to 6 weeks. After 8 weeks, the treated area was heavily infested with *Chara*. Hill (1960) concluded that tadpoles, walleyes, and small bluegills were more susceptible to acrolein toxicity than larger bluegills and bass (*Micropterus* spp.) in the pond. Acrolein is also effective in controlling trematodes that cause schistosomiasis wherein snails are the intermediate host, especially in irrigation systems. For example, native species of snails (*Lymnaea*, *Helisoma*), along with *Potamogeton* weeds, were destroyed within 12 km in the main irrigation canal of Kern County, California, after a single application of acrolein (Ferguson et al. 1961).

Acrolein was the most toxic of 15 herbicides tested for toxicity to fish (USEPA 1980). Responses by rainbow trout (*Oncorhynchus mykiss*) surviving 77 µg acrolein/L, a concentration that killed 50% in about 21 h, were characteristic of respiratory irritants (McKim et al. 1987). These responses included a steady increase in cough rate; decreases in ventilation rate, oxygen utilization, and heart

rate; increases in hematocrit; and decreases in total arterial oxygen, carbon dioxide, and pH (McKim et al. 1987). In studies by Bartley and Hattrup (1975), no-observable-effect concentrations of acrolein for rainbow trout were 240 µg/L for exposures of 4.8 h, and 48 µg/L for exposures of 48 h; these values are below the concentrations that control aquatic weeds. In the same study, rainbow trout that survived exposure to high sublethal concentrations for 48 h were unable to recover completely after acrolein treatments ended. Trout and other teleosts are poorly adapted to detoxify acrolein and other xenobiotic aldehydes (Parker et al. 1990). The low metabolic capacity of fish liver aldehyde dehydrogenase for aldehydes, in general, suggests that these compounds may be hazardous to fish populations (Parker et al. 1990). Applications of acrolein to waters where fish may be taken for human consumption should be made with caution; rainbow trout surviving exposure to acrolein in reservoirs or connecting canals frequently presented odor and taste problems to human consumers (Folmar 1980).

In addition to weeds, acrolein is used to control fouling organisms in cooling water systems. Effective control was established in a once-through cooling system of a steel mill with continuous application of 200 µg acrolein/L (Donohue et al. 1966). Acrolein controlled bacteria in condenser pipes of a power-plant cooling system, but only at extremely high concentrations of 125,000 µg/L for 120 h or 500,000 µg/L for 2 h (Starzecka 1975). Acrolein reduced settlement of young mussels (*Mytilus* sp.) in cooling seawater systems of power plants (Rijstebil and van Galen 1981). In recirculating cooling water systems, algae and bacteria can be controlled at 500 µg/L for 5 months or at 5000 µg/L for 1 week (Table 10.2).

Table 10.2 Acrolein Effects on Representative Aquatic Organisms

Taxonomic Group, Organism, Concentration, and Other Variables	Effect	Reference ^a
BACTERIA, ALGAE, AND MACROPHYTES		
Freshwater algae, <i>Anabaena</i> sp.; 690 µg/L; 24-h exposure	50% reduction in photosynthesis at 25°C	1
Aquatic bacteria: 3 species 62,000 µg/L; 48-h exposure	Some growth reduction, but recovery by 120 h	2
125,000 µg/L; 120-h exposure	LC100	2
500,000 µg/L; 2-h exposure	LC100	2
Freshwater alga, <i>Cladophora glomerata</i> 100 µg/L	Onset of photosynthesis inhibition at 30°C	1
760 µg/L; 24-h exposure	50% reduction in photosynthesis at 30°C	1
1000 µg/L; 24-h exposure	50% reduction in photosynthesis at 25°C	1
Alga, <i>Dunaliella bioculata</i> 100 µg/L; 48-h exposure	DNA concentration reduced 28%	3
200 µg/L; 48-h exposure	DNA concentration reduced 36% and RNA 28%	3
400 µg/L; 48-h exposure	DNA reduced 93%, RNA 68%, and proteins 74%	3
1000 µg/L; 48-h exposure	No development in 48 h	3
8000 µg/L; 3-h exposure	Ultrastructural anomalies and cytoplasmic inclusions	4
Elodea, <i>Elodea canadensis</i> Sublethal (actual exposure concentration and duration unknown)	Growth stimulation (from reduced competition by aufwuchs, bacteria, and epiphytic algae)	5
500 µg/L; 24-h exposure	Leaf cell deterioration	6, 7
2800 µg/L; 3-h exposure in irrigation canal	80% reduction in density; recovery began in 17 days	5
15,000 µg/L; 2–6-h exposure in Australian canals	Effective control for up to 21 km in flowing-water irrigation canals	8
18,000 µg/L; 2–12-h exposure in smaller channels and up to 72 h in major canals; New South Wales	Effective control	5
22,000 µg/L; 3-h exposure in irrigation canal	94% reduction in biomass after 14 days	5

Table 10.2 (continued) Acrolein Effects on Representative Aquatic Organisms

Taxonomic Group, Organism, Concentration, and Other Variables	Effect	Reference ^a
Filamentous algae, unidentified 500 µg/L; 5-month exposure; petroleum-refinery recirculating cooling-water system	Effective control	9
1000 µg/L; 20-h exposure in Arizona irrigation canal	Effective control for 2 weeks	10
3500 µg/L; 2-week exposure in petroleum refinery cooling water	Lethal	9
5000 µg/L; 1-week exposure in petroleum refinery cooling water	Lethal	9
Freshwater alga, <i>Enteromorpha intestinalis</i> 1800 µg/L; 24-h exposure	50% reduction in photosynthesis at 25°C	1
2500 µg/L for 24 h	50% reduction in photosynthesis at 20°C	1
>5000 µg/L for 24 h	50% reduction in photosynthesis at 15°C	1
Freshwater plants: 6 species of submerged plants, 2 species of floating plants, 4 groups of phytoplankton; irrigation drains, Egypt; 15,000–25,000 µg/L for 45 min, repeated 4 times	Effective control of all plants within 2–7 days; phytoplankton recovery over a 1-year period was most rapid for the Cyanophyceae, followed by the Bacilliarophyceae, Chlorophyceae, and Euglenophyceae, and resulting in altered biodiversity when compared to a control canal	11
Submerged macrophytes, 3 species (<i>Najas</i> sp., <i>Ceratophyllum</i> sp., and <i>Ipomea</i> sp.); 25,000 µg/L	All dead 1 week after application	6
Floating pondweed, <i>Potamogeton carinatus</i> 2000 µg/L for 12 h	LC50	12
10,000–15,000 µg/L for >1 h (actual exposure time unknown)	LC50	12
15,000 µg/L for 1.7 h	LC50	12
22,000–26,000 µg/L for >1 h (actual exposure time unknown)	LC80	12
Pondweed, <i>Potamogeton crispus</i> ; 20,000 µg/L for 5 h	All dead in 8 days	6
Pondweed, <i>Potamogeton tricarinatus</i> ; 4000 µg/L; 1-h exposure in irrigation canal	Minimum effective concentration	5
Submerged macrophyte, <i>Vallisneria gigantea</i> ; 26,000 µg/L for 1 h in irrigation canal	Minimum effective concentration	5
Ribbonweed, <i>Vallisneria spiralis</i> 1600 (95% confidence interval [CI] of 1300–2000) µg/L	50% reduction in biomass	12
3700 (95% CI of 3200–4600) µg/L for 1 h	80% reduction in biomass	12
INVERTEBRATES		
Snail, <i>Aplexa hypnorum</i> ; 151 µg/L for 96 h	Less than 50% mortality	13
Snail, <i>Australorbis glabratus</i> 1250 µg/L for 24 h	All adults and 90% of embryos survived	7
2500 µg/L for 24 h	35% of adults and 40% of embryos died	7
10,000 µg/L for 24 h	98% of adults and 100% of embryos died	6, 7
Barnacle, <i>Balanus ebarneus</i> ; 1600–2100 µg/L for 48 h	LC50	6
American oyster, <i>Crassostrea virginica</i> ; 50–55 µg/L for 96 h	50% reduction in shell growth rate	6, 14, 15
Daphnid, <i>Daphnia magna</i> 17–34 µg/L	MATC ^b	6, 16, 24
51 (95% CI of 43–62) µg/L for 48 h	50% immobilized	13
57–80 µg/L for 48 h	LC50	6

Table 10.2 (continued) Acrolein Effects on Representative Aquatic Organisms

Taxonomic Group, Organism, Concentration, and Other Variables	Effect	Reference ^a
Clam, <i>Elliptio complanata</i> ; 101 µg/L for 7 days	Acrolein not detected in tissues; glyceric acid and unidentified carbohydrates were the major metabolites	25
Mayfly, <i>Ephemerella walkeri</i> ; 100 µg/L for 1 h	No avoidance of acrolein by nymphs	17
Freshwater snails, 3 species (<i>Physa</i> , <i>Biomphalaria</i> , <i>Bulinus</i>); 25,000 µg/L for 3.5–4 h	All dead	14
Common mussel, <i>Mytilus edulis</i>		
200–1000 µg/L; exposed for as much as 8 h daily for 3 days	Valves closed immediately after start of exposure to acrolein, regardless of concentration or duration; effect in 45% of mussels at 200 µg/L, 80% at 400 µg/L, and 90% at 600 µg/L	8
600 µg/L; single 8-h exposure followed by 48-h of uncontaminated seawater	70% of the mussels (1–2.5 mm shell length) in the cooling water systems of power plants became detached in 3 days vs. 13% of controls	18
600 µg/L; 8-h exposure daily for 3 days	97% of mussels became detached	18
600 µg/L; 29-h continuous exposure	100% detachment	18
Northern crayfish, <i>Orconectes virilis</i> ; 101 µg/L for 7 days	Acrolein not detected in tissues; glycerol and lactic acid were the major metabolites	25
Brown shrimp, <i>Penaeus aztecus</i>		
100 µg/L for 48 h	LC50	14
100 µg/L for 48 h	50% loss in equilibrium	6, 15
Trematode, <i>Schistosoma mansoni</i>		
1250 µg/L for 20 min	Killed all miracidia	7
2500 µg/L	Killed all miracidia in 10 min, and all cercariae in 18 min	7
Midge, <i>Tanytarsus dissimilis</i> ; 151 µg/L for 48 h	Less than 50% mortality	13
VERTEBRATES		
Bowfin, <i>Amia calva</i> ; 62 µg/L for 24 h	LC50, fry	14
Goldfish, <i>Carassius auratus</i>		
80 µg/L for 24 h	LC50	6
1000–2000 µg/L for 3 h	Fatal	14
White sucker, <i>Catostomus commersoni</i> ; 14 (95% CI of 8–25) µg/L for 96 h	LC50	13
Longnose killifish, <i>Fundulus similis</i> ; 240 µg/L for 48 h	LC50	6, 15
Western mosquitofish, <i>Gambusia affinis</i>		
61 µg/L for 48 h	LC50	6, 14
149 µg/L for 24 h	LC50	14
Channel catfish, <i>Ictalurus punctatus</i> ; 20 µg/L for 7 days	Acrolein not detected in tissues; glycidol was the main metabolite	25
Bluegill, <i>Lepomis macrochirus</i>		
13 µg/L for 28 days	Whole fish, bioconcentration factor of 344	6
20 µg/L for 7 days, juveniles	Acrolein not detected in tissues; major metabolites were 1,3-propanediol and glyceric acid	25
33 (95% CI of 27–40) µg/L for 96 h	LC50	13
79 µg/L for 24 h	LC50	6, 19
90–100 µg/L for 96 h	LC50	6, 14
Largemouth bass, <i>Micropterus salmoides</i>		
160 µg/L for 96 h	LC50	6, 14
183 µg/L for 24 h	LC50	14
Rainbow trout, <i>Oncorhynchus mykiss</i>		
8 µg/L for 48 h	None dead	20
16 (95% CI of 14–19) µg/L for 96 h	LC50	13

Table 10.2 (continued) Acrolein Effects on Representative Aquatic Organisms

Taxonomic Group, Organism, Concentration, and Other Variables	Effect	Reference ^a
20, 50, or 100 µg/L; exposure for 4 h; trout collected 1, 4, and 7 days postexposure; cooked fillets evaluated for odor and taste by human panel	Unacceptable organoleptic qualities were recorded for fillets 1 and 4 days ($P = 0.05$) after treatment with 100 µg/L; some unacceptable qualities were detected 1 and 4 days after treatment with 50 µg/L, and at 7 days after treatment with 100 µg/L	17
29 (95% CI of 22–37) µg/L for 96 h	LC50	21
48 µg/L for 48 h	LC32	6, 20
65 µg/L for 24 h	LC50, fingerlings	6
77 µg/L for 20.5 h	LC50	21
90 µg/L for 4.8 h	No deaths	20
96 µg/L for 48 h	All dead	20
100 µg/L for 1 h	Avoidance by fry	6, 14, 23
150 µg/L	Lethal	22
240 µg/L for 4.8 h	LC10	20
410 µg/L for 4.8 h	LC70	20
>500 µg/L for 4.8 h	All dead	20
Chinook salmon, <i>Oncorhynchus tshawytscha</i> ; 80 µg/L for 24 h	LC50	6, 19
Fathead minnow, <i>Pimephales promelas</i>

^b Maximum acceptable toxicant concentration. Lower value in each pair indicates highest concentration tested producing no measurable effect on growth, survival, reproduction, or metabolism during chronic exposure; higher value indicates lowest concentration tested producing a measurable effect.

10.4.4 Birds

Acrolein was lethal to birds at single oral doses of 9100 µg/kg BW (Table 10.3). Observed signs of acrolein poisoning in subadult mallards (*Anas platyrhynchos*) after oral administration included regurgitation, a reluctance to leave the swimming area, slow responses, muscular incoordination, heavy-footed walking, phonation, wing tremors, running and falling, weakness, and withdrawal (Hudson et al. 1984). Treatment concentrations as low as 3300 µg/kg BW have produced signs of acrolein poisoning. These signs appeared as soon as 10 min after administration and persisted for as long as 36 days. At lethal oral concentrations, deaths occurred as soon as 32 min posttreatment and continued for several days (Hudson et al. 1984). Acrolein was lethal to developing

Table 10.3 Acrolein Effects on Birds

Organism, Route of Administration, Dose, and Other Variables	Effect	Reference ^a
MALLARD, <i>Anas platyrhynchos</i> Oral route; 9100 µg/kg body weight (BW), 95% confidence interval [CI] of 6300–13,100 µg/kg BW	LD50, age 3–5 months	1
DOMESTIC CHICKEN, <i>Gallus</i> sp. Inhalation route; adults subjected to 50,000 or 200,000 µg acrolein/L (113 or 454 mg/m ³) air via an endotracheal cannula for up to 27 days	Decreases in trachea complement of ciliated and goblet cells; inhibited mucus transport activity in trachea; lymphocytic inflammatory lesions in the tracheal mucosa; changes were more pronounced at the higher dose and with increasing exposures	2
Air sac injection route; embryos 2–3 days old; examined at day 13 >127 µg/kg fresh weight (FW) whole egg 182 µg/kg FW whole egg 1818 µg/kg FW whole egg	Dose-dependent decrease in survival LD50 LD80	3 3 3
Air sac injection route; embryos 3 days old 1 µg/kg FW whole egg 10 µg/kg FW whole egg 1000 µg/kg FW whole egg	20% developmental abnormalities vs. 5% in controls No malformations Lethal	4 4 4
Inner shell injection of membrane on heart route; embryos 72–76 h old; examined on day 14 of incubation 25 µg/kg FW whole egg 51 µg/kg FW whole egg 82 µg/kg FW whole egg 102 µg/kg FW whole egg 203 µg/kg FW whole egg	No deaths or malformations 50% dead or malformed LD50 71% dead, 6% malformed 97% dead, 3% malformed	5 5 5 5 5
Yolk-sac injection route; embryos 3 days old, examined at day 14 51 µg/kg FW whole egg 1018 µg/kg FW whole egg	LD50 LD90; no evidence of increased teratogenicity over controls	6 6

^a 1, Hudson et al. 1984; 2, Denine et al. 1971; 3, Chhibber and Gilani 1986; 4, Beauchamp et al. 1985; 5, Korhonen et al. 1983; 6, Kankaanpaa et al. 1979.

avian embryos when whole eggs were injected with 51 to 182 µg/kg FW. In descending order, embryos were most sensitive when acrolein was administered by way of the yolk sac (51 µg/kg), by inner shell (82 µg/kg), and by air sac (182 µg/kg) (Table 10.3). Acrolein is 50 times more toxic to embryos of the domestic chicken (*Gallus* sp.) than acrylonitrile, and 100 times more toxic than acrylamide (Kankaanpaa et al. 1979). Acrolein inhibits mucus transport in the trachea of the domestic chicken (Denine et al. 1971), probably through ciliostatic action (USEPA 1980). Adverse effects of acrolein were observed on chicken respiratory-tract physiology and pathology at greater than 50,000 µg/L air (Table 10.3).

Malformations of the eye, coelom, neck, back, wings, and legs were observed in surviving acrolein-treated chicken embryos (Korhonen et al. 1983) after whole eggs were injected with greater than 51 µg acrolein/kg FW (Table 10.3). In other studies, acrolein showed no clear evidence of teratogenicity in chicken embryos, although there is a dose-dependent embryotoxic effect (Beauchamp et al. 1985; Chhibber and Gilani 1986). Acrolein-treated chicken embryos had a higher frequency of abnormal limbs, abnormal neck, and everted viscera than the controls, but the frequency was not dose related. The overall incidence of abnormal embryos when treated at age 48 h was 24%, but only 4% in controls. In embryos given acrolein at age 72 h, these values were 26%, and 12% in controls (Chhibber and Gilani 1986).

10.4.5 Mammals

Acrolein is a strong cytotoxic and ciliostatic agent; its irritating effects on mucous membranes and its acute inhalation toxicity in mammals are well documented (Feron and Kruysse 1977; Feron et al. 1978; USEPA 1980; Astry and Jakab 1983; Beauchamp et al. 1985; Leach et al. 1987; Leikauf et al. 1989). A characteristic of acrolein is its pungent, offensive, and acrid smell, which is highly irritating to ocular and upper respiratory-tract mucosae (Beauchamp et al. 1985). Acrolein is toxic by all routes of exposure, and many of its toxic and biochemical effects are produced by interfering with critical sulphydryl groups (Srivastava et al. 1992). In isolated rat liver fractions, acrolein is a potent inhibitor of the high-affinity aldehyde dehydrogenase isozymes in mitochondrial and cytosolic fractions (Mitchell and Petersen 1988). Acrolein impairs DNA replication *in vitro* and inhibits certain mitochondrial functions (Feron et al. 1978). Studies with isolated rat liver-membrane proteins revealed that acrolein inhibits plasma membrane enzymes and alters the membrane protein profile; this may be due to acrolein-induced polymerization of plasma-membrane proteins (Srivastava et al. 1992).

Measurable adverse effects of acrolein have been documented in representative species of mammals, but the severity of the effects is contingent on the mode of administration, concentration, dose, and duration of exposure (Table 10.4). Single oral doses of 4000 µg/kg BW were lethal to guinea pigs, and 28,000 µg/kg BW to mice; diets containing the equivalent of 500 µg/kg BW and more decreased survival in rats after 102 weeks (Table 10.4). Concentrations of 60,000 µg acrolein/L in drinking water had no measurable adverse effects on cows (*Bos* sp.) after 24 h. Rats initially rejected drinking water containing 200,000 µg/L, but eventually tolerated this concentration (Table 10.4). Dermal toxicity seems low; rabbits that were immersed up to their necks in water containing 20,000 µg acrolein/L for 60 min showed no adverse effects (Table 10.4). No dermal sensitization occurred in healthy female guinea pigs (*Cavia* spp.) after repeated skin exposures to acrolein (Susten and Breitenstein 1990). In undiluted liquid or pungent vapor form, however, acrolein produces intense irritation of the eye and mucous membranes of the respiratory tract, and direct contact with the liquid can produce skin or eye necrosis (Beauchamp et al. 1985). A single intravenous injection of 850 µg acrolein/kg BW produced liver necrosis in rats; 6000 µg/kg BW caused increased embryo resorption in mice (Table 10.4). Rats receiving near-lethal doses of acrolein by subcutaneous injection had liver and kidney damage and lung pathology (USEPA 1980). Although subcutaneous injections revealed LD₅₀ values between 164,000 and 1,022,000 µg/kg BW in rabbits, these results are questionable because acrolein may be sequestered at the injection site and delay delivery to the systemic circulation (Beauchamp et al. 1985). A single intraperitoneal injection of 1000 µg/kg BW caused peritonitis in rats and 7000 µg/kg BW was lethal to mice; daily injections of 1000 µg/kg BW were eventually lethal to rats (Table 10.4). Sublethal intraperitoneal injections of acrolein induced ascites, increased hematocrit, and prolonged sleeping times (Beauchamp et al. 1985). Acquired tolerance to acrolein in mice given repeated intraperitoneal injections suggests that an increased metabolism can partially explain the acquired tolerance (Warholm et al. 1984).

The largest number of studies of the toxicity of acrolein in animals was conducted by way of inhalation, probably because acrolein has an appreciable vapor pressure under ambient conditions and inhalation is the principal exposure for humans (Beauchamp et al. 1985). Because of their intolerance to sharp and offensive odor and to intense irritation of conjunctiva and upper respiratory tract, humans have not suffered serious intoxication from acrolein. The strong lacrimation effect of acrolein is usually a warning to occupational workers. Physiological perception of acrolein by humans begins at about 500 to 1000 µg/L air with eye and nasal irritation. The irritating effects compel afflicted individuals to immediately leave the polluted area (Beauchamp et al. 1985). Laboratory animals died from inhalation of 8000 to 11,000 µg/L after 4 to 6 h, mice from 875,000 µg/L after 1 min, and rats from 660 µg/L for 24 days (Table 10.4). Animals dying from

acute and subacute exposure to acrolein vapor had lung injury with hemorrhagic areas and edema (Albin 1962). Repeated exposures of hamsters, rats, and rabbits to high sublethal concentrations of acrolein caused ocular and nasal irritation, growth depression, and respiratory tract histopathology in all species (Feron and Kruysse 1977) (Table 10.4). However, repeated exposures to low, tolerated concentrations of acrolein did not produce toxicological effects (Albin 1962), suggesting that acrolein effects are not cumulative and that minimal damage is quickly repaired.

Inhaled acrolein (in μg acrolein/L air) had sublethal effects at 10 to 50 for 1 min on rats (increased blood pressure and heart rate); at 10 for 5 weeks on mice (reduction in pulmonary compliance); at 140 to 150 for 2 min on humans (eye irritation in 30%); at 300 to 500 on humans (odor threshold); at 300 for 10 min on humans (acute irritation); at 400 for 13 weeks on rats (nasal histopathology); at 400 to 600 for 1 to 3 min on dogs (accumulations in upper respiratory tract); and at 1000 for 90 days on dogs, monkeys, and guinea pigs (ocular and nasal discharges) (Table 10.4). Sublethal effects of inhaled acrolein in representative small laboratory mammals were greatest on the upper respiratory tract and bronchial airways and included edema, ciliastasis, inflammation, degenerative loss of epithelia, altered ventilatory function, and bronchoconstriction (Feron and Kruysse 1977; Feron et al. 1978; USEPA 1980; Astry and Jakab 1983; Beauchamp et al. 1985; Barkin et al. 1986; Leach et al. 1987; Leikauf et al. 1989) (Table 10.4). Typical signs of toxicity from inhaled acrolein in small mammals include ocular and nasal irritation; growth depression; shortness of breath; lesions in the urinary tract, respiratory tract, trachea, and nasal passages; laryngeal edema; reduced resistance to bacterial infection; enlarged liver and heart; elevated blood pressure and heart rate; altered enzyme activities; and protein synthesis inhibition (USEPA 1980; Beauchamp et al. 1985; Leach et al. 1987) (Table 10.4). Signs of inhaled acrolein toxicity varied significantly with dose and species. For example, acrolein toxicity in rats at environmental concentrations was confined to local pathologic nasal changes, including metaplastic, hyperplastic, and dysplastic changes in the mucous, respiratory, and olfactory epithelium of the nasal cavity (Leach et al. 1987). Some inhaled toxicants, including acrolein, can prolong bacterial viability in the lung and thus enhance severeness of the disease. Mice convalescing from viral pneumonia became severely deficient in antibacterial defenses when exposed to acrolein (Astry and Jakab 1983). But acrolein-treated mice subjected to 100 $\mu\text{g}/\text{L}$ air (five consecutive daily 3-h exposures) were not significantly sensitive to pulmonary bacteria *Klebsiella pneumoniae* or *Streptococcus zooepidemicus* (Aranyi et al. 1986).

Acrolein may be a carcinogen, a cocarcinogen, or a tumor initiator. As an aldehyde with strong affinity for sulphydryl groups, acrolein is theoretically expected to remove free tissue thiols — compounds that protect bronchial epithelia against attack by carcinogens (Feron and Kruysse 1977; Feron et al. 1978). However, no carcinogenicity from inhalation of acrolein has been reported (Lijinsky and Reuber 1987). Nor was acrolein an evident cofactor in studies of respiratory-tract carcinogenesis with hamsters (*Cricetus* spp.) exposed to benzo[*a*]pyrene or diethylnitrosamine (Feron and Kruysse 1977). Moreover, long-term studies with rodents given acrolein by gavage did not increase incidences of neoplastic or nonneoplastic lesions (Parent et al. 1992). Other studies, however, suggest that acrolein is carcinogenic. Compounds closely related to acrolein are carcinogenic to rodents and humans and include acrylonitrile (vinyl cyanide) and vinyl acetate (Lijinsky 1988). Glycidaldehyde — an acrolein intermediate metabolite — is classified as an animal carcinogen by The International Agency for Research on Cancer; however, no convincing data are available on the carcinogenic potential of acrylic acid and other acrolein metabolites (Beauchamp et al. 1985). Acrolein can account, at least partially, for the initiating activity of cyclophosphamide carcinogenesis (Cohen et al. 1992). Cyclophosphamide and its analogs are a group of chemotherapeutic and immunosuppressive drugs. Toxic side effects of this drug group are attributed to its metabolites, especially acrolein (Cohen et al. 1992). Acrolein is a suspected carcinogen because of its 2,3-epoxy metabolite and its weak mutagenic activity in the *Salmonella* screen (Leach et al.

1987). Acrolein may be a weak carcinogen, as judged by the increased frequency of adrenal adenomas in female rats after exposure for 2 years to drinking water with 625,000 µg acrolein/L (Lijinsky and Reuber 1987). Acrolein has cancer-initiating activity in the rat urinary bladder, but studies with *N*-[4-(5-nitro-2-furyl)-2-thiazoyl] formamide precluded evaluation of acrolein as promoting a complete carcinogenic activity from low rodent survival (Cohen et al. 1992). Additional studies are needed to evaluate the carcinogenic potential of acrolein.

After intraamniotic injection, acrolein is teratogenic to rats *in vivo* but not *in vitro*. When administered intraamniotically to the whole embryo culture system of the rat on day 13 of gestation, acrolein caused edema, hydrocephaly, open eyes, cleft palate, abnormal umbilical cord, and defects of the limbs and face (Slott and Hales 1986). Beauchamp et al. (1985) suggest that acrolein-associated teratogenicity is caused by acrylic acid, an acrolein metabolite. Acrylic acid injected into amniotic fluid of rats on day 13 of gestation produced a dose-dependent increase in the percent of fetuses with skeletal and other abnormalities (Beauchamp et al. 1985).

Acrolein can react synergistically, additively, or antagonistically with other chemicals (Beauchamp et al. 1985). Rat embryos were protected by glutathione against acrolein-induced mortality, growth retardation, and developmental abnormalities — provided that glutathione was concurrently present with acrolein. When rat embryos were cultured in the presence of acrolein for 2 h prior to glutathione exposure, there was no protection against acrolein-induced embryolethality, teratogenicity, and growth retardation (Slott and Hales 1987). Acrolein effects — including altered liver enzyme activity in rats — were reduced by pretreatment of animals with chemicals that inhibited protein synthesis (NRC 1977). Exposure to acrolein is sometimes accompanied by exposure to formaldehyde and other short-chain saturated aliphatic aldehydes, which in combination cause allergic contact dermatitis (Susten and Breitenstein 1990). A 40-mL puff of cigarette smoke contains 8.2 µg acrolein and 4.1 µg formaldehyde; irritation, ciliastasis, and pathologic changes of the respiratory tract from both compounds have been widely studied (Egle and Hudgins 1974). The toxicities of acrolein and formaldehyde appear similar; both exert their principal effects in the nasal passages (Leach et al. 1987). Acrolein in combination with formaldehyde was synergistic in reducing respiratory rate in mice; however, mixtures of sulfur dioxide and acrolein were antagonistic (Beauchamp et al. 1985). Formaldehyde pretreatment (15,000 µg/L, 6 h daily for 9 days) of rats protects against respiratory rate depression by acrolein. Rats pretreated with formaldehyde had a 50% respiratory-rate depression at 29,600 µg acrolein/L vs. 6000 µg/L from acrolein alone (Babiuk et al. 1985), suggesting cross tolerance. Effects of interaction of acrolein with other toxicants are not comparable between rodents and humans. In rodents, the presence of irritant gases in smoke — such as acrolein — may delay the effects of other toxicants. In humans, however, the inhalation of acrolein and other irritant gases may cause a hypoxic effect that can enhance the effects of hypoxia-producing gases (Kaplan 1987).

Some chemicals normally contain acrolein as a metabolite or impurity. For example, allylamine toxicity to the rat cardiovascular system is believed to involve metabolism of allylamine to the highly reactive acrolein (Toraason et al. 1989). Certain mercapturic acids can be used as biological markers of exposure for chemicals that are metabolized to acrolein and excreted as mercapturic acid in the urine (Sanduja et al. 1989). In one case, rats given 13,000 µg acrolein/kg BW by gavage excreted 79% of the acrolein and 3-hydroxypropylmercapturic acid (3-OHPrMCA) in urine within 24 h. These data suggest that 3-OHPrMCA can be used as a marker of exposure to allylic and other compounds that lead to the formation of acrolein (Sanduja et al. 1989). The common industrial chemical MDP (2-methoxy-3,4-dihydro-2H-pyran) is frequently contaminated with acrolein during its synthesis; MDP causes severe irritancy and death of rats from accumulation of acrolein vapor (Ballantyne et al. 1989). Sparging acrolein-contaminated MDP with nitrogen gas before atmospheric release significantly reduced or abolished lethal toxicity to rats (Ballantyne et al. 1989).

Table 10.4 Acrolein Effects on Selected Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect	Reference^a
COW, <i>Bos</i> spp.		
Drinking water route; lactating dairy cows given 60,000 µg acrolein/L for 24 h	No change in feed or water intake or milk production; acrolein residues in milk <500 µg/L	1
DOG, <i>Canis familiaris</i>		
Inhalation route		
220, 1000, or 1800 µg/L air (0.5, 2.3, or 4.1 mg/m ³); continuous exposure for 90 days	Low concentration group appeared normal and gained weight. At 1000 µg/L, ocular and nasal discharges. At the high concentration, severe irritation evident plus nonspecific inflammation of brain, heart, lung, liver, and kidney; no deaths	2
400–600 µg/L air for 1–3 min	81–84% of acrolein retained; accumulations greater in upper respiratory tract than lower respiratory tract	3, 4
700 or 3700 µg/L air (1.6 or 8.4 mg/m ³); exposure for 8 h daily, 5 days weekly for 6 weeks	Low concentration group appeared normal and gained weight; high concentration group visibly affected with weight loss, excessive salivation, ocular discharges, labored breathing, and histopathology of lung, liver, and kidney; blood and serum chemistry normal	2
150,000 µg/L air (340 mg/m ³) for 30 min	LC50	3, 5, 6
GUINEA PIG, <i>Cavia</i> spp.		
Inhalation route		
200, 1000, or 1800 µg/L continuously for 90 days	The low concentration group appeared normal; at 1000 µg/L, pulmonary inflammation and liver necrosis; at high concentration, all had nonspecific inflammation of brain, heart, lung, liver, and kidney	2
400–1000 µg/L for 2 h	Decreased respiratory rate; effects reversed after exposure stopped	6, 7
400–1000 µg/L for as long as 12 h	Concentration-related increases in respiratory resistance, together with prolonged and deepened respiratory cycles	3
700 or 3700 µg/L; 8 h daily, 5 days weekly for 6 weeks	Low concentration group seemed normal. At high concentration, histopathology of lung, liver, and kidney	2
10,500 µg/L for 6 h	LC50	6
20,000 µg/L for 10 min	Bronchoconstriction	6
CAT, <i>Felis domesticus</i>		
Inhalation route		
650,000 µg/L air for 2.25 h	Died within 18 h	6
870,000 µg/L air for 2.5 h	Died during exposure	6
HUMAN, <i>Homo sapiens</i>		
Inhalation route		
20 µg/L air	Threshold for affecting electrocortical activity	6
30–40 µg/L air	Odor threshold for the most acrolein-sensitive people	6
90–300 µg/L air	Increasing concentration and increasing exposure caused increasing eye blinking, irritation, and decreasing respiratory frequency	8
140–150 µg/L air for 2 min	Eye irritation in 30% of subjects	6
250 µg/L air for 5 min	Moderate irritation of sensory organs	3, 5
300 µg/L air for 10 min	Considerable acute irritation	8
300–500 µg/L air	Odor threshold for most people	3, 6

Table 10.4 (continued) Acrolein Effects on Selected Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect	Reference ^a
1000 µg/L air for 1 min	Slight nasal irritation	3, 5
1000 µg/L for 5 min	Moderate nasal irritation; intolerable eye irritation	3, 5
1800 µg/L air for 1 min	Slight eye irritation	3
5500 µg/L air for 20 sec	Painful eye and nasal irritation	3, 5
21,800 µg/L air for 1 sec	Intolerable	3, 5
SYRIAN GOLDEN HAMSTER, <i>Mesocricetus auratus</i>		
Gavage route; 1000 µg/animal, equivalent to about 4000 µg/kg BW	Fatal within a few hours	11, 12
Inhalation route		
400 or 1400 µg/L air; exposure for 6 h daily, 5 days weekly for 13 weeks	No adverse effects at low concentration; nasal histopathology at high concentration	9
4000 µg/L air (9.2 mg/m ³); 7 h daily, 5 days weekly for 52 weeks	No effect on survival; no indication of cancer. Abnormal behavior, growth retardation, increased lung weight, decreased liver weight, nasal histopathology	10
6000 µg/L air (13.8 mg/m ³) for 4 h	Cytotoxic to airway cells	3
25,400 µg/L air for 4 h	LC50	6, 10
MOUSE, <i>Mus</i> sp.		
Drinking water route; 24,000 µg/L for 18 months	Death	29
Inhalation route		
10 µg/L air continuously for 5 weeks	Some reduction in pulmonary compliance	4
1000–2000 µg/L (2.3–4.6 mg/m ³) air for 24 h	Decreased pulmonary ability to kill bacteria <i>Staphylococcus aureus</i> and <i>Proteus mirabilis</i>	3
1700 µg/L air for 10 min	50% reduction in respiratory rate	6, 14
3000 or 6000 µg/L air for 8 h	Concentration-dependent impairment of pulmonary antibacterial responses	15
6000–15,000 µg/L air; 6 h daily, 5 days weekly for 6 weeks	Decreased body weight (6%) in all test groups, but not concentration related	3
66,000 µg/L for 6 h	LC50, 24 h postexposure	6
175,000 µg/L air for 10 min	LC50	3, 5, 6
875,000 µg/L air for 1 min	LC50	3, 5, 6
Intraperitoneal injection route		
4000 µg/kg BW; single injection	Plasma total lactic dehydrogenase activity (LDH) increased 5 times, with peak after 10 h	16
4000 µg/kg BW; multiple daily or weekly injections	Progressively less pronounced effect on LDH activity	16
7000 µg/kg BW; single injection	LD50	16
12,000 µg/kg BW; preceded by daily injections of 4000 µg/kg BW for 5 days	50% mortality	16
Oral route; 28,000 µg/kg BW	Acute oral LD50	3–6
RABBIT, <i>Oryctolagus</i> sp.		
Dermal route; immersed up to necks for 60 min in water with 20,000 µg/L	No adverse effects	1
Drinking water route		
9000 µg/L for 13 days	Miscarriages	29
36,000 µg/L for 13 days	Stomach ulcers	29
Inhalation route		
400 or 1400 µg/L; 6 h daily, 5 days weekly for 13 weeks	No adverse effects at low concentration; some signs of distress at 1400 µg/L	9
600 µg/L; 4 h daily for 30 days	No ocular effects	2
1700–2400 µg/L for 10 min; with or without 1000 µg ozone/L	Acrolein alone had no effect on respiratory rate. Ozone–acrolein mixtures produced a marked decrease in respiratory rate	6

Table 10.4 (continued) Acrolein Effects on Selected Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect	Reference^a
4900 µg/L air; 6 h daily, 5 days weekly for 13 weeks	Ocular and nasal irritation, growth depression, respiratory tract histopathology	10
6500–10,500 µg/L; exposure duration unknown	Emphysema, tracheobronchitis, some deaths	2
10,500 µg/L air for 6 h	LC50	6
Intravenous injection route; 3000, 4500, or 6000 µg acrolein/kg BW on day 9 of gestation; killed on day 28 of gestation	Embryo resorption was significantly higher in 6000 µg/kg group vs. controls, but was the same as controls in lower concentration groups	6
Percutaneous injection route		
164,000 µg/kg BW	LD50 for 20% acrolein in mineral spirits	3, 5
238,000 µg/kg BW	LD50 for 10% acrolein in mineral spirits	3, 5
335,000 µg/kg BW	LD50 for 20% acrolein in water	3, 5
562,000 µg/kg BW	LD50 for undiluted acrolein	3, 5
1,022,000 µg/kg BW	LD50 for 10% acrolein in water	3, 5
DOMESTIC SHEEP, <i>Ovis aries</i>		
Inhalation route via cervical trachea; ewes, 3–4 years old; exposed to smoke containing high (but unknown) concentrations of acrolein for 20 min; killed 1–22 days after exposure	Within 24 h of exposure, there was total sloughing of cervical tracheal epithelium and a 35% reduction in tracheal basal cells; trachea was normal 18–22 days after exposure	13
BABOON, <i>Papio anubis</i>		
Inhalation route; juveniles exposed to air concentrations of 12,000–2,780,000 µg acrolein/L (272–63,100 mg/m ³) for 5 min, then tested for learned avoidance/escape response	Avoidance/escape response enhanced in all animals at all concentrations tested. The group exposed to 1,025,000 µg/L air died with respiratory complications within 24 h postexposure. The group exposed to the highest concentration of 2,780,000 µg/L for 5 min died within 90 min postexposure with severe respiratory complications	17
LABORATORY WHITE RAT, <i>Rattus</i> sp.		
Dermal route; exposure duration and dose unknown	Skin burns; severe ocular effects	18
Drinking water route		
5000, 13,000, 32,000, 80,000, or 200,000 µg/L for 12 weeks	Water consumption in the 200,000 µg/L group was reduced by about 33% for the first 3 weeks; by week 12, all groups appeared normal and had apparently adapted to the odor and taste of acrolein	4
80,000 µg/L for 3 days	Some deaths	29
100,000 or 250,000 µg/L for 124 weeks	No increase in tumors over controls; no decrease in survival	11
100,000, 250,000, or 625,000 µg/L for 120 weeks	No significant decrease in survival when compared to controls. The 100,000 µg/L group had a 30% frequency of liver neoplasms and a 5% frequency of adrenal cortex neoplasms; however, no neoplasms were found in the 250,000 µg/L group. The 625,000 µg/L group had a 10% frequency of liver neoplasms vs. 25% in controls	12
200,000 µg/L for 90 days	No adverse effects	1
600,000, 1,200,000 or 1,800,000 µg/L for 60 days	Rats in the two high-concentration groups refused to drink and all died, apparently from dehydration. In the low-concentration group 20% died, but survivors were not dehydrated and had no tissue pathology	4

Table 10.4 (continued) Acrolein Effects on Selected Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect	Reference ^a
625,000 µg/L for 100 weeks	No decrease in survival; 20% of females developed adrenal cortical adenomas and 10% had neoplastic nodules in the adrenal cortex vs. 0% in controls	6
625,000 µg/L for 104 weeks	No decrease in survival. Increased frequency of adrenal cortex adenomas in females: 25% vs. 1.3% in controls	11
Inhalation route		
10 or 50 µg/L air for 1 min	Increased blood pressure and heart rate	19
10, 500, 1000, or 2400 µg/L air for 3 h	At 500 µg/L and higher, effects on respiratory mucosa included depletion of nonprotein sulfhydryl (NPSH) concentration and slight decrease in protein sulfhydryl (PSH) concentration. Effects on olfactory mucosa showed no changes in PSH at all test concentrations, but significant depletion of NPSH in the two high-concentration groups	20
100, 1000, or 3000 µg/L air; exposed 6 h daily, 5 days weekly for 3 weeks	No adverse effects in the two low-concentration groups. The high-concentration group had depressed spleen weight and body weight and extensive nasal histopathology	14
150, 510, or 1520 µg/L air; continuous exposure for 61 days	At low concentration, no respiratory tract lesions or deaths. At 510 µg/L, bronchial epithelium abnormalities but all survived. At high concentration, reduced survival; bronchopneumonia and bronchial abnormalities in survivors	6
220 or 660 µg/L air; exposed continuously for 60 days	No deaths at 220 µg/L; 70% died within 24 days at 660 µg/L	2
220, 1000, or 1800 µg/L air; exposed continuously for 90 days	The low concentration group appeared normal and gained weight. At 1000 µg/L, liver necrosis and pulmonary hemorrhage. At 1800 µg/L, all had nonspecific inflammation of brain, heart, lung, liver, and kidney	2
400 µg/L air; exposed 6 h daily, 5 days weekly for 13 weeks	Nasal histopathology	9
400, 1400, or 4000 µg/L air; exposed 6 h daily, 5 days weekly for 62 days	Some bronchial histopathology at 1400 µg/L; some deaths among males at 4000 µg/L	6
520 µg/L (1.2 mg/m ³); continuous exposure for 30 days	Decreased growth, altered liver enzyme activity	3
550 µg/L air; continuous exposure for up to 77 days	Upper respiratory irritation, reduced resistance to infection by <i>Salmonella</i> , and increased pulmonary macrophages; all effects disappeared by day 63	6
700 or 3700 µg/L air; exposed 8 h daily, 5 days weekly for 6 weeks	No adverse effects noted at low concentration. At 3700 µg/L, histopathology of lung, liver, and kidney	2
2000 µg/L air for 40 h	Increased hepatic alkaline phosphatase activity; increased liver and adrenal weight	3
2500–5000 µg/L air for 1 min	Cardioinhibitory effect that was reversed within 10 s after inhalation of acrolein ceased	19
4900 µg/L air; exposed 6 h daily, 5 days weekly for 13 weeks	50% mortality during first 4 weeks with no deaths thereafter. Survivors had depressed growth and respiratory tract histopathology	9
6000–8888 µg/L air; exposed 6 h daily, 5 days weekly for 3 weeks	Most died within 5 exposure days	14
8000–8300 µg/L air for 4 h	LC50 within 14 days; death due to lung injury	5, 6, 21
26,000 µg/L air for 1 h	LC50	21
43,500–304,000 µg/L air for 30 min	Respiratory distress; nasal and ocular irritation; some deaths in 4–5 days; pulmonary edema; bronchial degeneration; excess blood in heart, liver, and kidney	2, 6

Table 10.4 (continued) Acrolein Effects on Selected Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect	Reference ^a
131,000 µg/L air for 30 min	50% dead in 3 weeks	6
283,000 µg/L air; daily 10-min exposures for 6 months	No deaths; some bronchial pathology	6
326,000 µg/L air; daily 10-min exposures for 6 months	50% dead; tracheobronchial pathology	6
435,000 µg/L air; daily 10-min exposures for 6 months	All dead; severe histopathology of respiratory tract	6
5,000,000–10,000,000 µg/L air for 5 min	Rats on a motor-driven exercise wheel were incapacitated within 5–7 min and died shortly thereafter	17
Intraamniotic injection route. Embryos given 0.1, 1, 10, or 100 µg of acrolein on day 13 of gestation; examined on day 20 of gestation	98–100% dead at 10 and 100 µg; 85% of live fetuses receiving 1 µg were malformed (edema, hydrocephaly, cleft palate, defects of limbs and tail); no teratogenic effects at 0.1 µg	6
Intraperitoneal injection route		
1000 µg/kg BW, single injection	Peritonitis	22
1000 µg/kg BW daily for at least 5 days	Lethal	22
2000 µg/kg BW twice a week for 6 weeks followed by uracil as 3% of the diet for 20 weeks, then control diet for 6 weeks	Acrolein followed by uracil produced a 60% incidence of papilloma in urinary bladder in treated group (acrolein plus uracil) vs. 27% in water controls (uracil only). No tumors in either group	22
2500 µg/kg BW daily	All dead after second dose	3
3360 µg/kg BW; single injection; tissues analyzed after 24 h	Most (89%) of the acrolein recovered was in the acid-soluble fraction of the liver, 3% in the liver lipids, and minor amounts (0.4–1.7%) in liver proteins and RNA and DNA fractions	3
Intravenous injection route		
50–500 µg/kg BW to spontaneously hypersensitive rats	At 50–200 µg/kg BW, blood pressure increased; at 300–500 µg/kg BW, blood pressure decreased	23
250–1000 µg/kg BW	Increased blood pressure within 5 s which peaked at 20–30 s and lasted about 1 min	19
850 or 1700 µg/kg BW	Liver necrosis	3
10,000 µg/kg BW	Cardioinhibitory effects	19
<i>In vitro</i> studies		
Cultured embryos		
4500 µg/L serum medium	Growth retardation; 50% malformation frequency among survivors	24, 25
6700 µg/L serum medium	Mortality of 64%; all surviving embryos malformed	24, 25
7800–9000 µg/L serum medium	All dead	24, 25
160 µg/L serum-free medium	50% frequency of malformations in brain, facial area, and heart	25
300–1100 µg/L serum-free medium	50–100% lethal	25
Cultured myocytes and fibroblasts from neonatal heart		
600 µg/L culture medium for 4 h	Myocyte ATP levels reduced	26
2800 µg/L culture medium for 4 h	Irreversible cell lysis and ciliastasis	26
Isolated liver fractions		
1700 µg/L medium	Mitochondrial aldehyde dehydrogenase (ALDH) activity inhibited 91%; cytosolic ALDH activity inhibited 33%	27
2700 µg/L medium; 5 s preincubation in aldehyde substrate	Inhibition of mitochondrial and cytosolic ALDH	27
Oral route		
Daily gavage of 50, 500, or 2500 µg/kg BW for 102 weeks	Dose-related mortality in males during first year and in females during entire study; significant lethality in the 500 and 2500 µg/kg groups. No increased incidence of microscopic neoplastic or nonneoplastic lesions in treated rats; decreased creatinine phosphokinase levels in treated rats	28

Table 10.4 (continued) Acrolein Effects on Selected Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect	Reference ^a
Two treatments of 4000–10,000 µg/kg BW (estimated), 2–3 days apart; total dose of 8000–20,000 µg/kg BW	All died shortly after the second dose	12
5000 µg/kg BW daily for 9 days via stomach intubation	No deaths	3
10,000 µg/kg BW, single stomach intubation	Fatal	3
25,000 µg/kg BW, single gastric dose	Lethal within 48 h	22
42,000–46,000 µg/kg BW, single dose	LD50 within 14 days	3–6, 18, 22
SQUIRREL MONKEY, <i>Saimiri sciurea</i>		
Inhalation route		
220, 1000, or 1800 µg/L air; continuous exposure for 90 days	Low-concentration group appeared normal and gained weight; 1000 µg/L monkeys were visibly affected with ocular and nasal discharges. No deaths at 1800 µg/L, but excessive salivation, ocular discharges, and hyperplasia of trachea	2
700 or 3700 µg/L air; 8 h daily, 5 days weekly for 6 weeks	Low-concentration group appeared normal. High-dose group had weight loss; histopathology of lung, liver, and kidney; 22% mortality (2 of 9 died on days 6 and 9 of exposure), excessive salivation, and frequent blinking	2

10.5 RECOMMENDATIONS

Agricultural crops can usually tolerate as much as 15,000 µg acrolein/L of irrigation water; however, aquatic invertebrates and fish die in acute exposures to 55 to 68 µg/L or in chronic exposures to greater than 21 µg/L (Table 10.5). Those who use acrolein to control submerged aquatic macrophytes are strongly advised that acrolein treatment at recommended application concentrations also eliminates nontarget fish and aquatic invertebrates. No acrolein criteria are now available or promulgated by regulatory agencies for the protection of avian and terrestrial wildlife; this seems to be a high-priority research need. Beauchamp et al. (1985) recommend additional research in several areas: long-term effects of acrolein inhalation on carcinogenicity and respiratory histology with rodent models; biochemical mechanisms of acrolein toxicity; genotoxic potential with chromosome breakage and exchange systems; acute and chronic toxicity from interaction effects of acrolein with other gases; and fate of accumulated acrolein in animals.

The human threshold concentration of acrolein in the United States for an 8-h workday/40-h workweek is 110 µg/L (0.25 mg/m³) air; the short-term exposure limit is 350 µg/L (0.8 mg/m³) air and is predicated on continuous exposure of workers for short intervals (Table 10.5) (Beauchamp et al. 1985). Humans can tolerate a total daily intake of 47.8 µg acrolein, equivalent to 0.68 µg/kg BW by a 70-kg individual (Table 10.5).

For handling acrolein, gloves, vapor-proof goggles or a full face mask, and other protective clothing are mandatory (Albin 1962; Beauchamp et al. 1985; NIOSH 1990). Acrolein spills should be neutralized with 10% sodium bisulfite solutions (Albin 1962). Air packs or fresh-air breathing masks, safety showers, and eye baths should be available wherever acrolein is handled (Beauchamp

et al. 1985). Purging confined areas with nitrogen is recommended prior to entering a suspected acrolein-contaminated enclosure. The eyes are particularly susceptible to liquid acrolein and, if exposed, should receive prompt treatment, although severe residual injury is probable regardless of treatment. Dilute solutions of acrolein may also cause residual eye injury. Acrolein represents a serious fire hazard because of its high flammability and potential for vapors to form explosive mixtures with air. Flame-proof electrical equipment and proper grounding are required to prevent acrolein ignition. Individuals exposed to acrolein by inhalation should be removed from the area and given oxygen; subsequent treatment by physicians of pulmonary inflammation with corticosteroids and hydroxocobalamin is recommended even if there are no symptoms (Beauchamp et al. 1985) because adverse effects from acrolein exposure may not become apparent until 4 to 24 h after exposure (Albin 1962). Oxygen therapy should be continued and analgesics given for relief of other symptoms as necessary (Beauchamp et al. 1985). There are many synthetic and natural sources of acrolein; however, special precautions are recommended when acrolein occurs as a contaminant in the synthesis of widely used chemicals such as 2-methoxy-3,4-dihydro-2H-pyran (Ballantyne et al. 1989).

Table 10.5 Proposed Acrolein Criteria for the Protection of Living Resources and Human Health

Resource, Criterion, and Other Variables	Concentration	Reference ^a
AGRICULTURAL CROPS		
Irrigation water, tolerated level	<15,000 µg/L	1
AQUATIC LIFE		
<i>Freshwater organisms</i>		
Sensitive species, tolerated level		
Acute exposures	<68 µg/L	2
Chronic exposures	<21 µg/L	2
Rainbow trout, safe level	20 µg/L for <48 h or 200 µg/L for <4.8 h	3
Marine organisms; acute exposures, tolerated level	<55 µg/L	2
LABORATORY WHITE RAT		
<i>Air</i>		
Maximum daily average	<13 µg/L (<0.03 mg/m ³)	7
Maximum daily	<44 µg/L (<0.1 mg/m ³)	7
HUMAN HEALTH		
<i>Air</i>		
Maximum allowable emission concentration in populated areas of former Soviet Union	132 µg/L (0.3 mg/m ³)	4
No observable effect level	<22 µg/L (<0.05 mg/m ³)	4
90-day confined space (i.e., submarines) guideline	22 µg/L (0.05 mg/m ³)	5
Odor threshold	<44 µg/L (<0.1 mg/m ³)	4
Maximum acceptable concentration in room air of former Soviet Union	44 µg/L (0.1 mg/m ³)	2, 4
Irritation threshold	44–88 µg/L (0.1–0.2 mg/m ³)	4
Occupational exposure standard (8 h daily, 40 h work week) in United States; not to exceed in most European countries, Australia, and Japan	100–110 µg/L (0.25 mg/m ³)	2, 4–6, 8
Occupational exposure standard in Hungary and former Soviet Union	308 µg/L (0.7 mg/m ³)	4
Maximum 15-min exposure limit in U.S. workplace	300–352 µg/L (0.8 mg/m ³)	4, 8
Ceiling standard for occupational exposure in the former Czechoslovakia	440 µg/L (1.0 mg/m ³)	4

Table 10.5 (continued) Proposed Acrolein Criteria for the Protection of Living Resources and Human Health

Resource, Criterion, and Other Variables	Concentration	Reference ^a
Acceptable ambient air concentrations		
New York	0.83 µg/m ³ for 1 year	9
Florida	2.5 µg/m ³ for 8 hr	9
North Dakota	8.0 µg/m ³ for 1 hr	9
North Carolina	80 µg/m ³ for 15 min	9
Diet		
Water plus consumption of contaminated aquatic organisms from that water body	<320 µg/L medium	2
Consumption of contaminated aquatic organisms alone	<780 µg/L medium	2
Food packaging materials; food starch	<0.6%	2
Total daily intake	<47.8 µg = <0.68 µg/kg body weight daily for a 70-kg person	2

^a 1, Ferguson et al. 1961; 2, USEPA 1980; 3, Bartley and Hattrup 1975; 4, Beauchamp et al. 1985; 5, Lyon et al. 1970; 6, Leach et al. 1987; 7, NRC 1977; 8, NIOSH 1990; 9, ATSDR 1990.

10.6 SUMMARY

Acrolein ($\text{CH}_2 = \text{CHCHO}$) is the simplest member of the class of unsaturated aldehydes and enters the environment from incomplete combustion of fossil fuels, industrial discharges, herbicides, chemical control agents of fouling organisms, and normal metabolic processes of animals. Acrolein is volatile, flammable, and explosive. Biochemical and toxic effects of acrolein are caused by its reaction with sulfhydryl compounds to form a stable thiol ether. Acrolein metabolites under certain conditions are reportedly mutagenic, teratogenic, or carcinogenic. Acrolein degrades quickly in soils and in plant tissues. In water, the half-time persistence is usually less than 50 h and in the atmosphere, less than 3 h. In treated irrigation canals, acrolein probably eliminates or seriously depletes all populations of aquatic fauna in treated areas. Recommended herbicidal concentrations of acrolein for the control of submerged aquatic weeds usually exceed 1000 µg/L; however, short-term tests with various species show that frog tadpoles die at 7 µg/L, representative fish are killed at 14 to 62 µg/L, and sensitive crustaceans are immobilized or die at 34 to 80 µg/L. Terrestrial plants and insects are comparatively resistant to acrolein: terrestrial plants tolerated 500 µg acrolein/L air and 25,000 µg/L in irrigation water, and adult fruitflies (*Drosophila melanogaster*), 3,700,000 µg acrolein/L culture medium. Birds are adversely affected by concentrations greater than 51 µg acrolein/kg whole egg by injection of eggs, greater than 9100 µg/kg body weight (BW) by single oral doses, and greater than 50,000 µg/L (greater than 113 mg/m³) by air concentrations. Mammals were affected by 50 µg acrolein/L air for 1 min, and 4000 to 28,000 µg/kg BW by single oral doses, or when fed diets equivalent to 500 µg/kg BW for 102 weeks. Proposed acrolein criteria for the protection of various resources include less than 15,000 µg/L in irrigation water of agricultural crops, less than 68 µg/L for aquatic fauna in acute exposures and less than 21 µg/L in chronic exposures, and less than 44 µg/L (less than 0.1 mg/m³) in air for rats. No acrolein criteria are presently available for the protection of avian and terrestrial wildlife. Acrolein criteria for the protection of human health include less than 320 µg/L in drinking water, less than 110 µg/L in air (less than 0.25 mg/m³), and less than 0.68 µg/kg BW daily intake from all sources. More research is needed on acrolein and its metabolites.

CHAPTER 11

Atrazine

11.1 INTRODUCTION

Atrazine (2-chloro-4-ethylamino-6-isopropylamino-1,3,5-triazine) is the most heavily used agricultural pesticide in North America (DeNoyelles et al. 1982; Stratton 1984; Hamilton et al. 1987; Eisler 1989) and is registered for use in controlling weeds in numerous crops, including corn (*Zea mays*), sorghum (*Sorghum vulgare*), sugarcane (*Saccharum officinarum*), soybeans (*Glycine max*), wheat (*Triticum aestivum*), pineapple (*Ananas comusus*), and various range grasses (Reed 1982; Grobler et al. 1989; Neskovic et al. 1993). Atrazine was first released for experiment station evaluations in 1957 and became commercially available in 1958 (Hull 1967; Jones et al. 1982). In 1976, 41 million kg (90 million pounds) were applied to 25 million ha (62 million acres) on farms in the United States, principally for weed control in corn, wheat, and sorghum crops. This volume represented 16% of all herbicides and 9% of all pesticides applied in the United States during that year (DeNoyelles et al. 1982; Hamala and Kollig 1985). By 1980, domestic usage had increased to 50 million kg (Reed 1982). In Canada, atrazine was the most widely used of 77 pesticides surveyed (Frank and Sirons 1979). Agricultural use of atrazine has also been reported in South Africa, Australia, New Zealand, Venezuela, and in most European countries (Reed 1982; Neskovic et al. 1993). Current global use of atrazine is estimated at 70 to 90 million kg annually, although Germany banned atrazine in 1991 (Steinberg et al. 1995). Resistance to atrazine has developed in various strains of weeds typically present in crop fields — sometimes in less than two generations (Bettini et al. 1987; McNally et al. 1987) — suggesting that future agricultural use of atrazine may be limited.

Atrazine has been detected in lakes and streams at levels ranging from 0.1 to 30.3 µg/L; concentrations peak during spring, which coincides with the recommended time for agricultural application (Hamilton et al. 1987; Richards and Baker 1999). In runoff waters directly adjacent to treated fields, atrazine concentrations of 27 to 69 µg/L have been reported and may reach 1000 µg/L (DeNoyelles et al. 1982). Some of these concentrations are demonstrably phytotoxic to sensitive species of aquatic flora (DeNoyelles et al. 1982; Herman et al. 1986; Hamilton et al. 1987). Although atrazine runoff from Maryland cornfields was suggested as a possible factor in the decline of submerged aquatic vegetation in Chesapeake Bay, which provides food and habitat for large populations of waterfowl, striped bass (*Morone saxatilis*), American oysters (*Crassostrea virginica*), and blue crabs (*Callinectes sapidus*), it was probably not a major contributor to this decline (Forney 1980; Menzer and Nelson 1986).

11.2 ENVIRONMENTAL CHEMISTRY

Atrazine is a white crystalline substance that is sold under a variety of trade names for use primarily as a selective herbicide to control broadleaf and grassy weeds in corn and sorghum

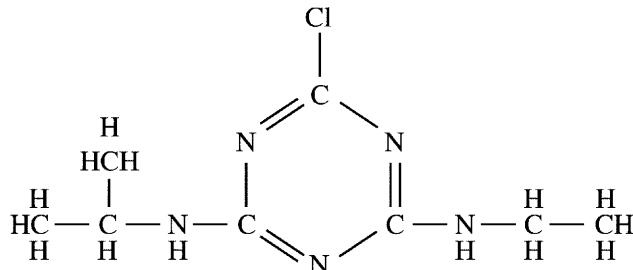

Figure 11.1 Structural formula of atrazine.

(Table 11.1; Figure 11.1). It is slightly soluble in water (33 mg/L at 27°C), but comparatively soluble (360 to 183,000 mg/L) in many organic solvents. Atrazine is usually applied in a water spray at concentrations of 2.2 to 4.5 kg/ha before weeds emerge. Stored atrazine is stable for several years, but degradation begins immediately after application (Table 11.1). The chemical is available as a technical material at 99.9% active ingredient and as a manufacturing-use product containing 80% atrazine for formulation of wettable powders, pellets, granules, flowable concentrates, emulsifiable concentrates, or tablets (U.S. Environmental Protection Agency [USEPA] 1983).

There are three major atrazine degradation pathways: hydrolysis at carbon atom 2, in which the chlorine is replaced with a hydroxyl group; N-dealkylation at carbon atom 4 (loss of the ethylpropyl group) or 6 (loss of the isopropyl group); and splitting of the triazine ring (Knuesli et al. 1969; Reed 1982). The dominant phase I metabolic reaction in plants is a cytochrome P450-mediated N-dealkylation, while the primary phase II reaction is the glutathione S-transferase (GST)-catalyzed conjugation with glutathione (Egaas et al. 1993). The presence of GST isoenzymes that metabolize atrazine has been demonstrated in at least 10 species: in the liver of rainbow trout (*Oncorhynchus mykiss*), starry flounder (*Pleuronectes stellatus*) English sole (*Pleuronectes vetulus*), rat (*Rattus norvegicus*), mouse (*Mus musculus*), the leaves of common groundsel (*Senecio vulgaris*), and soft tissues of the cabbage moth (*Mamestra brassica*) and the Hebrew character moth (*Orthosia gothica*) (Egaas et al. 1993).

The major atrazine metabolite in both soil and aquatic systems is hydroxyatrazine. In soils, it accounts for 5 to 25% of the atrazine originally applied after several months compared to 2 to 10% for all dealkylated products combined, including deethylated atrazine and deisopropylated atrazine (Stratton 1984; Schiavon 1988a, 1988b). Atrazine can be converted to nonphytotoxic hydroxyatrazine by chemical hydrolysis, which does not require a biological system (Dao 1977; Wolf and Jackson 1982). Bacterial degradation, however, proceeds primarily by N-dealkylation (Giardi et al. 1985). In animals, N-dealkylation is a generally valid biochemical degradation mechanism (Knuesli et al. 1969). In rats, rabbits, and chickens, most atrazine is excreted within 72 hours; 19 urinary metabolites — including hydroxylated, N-dealkylated, oxidized, and conjugated metabolites — were found (Reed 1982). There is general agreement that atrazine degradation products are substantially less toxic than the parent compound and not normally present in the environment at levels inhibitory to algae, bacteria, plants, or animals (DeNoyelles et al. 1982; Reed 1982; Stratton 1984).

Residues of atrazine rapidly disappeared from a simulated Northern Prairie freshwater wetland microcosm during the first 4 days, primarily by way of adsorption onto organic sediments (Huckins et al. 1986). This is consistent with the findings of others who report 50% loss (T_b 1/2) from wetlands in about 10 days (Alvord and Kadlec 1996) and freshwater in 3.2 days (Moorhead and Kosinski 1986), 82% loss in 5 days, and 88 to 95% loss in 55 to 56 days (Lay et al. 1984; Runes and Jenkins 1999), although one report presents evidence of a 300-day half-life for atrazine (Yoo and Solomon 1981), and another for months to years in the water column of certain Great Lakes (Schottler and Eisenreich 1994). In estuarine waters and sediments, atrazine is inactivated by adsorption and metabolism; half-time persistence in waters has been estimated to range between

Table 11.1 Chemical and Other Properties of Atrazine

Variable	Data
Chemical name	2-chloro-4-ethylamino-6-isopropylamino-1,3,5-triazine
Alternate names	CAS 1912-24-9, ENT 28244, G-30027, Aatrex, Aatrex 4L, Aatrex 4LC, Aatrex Nine-0, Aatrex 80W, Atranex, ATratol, Atratol 8P, Atratol 80W, Atrazine 4L, Atrazine 80W, Atred, Bicep 4.5L, Co-Op, Co-Op Atra-pril, Cristatrina, Crisazine, Farmco atrazine, Gasparim, Gesaprim, Gesaprim 500 FW, Griffex, Primatal A, Shell atrazine herbicide, Vectal, Vectal SC
Primary uses	Selective herbicide for control of most annual broadleaf and grassy weeds in corn, sugarcane, sorghum, macadamia orchards, rangeland, pineapple, and turf grass sod. Nonselective herbicide for weed control on railroads, storage yards, along highways, and industrial sites. Sometimes used as selective weedicide in conifer reforestation, Christmas tree plantations, and grass seed fields
Major producer	Ciba-Geigy Corporation
Application methods	Usually as water spray or in liquid fertilizers applied preemergence, but also may be applied preplant or postemergence. Rates of 2–4 pounds/acre (2.24–4.48 kg/ha) are effective for most situations; higher rates are used for nonselective weed control, and on high organic soils
Compatibility with other pesticides	Compatible with most other pesticides and fertilizers when used at recommended rates. Sold in formulation with Lasso®, Ramrod®, and Bicep®
Stability	Very stable over several years of shelf life, under normal illumination and extreme temperatures. Stable in neutral, slightly acid, or basic media. Sublimes at high temperatures and when heated, especially at high temperatures in acid or basic media, hydrolyzes to hydroxyatrazine (2-hydroxy-4-ethylamino-6-isopropylamino-S-triazine), which has no herbicidal activity
Empirical formula	$C_8H_{14}ClN_5$
Molecular weight	215.7
Melting point	173°C to 175°C
Vapor pressure	5.7×10^{-8} mm mercury at 10°C, 3.0×10^{-7} at 20°C, 1.4×10^{-6} at 30°C, and 2.3×10^{-5} at 50°C
Henry's Law constant	6.13×10^{-8} to 2.45×10^{-7} atm-m³/mole
Physical state	The technical material is a white, crystalline, noncombustible, noncorrosive substance
Purity	No impurities or contaminants that resulted from the manufacturing process were detected
Solubility	
Water	22 mg/L at 0°C, 32 mg/L at 25°C, 320 mg/L at 85°C
N-Pentane	360 mg/L at 27°C
Petroleum ether	12,000 mg/L at 27°C
Methanol	18,000 mg/L at 27°C
Ethyl acetate	28,000 mg/L at 27°C
Chloroform	52,000 mg/L at 27°C
Dimethyl sulfoxide	183,000 mg/L at 27°C
Log K_{ow}	2.71

Data from Anonymous 1963; Hull 1967; Knuesli et al. 1969; Gunther and Gunther 1970; Reed 1982; Beste 1983; Hudson et al. 1984; Huber and Hock 1986; Huckins et al. 1986; USEPA 1987; Grobler et al. 1989; Du Preez and van Vuren 1993.

3 and 30 days, being shorter at elevated salinities. For sediments, this range was 15 to 35 days (Jones et al. 1982; Stevenson et al. 1982; Glotfelty et al. 1984; Isensee 1987). The comparatively rapid degradation of atrazine to hydroxyatrazine in estuarine sediments and water column indicates a low probability for atrazine accumulation in the estuary, and a relatively reduced rate of residual phytotoxicity in the estuary for the parent compound (Jones et al. 1982).

Atrazine is leached into the soil by rain or irrigation water. The extent of leaching is limited by the low water solubility of atrazine and by its adsorption onto certain soil constituents (Anonymous 1963). Runoff loss in soils ranges from 1.2 to 18% of the total quantity of atrazine applied, but usually is less than 3% (Wolf and Jackson 1982). Surface runoff of atrazine from adjacent conventional tillage and no-tillage corn watersheds in Maryland was measured after single annual applications of 2.2 kg/ha for 4 years (Glenn and Angle 1987). Most of the atrazine in surface runoff was lost during the first rain after application. In 1979, the year of greatest precipitation, 1.6% of the atrazine applied moved from the conventional tillage compared to 1.1% from the no-tillage

watershed, suggesting that no-tillage should be encouraged as an environmentally sound practice (Glenn and Angle 1987). Lateral and downward movement of atrazine was measured in cornfield soils to a depth of 30 cm when applied at 1.7 kg/ha to relatively moist soils; in lower elevation soils, atrazine accumulated by way of runoff and infiltration (Wu 1980). Downward movement of atrazine through the top 30 cm of cornfield soils indicates that carryover of atrazine to the next growing season is possible; between 5 and 13% of atrazine was available 1 year after application (Wu 1980; Wu and Fox 1980). Atrazine is not usually found below the upper 30 cm of soil in detectable quantities, even after years of continuous use; accordingly, groundwater contamination by atrazine is not expected at recommended application rates (Anonymous 1963; Hammons 1977; Wolf and Jackson 1982; Beste 1983).

Atrazine persistence in soils is extremely variable. Reported T_b 1/2 values ranged from 20 to 100 days in some soils to 330 to 385 days in others (Jones et al. 1982). Intermediate values were reported by Forney (1980), Stevenson et al. (1982), and Stratton (1984). Atrazine activity and persistence in soils is governed by many physical, chemical, and biological factors. In general, atrazine loss was more rapid under some conditions than others. It was more rapid from moist soils than from dry soils during periods of high temperatures than during periods of low temperatures, from high organic and high clay content soils than from sandy mineral soils, during summer than in winter, from soils with high microbial densities than from those with low densities, from soils of acidic pH than from those of neutral or alkaline pH, during storm runoff events than during normal flows, at shallow soil depths than at deeper depths, and under conditions of increased ultraviolet irradiation (Anonymous 1963; McCormick and Hiltbold 1966; Hull 1967; Gunther and Gunther 1970; Dao 1977; Hammons 1977; Frank and Siron 1979; Forney 1980; Stevenson et al. 1982; Wolf and Jackson 1982; Beste 1983; USEPA 1987). Microbial action, usually by way of N-dealkylation and hydrolysis to hydroxyatrazine, probably accounts for the major breakdown of atrazine in the soil, although nonbiological degradation pathways of volatilization, hydroxylation, dealkylation, and photodecomposition are also important (Hull 1967; Gunther and Gunther 1970; Reed 1982; Menzer and Nelson 1986). The photolytic transformation rate of atrazine is enhanced at higher atrazine concentrations and in the presence of dissolved organic carbon (DOC) and DOC mimics (Hapeman et al. 1998).

11.3 CONCENTRATIONS IN FIELD COLLECTIONS

Although annual use of atrazine in the United States is about 35 million kg (Alvord and Kadlec 1996; Carder and Hoagland 1998), atrazine concentrations in human foods are negligible. Monitoring of domestic and imported foods in the human diet by the U.S. Food and Drug Administration between 1978 and 1982 showed that only 3 of 4500 samples analyzed had detectable atrazine residues. Two samples in 1980 contained 0.01 and 0.08 mg atrazine/kg and one in 1978, following a known contamination incident, contained 47 mg/kg (Reed 1982).

Atrazine was present in 100% of 490 samples analyzed in Lakes Michigan, Huron, Erie, and Ontario in 1990 to 1992. Concentrations were highest in Lake Erie at 0.11 µg/L (Schottler and Eisenreich 1994). Atrazine concentrations in river waters of Ohio show strong seasonality (1995 to 1998), with the period of higher concentrations lasting 6 to 12 weeks, beginning with the first storm runoff following application, usually in May (Richards and Baker 1999). The use of atrazine in the U.S. Great Lakes Basin is estimated at 2.7 million kg annually, and more than 600,000 kg atrazine have entered the Great Lakes (Schottler and Eisenreich 1994). Atrazine and its metabolites have been observed in freshwater streams contiguous to agricultural lands; 0.1 to 3% of the atrazine applied to the fields was lost to the aquatic environment (Jones et al. 1982). Atrazine concentrations as high as 691 µg/L were reported in agricultural streams during storm runoff events (Carder and Hoagland 1998). In some cases, atrazine concentrations in runoff waters from treated cornfields can exceed 740 µg/L (Table 11.2). Elevated levels were associated with high initial treatment rates, major storms shortly after application, conventional tillage practices (vs. no tillage), and increased

flow rates, increased suspended solids, and increased dissolved nitrates and nitrites. Concentrations in runoff water usually declined rapidly within a few days (Forney 1980; Setzler 1980; Stevenson et al. 1982). In 1991, maximum atrazine concentrations in the Des Plaines River, Illinois, after spring rains, briefly exceeded the federal proposed drinking water criterion of 3 µg/L (Alvord and Kadlec 1996). Groundwater contamination by way of atrazine treatment of cornfields has been unexpectedly reported in parts of Colorado, Iowa, and Nebraska. Contamination was most pronounced in areas of highly permeable soils that overlie groundwater at shallow depths (Wilson et al. 1987).

The total amount of atrazine reaching the Wye River, Maryland, estuary depended on the quantity applied in the watershed and the timing of runoff. In years of significant runoff, 2 to 3% of the atrazine moved to the estuary within 2 weeks after application and effectively ceased after 6 weeks (Glotfelty et al. 1984). In Chesapeake Bay waters, a leakage rate of 1% of atrazine from agricultural soils resulted in aqueous concentrations averaging 17 µg/L—concentrations potentially harmful to a variety of estuarine plants (Jones et al. 1982). The maximum recorded atrazine concentration in runoff water entering Chesapeake Bay was 480 µg/L (Forney 1980). However, these concentrations seldom persisted for significant intervals and only rarely approached those producing long-term effects on submerged aquatic vegetation (Glotfelty et al. 1984).

Atmospheric transport of atrazine-contaminated aerosol particulates, dusts, and soils may contribute significantly to atrazine burdens of terrestrial and aquatic ecosystems. The annual atmospheric input of atrazine in rainfall to the Rhode River, Maryland, as one example, was estimated at 1016 mg/surface ha in 1977, and 97 mg/ha in 1978 (Wu 1981). A similar situation exists with fog water. When fog forms, exposed plant surfaces become saturated with liquid for the duration of the fog (Glotfelty et al. 1987).

11.4 EFFECTS

11.4.1 General

In terrestrial ecosystems, atrazine effectively inhibits photosynthesis in target weeds and can also affect certain sensitive crop plants. Atrazine metabolites are not as phytotoxic as the parent compound. Degradation is usually rapid, although atrazine can persist in soils for more than one growing season. Soil fauna may be adversely affected shortly after initial atrazine application at recommended levels, but long-term population effects on this group are considered negligible.

Sensitive species of aquatic flora experience temporary adverse effects at concentrations as low as 1.0 to 5.0 µg/L. However, most authorities agree that potentially harmful levels (i.e., >10 µg/L for long periods) have not been documented and are probably unrealistic under current application protocols and degradation rates. The observed declines in submerged aquatic vegetation in the Chesapeake Bay are not now directly attributable to atrazine use. Atrazine indirectly affects aquatic fauna at concentrations of 20 µg/L and higher by reducing the food supply of herbivores and, to some extent, their macrophyte habitat. Direct adverse effects on growth and survival of aquatic fauna were evident in the range of 94 to 500 µg/L. Bioaccumulation of atrazine is limited and food chain biomagnification is negligible in aquatic ecosystems.

Birds show a low probability for atrazine uptake and accumulation. Known acute oral LD50 and dietary LD50 values are high: >2000 mg/kg body weight and 5000 mg/kg diet. Indirect ecosystem effects of atrazine on insect- and seed-eating birds are not known and seem to merit study. Data are lacking for mammalian wildlife, but tests with domestic livestock and small laboratory animals strongly indicate that this group is comparatively resistant to atrazine. Acute oral LD50 values are >1750 mg/kg body weight, and no adverse effects are evident at dietary levels of 25 mg/kg food (about 1.25 mg/kg body weight) and sometimes 100 mg/kg food over extended periods.

11.4.2 Terrestrial Plants and Invertebrates

Atrazine enters plants primarily by way of the roots and secondarily by way of the foliage, passively translocated in the xylem with the transpiration stream, and accumulates in the apical meristems and leaves (Hull 1967; Forney 1980; Reed 1982; Wolf and Jackson 1982). The main phytotoxic effect is the inhibition of photosynthesis by blocking the electron transport during Hill reaction of photosystem II. This blockage leads to inhibitory effects on the synthesis of carbohydrate, a reduction in the carbon pool, and a buildup of carbon dioxide within the leaf, which subsequently causes closure of the stomates, thus inhibiting transpiration (Stevenson et al. 1982; Jachetta et al. 1986; Shabana 1987).

Atrazine is readily metabolized by tolerant plants to hydroxyatrazine and amino acid conjugates. The hydroxyatrazine can be further degraded by dealkylation of the side chains and by hydrolysis of resulting amino groups on the ring and some carbon dioxide production (Hull 1967; Reed 1982; Beste 1983). Resistant plant species degrade atrazine before it interferes with photosynthesis. Corn, for example, has an enzyme (2,4-dihydroxy-7-methoxy-1,4-[2H]-benzoxazin-3-[4H]-one) that degrades atrazine to nonphytotoxic hydroxyatrazine (Wu 1980; Stevenson et al. 1982). In sensitive plants, such as oats, cucumber, and alfalfa, which are unable to detoxify atrazine, the compound accumulates, causing chlorosis and death (Anonymous 1963; Hull 1967). Corn and sorghum excrete about 50% of accumulated atrazine and metabolize the rest to insoluble residues that are indigestible to sheep (*Ovis aries*) and rats (*Rattus* sp.). These results strongly suggest that the final disposition of atrazine metabolites does not occur in either plants or animals, but ultimately through microbial breakdown (Bakke et al. 1972b).

Long-term applications of atrazine for weed control in corn result in degradation products, mainly hydroxylated analogues, that may persist in soil for at least 12 months after the final herbicide application, and may enter food crops planted in atrazine-treated soil in the years after cessation of long-term treatment (Frank and Siron 1979; Kulshrestha et al. 1982). In one example, atrazine was applied to a corn field for 20 consecutive years at rates of 1.4 to 2.2 kg/ha (Khan and Saidak 1981). Soils collected 12 months after the last application contained atrazine (55 µg/kg dry weight), hydroxyatrazine (296 µg/kg), and various mono-dealkylated hydroxy analogues (deethylatrazine at 14 µg/kg, deethylhydroxyatrazine at 17 µg/kg, and desopropylhydroxyatrazine at 23 µg/kg). Oat (*Avena sativa*) seedlings grown in this field contained hydroxyatrazine (64 to 73 µg/kg fresh weight) and desopropylhydroxyatrazine (84 to 116 µg/kg). Similar results were obtained with timothy, *Phleum pratense* (Khan and Saidak 1981). In areas with a relatively long growing season, a double cropping of soybeans (*Glycine max*) — planted after corn is harvested for silage or grain — is gaining acceptance. Under conditions of warm weather, relatively high rainfall, and sandy soils, soybeans can be safely planted after corn (14 to 20 weeks after atrazine application) when rates of atrazine normally recommended for annual weed control (1.12 to 4.48 kg/ha) are used (Brecke et al. 1981).

Seed germination of sensitive species of plants was reduced by 50% at soil atrazine concentrations between 0.02 and 0.11 mg/kg (Table 11.3). Mustard (*Brassica juncea*) was especially sensitive and died shortly after germination. Soil atrazine residues of this magnitude were typical of those remaining at the beginning of a new growing season following corn in sandy loam under tropical conditions (Kulshrestha et al. 1982). Reduction in seed germination was also noted at soil atrazine concentrations of 0.25 to 0.46 mg/kg for the lentil *Lens esculenta*, the pea *Pisum sativum*, and the grain *Cicer arietinum* (Kulshrestha et al. 1982). Many species of mature range grasses are tolerant of atrazine but are susceptible as seedlings; seedlings of the most sensitive three species of eight tested were adversely affected in soils containing 1.1 mg atrazine/kg (Bahler et al. 1984) (Table 11.3).

Soil fungi and bacteria accumulated atrazine from their physicochemical environment by factors of 87 to 132 (Wolf and Jackson 1982), probably through passive adsorption mechanisms. Atrazine stimulated the growth of at least two common species of fungal saprophytes known to produce antibiotics: *Epicoccum nigrum* and *Trichoderma viride* (Richardson 1970). *Trichoderma*, for example, grew rapidly at all treatments tested (up to 80 mg/kg soil) and showed optimal growth 3 to 10 days postinoculation (Rodriguez-Kabana et al. 1968). Atrazine suppressed the growth of various species of soil fungi, including *Rhizoctonia solani*, *Sclerotium rolfsii*, and *Fusarium* spp., and stimulated the growth of other species known to be antagonistic to *Fusarium*. This selectivity is likely to induce a shift in the fungal population of atrazine-treated soil that would be either harmful or beneficial to subsequent crops, depending on whether saprophytic or pathogenic fungi attained dominance (Richardson 1970).

At 2.5 mg atrazine/kg soil, equivalent to 2 kg/ha in the top 10 cm, field and laboratory studies demonstrated that mortality in arthropod collembolids (*Onchiurus apuanicus*) was 47% in 60 days; however, fecundity was not affected at dose levels up to 5.0 mg/kg soil. It was concluded that

atrazine applications at recommended treatment levels had negligible long-term population effects on sensitive species of soil fauna (Mola et al. 1987). At 5 or 8 kg atrazine/ha, all species of soil fauna tested, except some species of nematodes, were adversely affected (Popovici et al. 1977). One month postapplication, population reductions of 65 to 91% were recorded in protozoa, mites, various insect groups, and collembolids at 5 kg/ha; after 4 months, populations were still depressed by 55 to 78% (Popovici et al. 1977). At 9 kg atrazine/ha, soil faunal populations of beetles, collembolids, and earthworms remained depressed for at least 14 months after initial treatment (Mola et al. 1987). Final instar larvae of the cabbage moth (*Mamestra brassica*) fed synthetic diets for 48 h containing 500 or 5000 mg atrazine/kg rations had significant changes in xenobiotic metabolizing activities of soft tissues and midgut, especially in aldrin epoxidase substrates; growth was retarded in the high-dose group (Egaas et al. 1993).

Table 11.3 Atrazine Effects on Selected Species of Terrestrial Plants

Species, Dose, and Other Variables	Effect and Reference
Soil alga, <i>Chlorella vulgaris</i>	
0.1 and 0.5 mg/L soil water	Chlorophyll production stimulated (Torres and O'Flaherty 1976)
1.0 mg/L and higher	Chlorophyll production inhibited; more-than-additive toxicity observed in combination with simazine and malathion (Torres and O'Flaherty 1976)
Mustard, <i>Brassica juncea</i>	
20 mg/kg dry weight soil	Seed germination reduced 50%; death shortly thereafter (Kulshrestha et al. 1982)
Cyanobacteria, 4 species, isolated from rice-cultivated soils in Egypt	
50 mg/L soil water for 7 days	Suppressed pigment biosynthesis in <i>Aulosira fertissima</i> and <i>Tolyphothrix tenuis</i> , reduced growth in <i>Anabaena oryzae</i> and <i>Nostoc muscorum</i> , and reduced carbohydrate content in <i>Nostoc</i> and <i>Tolyphothrix</i> (Shabana 1987)
100–500 mg/L soil water for 7 days	All variables affected in all species (Shabana 1987)
Barley, <i>Hordeum vulgare</i>	
50 mg/kg dry weight soil	Seed germination reduced 50% (Kulshrestha et al. 1982)
Oat, <i>Avena sativa</i>	
70 mg/kg dry weight soil	Seed germination reduced 50% (Kulshrestha et al. 1982)
Wheat, <i>Triticum aestivum</i>	
110 mg/kg dry weight soil	Seed germination reduced 50% (Kulshrestha et al. 1982)
0.6 kg/ha	Effectively controls weeds in wet sandy soils; some damage to crop possible in dry clay soils (Amor et al. 1987)
Range grasses, four species, seedlings	
1.1 mg/kg soil	Survival reduced, and growth reduced in surviving seedlings (Bahler et al. 1984)
Weed, <i>Chenopodium album</i> , seedlings from French garden never treated with chemicals	
0.5 kg/ha	Survival 12%; progeny of these survivors were resistant to 1 kg/ha treatment (Bettini et al. 1987)
1.0 kg/ha	Fatal to 100% (Bettini et al. 1987)
Corn, <i>Zea mays</i>	
1.25 kg/ha	No effect on growth or yield (Malan et al. 1987)
5.0 kg/ha	Severe phytotoxicity 25–30 days after planting; growth inhibition during early development. Recovery, with no negative effect on final yield (Malan et al. 1987)
Soybean, <i>Glycine max</i> , planted after corn, <i>Zea mays</i>	
2.24 kg/ha	No effect on yield when planted at least 8 weeks after atrazine application (Brecke et al. 1981)
4.48 kg/ha	At least 10-week interval required after atrazine application for successful germination (Brecke et al. 1981)

11.4.3 Aquatic Plants

Since the mid-1960s, seagrasses and freshwater submersed vascular plants have declined in many aquatic systems, especially in Chesapeake Bay (Forney and Davis 1981; Stevenson et al. 1982; Kemp et al. 1983; Cunningham et al. 1984). These plants provide food and habitat to diverse and abundant animal populations. In Chesapeake Bay, this decline has been associated with an overall decline in the abundance of fish and wildlife, and has been interpreted as an indication of serious disturbance in the ecological balance of the estuary. More than 10 native species of submersed aquatic plants in Chesapeake Bay have decreased in abundance. In the upper estuary, this decline was preceded by an invasion of Eurasian watermilfoil (*Myriophyllum spicatum*), which eventually also died back (Kemp et al. 1983). Runoff of herbicides, including atrazine, from treated agricultural lands has been suggested as a possible factor involved in the disappearance of Chesapeake Bay submersed vegetation. During the past 20 years, the most widely used herbicide in the Chesapeake Bay watershed — and in the surrounding coastal plain — has been atrazine. Since its introduction into the region in the early 1960s, atrazine use has grown to about 200,000 kg annually in Maryland coastal communities alone (Kemp et al. 1983). Potentially phytotoxic concentrations of atrazine would be expected in estuaries with the following characteristics (which seem to apply in most of upper Chesapeake Bay): immediately adjacent to cornfields in the watershed; rains occur shortly after atrazine application; clay soils in fields producing more rapid runoff; soils with circumneutral pH and relatively low organic content; and large estuarine areas of low salinity and poor mixing (Stevenson et al. 1982).

Most authorities agree that atrazine could induce some loss in aquatic vegetation but was not likely to have been involved in the overall decline of submersed plants in Chesapeake Bay (Forney 1980; Plumley and Davis 1980; Forney and Davis 1981; Kemp et al. 1983, 1985; Jones et al. 1986), and that nutrient enrichment and increased turbidity probably played major roles (Kemp et al. 1983, 1985). In the open waters of Chesapeake Bay, atrazine concentrations have rarely exceeded 1 µg/L. In major tributaries, such as the Choptank and Rappahanock Rivers, concentrations of 5 µg/L can occur after a major spring runoff. These runoffs sometimes generate transient, 2- to 6-hour concentrations up to about 40 µg/L in secondary tributaries (Kemp et al. 1983). In some small coves on the Chesapeake Bay, submersed plants may be exposed periodically to atrazine concentrations of 5 to 50 µg/L for brief periods during runoffs; however, dilution, adsorption, and degradation tend to reduce concentrations in the water phase to <5 µg/L within 6 to 24 h (Jones et al. 1986). Since atrazine degrades rapidly in estuarine conditions (half-time persistence [T_b 1/2] of 1 to 6 weeks), concentrations of atrazine on suspended and deposited estuarine sediments were seldom >5 µg/kg, suggesting little potential for accumulation (Kemp et al. 1983). The photosynthesis of redheadgrass (*Potamogeton perfoliatus*) was significantly inhibited by atrazine concentrations of 10 to 50 µg/L; however, it returned to normal levels within 1 h after atrazine was removed (Jones et al. 1986). Recovery of redheadgrass within several weeks has also been documented after exposure to 130 µg/L for 4 weeks (Cunningham et al. 1984). In Chesapeake Bay, potential long-term exposure of submersed aquatic plants to concentrations of atrazine in excess of 10 µg/L is doubtful. Therefore, any observed reductions in photosynthesis by these plants under such conditions would be minor and reversible (Jones et al. 1986).

Some authorities, however, suggest that the effects of atrazine on aquatic plants may be substantial. For example, atrazine concentrations between 1 and 5 µg/L adversely affect phytoplankton growth and succession; this, in turn, can adversely affect higher levels of the food chain, beginning with the zooplankton (DeNoyelles et al. 1982). Also, exposure to environmentally realistic concentrations of 3.2 to 12 µg atrazine/L for about 7 weeks was demonstrably harmful to wild celery (*Vallisneria americana*), a submersed vascular plant in Chesapeake Bay (Correll and Wu 1982). At highest concentrations of 13 to 1104 µg/L for 3 to 6 weeks, growth of representative submersed macrophytes in Chesapeake Bay was significantly depressed, and longer exposures were fatal to most species (Forney 1980). Atrazine concentrations of 100 µg/L reportedly cause permanent changes in algal community structure after exposure for 14 days, including decreased density

and diversity, altered species composition, and reduced growth (Hamala and Kollig 1985). It seems that additional research is needed on the role of atrazine and on its interactions with other agricultural chemicals in regard to observed declines in submerged plants. It is emphasized that degradation products of atrazine did not play a role in the disappearance of the submerged vascular plants from the Chesapeake Bay. For example, 500 µg/L of deethylated atrazine was needed to produce 20 to 40% photosynthetic inhibition in four major species of submerged macrophytes in 2 hours, but only 95 µg/L of the parent atrazine caused 50% inhibition in a similar period (Jones and Winchell 1984).

Many studies have been conducted on the effects of atrazine on various species of aquatic flora under controlled conditions (Table 11.4). At concentrations of 1 to 5 µg/L and exposure periods of 5 minutes to 7 weeks, documented adverse effects in sensitive species included inhibition of photosynthesis, growth, and oxygen evolution (Table 11.4). Higher concentrations were associated with altered species composition, reduced carbon uptake, reduced reproduction, high accumulations of atrazine, decreased chlorophyll *a* production, ultrastructural changes on chloroplasts, and death (Table 11.4). Phytotoxic effects were significantly increased at elevated levels of incident illumination, elevated water temperatures, decreased water pH, decreased dissolved oxygen concentrations, decreased nutrient content, and at increasing atrazine concentrations in the water column (Forney and Davis 1981; Karlander et al. 1983; Jones and Estes 1984; Malanchuk and Kollig 1985; Mayasich et al. 1986). Phytotoxicity was not significantly influenced by atrazine concentrations in the sediments or hydrosoils, or by the salinity of the medium (Forney 1980; Forney and Davis 1981; Jones and Estes 1984; Huckins et al. 1986). There are marked differences in sensitivity to atrazine among estuarine marsh plant species (Lytle and Lytle 1998). Atrazine, at typical concentrations occurring in areas draining agricultural fields, should pose no significant adverse effects to *Spartina alterniflora*. In contrast, *Juncus roemerianus* at 250 µg atrazine/L or greater will likely die or decline (Lytle and Lytle 1998).

Atrazine was 4 to 10 times more effective than its degradation products in producing growth reduction, photosynthesis inhibition, and acetylene-reducing ability in two species of green algae (*Chlorella pyrenoidosa* and *Scenedesmus quadricauda*) and three species of cyanobacteria (*Anabaena* spp.) (Stratton 1984). Atrazine reduced growth 50% at 0.03 to 5.0 mg/L and inhibited photosynthesis 50% at 0.1 to 0.5 mg/L. Comparable values for deethylated atrazine were 1.0 to 8.5 mg/L for growth reduction and 0.7 to 4.8 mg/L for photosynthesis inhibition. For deisopropylated atrazine, these values were 2.5 to >10 mg/L for growth reduction and 3.6 to 9.3 mg/L for photosynthesis inhibition; hydroxyatrazine and diaminoatrazine were nontoxic to most cultures tested (Stratton 1984). Smooth cordgrass (*Spartina alterniflora*), the major emergent species in North American salt marshes, is only slightly affected by relatively high levels of atrazine, due possibly to its ability to metabolize this compound (Davis et al. 1979; Forney and Davis 1981; Stevenson et al. 1982). Studies with radiolabeled atrazine and *Spartina* roots were conducted during 2-day exposures, followed by 28 days in atrazine-free solution (Pillai et al. 1977; Weete et al. 1980). After 2 days, 90% of the atrazine had translocated to the shoots. Atrazine was readily metabolized to chloroform-soluble substances, then to water-soluble substances, and finally to insoluble substances. Atrazine in the chloroform-soluble fraction decreased from 85 to 24% by day 28; the aqueous fraction contained 15% at the start and 60% at day 28. The basis of *Spartina* resistance is due primarily to its ability to convert atrazine to N-dealkylation products, such as 2-chloro-4-amino-6-isopropylamino-s-triazine. However, at least 14 water-soluble metabolites were isolated; about half contained the fully alkylated triazine rings, and most of the others had the 4-amino-6-isopropylamino derivative. Acid hydrolysates of the metabolites contained small amounts of amino acids, suggesting that a conjugation pathway, in addition to N-dealkylation, may be operative in *Spartina*.

Freshwater species of algae are among the most sensitive of all aquatic species tested (Tang et al. 1998). The ability of freshwater algal cells to accumulate atrazine was significantly correlated with cell volume and surface area, and accumulations were higher in the more sensitive species. Uptake of radiolabeled atrazine by four species of freshwater green algae and four species of diatoms was rapid: about 90% of the total uptake occurred within the first hour of exposure during

exposure for 24 h; maximum levels were reached 3 to 6 h after initial exposure; and accumulations were higher in algae than in diatoms (Tang et al. 1998). A green alga (*Chlorella kessleri*) showed numerous adverse effects when subjected to sublethal concentrations of atrazine over a 72-h period, including dose-dependent growth inhibition, protein synthesis decrease, photosynthesis reduction, and stimulation of fatty acid synthesis (El-Sheekh et al. 1994).

Estuarine fungi contribute substantially to plant detritus due to their abundance and potential for degradation. Fungi are known to accumulate soluble atrazine from seawater through sorption, and release up to 2.2% as hydroxyatrazine and other atrazine metabolites; another 4.6% is more tightly associated and less available to the external environment. The combined processes result in atrazine accumulation, and may contribute to its transport and redistribution through the estuary (Schocken and Speedie 1982, 1984).

11.4.4 Aquatic Animals

A marine copepod (*Acartia tonsa*) was the most sensitive aquatic animal tested against direct effects of atrazine, having a 96-h LC50 of 94 µg/L (Table 11.5). Atrazine was most toxic to estuarine crustaceans at low salinities; however, it was most toxic to estuarine fishes at high salinities (Hall et al. 1994). Adverse effect levels to selected species of aquatic invertebrates and fishes ranged from 120 µg/L to 500 µg/L, based on lifetime exposure studies (Table 11.5). The most sensitive criterion measured during long-term chronic exposure varied among species. Among freshwater invertebrates, for example, the most useful criterion was survival for *Gammarus*, the number of young produced for *Daphnia*, and developmental retardation for *Chironomus* (Macek et al. 1976).

Ambient concentrations as low as 20 µg atrazine/L have been associated with adverse effects on freshwater aquatic fauna, including benthic insects (Dewey 1986) and teleosts (Kettle et al. 1987), although effects were considered indirect. For example, the abundance of emerging chironomids (*Labrundinia pilosella*) and other aquatic insects declined at 20 µg atrazine/L (Dewey 1986). Richness of benthic insect species and total emergence declined significantly with atrazine addition. The effects were primarily indirect, presumably by way of reduction in food supply of nonpredatory insects, and to some extent their macrophyte habitat. Dietary habits and reproductive success were negatively affected in three species of fish after exposure for 136 days in ponds containing 20 µg atrazine/L (Kettle et al. 1987). About 70% of the original concentration applied was present in water at the end of the study. The reproduction of channel catfish (*Ictalurus punctatus*) and gizzard shad (*Dorosoma cepedianum*) failed, and that of bluegills, as measured by number of young per pond, was reduced more than 95%. Also, the number of prey items in the stomachs of bluegills was significantly higher in control ponds (25.6) than in a treated pond (3.8), and the number of taxa represented was significantly greater. Macrophyte communities in treated ponds were reduced more than 60% in 2 months. The authors concluded that the effects of atrazine on bluegills were probably indirect, and that the reduction of macrophytes that had provided habitat for food items led to impoverished diets and more cannibalism by adult bluegills (Kettle et al. 1987).

Bioaccumulation of atrazine from freshwater is limited, and food chain biomagnification is negligible (Cossarini-Dunier et al. 1988; Du Preez and van Vuren 1992). Rainbow trout fed diets containing 100 mg atrazine/kg of ration for 84 days had no significant accumulations in tissues, although some accumulation occurred (maximum of 0.9 mg/kg lipid weight in liver) at 1000 mg/kg ration (Cossarini-Dunier et al. 1988). In a farm pond treated once with 300 µg atrazine/L, residues at 120 days posttreatment ranged between 204 and 286 µg/kg in mud and water, and from not detectable in bullfrog (*Rana catesbeiana*) tadpoles to 290 µg/kg (all fresh weights) in whole bluegills; values were intermediate in zooplankton and clams. No residues were detectable in biological components at 1 year posttreatment, when residues were <21 µg/kg in water and mud (Klaasen and Kadoum 1979). In a laboratory stream treated four times with 25 µg atrazine/L for 30 days, followed by depuration for 60 days, maximum accumulation factors ranged from about 4 in annelids to 480 in mayfly nymphs; however, residue concentrations declined to posttreatment

Table 11.4 Atrazine Effects on Selected Species of Aquatic Plants

Species, Dose, and Other Variables	Effect and Reference
PHYTOPLANKTON COMMUNITIES IN EXPERIMENTAL MICROCOOSMS	
0.5–5.0 µg/L, 39 weeks	No measurable adverse effects (Brockway et al. 1984)
1.0–5.0 µg/L, several days	Reduced photosynthesis in sensitive species (DeNoyelles et al. 1982)
>17.9 µg/L, 21 days	Decreased oxygen production, decreased content of calcium and magnesium (Pratt et al. 1988)
12 µg/L, 4 weeks	Biovolume of benthic algal communities was reduced at both dose levels when compared to controls (Carder and Hoagland 1998)
20 µg/L, 20 days	Altered species composition (DeNoyelles and Kettle 1985)
20 µg/L, 136 days	Reduced growth, altered succession; atrazine-resistant species now dominant (DeNoyelles et al. 1982)
50 µg/L, 12 days	Oxygen production decreased 20–30% (Brockway et al. 1984)
100 µg/L, 14 days	Algal densities and biomass reduced, diversity decreased, and species composition altered. Within 16 days after removal of atrazine stress, net productivity was indistinguishable from controls, but community structure remained altered at day 21 (Hamala and Kollig 1985)
100 µg/L, 20 days	Carbon uptake reduced >40% (DeNoyelles and Kettle 1985)
500 µg/L, 53 days	Immediate decline in primary productivity and community metabolism; no recovery (Stay et al. 1985)
5000 µg/L, 12 days	Death (Brockway et al. 1984)
ALGA, <i>Cyclotella meneghiniana</i>	
1.0 µg/L, 5 min	Some inhibition in oxygen evolution (Millie and Hersh 1987)
99–243 µg/L, 5 min	Oxygen evolution reduced 50% (Millie and Hersh 1987)
500 µg/L, 5 min	Oxygen evolution 100% inhibited (Millie and Hersh 1987)
WILD CELERY, <i>Vallisneria americana</i>	
1.3 µg/L, 47 days	No measurable effect (Correll and Wu 1982)
3.2 µg/L, 49 days	Some reduction in leaf area (Correll and Wu 1982)
12 µg/L, 47 days	LC50; reduced reproduction and leaf area in survivors (Correll and Wu 1982)
75 µg/L, 12–28 days	Inhibited photosynthesis (Correll and Wu 1982)
100 µg/L, 6 weeks	Growth inhibited 29% (Forney and Davis 1981)
120 µg/L, 30 days	LC100 (Correll and Wu 1982)
163 µg/L, 21–42 days	Growth inhibition of 50% (Forney 1980)
320 µg/L, 6 weeks	Growth inhibited 36% (Forney and Davis 1981)
ELODEA, <i>Elodea canadensis</i>	
3.2 µg/L, 3–4 weeks	Growth inhibited 1% (Stevenson et al. 1982)
13 µg/L, 21–42 days	Growth inhibited 50% (Forney 1980)
32 µg/L, 3–4 weeks	Growth inhibited 15–39% (Forney and Davis 1981)
100 µg/L, 3–4 weeks	Growth inhibited 53% (Forney and Davis 1981)
REDHEADGRASS, <i>Potamogeton perfoliatus</i>	
4 µg/L, 4 weeks	Photosynthesis reduced 10% (Kemp et al. 1985)
10 µg/L, 3 weeks	Growth inhibited 15% (Forney and Davis 1981)
50 µg/L, 2 h	Equilibrium reached within 15 min, maximum residues of 3.5 mg/kg dry weight (Jones et al. 1986)
55 µg/L, 4 weeks	Photosynthesis reduced 50% (Kemp et al. 1985; Larsen et al. 1986)
80 µg/L, 2 h	Photosynthesis inhibited 50% (Jones et al. 1986)
100 µg/L, 2 h	Photosynthesis inhibition and residues of about 9.0 mg/kg dry weight; recovery rapid in atrazine-free medium but some photosynthetic depression for up to 77 h (Jones et al. 1986)
100 µg/L, 4 weeks	Photosynthesis inhibition; water levels of 87 µg atrazine/L at 4 weeks; recovery in 2–3 weeks in atrazine-free medium (Kemp et al. 1985)

Table 11.4 (continued) Atrazine Effects on Selected Species of Aquatic Plants

Species, Dose, and Other Variables	Effect and Reference
130 µg/L, 4 weeks	Decreased oxygen production immediately on exposure; significant recovery within 2 weeks despite constant atrazine concentrations (Cunningham et al. 1984)
320 µg/L, 3 weeks	Growth inhibited 45–54% (Forney and Davis 1981)
450–650 µg/L, 2 h	Photosynthesis inhibited 87%; residues of about 5 mg/kg dry weight (Jones et al. 1986)
474 µg/L, 21–42 days	Growth reduced 50% (Forney 1980)
1200 µg/L, 4 weeks	Pronounced phytotoxic effects; no recovery (Cunningham et al. 1984)
EURASIAN WATERMILFOIL, <i>Myriophyllum spicatum</i>	
5 µg/L, 4 weeks	Enhanced oxygen production (Kemp et al. 1985)
11 µg/L, 4 weeks	Photosynthesis reduced 1% (Kemp et al. 1985)
50 µg/L, 4 weeks	Oxygen production depressed (Kemp et al. 1985)
117 µg/L, 4 weeks	Photosynthesis reduced 50% (Kemp et al. 1985; Larsen et al. 1986)
320 µg/L, 4 weeks	Growth inhibited 22% (Forney and Davis 1981)
1000 µg/L, 4 weeks	Growth inhibited 62% (Forney and Davis 1981)
1000 µg/L, 4 weeks	Residues <1 µg/kg (Kemp et al. 1985)
1104 µg/L, 21–42 days	Growth inhibited 50% (Forney 1980)
COMMON CORDGRASS, <i>Spartina alterniflora</i>	
10 µg/L, 3–4 weeks	Biomass reduction of 6% (Stevenson et al. 1982)
Exposed for 35 days to 30, 250, or 3000 µg atrazine/L	The high concentration significantly enhanced peroxidase activity but did not affect growth or chlorophyll production (Lytle and Lytle 1998)
100 µg/L, 3–4 weeks	Biomass reduction of 34% (Stevenson et al. 1982)
1000 µg/L, 3–4 weeks	Biomass reduction of 46% (Stevenson et al. 1982)
SHOAL GRASS, <i>Halodule wrightii</i>	
10, 40, or 120 µg/L for 22 days	Enhanced growth when compared to controls (Mitchell 1985)
420 µg/L for 22 days	Above-ground biomass reduced 26% (Mitchell 1985)
1490 µg/L for 22 days	Above-ground biomass reduced 45% compared to controls (Mitchell 1985)
MARINE ALGA, <i>Nannachloris oculata</i>	
15 µg/L, 7 days	Growth reduction (Mayasich et al. 1987)
50 µg/L, 72 h	Some growth inhibition; inhibition greatest under conditions of elevated temperature and illumination (Karlander et al. 1983)
ALGA AND MACROPHYTES (various species)	
20 µg/L, 6 weeks	Bioconcentration factors up to 32 (Huckins et al. 1986)
21–132 µg/L, 14 days	50% reduction in growth rate of 4 species of freshwater macrophytes (Fairchild et al. 1998)
SUBMERGED AQUATIC MACROPHYTES	
4 species: <i>Potamogeton</i> sp., <i>Ruppia</i> sp., <i>Myriophyllum</i> sp., <i>Zannichellia</i> sp.	
20 µg/L, 2 h	Photosynthesis inhibition of about 1% (Jones and Winchell 1984)
95 µg/L, 2 h	Photosynthesis inhibition 50%; atrazine significantly more effective than deethylated atrazine, deisopropylated atrazine, and hydroxyatrazine, in that order, in effecting inhibition (Jones and Winchell 1984)
ALGAE (various species)	
22 µg/L, 7 days	No effect on photosynthesis rate, chlorophyll content, or cell numbers (Plumley and Davis 1980)
37–308 µg/L, 24 h	Carbon uptake reduced 50% (Larsen et al. 1986)

Table 11.4 (continued) Atrazine Effects on Selected Species of Aquatic Plants

Species, Dose, and Other Variables	Effect and Reference
60–100 µg/L, 72 h	Growth inhibited 50% in 7 species (Mayer 1987)
60–460 µg/L, 1 h	Oxygen evolution inhibited 50% in 18 species (Hollister and Walsh 1973)
77–102 µg/L, 24 h	Photosynthesis reduction of 50% (Larsen et al. 1986)
90–176 µg/L, 96 h	50% inhibition in chlorophyll fluorescence for 5 species of freshwater algae (Fairchild et al. 1998)
80–907 µg/L, 3 weeks	Growth inhibited 50% (Larsen et al. 1986)
100 µg/L, 2 h	Growth inhibited 50% in 3 species (Mayer 1987)
100 µg/L, 3 days	Reduced productivity; complete recovery by day 7 (Moorehead and Kosinski 1986)
100–300 µg/L, 10 days	Growth inhibited 50% in 4 species (Mayer 1987)
100–460 µg/L, 72 h	Growth inhibited 50% in 8 species (Mayer 1987)
220 µg/L, 7 days	Reduced photosynthesis; no effect on chlorophyll production and cell division rate in 3 estuarine species (Plumley and Davis 1980)
ESTUARINE MARSH PLANT, <i>Juncus roemerianus</i>	
Exposed for 35 days to 30, 250, or 3000 µg atrazine/L	A dose-dependent response was evident in increased lipid peroxidation products, and inhibited chlorophyll production (Lytle and Lytle 1998)
ALGAE, <i>Chlorella</i> spp.	
54 µg/L, 10 days	Growth reduction of 30% (Gonzalez-Murua et al. 1985)
200 µg/L, 48 h	Photosynthesis reduced 30%, but no effect on growth (Lay et al. 1984)
250 µg/L, 7 days	Growth reduction; 90% of atrazine passively accumulated within 1 h (Veber et al. 1981)
SUBMERSED VASCULAR PLANT, <i>Zannichellia palustris</i>	
75 µg/L, 21–42 days	Photosynthesis inhibition (Correll and Wu 1982)
SUBMERSED VASCULAR PLANT, <i>Potamogeton pectinatus</i>	
75 µg/L, 21–42 days	Photosynthesis stimulation (Correll and Wu 1982)
650 µg/L, 21–42 days	Photosynthesis inhibition (Correll and Wu 1982)
SUBMERSED VASCULAR PLANT, <i>Zostera marina</i>	
75 µg/L, 21–42 days	Photosynthesis stimulation (Correll and Wu 1982)
650 µg/L, 21–42 days	Photosynthesis inhibition (Correll and Wu 1982)
PERIPHYTON COMMUNITIES IN FRESHWATER ENCLOSURES	
80–1560 µg/L, 10 months	Declines in net production, cell numbers, biomass, number of taxa, and chlorophyll activity; larger algal species (<i>Mougeotia</i> , <i>Oedogonium</i> , <i>Tolyphothrix</i> , <i>Epithemia</i>) were the most sensitive. At higher concentrations, population shifted from a chlorophyte-dominated to a diatom-dominated community (Hamilton et al. 1987)
100 µg/L, 2 treatments, 6 weeks apart	After initial application, all blue-green algae disappeared and organic matter significantly decreased. Within 3 weeks of second treatment, a 36–67% reduction in organic matter, chlorophyll, algal biomass, and rate of carbon assimilation was measured. Some species of green algae decreased in abundance, but others increased (Herman et al. 1986)
DUCKWEED, <i>Lemna</i> sp.	
92 µg/L, 96 h	50% reduction in frond count (Fairchild et al. 1998)
250 µg/L, 15 days	Ultrastructural changes on chloroplasts of mesophyll cells; no effect on chlorophyll and lipid distribution (Beaumont et al. 1980; Grenier et al. 1987)

levels within a few days after depuration began. Maximum atrazine concentrations recorded, in mg/kg whole organism fresh weight, were 0.2 in the clam *Strophitus rugosus*, 0.4 in the snail *Physa* sp., 0.9 in crayfish *Orconectes* sp., 2.4 in the mottled sculpin *Cottus bairdi*, 3.0 in the amphipod *Gammarus pseudolimnaeus*, and 3.4 in mayflies *Baetis* sp. (Lynch et al. 1982). In studies with the freshwater snail *Ancylus fluviatilis* and fry of the whitefish *Coregonas fera*, atrazine was rapidly accumulated from the medium by both species and saturation was reached within 12 to 24 h; bioconcentration factors were 4 to 5 at ambient water concentrations of 50 to 250 µg atrazine/L (Gunkel and Streit 1980; Gunkel 1981). Elimination of atrazine was rapid: 8 to 62 min for *C. fera*, and 18 min for *A. fluviatilis*. No accumulation of atrazine was recorded in molluscs, leeches, cladocerans, or fish when contamination was by way of the diet (Gunkel and Streit 1980; Gunkel 1981). Atrazine accumulations in *Daphnia pulicaria* were significantly correlated with whole-body protein content at low (8°C) water temperatures, and with fat content at elevated (20°C) water temperatures (Heisig-Gunkel and Gunkel 1982).

Atrazine is rapidly degraded in boxcrabs (*Sesarma cinereum*) feeding on smooth cordgrass (*Spartina alterniflora*) grown in radiolabeled atrazine solution. After 10 days, only 1.2% of the total radioactivity in the crab was unchanged atrazine, compared to 24% in the food source. The accumulation of water-soluble atrazine metabolites (86% of total radioactivity) in *Sesarma* suggested that glutathione conjugation, or a comparable pathway, was responsible for the almost complete degradation and detoxification of atrazine in crabs (Davis et al. 1979; Pillai et al. 1979). Atrazine does not appear to be a serious threat to crabs in Chesapeake Bay, where water concentrations of 2.5 µg/L have been recorded, although it could have an indirect effect on crabs by decreasing the algae population, which composes a portion of their diet (Plumley et al. 1980).

Table 11.5 Lethal and Sublethal Effects of Atrazine on Selected Species of Aquatic Animals
(Concentrations listed are in micrograms of atrazine per liter of medium.)

Ecosystem, Organism, and Other Variables	Concentration (g/L)	Effect	Reference ^a
FRESHWATER INVERTEBRATES			
Freshwater shrimp, <i>Paratya australiensis</i>	10–50	MATC ^b	15
Midge, <i>Chironomus riparius</i>			
Adults	20	Whole-body residue of 160 µg/kg in 6 weeks	1
Larvae	20	Whole-body residue of 569 µg/kg in 6 weeks	1
Cladoceran, <i>Daphnia magna</i>	20	After 6 weeks, whole-body residue of 300 µg/kg	1
<i>D. magna</i>	200	Exposure for six generations. Number of young per female in 21 days did not differ from controls in generations 1, 2, and 3, but significant reduction measured in generations 4, 5, and 6	2
<i>D. magna</i>	6900	LC50 (48 h)	3
Scud, <i>Gammarus fasciatus</i>	60–140	MATC ^b	3
<i>G. fasciatus</i>	>2400	Some deaths in 48 h	3
<i>G. fasciatus</i>	5700	LC50 (48 h)	3
Midge, <i>Chironomus tentans</i>	110–230	MATC ^b	3
<i>C. tentans</i>	500	Some deaths in 48 h	3
<i>C. tentans</i>	720	LC50 (48 h)	3
Leeches, 2 species (<i>Glossiphonia complanata</i> , <i>Helobdella stagnalis</i>)	<1000	Adverse effects on growth, food intake, and egg production	11
Leeches, 2 spp.	6300–9900	LC50 (28 days)	11
Leeches, 2 spp.	16,000	No deaths in 96 h	11

Table 11.5 (continued) Lethal and Sublethal Effects of Atrazine on Selected Species of Aquatic Animals
 (Concentrations listed are in micrograms of atrazine per liter of medium.)

Ecosystem, Organism, and Other Variables	Concentration (g/L)	Effect	Reference ^a
FRESHWATER VERTEBRATES			
Goldfish, <i>Carassius auratus</i>	0.5, 5, or 50	After 24 h, accelerated swimming performance at 0.5 µg/L; reduced grouping behavior and increased surfacing activity at 5.0 and 50 µg/L	27
<i>C. auratus</i>	100, 1000 or 10,000	After 10 min, all concentrations had a significant increase in burst swimming reactions	27
Rainbow trout, <i>Oncorhynchus mykiss</i>	5–40	Lowest observed effective concentrations for producing adverse effects on gills and kidneys (5 µg/L), liver and heart (10 µg/L), enzyme activities and other tissues (20–40 µg/L)	24
<i>O. mykiss</i>	5–80	Juveniles exposed for 28 days had alterations of renal corpuscles and renal tubules at 5, 10, 20, or 40 µg/L exposures; necrosis of endothelial cells and renal hematopoietic tissue were prominent at 80 µg/L	17
<i>O. mykiss</i>	10	After 14 days, no adverse effects on survival, growth, or liver xenobiotic metabolizing activities	16
<i>O. mykiss</i>	50	Plasma protein decreased after 10 days	15
<i>O. mykiss</i>	340	No deaths; decreased growth; increased plasma glucose	15
<i>O. mykiss</i>	1400–2800	After 96 h, reduced motility, balance disturbances, darkening of the body surface; kidney histopathology	17
<i>O. mykiss</i>	2000	Predicted no adverse effect on survival after 30 days for fingerlings	26
<i>O. mykiss</i>	4500–24,000	LC50 (96 h)	4, 6, 26
Cricket frog, <i>Acris crepitans</i>	30–600	Tadpoles exposed through metamorphosis had normal growth and normal time to reach metamorphosis	18
Wood frog, <i>Rana sylvatica</i>	30–600	Tadpoles exposed through metamorphosis developed normally	18
Brook trout, <i>Salvelinus fontinalis</i>	60–120	MATC ^b	3
<i>S. fontinalis</i>	450	Reduced incubation time of developing embryos	3
<i>S. fontinalis</i>	740	After 44 weeks, concentration in muscle <0.2 mg/kg fresh weight	3
<i>S. fontinalis</i>	6300 (4100–9700)	LC50 (8 days)	3
Freshwater fishes, various species	60–2130	No deaths in 96 h	25
	8800–76,000	LC50 (96 h) range	25
Bluegill, <i>Lepomis macrochirus</i>	90–500	MATC ^b	3, 13
<i>L. macrochirus</i>	94	After 78 weeks, concentration in muscle <0.2 mg/kg fresh weight	3
<i>L. macrochirus</i>	500	At 28 days, fish were lethargic, ate poorly, and swam erratically	3
<i>L. macrochirus</i>	6700	LC50 (7 days)	3
<i>L. macrochirus</i>	8000–42,000	LC50 (96 h)	3–6
<i>L. macrochirus</i>	46,000	LC50 (24 h)	6
Fathead minnow, <i>Pimephales promelas</i>	210	After 43 weeks, concentration in eviscerated carcass was <1.7 mg/kg fresh weight	3
<i>P. promelas</i>	210–520	MATC ^b	3, 13
<i>P. promelas</i> fry	520	LC25 (96 hours)	3
<i>P. promelas</i>	15,000 (11,000–20,000)	LC50 (8 days)	3

Table 11.5 (continued) Lethal and Sublethal Effects of Atrazine on Selected Species of Aquatic Animals
 (Concentrations listed are in micrograms of atrazine per liter of medium.)

Ecosystem, Organism, and Other Variables	Concentration (g/L)	Effect	Reference ^a
Zebrafish, <i>Brachydanio rerio</i>	Exposed for 5 weeks to 5, 25, 125, 625, or 3125 µg/L under conditions of light and dark habitat preferences	After 1 week, all atrazine-treated fish significantly avoided light habitats when compared to controls; this became more pronounced after 5 weeks of exposure	25
<i>B. rerio</i>	300–1300	MATC ^b	14
<i>B. rerio</i>	1300	LC50 (96 h), embryos	14
<i>B. rerio</i>	37,000	LC50 (96 h), adults	14
Banded tilapia, <i>Tilapia sparrmanii</i>	310–6700	Sublethal effects after 72 h include decreased activity, color changes, "coughing," and maximum blood atrazine concentrations of about 3 mg/L	20
<i>T. sparrmanii</i>	320–6700	Maximum bioconcentration factors after 72 h ranged between 5.1 for muscle (7.7 mg/kg FW) and 20.0 for ovaries (50.6 mg/kg FW)	21
<i>T. sparrmanii</i>	8100	No deaths in 72 h. Oxygen consumption decreased in first 3 h of exposure	22
Northern leopard frog, <i>Rana pipiens</i>	650	Predicted no adverse effect on survival for late-stage larvae after 30 days	26
<i>R. pipiens</i>	5100	As above for early-stage larvae	26
<i>R. pipiens</i>	14,500	LC50 (96 h) for late-stage larvae	26
<i>R. pipiens</i>	47,600	LC50 (96 h) for early-stage larvae	26
American toad, <i>Bufo americanus</i>	690	Predicted no effect on survival of late-stage larvae after exposure for 30 days	26
<i>B. americanus</i>	1900	As above for early-stage larvae	26
<i>B. americanus</i>	10,700	LC50 (96 h) for late-stage larvae	26
<i>B. americanus</i>	26,500	LC50 (96 h) for early-stage larvae	26
Mozambique tilapia, <i>Tilapia mossambicus</i>	1100	No deaths in 90 days. Increased growth and body water content; disrupted serum electrolytes	23
<i>T. mossambicus</i>	8800	LC50 (96 h)	23
Common carp, <i>Cyprinus carpio</i>	1500–6000	After 14 days, gill and liver histopathology and disrupted alkaline phosphatase activity in serum, heart, liver, and kidneys	19
<i>C. carpio</i>	18,800	LC50 (96 h), juveniles weighing 4.3 g	19
Channel catfish, <i>Ictalurus punctatus</i> , fingerlings	4300	Predicted no adverse effect on survival after exposure for 30 days	26
<i>I. punctatus</i>	23,800	LC50 (96 h)	26

MARINE INVERTEBRATES

Mysid shrimp, <i>Mysidopsis bahia</i>	80–190	MATC ^b	7
<i>M. bahia</i>	1000 (650–3100)	LC50 (96 h)	7
Copepod, <i>Acartia tonsa</i>	94 (52–167)	LC50 (96 h)	7
Copepod, <i>Eurytemora affinis</i>	500	LC50 (96 h) at 0.5% salinity	12
<i>E. affinis</i>	2600	LC50 (96 h) at 1.5% salinity	12
<i>E. affinis</i>	13,200	LC50 (96 h) at 2.5% salinity	12
Brown shrimp, <i>Penaeus aztecus</i>	1000	50% immobilized in 48 h	8
American oyster, <i>Crassostrea virginica</i>	1000	No effect on survival or growth	9
<i>C. virginica</i>	>1000	Growth reduced 50% in 96 h	8
<i>C. virginica</i>	>30,000	No effect on development in 48 h	7
"Shrimp"	1000	LC30 (96 h)	9

Table 11.5 (continued) Lethal and Sublethal Effects of Atrazine on Selected Species of Aquatic Animals
 (Concentrations listed are in micrograms of atrazine per liter of medium.)

Ecosystem, Organism, and Other Variables	Concentration (g/L)	Effect	Reference ^a
Pink shrimp, <i>Penaeus duorarum</i>	6900	LC50 (96 h)	7
Grass shrimp, <i>Palaemonetes pugio</i>	9000	LC50 (96 h)	7
Fiddler crab, <i>Uca pugilator</i>	>29,000	LC50 (96 h)	7
Fiddler crab, <i>Uca pugnax</i>	100,000	Interfered with escape response when exposed in August; negligible effects in November; young males most sensitive	10
<i>U. pugnax</i>	1–10 × 10 ⁶	Reduced survival after 10 weeks	10
Mud crab, <i>Neopanope texana</i>	750,000	No deaths in 96 h	9
<i>N. texana</i>	1 × 10 ⁶	LC50 (96 h)	9
MARINE FISHES			
Sheepshead minnow, <i>Cyprinodon variegatus</i>	1900–3400	MATC ^b	7
<i>C. variegatus</i>	2000–2300	LC50 (96 h) at 1.5–2.5% salinity	12
<i>C. variegatus</i>	16,200	LC50 (96 h) at 0.5% salinity	12
Spot, <i>Leiostomus xanthurus</i>	8500	LC50 (96 h)	7

^a 1, Huckins et al. 1986; 2, Kaushik et al. 1985; 3, Macek et al. 1976; 4, Beste 1983; 5, Klaasen and Kadoum 1979; 6, Mayer and Ellersiek 1986; 7, Ward and Ballantine 1985; 8, Mayer 1987; 9, Stevenson et al. 1982; 10, Plumley et al. 1980; 11, Streit and Peter 1978; 12, Hall et al. 1994; 13, DuPreez and van Vuren 1992; 14, Gorge and Nagel 1990; 15, Davies et al. 1994; 16, Egaas et al. 1993; 17, Fischer-Scherl et al. 1991; 18, Gucciardo and Farrar 1996; 19, Neskovic et al. 1993; 20, Grobler-van Heerden et al. 1991; 21, Du Preez and van Vuren 1992; 22, Grobler et al. 1989; 23, Prasad and Reddy 1994; 24, Bruggemann et al. 1995; 25, Steinberg et al. 1995; 26, Howe et al. 1998; 27, Saglio and Trijasse 1998.

^b Maximum acceptable toxicant concentration. Lower value in each pair indicates highest concentration tested producing no measurable effect on growth, survival, reproduction, or metabolism during chronic exposure; higher value indicates lowest concentration tested producing a measurable effect.

11.4.5 Birds

Atrazine is not acutely lethal to birds at realistic environmental levels; that is, oral LD50 values were >2000 mg/kg BW and dietary LC50 values were >5000 mg/kg ration (Table 11.6). Also, the probability is low for chronic effects of atrazine on wetland aquatic organisms and for biomagnification of toxic residues through waterfowl food chains (Huckins et al. 1986). However, indirect effects of atrazine on insect- and seed-eating birds have not been investigated, and this may be critical to the survival of certain species during nesting and brood-rearing. Studies are needed on the potential indirect ecosystem effects of atrazine, with special reference to seed-eating birds.

Domestic chickens (*Gallus* sp.) rapidly metabolized atrazine by way of partial N-dealkylation accompanied by hydrolysis. Dealkylation occurred mainly at the ethylamino group, resulting in intermediate degradation products (Foster and Khan 1976; Khan and Foster 1976). *In vitro* studies with bird liver homogenates also demonstrated active transformation of atrazine and its metabolites. Chicken liver homogenates released nonextractable atrazine residues that had accumulated in corn plants, present mainly as 2-chloro-mono-N-dealkylated compounds, and subsequently metabolized them to 2-hydroxy analogues (Khan and Akhtar 1983). Liver homogenates in the goose (*Anser* sp.) contained enzyme systems that metabolized atrazine by partial N-dealkylation and hydrolysis. Hydrolysis predominated and resulted in the formation of hydroxyatrazine, which does not undergo further degradation by dealkylation. But partly N-dealkylated metabolites, such as deethylatrazine and deisopropylatrazine, were further hydrolyzed to the corresponding hydroxy analogues (Foster et al. 1980).

Table 11.6 Atrazine Effects on Selected Species of Birds

Species, Dose, and Other Variables	Effect and Reference
CHICKEN, <i>Gallus</i> sp.	
Laying hens were fed diets containing 100 mg/kg for 7 days	No visible adverse physiological effects or signs of toxicity. No effect on egg production or growth. No residues of atrazine or its metabolites detected in eggs. In excreta, however, atrazine and atrazine metabolites were detected after 24 h on treated diet and remained measurable until day 11, or after 4 days on an untreated diet (Foster and Khan 1976; Reed 1982)
Adults fed diets containing 100 mg/kg for 7 days, followed by uncontaminated diet for 7 days. Residues of atrazine and its metabolites were determined in selected tissues	Residues, in mg/kg FW, were as follows: atrazine, 38.8 in abdominal fat and 0.04 in muscle; hydroxyatrazine, 16.2 in liver, 4.3 in kidney 2.5 in oviduct, 0.7 in abdominal fat, and 0.5 in gizzard; and deethylhydroxyatrazine, 15.5 in liver, 2.3 in kidney, 0.8 to 1.8 in muscle, and 0.3 in gizzard (Khan and Foster 1976)
RING-NECKED PHEASANT, <i>Phasianus colchicus</i>	
Males, age 3 months, given 2000 mg/kg body weight (BW), administered orally	Survivors showed weakness, hyperexcitability, ataxia, and tremors; remission by day 5 posttreatment (Hudson et al. 1984)
MALLARD, <i>Anas platyrhynchos</i>	
Females, age 6 months, given 2000 mg/kg BW, administered orally	Survivors showed weakness, tremors, ataxia, and weight loss. Signs of poisoning appeared within 1 h posttreatment and persisted up to 11 days (Tucker and Crabtree 1970; Hudson et al. 1984)
19,650 mg/kg diet for 8 days	LD50 (Beste 1983)
COTURNIX, <i>Coturnix japonica</i>	
Chicks, age 7 days, given diets containing 5000 mg/kg for 5 days plus 3 days on untreated feed	One of 14 birds tested died on day 3 of feeding; no other adverse effects reported (Hill and Camardese 1986)
NORTHERN BOBWHITE, <i>Colinus virginianus</i>	
5760 mg/kg diet for 8 days	LD50 (Beste 1983)

11.4.6 Mammals

Data are lacking for atrazine's effects on mammalian wildlife, although there is a growing body of evidence on domestic and small laboratory mammals. Available data demonstrate that mammals are comparatively resistant to atrazine, and that the compound is not carcinogenic, mutagenic, or teratogenic (Reed 1982) (Table 11.7). However, there is a reported increase in the incidence of mammary gland tumors in rats given dietary equivalents of a lifetime dose of 70 mg atrazine/kg BW (Egaas et al. 1993). There have been no established cases of skin irritation resulting from experimental or commercial applications of atrazine, and no documented cases of poisoning in man (Anonymous 1963; Hull 1967). No observable ill effects were detected in cattle, dogs, horses, or rats fed diets that included 25 mg atrazine/kg food over extended periods (Beste 1983). Most members of the triazine class of herbicides, including atrazine, have low acute oral toxicities — usually >1000 mg/kg body weight (Murphy 1986) (Table 11.7). But at dosages bordering on lethality, rats showed muscular weakness, hypoactivity, drooped eyelids, labored breathing, prostration (Beste 1983), altered liver morphology and renal function (Santa Maria et al. 1986, 1987), and embryotoxicity (Peters and Cook 1973). There seems to be a causal link between tumor formation and triazine-mediated hormonal balance, suggesting the existence of a threshold value below which contact with atrazine will have no effect on tumor formation (Egaas et al. 1993).

Biomarkers of atrazine exposure is a developing field (Lu et al. 1998) that merits additional research. For example, concentrations of atrazine in saliva of rats was significantly correlated with rat free atrazine plasma concentrations. About 26% of the atrazine in rats is bound to plasma proteins (and is unavailable for transport from blood to saliva) and is independent of plasma levels of atrazine. Salivary concentrations of atrazine reflect total plasma free atrazine concentration — in the 50 to 250 µg/L range — which may be of toxicological significance (Lu et al. 1998).

Animals feeding on atrazine-treated crops are at limited toxicological risk. Crop plants metabolize atrazine to hydroxyatrazine, dealkylated analogues, and cysteine- and glutathione-conjugates of atrazine; mature plants contain little unchanged atrazine. Bound atrazine residues in plants are of limited bioavailability to animals (Bakke et al. 1972a; Khan and Akhtar 1983; Khan et al. 1985). Metabolic degradation of atrazine in mammals is usually rapid and extensive; unchanged atrazine was recovered only from the feces (Anonymous 1963). Liver enzyme systems in pigs, rats, and sheep metabolize atrazine by partial N-dealkylation and hydrolysis (Bakke et al. 1972a; Dauterman and Muecke 1974; Foster et al. 1980). However, atrazine is reportedly converted *in vivo* to N-nitrosoatrazine in mice, *Mus* sp. (Krull et al. 1980). Since N-nitrosoatrazine is carcinogenic and mutagenic to laboratory animals (Krull et al. 1980), more research is recommended on the extent of nitrosation of atrazine in the environment.

Table 11.7 Lethal and Sublethal Effects of Atrazine on Selected Species of Mammals

Organism, Dose, and Other Variables	Effect and Reference
CATTLE, COW, <i>Bos</i> spp.	
30 mg atrazine/kg diet for 21 days	Tissue residues <0.1 mg/kg fresh weight (Reed 1982)
100 mg atrazine/kg diet for 21 days	No detectable atrazine (<0.04 mg/kg) or hydroxyatrazine (<0.05 mg/kg) found in milk (Reed 1982)
DOMESTIC SHEEP, <i>Ovis aries</i>	
30 mg atrazine/kg diet for 28 days	Tissue residues <0.1 mg/kg fresh weight (Reed 1982)
100 mg atrazine/kg diet for 28 days	No adverse effects (Reed 1982)
MICE, <i>Mus</i> spp.	
46.4 mg/kg body weight (BW) given daily on days 6 through 14 of pregnancy	No effect on reproduction (Peters and Cook 1973)
82 mg/kg diet for 18 months	Negative oncogenicity results (Reed 1982)
1750–3900 mg/kg BW	Acute oral LD50 value (Anonymous 1963; Hull 1967; Reed 1982)
DOG, <i>Canis familiaris</i>	
150 mg/kg diet for 2 years, equivalent to 3.75 mg/kg BW daily	No observable effect level (Reed 1982)
1500 mg/kg diet for 2 years	No oncogenic effects; decreased body weight, reduced hemoglobin and hematocrit (Reed 1982)
LABORATORY WHITE RAT, <i>Rattus</i> spp.	
Inhalation exposure to a dust aerosol of Atrazine 80W (80% wettable powder) for 1 h to concentrations between 1.8 and 4.9 mg/L atmosphere	No deaths, or signs of toxicological or pharmacological effects (Hull 1967)
100 mg/kg diet for 2 years, equivalent to 5 mg/kg BW daily	No gross microscopic signs of toxicity (Anonymous 1963; Reed 1982; Beste 1983)
100 mg/kg diet for 3 generations, equivalent to 5 mg/kg BW daily	No teratogenic or reproductive effects (Reed 1982)
Daily oral administration on days 6–15 of gestation, in mg/kg BW	
10	No adverse maternal or fetal effects (Infurna et al. 1988)
70	Increased salivation; initial reduction in feed consumption (Infurna et al. 1988)

Table 11.7 (continued) Lethal and Sublethal Effects of Atrazine on Selected Species of Mammals

Organism, Dose, and Other Variables	Effect and Reference
700	Mortality 78% before necropsy; increased incidences of salivation, ptosis, bloody ulva, swollen abdomen, and fetal skeletal malformations (Infurna et al. 1988)
100, 200, 400, or 600 mg/kg BW daily, given orally for 14 days	All dose levels increased elimination of sodium, potassium, chloride, and urine protein; interference with creatinine clearance at 200 mg/kg BW and higher (Santa Maria et al. 1986)
100, 200, 400, or 600 mg/kg BW daily, given orally for 14 days	At 100 mg/kg, significant increases in serum lipids, serum alkaline phosphatase, and serum alanine aminotransferase; no liver histopathology. At 200 mg/kg, a significant reduction in body weight. At 400 mg/kg, liver enlargement and loss in body weight. A dose-dependent decrease in growth and in serum glucose and a dose-related increase in total serum lipids were recorded. At 600 mg/kg, liver histopathology (Santa Maria et al. 1987)
100, 300, or 900 mg/kg diet for 3 weeks	Except for lymphopenia, which was observed at all dose levels, no other effects were measured in the 100 and 300 mg/kg groups. At 900 mg/kg, significant decreases occurred in body weight, food intake, blood lymphocytes, and thymus weight, and significant increases occurred in thyroid weight, mesenteric lymph nodes, and histopathology (Vos et al. 1983)
200 mg/kg BW injected subcutaneously on days 3, 6, and 9 of gestation	No effect on number of pups per litter or on weight at weaning (Peters and Cook 1973)
800, 1000, or 2000 mg/kg BW injected subcutaneously on days 3, 6, and 9 of gestation	At 2000 mg/kg BW, most pups born dead; at 800 and 1000 mg/kg BW, litter size reduced 50–100% (Peters and Cook 1973)
1000 mg atrazine/kg diet from first day of pregnancy throughout gestation	No effect on number of pups per litter or on weight on weaning (Peters and Cook 1973)
1000 mg/kg diet for 2 years, equivalent to 50 mg/kg BW daily	No signs of oncogenicity, but reduced food intake and lower body weight (Reed 1982)
1800–5100 mg/kg BW	Acute oral LD50 (Anonymous 1963; Hull 1967; Reed 1982; Beste 1983)
WHITE RABBIT, <i>Oryctolagus cuniculus</i>	
Daily oral administration on gestational days 7 through 19, in mg/kg BW	
1	No adverse maternal or fetal affects (Infurna et al. 1988)
5	Moderate reductions in food consumption and body weight gain (Infurna et al. 1988)
75	Increased abortion rate; no death of does. Weight loss, reductions in feed consumption and fetal and embryotoxic effects, including reduced fetal weight and increased incidence in skeletal variations (Infurna et al. 1988)
9300	Acute dermal LD50 (Beste 1983)

11.5 RECOMMENDATIONS

Labels on products containing atrazine are required to contain information on acceptable uses and potential hazards to groundwater and to fish and wildlife (USEPA 1983). At present, atrazine is approved for use as an herbicide to control broadleaf and grassy weeds on corn, sorghum, sugarcane, pineapple, macadamia nuts, rangeland, turf grass sod, conifer reforestation areas, Christmas tree plantations, grass seed fields, noncrop land, guava, grass in orchards, millet, perennial ryegrass, and wheat. Because atrazine is expected to leach into groundwater, it was recommended (USEPA 1983) that labels of atrazine products bear the following statement: “Atrazine leaches readily and accepted label rates have been found to result in contamination of water supplies by way of groundwater. Therefore, users are advised to avoid use of atrazine in well-drained soils, particularly in areas having high groundwater tables.” Cautionary statements on potential hazards to living resources is another labeling requirement: “This pesticide is toxic to aquatic invertebrates.

Do not apply to water or wetlands. Runoff and drift from treated areas may be hazardous to aquatic organisms in neighboring areas. Do not contaminate water by cleaning of equipment or disposal of wastes. Do not discharge into lakes, streams, ponds, or public water supplies unless in accordance with an [approved USEPA] permit." (USEPA 1983)

Permissible tolerances for atrazine range from 0.02 mg/kg in meat, milk, and eggs, to 15 mg/kg in orchard grass forage, fodder, and hay (Reed 1982; USEPA 1983). However, the 15 mg/kg tolerance in forage is considered high, and a new upper limit of 4 mg/kg is proposed. This limit would be expressed in terms of atrazine and three major metabolites (Reed 1982; USEPA 1983):

2-Amino-4-chloro-6-isopropylamino-1,3,5-triazine
2-Amino-4-chloro-6-ethylamino-1,3,5-triazine
2-Chloro-4,6-diamino-1,3,5-triazine

The maximum recommended safe level of atrazine to algal diatoms is 10 µg/L (Karlander et al. 1983), although temporary inhibition of chlorophyll production in sensitive algal species has been reported in the range of 1 to 5 µg/L (Torres and O'Flaherty 1976). Proposed atrazine concentrations for aquatic life protection range from about 1 to 11 µg/L: 1 to 2 µg/L for protection of estuarine productivity (Stevenson et al. 1982; Ward and Ballantine 1985); 1 to 7 µg/L for no adverse effect levels to most species of submerged aquatic vegetation (Glotfelty et al. 1984); less than 5 µg/L to prevent gill and kidney histopathology in rainbow trout and disrupted swimming behavior in zebrafish (Steinberg et al. 1995) and goldfish (Saglio and Trijasse 1998); 5 to 10 µg/L for minor reductions in photosynthesis in sensitive species of aquatic macrophytes (Glotfelty et al. 1984); 9 µg/L for sensitive aquatic invertebrates, as judged by an uncertainty factor of 10 applied to a 96-hour LC₅₀ (Ward and Ballantine 1985); and 11 µg/L for salt marsh algae, based on the least effect level of 110 µg/L, and an uncertainty factor of 10 (Plumley and Davis 1980). Atrazine concentrations >11 µg/L sometimes occur during periods of runoff and non-flushing (Stevenson et al. 1982), but rarely persist at levels necessary to markedly inhibit photosynthesis in aquatic plants (i.e., 60 to 70 µg/L) (Glotfelty et al. 1984). At 80 µg/L, rainbow trout show kidney necrosis of endothelial cells after exposure for 28 days (Fischer-Scherl et al. 1991), and this suggests that atrazine criteria that protect sensitive plants will also protect aquatic vertebrates.

In laboratory animals, atrazine is only slightly toxic on an acute basis. No carcinogenic, mutagenic, or reproductive effects have been seen at low doses, and reduced food intake and body weight were the primary adverse effects seen at high doses in chronic studies with rats and dogs (Reed 1982). However, data are lacking on indirect ecosystem effects of atrazine application on terrestrial wildlife — especially on insectivores and granivores. Studies should be initiated in this subject area.

No allowable daily intake of atrazine in the human diet has been established, although 0.0375 mg/kg body weight daily has been proposed — equivalent to 2.25 mg daily for a 60-kg adult, or 1.5 mg/kg diet based on 1.5 kg food daily (Reed 1982). In humans, the theoretical maximum residue contribution (TRMC) — a worst-case estimate of dietary exposure — is 0.77 mg daily, assuming 1.5 kg of food eaten daily; this is equivalent to 0.51 mg/kg diet, or 0.013 mg/kg body weight daily for a 60-kg person (USEPA 1983). Another TRMC calculation is based on 0.233 mg daily per 1.5 kg diet, equivalent to 0.156 mg/kg diet, or 0.0039 mg/kg body weight daily for a 60-kg person (Reed 1982). Both TRMC estimates are substantially below the proposed limit of 0.0375 mg/kg body weight daily. Lifetime exposure to drinking water concentrations of 2.3 µg atrazine/L poses negligible risk to human health, as judged by the no adverse effect level of 7.5 µg/L when 1% of the allowable daily intake is obtained from this source (USEPA 1987; Wilson et al. 1987). Higher allowable concentrations are proposed over short periods: 123 µg/L for adults and 35 µg/L for children over a 10-day period (USEPA 1987). The proposed drinking water criterion to protect human health in western Europe is <0.1 µg/L (Fischer-Scherl et al. 1991). In the United States, it should not exceed 3.0 µg atrazine/L drinking water (Alvord and Kadlec 1996; Carder and Hoagland 1998), although Ryals et al. (1998) recommend less than 3.6 µg atrazine/L.

Additional data are needed on toxicity, environmental fate, and chemistry of atrazine in order to maintain existing registrations or to permit new registrations (USEPA 1983). Specifically, data are needed on mobility and degradation rates of atrazine and its metabolites in soils; accumulation studies in rotational crops, fish, and aquatic invertebrates; and chronic testing with representative flora and fauna on survival, reproduction, carcinogenesis, teratogenesis, and mutagenesis (USEPA 1983). Animal metabolism studies are required if tolerances for residues in animal products are expressed in terms of atrazine and its metabolites (USEPA 1983). Finally, more research on aquatic species is merited on synergistic and additive effects of atrazine in combination with other agricultural chemicals at realistic environmental levels of 1 to 50 µg/L, and on the toxic effects of dealkylated atrazine metabolites (Stevenson et al. 1982).

11.6 SUMMARY

The herbicide atrazine (2-chloro-4-ethylamino-6-isopropylamino-1,3,5-triazine) is the most heavily used agricultural pesticide in North America. In the United States alone, more than 50 million kg (110 million pounds) are applied annually to more than 25 million ha (62 million acres), primarily to control weeds in corn and sorghum. Residues have been detected at phytotoxic concentrations in groundwater, lakes, and streams as a result of runoff from treated fields. Atrazine degrades rapidly, usually by way of hydrolysis, nitrogen dealkylation, and splitting of the triazine ring to less toxic compounds not normally inhibitory to plants and animals. The half-time persistence of atrazine in soils is usually about 4 days, but may range up to 385 days in dry, sandy, alkaline soils, under conditions of low temperature and low microbial densities. Half-time persistence is about 3 days in freshwater, 30 days in marine waters, 35 days in marine sediments, and less than 72 h in vertebrate animals.

Sensitive species of aquatic plants experience temporary, but reversible, adverse effects at concentrations in the range of 1 to 5 µg atrazine/L. However, potentially harmful phytotoxic concentrations of atrazine (i.e., >10 µg/L for extended periods) have not been documented in the environment and are probably unrealistic under current application and degradation rates. Aquatic fauna are indirectly affected at atrazine concentrations of 20 µg/L and higher, partly through reduction of the food supply of herbivores, and partly through loss of macrophyte habitat. Direct adverse effects to aquatic invertebrates and fishes were measured at 94 µg/L and higher. Bioaccumulation of atrazine is limited, and food chain biomagnification is negligible in aquatic ecosystems. Birds are comparatively resistant to atrazine, having a low probability for uptake and retention. Known acute oral LD₅₀ values for birds are >2000 mg/kg body weight, and dietary LD₅₀ values are >5000 mg/kg ration. However, indirect ecosystem effects of atrazine on seed- and insect-eating birds are unknown, and should be investigated. Data are lacking for atrazine toxicity to mammalian wildlife, but tests with domestic livestock and small laboratory animals indicate that this group is also comparatively resistant. Acute oral LD₅₀ values for mammals are >1750 mg/kg body weight. No adverse effects were measured at chronic dietary levels of 25 mg/kg (about 1.25 mg/kg body weight) and, for some species, 100 mg/kg diet.

Proposed criteria for aquatic life protection include <5 µg atrazine/L for sensitive species of aquatic flora and fauna, and <11 µg/L for most species of aquatic plants and animals. No criteria have been promulgated for human or animal health protection, although it has been suggested that <3.0 µg/L in drinking water, and <0.0375 mg atrazine/kg body weight (<2.25 mg daily for a 60-kg adult, <1.5 mg/kg diet based on consumption of 1.5 kg food daily) would pose negligible risk to human health. Additional data are needed on toxicity, environmental fate, and chemistry of atrazine and its metabolites in order to maintain existing registrations or to permit new registrations. In particular, more research is needed on possible synergistic or additive effects of atrazine with other agricultural chemicals in aquatic environments.

CHAPTER 12

Carbofuran

12.1 INTRODUCTION

Carbofuran is a broad-spectrum systemic insecticide, acaricide, and nematicide that is widely used in forestry and in agricultural crop production of corn, alfalfa, peanuts, rice, sugarcane, tobacco, potatoes, strawberries, onions, mixed vegetables, mustard, carrots, sunflowers, turnips, and many other crops (Anonymous 1971; Dorrough 1973; Palmer and Schlinke 1973; Kuhr and Dorrough 1976; U.S. Environmental Protection Agency [USEPA] 1976; Finlayson et al. 1979; Flickinger et al. 1980; Hayes and Laws 1991; Trotter et al. 1991; Ballantyne and Marrs 1992). Carbofuran, together with other carbamate compounds, organophosphorus insecticides, and pyrethroids, are the major substitutes for the more persistent pesticides such as DDT, chlordane, and heptachlor. In 1974, domestic carbofuran use was slightly over 3.2 million kg (7 million pounds) active ingredients, most of which was applied to control corn pests (USEPA 1976). By 1989, annual use was about 4.5 million kg, mostly in granular formulations (USEPA 1989a). As a group, the carbamates, including carbofuran, have controlled insects effectively; their residual life in the environment is relatively short. Excretion from the animal body is comparatively rapid and almost quantitative, and the terminal residues produced are polar and formed by chemical processes normally considered as steps in metabolic detoxication.

Flowable and granular formulations of carbofuran have histories of heavy wildlife losses associated with recommended rates of application as well as misuse (Flickinger et al. 1986). At recommended application rates, which ranged from 0.28 to 10.9 kg active ingredients/ha (0.25 to 9.7 lb/acre), and in a variety of formulations, carbofuran was responsible for sporadic kills of fish, wildlife, beneficial insects, and terrestrial and aquatic invertebrates (Eisler 1985; USEPA 1989a; Trotter et al. 1991; Mineau 1993). In California between 1984 and 1988, carbofuran residues up to 640 mg/kg fresh weight (FW) were measured in gizzard and crop content of dead birds found near rice fields treated with granular carbofuran; secondary intoxication was noted in raptors that fed on carbofuran-poisoned ducks (Littrell 1988). A decline of 80% in populations of striped bass (*Morone saxatilis*) in California was attributed, in part, to carbofuran and other contaminants in agricultural drainwater associated with rice culture (Bailey et al. 1994). Carbofuran was implicated in the deaths of egrets and herons found dead in San Joaquin County, California, in 1991 near an area treated a few days earlier to control grape phylloxera. Brain cholinesterase activity in birds was inhibited, and food items (crayfish) in crop contained 0.6 mg carbofuran/kg FW (Hunt et al. 1995). Aerial spraying of carbofuran to control grasshoppers killed California gulls (*Larus californicus*). In a carbofuran-sprayed field, gulls were found convulsing with their gullets packed with grasshoppers containing 4 to 7 mg carbofuran/kg (Leighton et al. 1987). Among birds that only occasionally consume domestic crops, carbofuran applied to vegetables reportedly killed about 1400 ducks, largely green-winged teal (*Anas carolinensis*), pintail (*A. acuta*), and American widgeon (*A. americana*) in British Columbia between 1973 and 1975 (Flickinger et al. 1980). Carbofuran

applied to alfalfa killed 2450 American widgeons at one California location in 1974 (Stickel 1975), 500 Canada geese (*Branta canadensis*) in southern Oklahoma in 1976, 1000 widgeons in Kansas in 1976, and more than 1063 widgeons in California in 1976/1977 (Flickinger et al. 1980). Secondary poisoning of red-shouldered hawks (*Buteo lineatus*) was reported after the application of carbofuran to Maryland cornfields (Balcomb 1983). Carbofuran-contaminated sand (7 g carbofuran and metabolites/kg dry weight sand) is associated with the death of Pacific Island seabirds, crabs, and insects which come into contact with the sand (David et al. 1999). Secondary poisoning was also documented in northern harriers (*Circus cyaneus*) feeding on a dead eastern cottontail rabbit (*Sylvilagus floridanus*) (Mineau 1993). Aerial application to flooded rice fields in various portions of Texas between 1970 and 1975 at the rate of 0.56 kg/ha resulted in deaths of three species of sandpipers (*Erolia* spp.) and red-winged blackbirds (*Agelaius phoeniceus*), as well as frogs, crayfish, leeches, earthworms, and four species of fish. However, no carbofuran residues were detectable among survivors 2 to 11 days postexposure (Flickinger et al. 1980). Carbofuran was responsible for the deaths of American crows (*Corvus brachyrhynchos*), a red-tailed hawk (*Buteo jamaicensis*), and European starlings (*Sturnus vulgaris*) in a Pennsylvania cornfield in 1986; an intentional poisoning of starlings by a farmer is the most probable explanation of the high carbofuran residues (67 to 425 mg/kg) found in stomach contents (Stone and Gradoni 1986). Application of granular carbofuran to Virginia cornfields in 1991 was accompanied by deaths from anticholinesterase poisoning of mammals, birds, and reptiles. Carbofuran residues were found in the upper gastrointestinal tract of 81% of the birds examined (Stinson et al. 1994). Many die-offs of adult waterfowl wintering in the southern United States have been attributed to carbofuran use (Martin and Forsyth 1993). Granular formulations of carbofuran were especially toxic to birds, and their sale and use was prohibited after September 1, 1994, except for some minor uses (USEPA 1989a, 1991).

12.2 CHEMICAL PROPERTIES AND PERSISTENCE

Carbofuran (2,3-dihydro-2,2-dimethyl-1,7-benzofuranyl methylcarbamate) is also known as Furadan, Bay 70142, Brifur, Crisfuran, Cristofuran, CAS 1563-66-2, Curaterr, D-1221, ENT-27164, FMC 10242, Niagara NIA-10242, OMS 864, Pillarfuran, and Yaltox (Leuck et al. 1968; Johnson and Finley 1980; Hayes and Laws 1991). Carbofuran has a molecular weight of 221.25 and a melting point of 150 to 152°C. It is comparatively stable under neutral or acidic conditions, but degrades rapidly in alkaline media (Anonymous 1971; Trotter et al. 1991). This white, crystalline solid of empirical formula $C_{12}H_{15}NO_3$ (Figure 12.1) is soluble at concentrations up to 700 mg/L in water, but at <30 mg/L in various organic solvents. It degrades at >130°C and supports combustion if ignited (FMC 1979). The compound is available as a wettable powder, a granular formulation, and in solution as a flowable formulation (Anonymous 1971; USEPA 1976; Trotter et al. 1991).

Pharmacologically, carbofuran inhibits cholinesterase, resulting in stimulation of the central, parasympathetic, and somatic motor systems. Sensitive biochemical tests have been developed to measure cholinesterase inhibition in avian and mammalian brain and plasma samples and are useful in the forensic assessment of carbamate exposure in human and wildlife pesticide incidents (Ballantyne and Marrs; Hunt and Hooper 1993). Acute toxic clinical effects resulting from carbofuran exposure in animals and humans appear to be completely reversible and have been successfully treated with atropine sulfate. However, treatment should occur as soon as possible after exposure because acute carbofuran toxicosis can be fatal; younger age groups of various species are more susceptible than adults (Finlayson et al. 1979). Carbofuran labels indicate that application is forbidden to streams, lakes, or ponds. In addition, manufacturers have stated that carbofuran is poisonous if swallowed, inhaled, or absorbed through the skin. Users are cautioned not to breathe carbofuran dust, fumes, or spray mist; and treated areas should be avoided for at least 2 days (Anonymous 1971). Three points are emphasized at this juncture. First, some carbofuran degradation

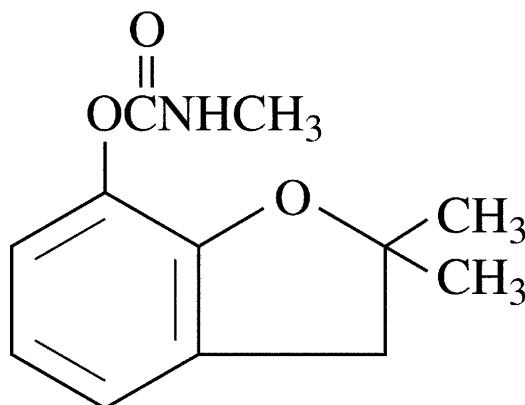

Figure 12.1 Structural formula for carbofuran (2,3-dihydro-2,2-dimethyl-1,7-benzofuranyl methylcarbamate).

products have not been identified. Second, toxicologic, mutagenic, carcinogenic, and teratogenic properties of most carbofuran degradation products have not been satisfactorily evaluated. And third, numerous physical, chemical, and biological vectors modify carbofuran degradation processes, as well as biological uptake, retention, and translocation. Each of these points is developed in greater detail later.

Carbofuran is metabolized by hydroxylation and hydrolysis in plants, insects, and mammals (Metcalf et al. 1968). The primary transformation product in most plants appears to be 3-hydroxy-carbofuran. However, levels of 3-hydroxycarbofuran and other degradation products in plants are influenced by numerous factors, including plant age, soil type, pesticide formulation, application method and rate, and weather conditions, as shown later. Oxidation of unconjugated 3-hydroxy-carbofuran yields 3-ketocarbofuran, which is, in turn, rapidly hydrolyzed to the much less toxic 3-ketocarbofuran phenol. Accordingly, 3-ketocarbofuran is not likely to be detected as a terminal residue in plants above trace levels. Residue analyses indicated that carbofuran and 3-hydroxycarbofuran are the compounds that occur most often in plant tissues after treatment (Finlayson et al. 1979). In measurements of carbofuran and its degradation products in corn at 117 and 149 days after carbofuran application (Table 12.1), the decrease of 62% in the total carbamate residues detected between silage and harvest was attributed to cessation of root uptake, volatilization from

Table 12.1 Carbofuran and Its Degradation Products (mg/kg dry weight) in Corn (*Zea mays*) at Silage Stage (117 days) and at Harvest (149 days) Following Application of Carbofuran (10%) Granules at 5.41 kg/ha

drying plant surfaces, and further degradation to phenolic compounds. No losses of carbofuran or 3-hydroxycarbofuran were detected in fortified corn silage after storage at -18°C for 1 year (Finlayson et al. 1979).

Granular carbofuran is believed to persist for at least several months in the Fraser Delta of British Columbia under conditions of high humidity and low pH, and to kill waterfowl and cause secondary poisoning of raptors. During the winter of 1990 in British Columbia, bald eagles (*Haliaeetus leucocephalus*) and red-tailed hawks (*Buteo jamaicensis*) found dead or moribund had evidence of anticholinesterase exposure and crop contents that contained as much as 200 mg carbofuran/kg (Elliott et al. 1996). Bald eagles, red-tailed hawks, and coyotes (*Canis latrans*) found dead in a field in Kansas in December 1992 were poisoned by flowable carbofuran placed on sheep (*Ovis aries*) carcasses in October 1992 to kill coyotes. Flowable carbofuran can cause direct and secondary deaths of wildlife under some circumstances for at least 60 days. In this case, cold, dry weather and snow cover contributed to carbofuran preservation on the carcass (Allen et al. 1996).

Carbofuran residues of 10.8 to 13.3 mg/kg in vegetation usually declined by 50% in 24 h (Forsythe and Westcott 1994). Variation in content of carbofuran and its degradation products was evident among crop species (Finlayson et al. 1979). Strawberries (*Fragaria vesca*), for example, contained higher residues of phenol than either carbamate or hydroxy products. Carbofuran can persist in Mugho pine needles for at least 2 years at insecticidally active concentrations. This unequal distribution of carbofuran in different parts of a plant has also been observed for tobacco (*Nicotiana tabacum*), in which more of the compound was in large leaves than in the tops of plants, suggesting that carbofuran moved in the plant fluids to the point of greatest transpiration in the leaves (Finlayson 1979).

Carbofuran in animals may also be hydrolyzed to produce carbofuran-7-phenol. Hydrolysis of the 3-hydroxyderivative leads to formation of 3-hydrocarbofuran-7-phenol. Other degradation products include *N*-hydroxymethyl carbofuran and, as in plants, 3-hydroxy- and 3-ketoderivatives. All of these compounds may become conjugated and excreted by animals in urine and, presumably, bile (Metcalf et al. 1968; Finlayson et al. 1979). At least 10 metabolites of carbofuran are known at present; their interrelations are shown in detail by Menzie (1978).

Carbofuran accumulates in surface waters because of its relatively high water solubility and its relatively low adsorption on soils and sediments. It is stable in acid waters but is subject to increasing chemical hydrolysis as the water becomes more alkaline (Trotter et al. 1991). In water, the carbofuran degradation rate is strongly influenced by pH. The time to 50% degradation of carbofuran in water was 3.2 years at pH 4.5; 13.3 years at pH 5.0 and 6.0; 1.9 months at pH 7.0; 1 week at pH 8.0 (Chapman and Cole 1982); and only 5 h at pH 9.5 (Trotter et al. 1991). The rate of carbofuran loss is also influenced by sunlight, trace impurities, and temperature, but not as dramatically as by pH (Seiber et al. 1978; Trotter et al. 1991). Carbofuran is highly mobile and has the potential to leach into groundwater where it could persist under conditions of low temperature and low pH (USEPA 1989a, 1989b).

Persistence of carbofuran in soils is a function of many factors, including pesticide formulation, rate and method of application, soil type, pH, rainfall, temperature, moisture content, and microbial populations (Ahmad et al. 1979; Deuel et al. 1979; Finlayson et al. 1979; Fuhremann and Lichtenstein 1980; Gorder et al. 1982). Results of several studies indicate that loss from soil samples also takes place at low temperatures when air drying is used. This loss may present a problem to chemists who are unable to conduct analyses immediately after samples are collected (Finlayson et al. 1979). Soil pH is one of the more extensively documented variables affecting degradation; it may become increasingly important as acidic precipitation (acid rain) increases. Carbofuran decomposes rapidly at pH levels >7.0, but becomes increasingly stable as pH decreases. The hydrolysis half-life is about 16 years at a soil pH of 5.5; the half-lives are about 35, 6, and 0.25 days at pH levels of 7.0, 8.0, and 9.0, respectively (Finlayson et al. 1979). Similar results were reported by Getzin (1973), Caro et al. (1976), Seiber et al. (1978), and, in Table 12.2, by Chapman and Cole

(1982). Temperature and moisture content of soils were both positively related to degradation of carbofuran to 3-hydroxycarbofuran, 3-ketocarbofuran, carbofuran phenol, and 3-ketocarbofuran phenol. In general, an increase in temperature from 15 to 27°C had a greater influence on degradation than did an increase from 27 to 35°C, although 27 to 35°C was the range in which maximum degradation rates were observed (Ou et al. 1982). Similar results were recorded by Caro et al. (1976), Seiber et al. (1978), and Gorder et al. (1982).

The role of soil bacteria in carbofuran degradation is unclear. Most investigators agree that carbofuran is hydrolyzed to its phenol, which is immediately bound to soil constituents and then metabolized by microorganisms, either slowly (Getzin 1973; Siddaramapa et al. 1978) or rapidly, especially when associated with a *Pseudomonas* sp. isolate (Felsot et al. 1981). Others believe that carbofuran is degraded primarily by chemical hydrolysis, in which bacterial processes assume a negligible role (Venkatswarlu and Sethunathan 1978; Finlayson et al. 1979). Evidence exists demonstrating that

- Soil microbial populations increased by up to 3 times following application of carbofuran (Mathur et al. 1976, 1980)
- Prior treatment with carbofuran produced rapid degradation attributed to acclimatized soil bacteria (Felsot et al. 1981)
- Estuarine bacteria are comparatively resistant to carbofuran (Brown et al. 1975)
- Sterilized soils did not show evidence of carbofuran degradation (Felsot et al. 1981)
- Degradation to carbofuran phenol was most rapid under anaerobic conditions (Venkatswarlu and Sethunathan 1978).

It appears that additional research is required on bacterial degradation of carbofuran, with special emphasis on acid-resistant strains.

12.3 LETHAL EFFECTS

12.3.1 General

In acute toxicity tests with aquatic organisms, LC50 (96 h) values — with only one exception — exceeded 130 µg/L. The exception was the larva of a marine crab with an LC50 (96 h) value of 2.5 µg/L. In tests of longer duration with fish, safe concentrations were estimated to range between 15 and 23 µg/L. Among the most sensitive species of birds tested, the acute oral LD50 was 238 µg/kg body weight (BW), the dietary carbofuran LD50 value was 190 mg/kg ration, dermal LD50 values exceeded 100 mg/kg BW, and the LC100 value in drinking water was 2 mg/L. Mammals were comparatively resistant, having LD50 acute oral toxicities >2 mg/kg BW, a dietary LD38 of 100 mg/kg ration after 8 months, and dermal LD50 values >120 mg/kg BW. However, only 2 µg/L as an aerosol killed 50% of rhesus monkeys in 6 hours, and 40 µg/L killed all pheasants within 5 min. Bees and earthworms were relatively sensitive to carbofuran, but test conditions were sufficiently different to preclude a strict comparison with vertebrate species. Among photosynthetic species, concentrations of 200 mg/L carbofuran partly inhibited germination of rice seeds, but not other species tested, after exposure for 24 hours. Effects of carbofuran on plants are considered negligible when contrasted to faunal damage effects.

12.3.2 Aquatic Organisms

Among freshwater organisms, LC50 values for carbofuran ranged from 130 to 14,000 µg/L in tests of 72 to 96 h. Fish were the most sensitive and worms the most resistant ([Table 12.3](#)). A relatively narrow toxic range for carbofuran in the climbing perch (*Anabas testudineus*) was indicated by the LC0 (120 h) value of 560 µg/L and the LC100 (24 h) value of 1560 µg/L (Bakthavasalam and Reddy 1981). It is noteworthy that carbofuran was not as toxic to aquatic biota as were various cyclodiene chlorinated hydrocarbon insecticides, almost all of which were subsequently withdrawn from commercial use and replaced by carbofuran and other carbamates, and organophosphorus and other compounds.

In flow-through toxicity tests with the marine sheepshead minnow (*Cyprinodon variegatus*), LC50 values had stabilized by day 60 of exposure with no significant mortality afterwards. However, the LC50 value was 386 µg/L at 96 h, or 7.8 times greater than that (49 µg/L) at 131 days ([Table 12.3](#)). At concentrations up to 49 µg/L, carbofuran did not significantly affect the growth of parent fish nor the number of eggs produced. But mortality of fry from fish exposed to 23 and 49 µg/L was measurably greater than that of controls (Parrish et al. 1977). On the basis of these and other observations that indicate that growth of surviving fry in all concentrations was not affected and that carbofuran was degraded rapidly in seawater and in sheepshead minnows, it was concluded that the MATC (maximum allowable toxicant concentration) for carbofuran and sheepshead minnow lies between 15 and 23 µg/L (Parrish et al. 1977). This observation is similar to that of Caldwell (1977), who demonstrated that adult Dungeness crabs (*Cancer magister*) showed no deleterious effects on growth, survival, or reproduction during exposure to 25 µg/L of carbofuran for 69 days. Larvae of Dungeness crabs were substantially more sensitive than adults in 96-h tests ([Table 12.3](#)). In addition, Caldwell (1977) indicated that 1.5 µg/L of carbofuran inhibited swimming ability in zoeal stages of Dungeness crabs, and 1.0 µg/L inhibited molting and prevented metamorphosis to more advanced larval stages. These observations require verification because mortality in control groups was high, a typical problem in bioassays with larvae of marine invertebrates.

Table 12.3 Acute Toxicities of Carbofuran to Aquatic Organisms
 (Concentrations shown are in micrograms of carbofuran per liter of medium [g/L] fatal to 50% of test organisms in the designated time period.)

12.3.3 Birds and Mammals

Acute oral toxicities of carbofuran to birds ranged from 238 µg/kg body weight (BW) for fulvous whistling-ducks (*Dendrocygna bicolor*) to 38,900 µg/kg BW for domestic chickens (Table 12.4). The fulvous whistling-duck has been listed as endangered since 1972 by the Texas Organization for Endangered Species (Flickinger et al. 1980). Concentrations of 1 mg/L of carbofuran

in the drinking water of the ducks caused symptoms of intoxication in 7 days, and 2 mg/L was lethal in the same period (Tucker and Crabtree 1970). Acute symptoms of carbofuran poisoning in birds, which may persist for up to 7 days, include a loss in muscular coordination, wings crossed high over the back, head nodding, vocal sounds, salivation, tears, diarrhea, immobility with wings spread, labored breathing, eye pupil constriction, arching of back, and arching of neck over back. Death may occur within 5 min after ingestion (Tucker and Crabtree 1970). Birds given a fatal oral dose of carbofuran showed a depression in brain cholinesterase activity of 83 to 91% within 8 h of dosing (Wiemeyer and Sparling 1991). Among mallards (*Anas platyrhynchos*), sensitivity to carbofuran was greater in ducklings than in older birds (Table 12.4). This relation appears to hold true for other birds for which data are available.

Acute oral toxicities of carbofuran to various species of mammals ranged from 2000 µg/kg BW in mice to 34,500 µg/kg BW in rats (Table 12.4). Mammals were generally more resistant than birds to acute biocidal properties of carbofuran.

^a 1, Tucker and Crabtree 1970; 2, Hudson et al. 1972; 3, Schafer et al. 1983; 4, Sherman and Ross 1969; 5, Finlayson et al. 1979; 6, Wolfe and Esher 1980; 7, Palmer et al. 1973; 8, Wiemeyer and Sparling 1991; 9, Mineau 1993; 10, Hayes and Laws 1991; 11, Hill 1992.

The ingestion of carbofuran by mallard ducklings walking through carbofuran-sprayed vegetation appears to be the critical mode of intake, with dermal absorption being minimal (Martin and Forsyth 1993). In one case, deaths were observed among mallard ducklings exposed to vegetation sprayed with 132 or 264 g carbofuran/ha; mortality was associated with depression of brain acetylcholinesterase activity by more than 53%. Treated ducklings seemed to spend a larger proportion of time than controls hidden in emergent vegetation, but this was not statistically significant at the 0.05 level (Martin and Forsyth 1993). Mallard ducklings force-fed carbofuran for 10 days at 0.85 mg/kg BW daily (but not at 0.45 mg/kg BW daily) had survival of 31% and delayed fledging in survivors (Martin et al. 1991a). Carbofuran administered to birds in the diet for 5 days, plus 3 days postexposure on an untreated diet, produced 50% kill values of 140 to 1459 mg carbofuran/kg ration. Younger birds were more sensitive than older ones (Table 12.5). Food consumption in groups of Japanese quail (*Coturnix japonica*) with high carbofuran-induced mortality was markedly depressed during the first 3 days of treatment (Hill and Camardese 1982). Red-winged blackbirds, the most sensitive bird species tested in food repellency tests, consumed a normal ration of food contaminated with carbofuran (Schafer et al. 1983). As a result, carbofuran has a high potential for causing acute poisoning episodes in birds (Schafer et al. 1983).

Secondary poisoning of avian raptors with carbofuran has been documented (Balcomb 1983; USEPA 1989a; Mineau 1993). Consider the case of a female red-shouldered hawk in adult plumage weighing 683 g, found in a cornfield near Beltsville, Maryland, in May 1981. The field had been treated the previous day with Furadan 10 granules (10% carbofuran), applied at 1.12 kg/ha active ingredients. The bird was entirely paralyzed except for some head and neck movement, salivating a brown fluid, and respiring in rapid pants. These signs are consistent with those observed in birds dosed in the laboratory with carbofuran. Stomach contents contained remains of a northern short-tailed shrew (*Blarina brevicauda*) and a common grackle (*Quiscalus quiscula*). A total of 96.6 µg carbofuran was extracted from the gastrointestinal tract and stomach contents and tissues. Judging by the body weight of the hawk and an LD₅₀ range of 0.26 to 5.6 mg/kg BW in various nondonesticated birds (Table 12.4), this amount of carbofuran would constitute between 2.5 and 59% of the known LD₅₀ values. However, carbofuran in birds is readily absorbed from the gut and widely transported in the body. Accordingly, the amount of toxicant extracted from the digestive tract was probably only a portion of that ingested by the hawk. In the same cornfield, at the same time, a smaller adult red-shouldered hawk (possibly the female's mate) was found that showed similar, but less severe, signs. Within 24 h, it appeared to have recovered completely and was released. As judged by carbofuran residues in small mammals and birds at this site, the residues present in the digestive tract of the female hawk, and the nature of the toxic symptoms observed, the two red-shouldered hawks were probably poisoned by carbofuran acquired from small vertebrate prey or scavenged from the treated areas (Balcomb 1983).

Field application of carbofuran granules to corn, at planting, in Maryland during 1980 was presumed to be responsible for deaths of songbirds (order Passeriformes) and white-footed mice (*Peromyscus leucopus*). All organisms contained high levels of carbofuran in the gastrointestinal tract and liver, suggesting extensive feeding in treated fields (Balcomb et al. 1984a). A similar situation occurred in Perry, Florida, after treatment of pine seed orchards (Overgaard et al. 1983). Laboratory studies with house sparrows (*Passer domesticus*) and red-winged blackbirds demonstrated that ingestion of a single carbofuran granule is fatal to either species (Balcomb et al. 1984a, 1984b; Mineau 1993). In groups of old-field mice (*Peromyscus polionotus*) fed diets containing 100 mg carbofuran/kg ration for 8 months, mortality was 38%. However, growth, development, and behavior were normal among survivors from this group and their offspring (Wolfe and Esher 1980). In a preliminary study with rats and old-field mice fed 100 mg carbofuran/kg ration, parents lost weight (but none died), and the survival of young was reduced (Wolfe and Esher 1980) (Table 12.5).

^a Concentration of carbofuran in diet, in mg/kg (ppm) fresh weight ration.^b 1, Hill et al. 1975; 2, Hill and Camardese 1983; 3, Wolfe and Esher 1980.

Aerosol toxicity of carbofuran to warm-blooded animals ranged from about 2 µg/kg for rhesus monkeys to 110 µg/kg for rats (Table 12.6). These values substantially exceed the established Threshold Limit Value (TLV) of 0.05 µg/kg (50.0 µg/m³) for protection of human health (Draper et al. 1981). The TLV is a time-weighted concentration for a 40-h work week that nearly all workers can withstand without adverse effects, including eye and skin irritations and other minor irritations. Inhalation doses to humans were estimated during and immediately after aerial spraying of Furadan 4-Flowable at the rate of 446 g active ingredients carbofuran/ha, a concentration that generally controls most pests. During aerial sprayings at this level, the concentration of carbofuran in ambient air did not exceed 0.0033 µg/L at any location (Draper et al. 1981), suggesting that most birds and wildlife are afforded a high degree of protection during aerial spraying at recommended dosages. Studies with rats subjected to 1.2 µg/L of carbofuran aerosols for 50 to 70 min showed a substantial (55%) decrease in red blood cell cholinesterase 10 min posttreatment and a return to normal levels in 2 h (Ferguson et al. 1982). After 8 h, a maximum of 55% of the carbofuran was excreted by respiration (38%) or in the urine (12%) or feces (5%); the remainder was located primarily in the liver and gastrointestinal tract. Plasma half-lives in rats for carbofuran (36 min) and 3-hydroxycarbofuran (62 min) were similar to those previously determined after oral and intravenous exposures (Ferguson et al. 1982).

Table 12.6 Acute Aerosol Inhalation Toxicity of Carbofuran to Warm-Blooded Animals

Carbofuran is not considered a chronic health hazard to humans because all existing evidence demonstrates that carbofuran is neither carcinogenic, mutagenic, or teratogenic. The database is considered acceptable and complete (USEPA 1989a). Dermal toxicity of carbofuran to birds and mammals is comparatively low. The LD50 dermal values ranged from about 1000 mg/kg BW in cattle (Palmer et al. 1981) down to 100 mg/kg BW in birds (i.e., house sparrows and queleas) (Schafer et al. 1983). Rats and rabbits were intermediate in sensitivity at 120 and 885 mg/kg BW, respectively (Draper et al. 1981). Birds contaminated by carbofuran spray could possibly ingest significant amounts while preening (Finlayson et al. 1979), but such ingestion has not been demonstrated. For humans, the maximum potential dermal exposure based on exposed face, hands, forearms, back and front of the neck, and "V" of the chest is 3.1 mg (Draper et al. 1981) or 0.04 mg/kg BW for a person weighing 70 kg. This relationship suggests that human populations would be at greater risk than wildlife populations under recommended carbofuran spray application protocols.

12.3.4 Terrestrial Invertebrates

At recommended field application rates of granular carbofuran formulations, some losses of earthworms, springtails, and other soil-inhabiting organisms should be expected. Spray and dust formulations adversely affect honeybees and other airborne crop pollinators (Finlayson et al. 1979). Bees are extremely susceptible to carbofuran. In one study with honeybees (*Apis* spp.) subjected to high levels of carbofuran, some young adults in the contaminated hive were unable to emerge from their cells, and those that did emerge remained weak and unfed. Eventually, the hive became vulnerable to invasion by the greater wax moth (*Galleria melonella*), an insect that subsequently destroyed the entire hive (Keener and Pless 1974). The LD50 dose for honeybees was estimated at 0.16 µg/bee. If 1.12 kg carbofuran/ha were uniformly distributed at a height of 10 m, flying bees could encounter a lethal dose in only 2 seconds (Atkins et al. 1976).

Studies with susceptible and selectively bred carbofuran-resistant houseflies (*Musca domestica*) indicated that LD50 values for susceptible and resistant strains were 0.1 and 1.3 µg/insect, respectively (Dorough 1973). Resistant flies contained up to 34% more cholinesterase than susceptible strains and could excrete carbofuran almost twice as fast (Dorough 1973). Carbofuran resistance among pestiferous insects is not yet widely known or adequately documented.

Among earthworms, the characteristic symptoms of carbofuran poisoning were rigidity, immobility, lesions, and segmental swelling, as well as cholinesterase inhibition (Stenerson et al. 1973). Worms maintained in soils to which commercial applications of carbofuran had been applied developed two types of lesions within 72 h: multisegmental swelling that often ulcerated, causing death of the worm, and a discrete nodular mass protruding from the surface of the worm (Sileo and Gilman 1975). The LC50 values were 0.5 mg/kg soil at 5 h for *Lumbricus herculeus* (Lebrun et al. 1981), but 2.4 and 13.0 mg/kg soil at 5 days for *Lumbricus terrestris* and *Eisenia foetida*, respectively. The differences in sensitivity were attributed to a greater excretion rate of carbofuran by *Eisenia* (Gilman and Vardanis 1974). However, mortality of *Eisenia* was 50% after 14 days in soils containing 3.1 mg carbofuran/kg DW (Anton et al. 1993b). When applications of carbofuran to soils was 9.1 kg/ha, 50% of the *Lumbricus* died in 72 h (Ruppel and Laughlin 1977). At lower application rates of 2 kg/ha, populations of two species of Australian earthworms were reduced; juvenile stages were most severely affected (Martin 1980). The loss of earthworms could result in reduced food for many wildlife species.

Field application of granular carbofuran can result in contamination of earthworms under rainy conditions (Dietrich et al. 1995). Earthworms contaminated with carbofuran may cause secondary poisoning in birds of prey, including buzzards (*Buteo buteo*), red kites (*Milvus milvus*), and black kites (*Milvus migrans*). In one case, buzzards found dead in fodder and sugar beet fields treated with granular carbofuran were poisoned by consuming dead and dying earthworms, mostly *Lumbricus*.

terrestris, from these fields. Remains of earthworms — which contained as much as 3.2 mg carbofuran/kg FW — were detected in all buzzard crop contents (Dietrich et al. 1995). A similar case is documented for American robins (*Turdus migratorius*) (Mineau 1993). Finlayson et al. (1979) have suggested that the woodcock (*Philohela minor*), a species that consumes up to 50% of its body weight (about 125 g food) daily from earthworms, may be at special risk for carbofuran poisoning. If each worm contained 1.3 mg carbofuran/kg BW, a woodcock would then ingest 0.16 mg carbofuran or the equivalent of 0.65 mg/kg BW (Finlayson et al. 1979), an oral dose lethal to many bird species. To date, secondary poisoning of woodcocks has not been verified under controlled conditions.

12.3.5 Plants

Carbofuran was more toxic to blue-green alga (*Nostoc muscorum*) at pH 5 to 6 than at pH 7.5 to 10. Toxicity was lessened under conditions of reduced illumination and low population density (Kar and Singh 1978). All effects were observed at comparatively high carbofuran concentrations of 25 to 100 mg/kg. Seeds of okra (*Abelmoschus esculentus*) treated with carbofuran, at 1, 3, or 5% active ingredient carbofuran by weight of seed, germinated normally after 90 days of storage (Gaikwad and Pawar 1979). After 6 months of storage, however, germination was measurably reduced at all carbofuran treatments. Okra plants developed normally except for a reduction in plumule length, but this effect was also observed among okra seeds tested with a wide variety of agricultural chemicals.

The effect of carbofuran on the germination of seeds of cotton (*Gossypium hirsutum*), rice, and groundnut (*Arachis hypogea*) were investigated by Arunchalam and Lakshmanan (1979). In rice seeds exposed for 24 h to 100 or 200 mg/L carbofuran, germination decreased 8 and 23%, respectively. Seeds of the other two species were not affected at these exposure rates. Treated rice seedlings that germinated grew 2 to 3 times faster than controls, especially in the roots and leaves. No reasons were offered to account for these differences in rice plants. Carbofuran residues in seeds of the three test species exposed for 24 h to 100 ppm carbofuran ranged from 17.5 to 28.1 mg/kg. At 200 mg/kg carbofuran, these values ranged from 24.0 to 30.4 mg/kg. At 72 h posttreatment, residues had declined markedly to 0.1 to 4.7 mg/kg in the groups treated with 100 mg/L carbofuran, and 2.3 to 3.8 mg/kg in the groups treated with 200 mg/L. Observed growth promotion effects in certain plants by carbofuran and some of its metabolites may be due to effects on plant oxidase systems, rather than on insecticidal or nematocidal properties of the compound. However, the source of the effects has not been demonstrated conclusively (Finlayson et al. 1979).

12.4 SUBLETHAL EFFECTS

12.4.1 General

Most investigators agree that carbofuran degrades or is biotransformed rapidly, with negligible accumulations in biota. Numerous studies have demonstrated that carbofuran, at high sublethal concentrations, was capable of disrupting enzyme and lipid metabolism but that effects were reversible with no observable permanent damage. Three major data gaps appear still to exist. First, latent biochemical and physiological effects that appear at substantial intervals posttreatment have not been explained. Second, interaction of carbofuran with other environmental compounds, especially other agricultural chemicals, are largely unknown, and the effects may cause more than additive damage. Third, and most important, data are scarce or lacking on chronic toxicity, teratogenicity, mutagenicity, and carcinogenicity of the degradation products of carbofuran, especially degradation products that may also form nitroso compounds. (Nitrosated carbofuran metabolites, for example, are demonstrably mutagenic.)

12.4.2 Aquatic Organisms

Aquatic plants are comparatively resistant to carbofuran. Green alga (*Selenastrum capricornutum*) and several species of submergent macrophytes tolerated 1.0 mg carbofuran/L for 30 days without any measurable adverse effect (Johnson 1986). Elevated concentrations of 10.0 mg carbofuran/L did not affect growth or survival of duckweed (*Lemna minor*) or tubers of sago pondweed (*Potamogeton pectinatus*) (Trotter et al. 1991). Growth inhibition (50%) of algae (*Chlorella pyrenoidosa*) occurred in 96 h at 205 mg carbofuran/L, with no growth observed at 562 mg/L (Anton et al. 1993a). A similar case is documented for *Chlorella emersonii* (Sanchez and Ariz 1997). However, first instar daphnids (*Daphnia magna*) and fourth instar midge (*Chironomus raparius*) were effectively immobilized within 48 h at only 48 to 64 µg carbofuran/L (Johnson 1986). And larvae of the Japanese medaka (*Oryzias latipes*) exposed to 88 to 110 µg/L for 4 days had impaired swimming performance immediately after exposure, which remained impaired after 10 days in uncontaminated water (Heath et al. 1993).

Carbofuran reportedly disrupts enzyme and lipid metabolism in fishes and may not degrade as rapidly under field conditions as suggested by laboratory studies. However, most investigators argue that carbofuran, under current application rates, does not accumulate to a significant extent in aquatic systems and rapidly degrades under field and model microcosm study conditions. In studies with the African catfish (*Mystus vittatus*) exposed to 31 or 62 µg/L of carbofuran for 30 days, serum transaminases were significantly elevated (Verma et al. 1981a). In comparison with catfish exposed to concentrations of 21 µg/L or less during the same period, there were also significant depressions in alkaline phosphatase activity in the liver; acid phosphatase activity in the liver, kidneys, and gills; and glucose-6-phosphatase in the liver and kidneys (Verma et al. 1981b). In climbing perch, mean lipid levels in muscle and liver were elevated after exposure to an LC0 (120 h) dose of 560 µg/L carbofuran for 120 h. A similar pattern was observed following exposure to an LC100 (24 h) concentration of 1560 µg/L for 6 h (Bakthavathsalam and Reddy 1981). Carbofuran-induced alterations have also been documented in serum chemistry of the African catfish during immersion in 21 µg/L for 30 days (Verma et al. 1982b); in brain acetylcholinesterase activity of climbing perch and milkfish (*Channa punctatus*) 30 days after exposure to high sublethal levels for 48 h (Jash and Bhattacharya 1983); and in blood and tissue enzyme and ammonia levels in the air-breathing catfish (*Clarias batrachus*) 1 month after exposure for 30 days to 500 µg/L carbofuran (Mukhopadhyay et al. 1982). In field studies with *Trichogaster pectoralis*, a fish extensively cultured in flooded Malaysian rice paddies, Gill (1980) found that the degradation of carbofuran in the liver was slower than that reported for laboratory animals and suggested that caution be exercised in the extrapolation of rates of carbofuran oxidative hydroxylation activity from laboratory organisms to fishes cultured in rice fields. In fish, neurotoxic effects of carbofuran were localized to the brain regions that regulate motor activity and behavior. For example, adult snakeheads (*Channa punctatus*) exposed to 600 µg carbofuran/L for 15 days had a reduction in the level of neurotransmitters in the cerebral cortex of the brain (Gopal and Ram 1995). Histopathology of the liver and thyroid are reported in snakeheads after exposure for 6 months to extremely high sublethal (4.5 mg/L) concentrations of carbofuran (Ram 1988; Ram and Singh 1988).

Negligible accumulations of carbofuran were observed in egg masses of the caddisfly (*Triaenodus tardus*) during immersion for 120 h in water containing 8 µg/L of carbofuran; the low uptake was apparently related to the low partition coefficient of carbofuran (Bellick and Fels 1981). Rapid equilibrium and low accumulation was also reported for the sheepshead minnow (*Cyprinodon variegatus*). In a 28-day flow-through study, maximum tissue concentrations were measured between days 3 and 10 when upper concentration factors of 5 to 20 were recorded (Parrish et al. 1977). Field applications of carbofuran in farm ponds in Arkansas and Kansas were associated with low mortality in fish (Davey et al. 1976) or negligible effects on fish and plankton (Klaasen and Kadoum 1979). Kansas farm ponds subjected to 25 µg carbofuran/L contained 10.6 µg/L in surface waters 1 day later, but nondetectable residues thereafter; residues were <0.4 µg/kg at 1 day

in mud, zooplankton, and fish (Klaasen and Kadoum 1979). Farm ponds treated with 50 µg/L of carbofuran after 3 days contained 15 µg/L carbofuran in surface water and 26 to 46 µg/kg in mud, but nondetectable residues in biota; no measurable residues were found in any sample after 25 days (Klaasen and Kadoum 1979). When atrazine at 300 µg/L was applied in combination with 50 µg/L carbofuran, carbofuran was detectable in surface water at 23 days posttreatment at 1.5 µg/L, but not in the soil, biota, or any other compartment (Klaasen and Kadoum 1979).

Koeppe and Lichtenstein (1982), in a well-designed agromicrocosm study, evaluated the influence of percolating water on soils containing 3.6 mg/L of ¹⁴C-radiolabeled carbofuran. After 3 weeks, 49% of the carbofuran had been removed with percolating water from soils, and 37% was later recovered from soils and corn. In nonpercolated soils, 80% of the carbofuran was still associated with soils and corn. The aquatic components, including water, lake mud, plants (*Elodea*), and fish (the guppy *Poecilia*), contained 25% of the soil-applied carbofuran, although 49% had been initially added to the aquariums by way of percolated water. This loss of 24% was attributed partly to the degradation of carbofuran to CO₂. About 75% of all the radiocarbon was in lake mud, most of it unextractable. Carbofuran was the major compound recovered from control and percolated soils, accounting for 39% and 15%, respectively; 3-ketocarbofuran and 3-hydroxycarbofuran were identified as the major metabolites. The addition of captafol, a fungicide, to carbofuran-treated soils resulted in a more rapid disappearance of the insecticide from terrestrial soils and reduced uptake by corn. The addition of EPTC, an herbicide, had no measurable effect on terrestrial components, but EPTC and captafol both caused increased recoveries of ¹⁴C-labeled carbofuran residues from lake bottom mud. In another study, radiolabeled carbofuran was applied at 1.12 kg/ha to a model ecosystem containing seedling sorghum plants (*Sorghum halopense*), saltmarsh caterpillar larvae (*Estigmene acrea*), the alga *Oedogonium cardiacum*, freshwater clams (*Corbicula manilensis*), crabs (*Uca minax*), a cladoceran (*Daphnia* sp.), mosquito larvae, unidentified species of frogs and snails, and the freshwater macrophyte *Elodea canadensis* (Yu et al. 1979). Carbofuran was rapidly, but not completely, degraded in water to carbofuranphenol, 3-ketocarbofuran, 3-hydroxycarbofuranphenol, N-hydroxy-methylcarbofuran, 3-hydroxycarbofuran, and several unknown compounds. Carbofuran was highly toxic to crabs, clams, and *Daphnia* immediately after application to the model ecosystem, but all animals, except one crab, survived restocking 20 days later.

The freshwater bivalve molluscs *Glebula rotundata* and *Rangia cuneata* absorbed waterborne carbofuran but did not appear to concentrate it (Zakour 1980). Both species of clams were very tolerant, although symptoms of poisoning, such as shell gaping, foot extension, and incoordination, were evident when carbofuran exposures were high (75 mg/L). *Glebula* converted injected radiolabeled carbofuran to a variety of free metabolites, primarily hydrolysis products, and also polar carbofuran metabolites that were not degraded by conditions known to hydrolyze glycosidic conjugates. These polar metabolites may contain some type of amino acid moiety. The rate of carbofuran metabolism by *Glebula* was slower than that reported for most other animals, but was more rapid than that of plants and microorganisms (Table 12.7). Bacterial metabolism of carbofuran was negligible in both *in vivo* and *in vitro* studies with bivalve molluscs (Zakour 1980).

Table 12.7 Rates of Carbofuran Metabolism by Various Organisms

Organism	Parent Carbofuran Converted (%)	Time (d = day; h = hour)
Rat, <i>Rattus</i> sp.	100	24 h
Chicken, <i>Gallus</i> sp.	100	24 h
Saltmarsh caterpillar, <i>Estigmene</i> sp.	100	7 h
Intact cotton plant, <i>Gossypium</i> sp.	100	5 d
Alfalfa, roots, <i>Medicago</i> sp.	95	30 d
Land snail, <i>Helix aspersa</i>	90	1 h
Bean plants, <i>Phaseolus</i> sp.	68	3 d
House fly, <i>Musca</i> sp.	58	1 h

Table 12.7 (continued) Rates of Carbofuran Metabolism by Various

Organism	Parent Carbofuran Converted (%)	Time (d = day; h = hour)
Bivalve, <i>Glebula rotundata</i>	54–62	24–48 h
Tobacco, leaves, <i>Nicotiana</i> sp.	50	4 d
Microorganisms, unidentified	40–70	7–56 d
Cotton, leaves	20	2 d
Mugho pine, needles, <i>Pinus</i> sp.	17	14 d

Modified from Zakour, H.R. 1980. Toxicity, Uptake and Metabolism of the N-methyl-carbamate Pesticide Carbofuran by the Freshwater Bivalve Mollusc *Glebula rotundata* (Lamarck). Ph.D. Thesis, Rice University, Houston. 148 pp.

12.4.3 Birds

Short-term studies demonstrate that juvenile ring-necked pheasants (*Phasianus colchicus*) given a 3.6 mg carbofuran/kg grain diet (equivalent to 132 g/ha) for 5 days, followed by 3 days on a clean diet, had normal survival, growth, and brain acetylcholinesterase activity (Somers et al. 1991). Similarly, adult and nestling passerines were able to tolerate the dietary exposure resulting from ingestion of grasshoppers sprayed at the rate of 134 g/ha (Forsythe et al. 1994). Mallard ducklings, fed for up to 300 m through vegetation plots sprayed with 132 or 164 g carbofuran/ha, had normal growth and survival, but brain cholinesterase activity inhibition was directly related to spray rate and exposure distance (Martin et al. 1991b). Growth and cholinesterase activity levels in mallard ducklings were reduced at 0.25 mg carbofuran/kg BW daily (but not 0.15 mg/kg BW daily) for 10 days (Martin et al. 1991a).

Birds may encounter carbofuran through respiratory, dermal, and oral routes. Depending on the dietary requirements of particular species, ingestion of contaminated vegetables and poisoned invertebrates may be important exposure routes (Finlayson et al. 1979). Carbofuran may prove harmful alone or in combination with other substances. For example, male Japanese quail fed 0.5 mg carbofuran/kg ration for 18 weeks exhibited a 79% inhibition of plasma cholinesterase activity (Dieter and Ludke 1978). The reduction was slightly greater (84%) when carbofuran was fed in combination with 0.05 mg morsodren/kg ration, a methylmercury compound, although morsodren had no measurable effect on cholinesterase activity when fed alone at that dosage. Since many species of fish-eating birds frequently contain 0.05 mg/kg BW of mercury in various tissues, interaction effects of mercury with carbofuran and other cholinesterase-inhibiting compounds may produce synergistic, deleterious effects (Dieter and Ludke 1978).

Low oral dosages or high dietary levels of carbofuran produced no permanent damage in northern bobwhites. A single oral dose of 2 mg carbofuran/kg BW did not affect brain cholinesterase levels at 48 h, or growth, metabolic efficiency, or metabolized energy at 8 days (Solomon and Robel 1980). The activities of bobwhites fed 131 mg carbofuran/kg ration for 14 days were reduced, but this effect was temporary and recovery was complete within 14 days on a carbofuran-free diet. The temporarily reduced activity was attributed to the rapid metabolic breakdown of carbofuran (Robel et al. 1983). Among laying white leghorn hens, 80% of a single oral dose of 2.7 mg carbofuran/kg BW was eliminated in feces within 10 days (Hicks et al. 1970). All eggs contained detectable carbofuran; an egg with the highest concentration of 0.13 mg/kg developed on day 4. Residues in liver and kidney were about 2.6 mg/kg at 6 h but declined to 0.2 mg/kg in 24 h. Muscle and fat contained about 0.3 mg/kg at 6 h, and <0.1 mg/kg at 24 h. Hicks et al. (1970) indicated that hydroxylation of carbofuran and hydrolysis of the carbamate ester were the predominant pathways in the metabolism of carbofuran by laying hens. Similar results were obtained at single oral doses of 2.7 or 0.3 mg carbofuran/kg BW.

12.4.4 Mammals

Granular carbofuran applications at 7.9 to 11.2 kg/ha on conventionally tilled or no-till fields in Maryland and Pennsylvania in 1986 had no adverse effects on resident white-footed mice (*Peromyscus leucopus*). Exposed mice had normal blood chemistry, liver function, growth, migration, and populations (Albers et al. 1990). Among larger mammals, carbofuran is associated with a variety of stress symptoms, including increased salivation, muscle tremors, prostration, labored breathing, loss of appetite, and (in rare cases) death. These signs were observed in 1- to 2-week-old calves given single doses of carbofuran at 0.25 to 5.0 mg/kg BW orally or 0.05 to 0.1% dermally, in cattle yearlings at 1.0 to 5.0 mg/kg orally or 0.1% dermally, and in sheep at 2.5 to 5.0 mg/kg orally. All survivors had completely recovered at 5 days posttreatment (Palmer and Schlinke 1973). Ewes given 0.3 mg carbofuran/kg BW orally three times weekly for 43 days had elevated serum thyroxine levels (Rawlings et al. 1998), suggesting additional research on the use of metabolic hormones as biomarkers of carbofuran exposure.

Lactating cows fed corn silage containing 1.4 to 3.9 mg carbofuran/kg ration for 8 weeks, or about 74 mg carbofuran daily, showed no decrease in blood cholinesterase. Furthermore, no carbofuran residues were detected in the milk (Leuck et al. 1968). Other studies with lactating cows dosed orally with carbofuran (Dorough and Ivie 1968; Ivie and Dorough 1968) showed almost complete excretion in 10 days, mostly through urine (94%), feces (0.7%) and milk (0.2%). Carbofuran metabolites in urine, feces, and excreted milk included the 3-hydroxy-, 3-keto-, and 3-hydroxy-N-hydroxymethyl derivatives, both conjugated and free, and unknown constituents, perhaps carbon dioxide formed by carbofuran hydrolysis.

In investigations of the effects of carbofuran or its metabolites on mice and rats, pregnant mice receiving 0.01 or 0.5 mg dietary carbofuran/kg daily throughout gestation gave birth to viable, overtly normal offspring at term (Barnett et al. 1980). Significant elevation of serum immunoglobins was measured in 101-day-old male offspring of female parents receiving 0.5 mg/kg dietary carbofuran. This effect was not observed at day 400 or 800. In female offspring from the group receiving 0.01 mg/kg carbofuran, serum immunoglobins were significantly depressed at day 101, but not thereafter (Barnett et al. 1980). Disturbances in immunoglobulin contents may decrease immunocompetence and, thus, indirectly contribute to morbidity and premature mortality. In rats fed comparatively high dietary levels of 30 mg carbofuran/kg ration for 90 days, with mean daily intake of 1.97 mg carbofuran/kg BW, growth was significantly reduced and ventral prostate gland metabolism of RNA, DNA, and protein was altered (Shain et al. 1977). Prenatal exposure of mice to 0.01 mg carbofuran/kg BW daily, administered orally during gestation, resulted in persistent postnatal endocrine dysfunction in adults, specifically, the impairment of hepatic metabolism and elevation of plasma corticosterone (Crammer et al. 1978). Unexpectedly, however, at a higher dose of 0.05 mg/kg, there were no significant differences from controls, and the endocrine function of tested mice was normal. In female rats given a single dose of 0.05 mg carbofuran per kg body weight orally on the 18th day of gestation, acetylcholinesterase (AChE) activity decreased significantly in maternal and fetal blood and in the maternal liver within 1 hour (Cambon et al. 1979). At higher dosages of 0.25 and 2.5 mg/kg, AChE was also depressed in the fetal liver and in the maternal and fetal brains; the effects were not measurable 24 hours postadministration.

Carbamate pesticides can easily be converted to *N*-nitroso derivatives in the presence of sodium nitrite under acidic conditions. The *N*-nitroso form of carbofuran could possibly be formed in the human stomach (Nelson et al. 1981). Since carbofuran is used routinely on a variety of crops and nitrite is a common component of the human diet and present in human saliva, nitrosation of carbamates under conditions simulating those in the human stomach is possible. Lijinsky and Schmal (1978) tested nitrosocarbofuran and five other nitrosated carbamate pesticides for carcinogenicity in rats. Nitrosocarbofuran, at 16.5 mg/kg BW administered orally once weekly for 23 weeks, was the most toxic compound tested and caused the death of several animals by liver damage early in the experiment. Among survivors, nitrosocarbofuran was the most carcinogenic,

as judged by the numbers of carcinomas and tumors that developed. Nitrosation rates of carbofuran in the environment are not now adequately documented but conceivably could represent an environmental risk to wildlife. Surprisingly, nitrosocarbofuran was among the least mutagenic compounds tested in rats. No obvious explanation is available for the differences in carcinogenic and mutagenic properties (Lijinsky and Schmal 1978). It is noteworthy that data on chronic toxicity, teratogenicity, mutagenicity, and carcinogenicity of degradation products of carbofuran, especially carbofuran-7-phenol, and 3-hydroxycarbofuran-7-phenol are either scarce or lacking (Finlayson et al. 1979). A similar case is made for nitrosocarbofuran and other degradation products of carbofuran, which may also form nitroso compounds. Nelson et al. (1981) indicated that nitrosated 3-hydroxycarbofuran and 3-ketocarbofuran produced mutagenic responses in bacterial strains of *Salmonella* and chromosome aberrations in ovary cells of Chinese hamsters. Nitrosocarbofuran and 3-hydroxynitrosocarbofuran also induced large numbers of sister chromatid exchanges in the same cells. Furthermore, nitroso derivatives of carbofuran were considerably more active than nitroso forms of other carbamate pesticides in producing mutagenicity in *S. typhimurium* (Nelson et al. 1981). On the other hand, technical formulations of the parent carbofuran were neither genotoxic nor mutagenic to bacteria, yeast, or corn (Gentile et al. 1982).

12.4.5 Terrestrial Invertebrates

In decomposing the dead organic matter in a deciduous forest ecosystem, the detritus food chain may account for more than half the energy flowing through the ecosystem. Carbofuran can significantly disturb decomposition rates of litter communities, with profound consequences for nutrient recycling and incorporation of organic matter into the soils. For example, application of 0.29 kg/ha of carbofuran to a red maple (*Acer rubrum*) litter community near Ottawa, Canada, reduced daily decomposition rates by about 40%. All of the groups of macrodecomposers present, including Collembola, Acarina, Lepidoptera, Coleoptera, Diplopoda, and Annelida, have been shown to be susceptible to carbofuran and may have been affected by the treatment (Weary and Merriam 1978).

12.5 RECOMMENDATIONS

In Canada, for regulatory purposes, the tolerance level for carbofuran in animal tissues or food, feed, and fiber crops is based on the total carbamate content of the sample, as indicated by total carbofuran, 3-hydroxycarbofuran, 3-ketocarbofuran, and their conjugates (Finlayson et al. 1979), presumably carbofuran phenol, 3-ketocarbofuran phenol, and 3-hydroxycarbofuran phenol. In the United States, the tolerance level is based on carbofuran and four metabolites: 3-hydroxycarbofuran, carbofuran phenol, 3-hydroxycarbofuran phenol, and 3-ketocarbofuran phenol (USEPA 1976). Carbofuran levels considered safe range from 0.05 mg/kg (including 0.02 mg/kg carbofuran metabolites) in meat, fat, and meat by-products, to 40.0 mg/kg (including 20.0 mg/kg carbofuran metabolites) in alfalfa hay; intermediate values are 0.1 mg/L in milk, 0.2 mg/kg in corn grain, and 25.0 mg/kg in corn fodder and forage (USEPA 1976). The acceptable daily intake for protection of human health should not exceed 0.01 mg carbofuran/kg BW (Hayes and Laws 1991). No recommended carbofuran level is currently being promulgated by any regulatory agency for the protection of sensitive species of aquatic biota and wildlife.

On the basis of evidence presented herein, this author conservatively estimates that, in terms of total carbofuran in water, damage is possible to aquatic invertebrates at $>2.5 \mu\text{g/L}$ and to teleosts at $>15 \mu\text{g/L}$. These levels could be attained during a heavy rainfall shortly after carbofuran treatment of adjacent fields. Among sensitive species of warm-blooded animals, dietary concentrations as low as 10 $\mu\text{g/kg}$ ration have demonstrable effects, which were measurable only after extended periods postingestion. For comparison, this level is about 1/5 that allowed in meat by-products for

human consumption. Current maximum permissible aerosol levels of 0.05 µg/L (50 µg/m³) appear sufficient to protect wildlife with the proviso that concentrations not exceed 2.0 µg/L at any time.

Sporadic kills of migratory birds were associated with carbofuran formulations containing 3% active ingredients (a.i.). For example, migratory sandpipers died after eating Furadan 3 G granules (3% a.i.) applied to rice crops in Texas (Flickinger et al. 1980). The granules probably were ingested while the sandpipers were probing and skimming the surface of wet soil for insects and crustaceans. Other species of migratory waterfowl may have mistaken the small size and density of Furadan granules for seed, particularly in areas where concentrations of granules were abundant after misuse and careless applications. It appears that granular carbofuran formulations need to be developed that contain less than 3% a.i. in order to protect waterfowl, yet still maintain their effectiveness against target organisms. Nevertheless, the sale and use of granular formulations of carbofuran have been prohibited in the United States since September 1, 1994, except for five minor uses: bananas in Hawaii, spinach grown for seed, pine tree progeny tests, cucurbits (cucumbers, squash, pumpkins, cantaloupes, and watermelons), and dry-harvested cranberries (USEPA 1991). Total sales of granular carbofuran for these five uses is limited to 2500 pounds (1136 kg) annually. All other uses of granular carbofuran were to be deleted from the label, and remaining stocks were to be used before August 31, 1995 (USEPA 1991).

In rice field pest control, carbofuran should be applied before the fields are flooded and delayed to avoid peak bird migration. Research also appears warranted on the effects on fish and wildlife of the numerous carbofuran formulations used, especially liquid spray formulations (flowables), and on applications to crops other than rice, such as corn, alfalfa, and hay. Additional long-term research is urgently needed on potential impacts of degradation products of carbofuran on sensitive species of aquatic organisms and wildlife, with special attention to nitrosated carbofuran metabolites. Such data are now scarce or lacking. Research is also needed on chemical and biological interactions of carbofuran with other agricultural chemicals applied to the same locations, which are imperfectly understood. Finally, researchers must elucidate the significance of metabolic upset recorded in various species of laboratory mammals at considerable periods after carbofuran insult.

The American Ornithologists' Union passed a resolution in 1990 calling for the cancellation and immediate suspension of all carbofuran granular products — which has since been implemented — and urging the United States to also ban the liquid formulations (as quoted in Mineau 1993). Carbofuran flowable formulations are considered hazardous to the burrowing owl (*Athene cunicularia*), and nests have been abandoned following exposure. In Canada, all carbofuran formulations are prohibited within 250 m of owl burrows (Mineau 1993). In the United States, carbofuran prohibitions to protect endangered species of mammals and birds in fragile ecological areas are under consideration (USEPA 1989a, 1989b, 1991).

12.6 SUMMARY

Carbofuran (2,3-dihydro-2,2-dimethyl-1,7-benzofuranyl methylcarbamate) and other carbamate compounds, together with organophosphorus compounds, have virtually replaced the more persistent and hazardous organochlorine systemic pesticides used in agriculture. In general, carbofuran effectively controls insects through an anticholinesterase mode of action. Compared with chlorinated hydrocarbon insecticides, it has a relatively short residual life in the environment, degrades rapidly, and is almost completely excreted by nontarget organisms. Carbofuran degradation is complex and demonstrably modified by numerous biological and physicochemical factors. Little is known of the biological properties of the degradation products, especially nitrosated metabolites, in relation to chronic toxicity, teratogenicity, mutagenicity, or carcinogenicity.

At currently recommended application rates and in present formulations, carbofuran has caused sporadic, and sometimes extensive, field kills of fish, wildlife, and invertebrates. In short-term laboratory tests, significant death rates were observed at concentrations of about 200 µg carbofuran/L

(in water) for sensitive species of aquatic biota, 238 µg/kg BW (acute oral), and 190,000 µg/kg ration (dietary) for birds, and 2000 µg/kg BW (acute oral) and 100,000 µg/kg ration (dietary) for mammals. Among representative indicator species, harmful and sometimes life-threatening effects of carbofuran have been recorded for fish at nominal water concentrations of >15 µg/L and for aquatic invertebrates at >2.5 µg/L. For birds and mammals, harmful effects were observed at 10 to 50 µg/kg in the diet and 1000 µg/L in drinking water. For comparison, the "safe" level of carbofuran in meat products for human consumption is 50 µg/kg. Current maximum permissible aerosol levels of 0.05 µg/L (50.0 µg/m³) carbofuran appear sufficient to protect wildlife; however, evidence suggests that aerosol concentrations should never exceed 2 µg/L. Plants are significantly more resistant to carbofuran than are invertebrates and higher organisms. Carbofuran hazards to migratory waterfowl have been reduced by effectively prohibiting granular formulations. In rice culture, carbofuran should be applied before the fields are flooded and after the peak of bird migration. More research is merited on the biotic effects of various formulations of carbofuran, especially flowable formulations, and on applications to crops other than rice, such as corn, alfalfa, and hay.

CHAPTER 13

Chlordane

13.1 INTRODUCTION

Technical chlordane is a mixture of chlorinated hydrocarbons that has been used as an insecticide since its introduction in 1947. Chlordane was the first cyclodiene insecticide to be used in agriculture and was the second most important organochlorine insecticide in the United States in 1976/1977, behind toxaphene, with an estimated annual production of 9 million kg (Nomeir and Hajjar 1987). Chlordane is a leading insecticide in controlling termites, with about 1.2 million homes in the United States alone treated annually for this purpose (Nomeir and Hajjar 1987).

Chlordane has been detected in human milk in Canada, Japan, Mexico, Spain, Hawaii, and Mississippi (World Health Organization [WHO] 1984; Ohno et al. 1986). Chlordane compounds have been detected in oysters from the South Atlantic Ocean and Gulf of Mexico, in fish from the Great Lakes and major river basins of the United States, in the blubber of cetaceans from the coastal waters of North America, and in the Antarctic atmosphere (Kawano et al. 1988; Gooch et al. 1990). In fact, all available evidence suggests that chlordane is ubiquitous in the environment. Air and water transport of technical chlordane has resulted in the detection of chlordane and its metabolites in rainwater, drinking water, air, surface waters, soils, sediments, plankton, earthworms, fish, shellfish, birds and their eggs, aquatic invertebrates, cats, dogs, livestock, and humans (Zitko 1978; U.S. Environmental Protection Agency [USEPA] 1980; Sudershan and Khan 1980; Kerkhoff and Boer 1982; Wickstrom et al. 1983; Johnson et al. 1986; Nomeir and Hajjar 1987; Suzuki et al. 1988). Despite its widespread use, persistence, and tendency to accumulate in fat, there was no firm evidence of direct lethal or sublethal effects on terrestrial vertebrate wildlife until Blus et al. (1983) recorded several chlordane-related mortalities. A North Dakota marsh treated with chlordane had decreased reproductive success and some deaths of young of several bird species, but this was attributed to depletion of invertebrate prey and not to acute poisoning (Hanson 1952). Chlordane was implicated as the principal toxicant in 30 pesticide poisoning cases of hawks, owls, herons, and other birds in New York between 1982 and 1986 (Stone and Okoniewski 1988). In New York, Maryland, and New Jersey between 1986 and 1990, chlordane was implicated in the poisoning of opossum (*Didelphis virginiana*), red fox (*Vulpes vulpes*), striped skunk (*Mephitis mephites*), big brown bat (*Eptesicus fuscus*), eleven species of songbirds, and nine species of raptors (Okoniewski and Novesky 1993).

The U.S. Environmental Protection Agency (USEPA) considers chlordane as a probable human carcinogen (defined as inadequate evidence from human studies and sufficient evidence from animal studies), as judged by chlordane-induced cancer of the liver in domestic mice (Arruda et al. 1987). In 1978, the USEPA restricted chlordane use to subterranean termite control, nonfood plants, and root dip. Limited agricultural use was permitted until 1980. In 1987, the USEPA registered chlordane again, limiting its sale and use to licensed applicators for subterranean termite control (Arruda et al. 1987). However, it seems that significant home and garden use exists, especially for control of

termites and undesirable lawn insects (Wood et al. 1986). On April 14, 1988, the USEPA moved to cancel the registrations of termiticide products containing chlordane and to forbid the sale or commercial use of those products (U.S. Public Health Service [USPHS] 1994). Reviews on ecological and toxicological aspects of chlordane in the environment are available; particularly useful are those by Ingle (1965), Menzie (1974), the National Research Council of Canada [NRCC] (1975), the International Agency for Research on Cancer [IARC] (1979), the USEPA (1980, 1988), WHO (1984), Klaassen et al. (1986), Nomeir and Hajjar (1987), Eisler (1990), and USPHS (1994).

13.2 CHEMICAL AND BIOCHEMICAL PROPERTIES

Technical chlordane (64 to 67% chlorine) is produced by the condensation of cyclopentadiene and hexachlorocyclopentadiene to yield chlordene (Figure 13.1). Addition of chlorine across the 2-3 olefinic bond of chlordene forms *cis*-chlordane and *trans*-chlordane; substitution of chlorine into position 1 of chlordene forms heptachlor; and further addition of chlorine across the 2-3 olefinic bond forms *cis*-nonachlor and *trans*-nonachlor (Ribick and Zajicek 1983). Technical chlordane includes about 45 components. Its approximate composition is 19% *cis*-chlordane ($C_{10}H_6Cl_8$), 24% *trans*-chlordane ($C_{10}H_6Cl_8$), 21.5 to 25% chlordene isomers ($C_{10}H_6Cl_6$), 7 to 10% heptachlor ($C_{10}H_5Cl_7$), 7 to 10% *cis*- and *trans*-nonachlor ($C_{10}H_5Cl_9$), 2% Diels–Alder adduct of cyclopentadiene and pentachlorocyclopentadiene, 1% hexachlorocyclopentadiene, 1% octachlorocyclopentene, and 15.5% miscellaneous constituents (NRCC 1975; IARC 1979; USEPA 1980; WHO 1984; Gooch et al. 1990). Oxychlordane and heptachlor epoxide are toxicologically significant degradation products (Figure 13.1; Perttila et al. 1986; Gooch et al. 1990).

Chlordane produced before 1951 contained a significant quantity of hexachlorocyclopentadiene — a toxic irritant to warm-blooded animals. Chlordane produced since 1951 contains little or none of this compound (Ingle 1965). A high-purity chlordane formulation containing about 74% *cis*-chlordane and 24% *trans*-chlordane is also available (Nomeir and Hajjar 1987).

Chemical analysis of technical chlordane is difficult because of frequent variations in both the number and relative composition of components in weathered chlordane (Ribick and Zajicek 1983). Other difficulties are encountered from analytical interferences from various organochlorine compounds. Furthermore, the exact structure has not been determined for a number of compounds in technical chlordane, and the majority of compounds have not been isolated or synthesized for use as comparative standards (Ribick and Zajicek 1983).

Cis-chlordane (CAS number 5103-71-9) and *trans*-chlordane (CAS number 5103-74-2) are characterized by the following properties: molecular weight 409.76; chemical formula of $C_{10}H_6Cl_8$; viscous, amber-colored liquid; boiling point between 104 and 105°C for *trans*-chlordane, and between 106 and 107°C for *cis*-chlordane; density of 1.59 to 1.63 g/mL at 25°C; soluble in most organic solvents, but only sparingly soluble in water (9 µg/L at 25°C); vapor pressure of 0.00001 mmHg at 25°C; and a log K_{ow} (octanol/water partition coefficient) of 5.16 (Ingle 1965; NRCC 1975; IARC 1979; USEPA 1980, 1988; WHO 1984). Pesticides containing chlordane or technical chlordane have been sold under a variety of names including 1068, Aspon, Belt, CD-68, Chloridan, Chlordan, Chlorindan, Chlor-kil, Chlorodane, Chlortox, Cortilan-neu, Corodane, Dichloro-chlordene, Dichlorodene, Dowchlor, ENT 9932, HCS 3260, Kypclor, M 140, M 410, Niram, Niram 5% granular bait, Octachlor, Octa-klor, Octaterr, Ortho-klor, Synklor, Tat Chlor 4, Topiclor 20, Toxicchlor, and Velsicol 1068 (IARC 1979; Johnson and Finley 1980; Hudson et al. 1984; WHO 1984; Hill and Camardese 1986; Mayer 1987; USEPA 1988).

Technical chlordane is stable under ultraviolet (UV) light, although some components, such as chlordene, heptachlor, *cis*-chlordane, and *trans*-chlordane, will form photoisomers under high-intensity UV light in the presence of sensitizers, such as ketones (NRCC 1975; Menzie 1978). Several compounds were measured in alfalfa grown on soils treated with chlordane, including 1,2-

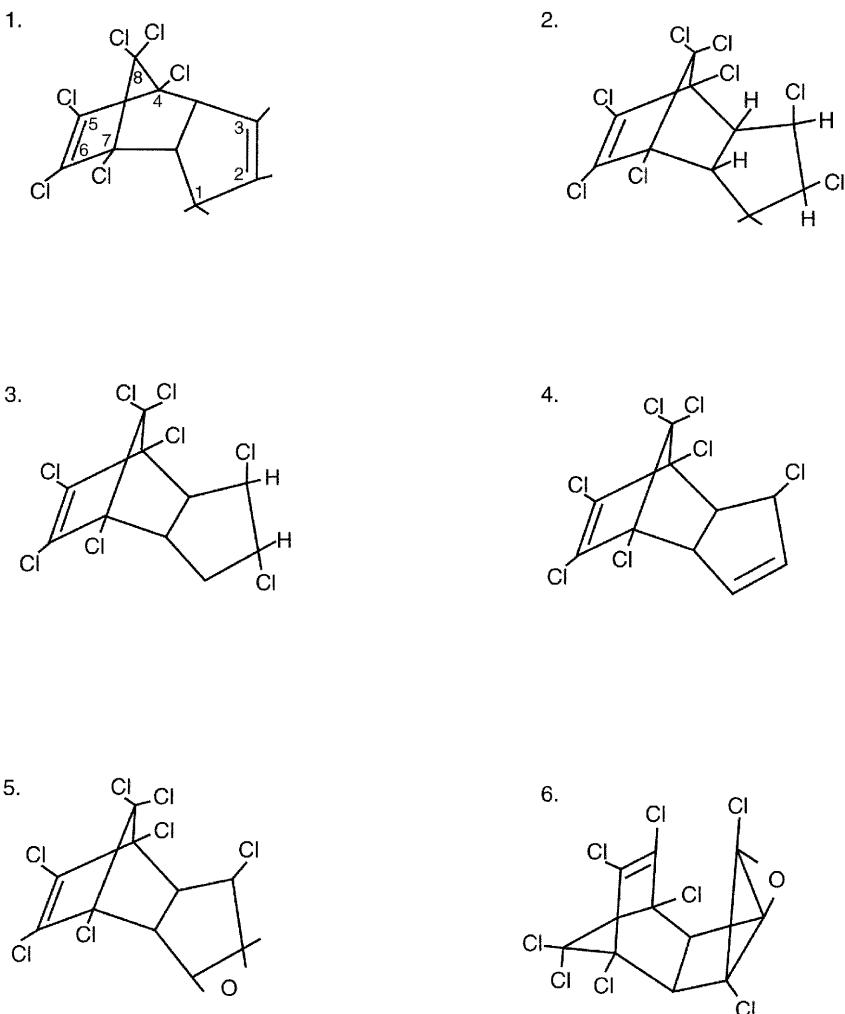

Figure 13.1 Chemical structure of chlordane-related compounds: **1**, chlordene (4,5,6,7,8,8-hexachloro-3a,4,7,7a-tetrahydro-4, 7-methanoindene); **2**, *cis*-chlordane, also known as *alpha*-chlordane (1-exo, 2-exo, 4,5,6,7,8,8-octachloro-2,3,3a,4,7,7a-hexahydro-4,7-methanoindene); **3**, *trans*-chlordane, also known as *gamma*-chlordane (1-exo, 2-*endo*, 4,5,6,7,8,8-octachloro-2,3,3a,4,7,7a-hexahydro-4,7-methanoindene); **4**, heptachlor (1,4,5,6,7,8,8-heptachloro-3a,4,7,7a-tetrahydro-4,7-methanoindene) — technical heptachlor contains about 15% *cis*-chlordane and 2.5% *trans*-chlordane; **5**, heptachlor epoxide (1,4,5,6,7,8,8-heptachloro-2,3-epoxy-3a,4,7,7a-tetrahydro-4,7-methanoindene); and **6**, oxychlordane, also known as octachlor epoxide (1-exo, 2-*endo*, 4,5,6,7,8,8-octachloro,2,3-exo-epoxy-2,3,3a,4,7,7a-hexahydro-4,7-methanoindene).

dichlorochlordanes, oxychlordanes, and photo-*cis*-chlordanes, as well as the parent chlordane compounds (WHO 1984). The half-life ($T_{1/2}$) of *cis*-chlordanes in water is comparatively short, between 1.1 and 17.5 h (Feroz and Khan 1979a). In soils, technical chlordane has a half-life ranging from 0.5 to 1.0 years for some samples, and 4 to 10 years for other samples. The lower $T_{1/2}$ values refer to the initial rapid disappearance of chlordane from the soil; if studies continue over several years, the remaining chlordane is relatively persistent, with a $T_{1/2}$ of 5 to 7 years (NRCC 1975). Measurable residues of chlordanes in soils were present more than 14 years after application (USEPA 1988). Chlordanes persist in soils because of its low solubility in water, relatively low vapor pressure, and high tendency to adsorb to soil particles. Accordingly, soil-bound chlordanes

are not likely to become serious contaminants of the lower soil strata or deep-water sources (WHO 1984). Transport into the hydrosphere from contaminated soils will occur through erosion of soil particles or sediments, not by desorption and dissolution (Klaassen et al. 1986).

Chlordane is a nerve stimulant. At low chronic doses, it produces hyperexcitability and lack of coordination in animals, and at high acute doses causes tremors and convulsions (Ingle 1965; Klaassen et al. 1986). Chlordane induces hepatic microsomal drug-metabolizing enzymes, resulting in enhanced biotransformation at low doses, although high doses may result in liver hypertrophy (Klaassen et al. 1986). The physiological target sites are in nerve and muscle membranes, presumably on proteins and phospholipids. The ultimate effect is axonic with membrane disruption, resulting in spastic muscle twitching and death (Greenhalgh 1986).

Chlordane is readily absorbed by warm-blooded animals through skin, diet, and inhalation. It is quickly distributed in the body and tends to concentrate in liver and fat (WHO 1984). Up to 75% of a single oral dose of chlordane administered to rats and mice was absorbed in the gut, and up to 76% of an aerosol dose was absorbed in the respiratory tract (Nomeir and Hajjar 1987). Rabbits absorbed 33% in the gut following oral administration (USEPA 1988). Chlordane residues in mammals were usually not measurable 4 to 8 weeks after cessation of exposure (Ingle 1965). Chlordane persistence in human serum and whole body was estimated at 88 days and 21 days, respectively; this compares to a Tb 1/2 of about 23 days in rats fed chlordane for 56 days (USEPA 1980).

Excretion kinetics of chlordane are complex, and different isomers exit through different pathways (USEPA 1980, 1988). In rats, chlordane elimination was almost complete 7 days after receiving single oral doses up to 1 mg/kg body weight (BW); 24 hours after treatment, 70% of the *cis*-chlordane and 60% of the *trans*-chlordane had been excreted (WHO 1984). In rodents, chlordane and its metabolites were usually excreted in feces, regardless of the administration route; the *cis*-isomer was excreted slightly faster than the *trans*-isomer, although identical metabolites seemed to be formed (Menzie 1969, 1980; USEPA 1980; WHO 1984; Nomeir and Hajjar 1987). In rabbits, however, up to 47% of the administered dose was voided in the urine, and *cis*- and *trans*-chlordane were excreted at the same rate (Nomeir and Hajjar 1987).

Microorganisms such as *Nocardiopsis* sp., an actinomycete, can metabolize *cis*- and *trans*-chlordane to at least eight solvent-soluble substances, including dichlorochlordanone, oxychlordanone, heptachlor, heptachlor *endo*-epoxide, chlordene chlorhydrin, and 3-hydroxy-*trans*-chlordane (Beaman and Matsumura 1981). Based on studies of chlordane metabolism in animals, four metabolic pathways are proposed (Feroz and Khan 1979a; WHO 1984; Nomeir and Hajjar 1987; USEPA 1988):

1. Hydroxylation to form 3-hydroxychlordanone, which on dehydration forms 1,2-dichlorochlordanone, with subsequent epoxidation to oxychlordanone (*trans*-chlordane is converted to oxychlordanone 7 times faster than is *cis*-chlordane)
2. Dehydrochlorination to form heptachlor, from which heptachlor epoxide and other hydroxylation products may be formed
3. Dechlorination to monochlorodihydrochlordanone
4. The replacement of chlorine by hydroxyl groups resulting in the formation of hydroxy metabolites, which are excreted or further transformed by conjugation with glucuronic acid

Metabolism of chlordanes and nonachlors to oxychlordanone is orders of magnitude greater in fish-eating and carnivorous birds than in marine mammals (Kawano et al. 1988). The reasons for this are unclear and merit further research.

Trans-nonachlor, a major component of technical chlordane, was frequently found as the major chlordane residue in humans, whereas oxychlordanone was the major component in rats fed technical chlordane (Nomeir and Hajjar 1987). *Trans*-nonachlor is converted efficiently by rat liver microsomes to *trans*-chlordane, but this ability is lacking in humans, resulting in the accumulation of *trans*-nonachlor in humans (Nomeir and Hajjar 1987).

Although technical chlordane is a mixture of compounds, two metabolites — heptachlor epoxide and oxychlordane — can kill birds when administered through the diet (Blus et al. 1983). These two metabolites originate from biological and physical breakdown of chlordanes in the environment, or from metabolism after ingestion. Heptachlor can result from breakdown of *cis*- and *trans*-chlordane, eventually oxidizing to heptachlor epoxide; oxychlordane can result from the breakdown of heptachlor, *cis*-chlordane, *trans*-chlordane, or *trans*-nonachlor (Blus et al. 1983). Heptachlor epoxide has been identified in soil, crops, and aquatic biota, but its presence is usually associated with the use of heptachlor, not technical chlordane — which also contains some heptachlor (NRCC 1975). Various components in technical chlordane may inhibit the formation of heptachlor epoxide or accelerate the decomposition of the epoxide, but the actual mechanisms are unclear (NRCC 1975).

In mammals, oxychlordane ($C_{10}H_4Cl_8O$) is a metabolite of *cis*- and *trans*-chlordanes and *trans*-nonachlor (Miyazaki et al. 1980), and has proven much more toxic and persistent than the parent chemicals (WHO 1984; Kawano et al. 1988). Oxychlordane has been measured in the fat of rats, dogs, and pigs fed either isomer, and in milk and cheese from cows fed alfalfa treated with technical chlordane (WHO 1984; Nomeir and Hajjar 1987; USEPA 1988). Oxychlordane was isolated and identified from adipose tissues of pigs fed diets for 90 days containing 300 mg/kg of *cis*-chlordane or *trans*-chlordane (Schwemmer et al. 1970). Sharply elevated oxychlordane levels were detected in milk from cows fed chlordane for 60 days. When chlordane was removed from their diet, oxychlordane residues in milk dropped rapidly during the week following termination and stabilized after 2 weeks (USEPA 1980). The Tb 1/2 for oxychlordane in beef cattle grazing in heptachlor-contaminated pastures for 4 weeks was about 92 days (Petterson et al. 1988). Rats and rabbits given chlordane orally or through the diet retained the highest levels in adipose tissue, followed by liver, kidney, brain, and muscle. Oxychlordane was the most persistent residue after chlordane was removed from the diet (WHO 1984; USEPA 1988).

13.3 USES

Chlordane was first produced commercially in the United States in 1947 and became available in five basic formulations, including 5% granules, oil solutions containing 2 to 200 g/L, and emulsifiable concentrates containing chlordane at 400 to 800 g/L (WHO 1984). Production of chlordane in the United States in 1971 was estimated at 11.3 million kg (Glooschenko and Lott 1977). By 1974, about 9.5 million kg of chlordane were used domestically to control commercial pests (35%); in homes, lawns, and gardens (30%); on corn (20%); turf (6%); potatoes (5%); tomatoes (2%); and other uses (IARC 1979). On March 6, 1978, the USEPA issued a cancellation proceeding on chlordane, allowing limited use on certain crops and pests until July 1, 1983, but no use thereafter except for underground termite control (IARC 1979; USEPA 1988). A similar situation exists in Japan, where the only permitted use of chlordane is for control of termites and powder post beetles (Miyazaki et al. 1980). Use in Japan is estimated at 500,000 kg per year (Yamagishi et al. 1981b).

In Canada, chlordane had been used in soils (usually at 0.45 to 4.5 kg/ha) against corn rootworms, strawberry root weevils, wireworms, white grubs, and subterranean cutworms infesting a wide range of crops (Glooschenko and Lott 1977). In the past, at least 75 different formulations containing chlordane as the active insecticidal ingredient had been registered for sale in Canada. The most widely sold formulation, accounting for about 60% of chlordane in soils, was the 25% granular type that was used extensively for corn rootworm control (NRCC 1975). Sales of chlordane in Canada increased about 10 times between 1969 and 1971 because of restrictions on DDT and other organochlorines; however, chlordane use was restricted in Canada in 1978 (Elliott et al. 1988).

13.4 CONCENTRATIONS IN FIELD COLLECTIONS

13.4.1 General

Chlordanes and their metabolites are ubiquitous in the environment at low concentrations, but at a high occurrence in samples analyzed. Atmospheric transport is considered to be the major route of global dissemination. Some chlordane isomers persist in soils for 3 to 15 years, although there seems to be little accumulation of chlordanes by crop plants grown in these soils. Lengthy persistence of various chlordane isomers, especially *cis*-chlordane and *trans*-nonachlor, has been reported in certain organisms, but this has varied greatly between species and tissues.

In living organisms, chlordane concentrations are usually highest in samples collected near areas where chlordane was applied to control termites or other pests, in predatory species, and in tissues with high lipid content. Food chain biomagnification is usually low, except in certain marine mammals. In some fishes, chlordane levels in muscle have been sufficient to endanger fish health ($>100 \mu\text{g/kg}$ fresh weight) or human fish consumers ($>300 \mu\text{g/kg}$ fresh weight).

13.4.2 Nonbiological Samples

Air and water transport of technical chlordane has resulted in the detection of chlordane and its metabolites in nonbiological samples worldwide (Table 13.1). Chlordane enters the atmosphere mainly through aerial applications of dust and spray formulations, soil erosion by wind, and volatilization from soil and water (WHO 1984). In aquatic systems, chlordane enters by way of surface runoff and rainfall; chlordane is rapidly adsorbed onto bottom sediments, where it persists (WHO 1984). Atmospheric transport of chlordanes is considered the major route of global dissemination (Pyysalo et al. 1981; Wickstrom et al. 1981). Levels of chlordane compounds in the marine atmosphere of the southern hemisphere are nearly the same as those of DDT and its metabolites; this strongly suggests that chlordane compounds are globally distributed and dispersed (Kawano et al. 1985). The yearly input of *cis*-chlordane to the Arctic Ocean from atmospheric sources is estimated at 3000 kg. If *cis*-chlordane constitutes 19% of technical chlordane, then more than 600,000 kg of technical chlordane have entered the Arctic Ocean since 1948 (Hoff and Chan 1986). Chlordane is frequently measured in the air of buildings where the compound has been used for insect control (WHO 1984). Chlordane has been found in household dust in the homes of farmers and pesticide formulators at exceedingly high mean levels: 5.8 to 23.1 mg/kg air-dried dust (WHO 1984).

Chlordane has been detected in both groundwater and surface water at low levels of 0.001 to 0.01 $\mu\text{g/L}$ (USEPA 1988). A high frequency of chlordane detection was noted in seawater samples collected from a Hawaiian marina: up to 90% of all samples contained *cis*-chlordane, and 68% contained *trans*-chlordane (IARC 1979). Because of chlordane's use as a soil-injected insecticide and its persistence, it has the potential to contaminate groundwater, particularly when it is applied near existing wells (USEPA 1988).

In soils, chlordane is comparatively immobile and persistent and has only a limited capacity for translocation into edible portions of food crops (NRCC 1975). Total chlordane content in cropland soils nationwide in 1971/72 averaged 0.05 to 0.06 mg/kg dry weight, and ranged between 0.01 and 7.9 mg/kg dry weight (Table 13.1). Maximum values, in excess of 3.0 mg/kg, were recorded in soils from Illinois (7.0), Ohio (5.0), Indiana (4.1), and Iowa (3.4) (Carey et al. 1978, 1979). The half-life of chlordane in soil when used at agricultural rates is about 1 year (IARC 1979), but residues may be measurable much longer, depending on soil type (NRCC 1975). For example, 10 years after application of 8.5 kg technical chlordane/ha, up to 20% of the active ingredients were still measurable; in another study, 15% of the active ingredients remained in turf soils after 15 years (WHO 1984). *Cis*- and *trans*-chlordanes were less persistent in mineral soils

than in organic mucky soils (WHO 1984). Chlordanes were usually detected in surface soils of basins receiving urban runoff water at a maximum concentration of 2.7 mg/kg. This decreased with soil depth to <0.03 mg/kg at depths below 24 cm (Nightingale 1987). Chlordane levels in soils near Air Force bases in the United States in 1975/76 were similar to those found in nonmilitary urban environments (Lang et al. 1979).

Chlordanes in sediments usually were highest in those sediments with the highest organic content, especially downstream from the center of anthropogenic activities (Smith et al. 1987). Sediments from a lake in which the overlying water column initially was treated to contain 10 µg technical chlordane/L contained measurable residues 2.8 years after application: total chlordanes — consisting of *cis*-chlordane, *trans*-chlordane, and *trans*-nonachlor — averaged 20 µg/kg and ranged up to 46 µg/kg (Albright et al. 1980). The yearly flux of chlordanes from sediments to the overlying water column has been estimated at 0.02 µg/m², based on measurements made in the Sargasso Sea and deep North Atlantic Ocean between 1978 and 1980 (Knap et al. 1986).

^a Concentrations are shown as mean, extremes in parentheses, maximum (Max.), and nondetectable (ND).

^b 1, IARC 1979; 2, USEPA 1980; 3, Kawano et al. 1985; 4, Hoff and Chan 1986; 5, DouAbul et al. 1988; 6, Nightingale 1987; 7, Albright et al. 1980; 8, Kawano et al. 1988; 9, Requejo et al. 1979; 10, WHO 1984; 11, Carey et al. 1978; 12, Carey et al. 1979; 13, Lang et al. 1979; 14, Frank et al. 1980; 15, Wood et al. 1986; 16, Smith et al. 1987; 17, Okoniewski and Novecky 1993; 18, Kucklick et al. 1994; 19, Johnson et al. 1993.

13.4.3 Terrestrial Crops

Maximum total chlordane concentrations in corn (*Zea mays*) and sorghum (*Sorghum halepense*) samples collected nationwide in 1971, in µg/kg dry weight, were 480 in corn kernel, 1260 in cornstalk, and 420 in sorghum (Carey et al. 1978). These values were somewhat lower in 1972: 150 in kernels, 410 in stalks, and 150 in sorghum (Carey et al. 1979). Concentrations in various crops grown in soils treated with 15 kg technical chlordane/ha were always <260 µg/kg dry weight when clay content was 12%, and <150 µg/kg when clay content was 28% (WHO 1984).

13.4.4 Aquatic Invertebrates

Extremely high levels of chlordanes (e.g., 1746 to 7643 µg/kg FW) were measured in several species of South Florida corals collected in 1985 (Table 13.2). It has been speculated that the elevated levels were due to the illegal disposal of chlordanes off Key Largo, Florida, in 1982 (Glynn et al. 1989).

Maximum concentrations of chlordanes in American oysters (*Crassostrea virginica*) taken in the Gulf of Mexico in 1976 were near 0.1 µg/kg dry weight (Table 13.2). Chlordane concentrations were substantially lower than concentrations of other organochlorines measured in oysters, such as DDT (28 µg/kg) and polychlorinated biphenyls (90 µg/kg), suggesting a need for additional studies on interaction effects of chlordane residues with those of other environmental chemicals (Rosales et al. 1979).

Marine clams and worms tended to underrepresent chlordane concentrations in the ambient sediments. Concentration factors were less than 0.2 for clams and 0.6 for worms (Ray et al. 1983). Similarly, chlordane concentrations in clams from the Shatt al-Arab River in Iraq closely reflected chlordane concentrations in water particulates when compared to levels in water columns or in sediments (DouAbul et al. 1988).

13.4.5 Fishes

Health advisories have been issued near Lawrence, Kansas, based on chlordane levels in edible fish tissues. In fish from the Kansas River, Kansas, in 1986, chlordanes were detected more frequently and at higher levels than other contaminants measured (Arruda et al. 1987). More than 80% of the sites sampled in Kansas had detectable chlordanes in fish; at more than 50% of these sites, levels exceeded 0.1 mg/kg fresh weight — a guideline for the protection of predatory fish. At three urban sites in Kansas, concentrations of chlordanes in fish have approached or exceeded

the Food and Drug Administration action level of 0.3 mg chlordane/kg fresh weight for protection of human health. The most likely source of chlordane in fish from the Kansas River is urban and suburban use of chlordane as a termite control agent (Arruda et al. 1987). Other health advisories based on chlordane contamination have been issued. In 1985, people were warned not to eat shovelnose sturgeon (*Scaphirhynchus platorynchus*) from the Missouri and Mississippi Rivers. In 1987, advisories warned against sturgeon consumption in the Missouri River between Kansas City and St. Louis, and against bullhead catfishes, suckers, carps, sturgeons, and sturgeon eggs in the Mississippi River near St. Louis (Bush and Grace 1989). Chlordane residues in fish muscle decreased by 25 to 33% with baking, char broiling, and frying (Zabik et al. 1995).

In general, chlordane residues in fishes were elevated in the vicinity of sewage outfalls (Miskiewicz and Gibbs 1994), in older fishes (Borgmann and Whittle (1991), and near industrialized areas (McCain et al. 1996). Chlordane residues were detected in 36% of all fish samples collected in major domestic watersheds in 1976 (Veith et al. 1979). In the Great Lakes region in 1979, chlordane residues in fish tissues exceeded 100 µg/kg on a fresh weight basis in about 40% of the samples measured. Residues were highest in samples collected near Alton, Illinois, and Fairborn, Ohio (Kuehl et al. 1983). In 1987, chlordane was ubiquitous in catfish tissues throughout a 1968-km stretch of the Mississippi River and its tributaries, being highest in catfish from the Illinois River, Missouri River, Ohio River, and the Mississippi River near Chester, IL, Helena, AK, Arkansas City, AK, and at the confluence of the Old River, LA, and at Belle Chaise, LA (Leiker et al. 1991). Elevated concentrations of chlordanes in sediments, stomach contents, liver, and bile of winter flounder (*Pleuronectes americanus*) from 22 sites in the northeastern United States were significant risk factors for the development of several lesion types, including proliferative and necrotic lesions (Johnson et al. 1993).

The two most abundant components of technical chlordane found in fish tissues from Tokyo Bay, Japan, were *trans*-nonachlor and *cis*-chlordane (Yamagishi et al. 1981b) (Table 13.2). However, this may vary between locales. For example, *cis*-chlordane and *trans*-chlordane were the most abundant components in fish samples collected throughout Japan during the past 20 years, followed, in order, by *cis*-nonachlor, *trans*-nonachlor, and oxychlordane (Loganathan et al. 1989). Of the total chlordanes measured in muscle of northern pike (*Esox lucius*) from the Baltic Sea, 37% was *cis*-chlordane, 34% *trans*-chlordane, and 15% each *trans*-nonachlor and oxychlordane (Moilanen et al. 1982). For liver tissue of northern pike, 35% was oxychlordane, 28% *trans*-chlordane, 22% *cis*-chlordane, and 14% *trans*-nonachlor (Moilanen et al. 1982). In the United States, only chlordanes and nonachlors have been detected as significant residues in fish collected nationwide. The most abundant component was *cis*-chlordane, followed by *trans*-nonachlor, *trans*-chlordane, and *cis*-nonachlor (Ribick and Zajicek 1983). The two most abundant components were detected in about 93% of all fish samples collected in 1978 and 1979. Residues were usually highest in Hawaii, the Great Lakes, and the Corn Belt (Ribick and Zajicek 1983). Fish from the Manoa Stream in Hawaii had high residues because of heavy use of technical chlordane in pineapple culture and termite control (Ribick and Zajicek 1983). Nationwide monitoring of freshwater fishes showed that mean chlordane concentrations in whole fish did not change from 1980 to 1984, following a period of decline; however, *trans*-nonachlor replaced *cis*-chlordane as the most abundant component, suggesting a lower influx of chlordane to the aquatic environment from terminated use of chlordane in agriculture in the mid-1970s (Schmitt et al. 1990) (Table 13.2). Residues of *cis*-chlordane and *trans*-nonachlor — the most abundant and persistent of the chlordane components measured — were present at 85% and 89%, respectively, of the stations sampled in 1984 (Schmitt et al. 1990). Maximum chlordane levels in fish in 1984 occurred in the Great Lakes, Hawaii, watersheds of the Ohio, Missouri, and Mississippi Rivers, and in the Delaware and Raritan Rivers in the Northeast (Schmitt et al. 1990).

Atmospheric transport may be the main source of chlordane in Finland — a country that prohibits chlordane use — because chlordanes are distributed evenly in the Finnish environment (Pyysalo et al. 1983). No chlordane compounds were detected in rainbow trout (*Oncorhynchus*

mykiss) taken from lakes in eastern Finland, although measurable residues were detected in other fish species. This phenomenon is attributed to the superior ability of rainbow trout to metabolize chlordanes to oxychlordane (Pyysalo et al. 1981).

13.4.6 Amphibians and Reptiles

Chlordane residue data for amphibians and reptiles are extremely limited. Maximum concentrations of chlordane isomers did not exceed 70 µg/kg FW of oxychlordane in eggs of the American crocodile, *Crocodylus acutus*, or 250 µg/kg FW in carcass of the common garter snake, *Thamnophis sirtalis* (Table 13.2). However, California newts, *Taricha torosa*, taken near a lake treated with 10 µg/L technical chlordane had greatly elevated chlordane residues in liver and comparatively low concentrations in carcass, stomach, and stomach contents. After 14 days, livers contained about 34 mg/kg total chlordanes lipid weight — about 19% chlordanes, 9% nonachlors, and 6% chlorides (Albright et al. 1980). After 2.8 years, 98% of the total chlordanes was lost. *Trans*-nonachlor was the most persistent component in newt liver, accounting for up to 55% of the total chlordanes in specimens collected 2.8 years after application (Table 13.2) (Albright et al. 1980).

13.4.7 Birds

Technical chlordane components and their metabolites — especially oxychlordane — are comparatively elevated in tissues with high lipid content, in older birds, and in raptors (Table 13.2). The oxychlordane concentration of 5.2 mg/kg FW in the liver of one sharp-shinned hawk (*Accipiter striatus*) from the eastern United States was in the range (3 to 10 mg/kg FW liver) associated with acute toxicity of raptors (Wood et al. 1996) (Table 13.2). Other organochlorine compounds were frequently associated with chlordanes, sometimes at life-threatening concentrations. For example, eggs of peregrine falcons (*Falco peregrinus*) collected nationwide in 1986 to 1989 had DDT levels that ranged between 8.8 and 11.0 mg/kg FW, and total PCB concentrations as high as 14.0 mg/kg FW (Jarman et al. 1993).

Chlordane isomers occur frequently in birds collected nationwide. In 1976, for example, 41% of European starlings (*Sturnus vulgaris*) contained chlordane isomers. In 1979, 60% contained chlordane isomers (Cain and Bunck 1983). In 1982, oxychlordane was detected in 45% of all starlings analyzed, *trans*-nonachlor in 40%, *cis*-nonachlor in 9%, and *cis*- and *trans*-chlordanes in fewer than 2% (Bunck et al. 1987). Chlordane isomers were detected at frequencies exceeding 50% in wings of American black ducks (*Anas rubripes*) and mallards (*Anas platyrhynchos*) from the Atlantic Flyway in 1976/77 (White 1979), in eggs of 19 species of Alaskan seabirds in 1973 to 1976 (Ohlendorf et al. 1982), and in carcasses of ospreys (*Pandion haliaetus*) found dead in the eastern United States between 1975 and 1982 (Wiemeyer et al. 1987). Frequency of detection for chlordane isomers ranging between 14 and 40% has been reported in wings of black ducks and mallards from flyways other than the Atlantic Flyway (White 1979), in 19 species of passeriformes from the western United States in 1980 (DeWeese et al. 1976), and in seven species of Texas shorebirds in 1976/77 — although residues in shorebirds were below levels known to adversely affect reproduction or survival (White et al. 1980).

Carcasses of bald eagles (*Haliaeetus leucocephalus*) collected between 1978 and 1981 usually contained oxychlordane at 45 to 56% frequency, *trans*-nonachlor at 62 to 74%, *cis*-chlordanes at 38 to 45%, and *cis*-nonachlor at 38 to 47%. Frequency of occurrence in the brain was lower, ranging between 19 and 55% for individual isomers (Reichel et al. 1984). However, a positive correlation was established in bald eagles between concentration of chlordanes in brain on a fresh weight basis and in carcass on a lipid weight basis. This relation seems to extend to other avian species as well (Barbehenn and Reichel 1981). Bald eagles also contained appreciable quantities of other organochlorine compounds, and a few — for example, dieldrin — were sometimes present at concentrations

considered life-threatening (Reichel et al. 1984). A similar situation exists in other species of raptors (Ambrose et al. 1988).

Some chlordane isomers tend to persist in avian tissues for lengthy periods. In northern gannets (*Sula bassanoides*), the half-time persistence of *cis*-chlordane, *cis*-nonachlor, and oxychlordane was estimated at 11.2, 19.4, and 35.4 years, respectively (Elliott et al. 1988). Oxychlordane residues in the thick-billed murre (*Uria lomvia*) tend to be high because of rapid excretion through uropygial gland secretions of *cis*- and *trans*-chlordanes and nonachlors, and to biotransformation of these and other chlordane components to oxychlordane (Kawano et al. 1988). This observation is alarming because the metabolite oxychlordane has proven much more toxic and persistent than the parent chemicals (Kawano et al. 1988). Secondary poisonings of raptors after consumption of poisoned bait or prey that had accumulated a large quantity of chlordane were documented for the red-shouldered hawk (*Buteo lineatus*) and the great horned owl (*Bubo virginianus*); concentrations of oxychlordane and heptachlor epoxide found in brain and carcass of both species (Blus et al. 1983) were within the lethal range reported in experimental studies (Stickel et al. 1979).

Chlordane-induced mortality of the long-billed curlew (*Numenius americanus*) has been documented at least four times since 1978, despite restriction of technical chlordane use since 1980 to subterranean applications for termite control (Blus et al. 1985). Death of these curlews was probably due to over-winter accumulations of oxychlordane of 1.5 to 5.0 mg/kg brain FW and of heptachlor epoxide at 3.4 to 8.3 mg/kg — joint lethal ranges for oxychlordane and heptachlor epoxide in experimental birds — compared to 6 mg/kg brain for oxychlordane alone and 9 mg/kg for heptachlor epoxide alone (Blus et al. 1985). Additional research is needed on toxic interactions of chlordane components with each other and with other chemicals in the same environment.

13.4.8 Mammals

Chlordane levels in mammals were usually highest in lipids, in animals collected near areas of high chlordane use, and in aquatic mammals, especially marine species (Table 13.2). In mammals, lipid-soluble and persistent organochlorines are transferred from maternal lipid stores to pups during lactation. The milk of marine mammals is especially rich in lipids and can range up to 60%; about 98% of the chlordane pesticide residues in pups of marine mammals is accumulated from maternal milk (Jenssen et al. 1996). In the ringed seal (*Phoca hispida*), lactational transfer of chlordanes is estimated at 30% of the whole-body chlordane burden in the mature female (Nakata et al. 1998). Biomagnification of total chlordanes through the food chain was strongly evident in marine mammals; chlordanes were concentrated gradually from zooplankton, through squid and fish, to porpoises and dolphins (Kawano et al. 1986; Muir et al. 1988) (Table 13.2). Chlordane residues in marine mammals were positively related to lipid content and not to the age of the animal (Pertilla et al. 1986). Chlordanes and other organochlorine compounds in adipose tissues and milk of polar bears (*Ursus maritimus*) increased markedly on a lipid weight basis with increased fasting typical of hibernation. The possibility of chlordane-induced effects on the reproduction of polar bears exists and could be a factor in the slow decline of the western Hudson Bay, Canada, polar bears (Polischuk et al. 1995). Concentrations of chlordanes in adipose tissues of polar bears in their known range sampled between 1989 and 1993 ranged between 727 and 4632 µg/kg LW; adult males had 30% less chlordanes than females, and chlordane concentrations in both sexes were dominated by oxychlordane (46.8% of total chlordanes), nonachlors (19.9%), and heptachlor epoxide (7.7%) (Norstrom et al. 1998).

A high death rate over a 2-year period was evident in the little brown myotis (*Myotis lucifugus*) following application of chlordane. Young bats were most affected in the first year after application and adults in the second year (Kunz et al. 1977). Residues were greatly elevated in the brain and carcass of another bat, the gray myotis (*Myotis grisescens*) — an endangered species — found dead near areas of high chlordane use (Table 13.2). Animals reared in captivity for slaughter may

contain chlordane and other pesticides in tissues obtained most probably from forage, and possibly from drinking water. Some animals, such as bison (*Bison bison*), habitually roll in the dust and residual pesticides — including oxychlordane — adsorbed on soil particles may contribute to the residues (MacNeil et al. 1991). Chlordane levels in raccoons (*Procyon lotor*) from Mississippi declined between 1978 and 1988, with the decline attributed to decreased pesticide use of chlordane compounds (Ford and Hill 1990).

Chlordane levels in human blood were comparatively elevated among individuals living in residences treated with chlordane during the past 5 years, and in termite control operators. Oxy-chlordane levels were usually significantly higher than *trans*-nonachlor, except among those who consumed large quantities of fish (Wariishi et al. 1986; Wariishi and Nishiyama 1989).

Table 13.2 Chlordane Concentrations in Field Collections of Selected Animals (Values shown are in micrograms per kg [parts per billion] fresh weight [FW], dry weight [DW], or lipid weight [LW].)

Taxonomic Group, Organism, Chlordane Isomer, and Other Variables	Concentration ^a (g/kg)	Reference ^b

San Joaquin River, CA, 1981, whole, total chlordanes	Max. 273 FW; Max. 3578 LW	17
Shad, <i>Dorosoma</i> spp., Louisiana, 1978–79, whole body		
<i>cis</i> -Chlordane	Max. 76 FW	10
<i>trans</i> -Chlordane	Max. 82 FW	10
<i>cis</i> -Nonachlor	Max. 26 FW	10
<i>trans</i> -Nonachlor	Max. 12 FW	10
Northern pike, <i>Esox lucius</i> , Baltic Sea, 1971–82, total chlordanes		
Muscle		
1971	(100–1000) LW	13
1972	(100–1300) LW	13
1973	100 LW	13
1974	800 LW	13
1975	1900 LW	13
1978	(2600–3100) LW	13
1982	(2300–6300) LW	13
Liver		
1971	(100–400) LW	13
1972	(100–300) LW	13
1973	500 LW	13
1974	600 LW	13
1975	700 LW	13
1978	700 LW	13
1982	(1100–2100) LW	13
Fish; Australia; 1989; near sewage outfall, oxychlordane		
Sharks and rays, 6 species		
Liver	Max. 100 FW	96
Muscle	Max. 40 FW	96
Bony fishes, 14 species		
Liver	Max. 860 FW	96
Muscle	Max. 40 FW	96
Fish; Tampa Bay, FL; 1990–92; livers		
Hardhead catfish, <i>Arius felis</i>	14–55 DW	88
Gulf killifish, <i>Fundulus grandis</i>	25–410 DW	88
Longnose killifish, <i>Fundulus majalis</i>	40–560 DW	88
Red drum, <i>Sciaenops ocellatus</i>	170–1080 DW	88
Fish; New Jersey; 1986–91; skin-on muscle fillets; total chlordanes; Camden region vs. Delaware region		
Common carp, <i>Cyprinus carpio</i>		
1986–87	260 FW vs. 51 FW	93
1988–91	275 FW vs. No data	93
Brown bullhead, <i>Ictalurus nebulosus</i>		
1986–87	124 FW vs. 6 FW	93
1988–91	102 FW vs. 65 FW	93
Largemouth bass, <i>Micropterus salmoides</i>		
1986–87	21 FW vs. No data	93
1988–91	48 FW vs. 5 FW	93
Fish, 2 species, muscle, Belmont Lake, Long Island, NY, total chlordanes	380–5200 FW	18
Fish, 4 species, Chesapeake Bay, MD, 1976–80, total chlordanes		
Muscle	70–120 FW; Max. 310–700 FW	19
Gonad	(10–1900) FW	19

Table 13.2 (continued) Chlordane Concentrations in Field Collections of Selected Animals (Values shown are in micrograms per kg [parts per billion] fresh weight [FW], dry weight [DW], or lipid weight [LW].)

Taxonomic Group, Organism, Chlordane Isomer, and Other Variables	Concentration ^a (g/kg)	Reference ^b
Fish, various species, Maryland, Patuxent River, whole, maximum values, total chlordanes		
1978 vs. 1979	190 FW vs. 480 FW	86
1980 vs. 1981	90 FW vs. 81 FW	86
1982 vs. 1983	275 FW vs. 884 FW	86
1984 vs. 1988	487 FW vs. 90 FW	86
Fish, 4 species, eastern Finland, 1979–82		
Liver		
<i>cis</i> -Chlordane	(ND–76) FW	20
<i>trans</i> -Chlordane	(ND–277) FW	20
<i>trans</i> -Nonachlor	(ND–20) FW	20
Total chlordanes	Max. 320 FW; Max. 410 LW	21
Muscle		
<i>cis</i> -Chlordane	(ND–53) FW	20
<i>trans</i> -Chlordane	(ND–232) FW	20
<i>trans</i> -Nonachlor	(ND–20) FW	20
Total chlordanes	Max. 1770 LW	21
Fish, Great Lakes, 1990–91; skin-on fillets; raw; total chlordanes		
White bass, <i>Morone chrysops</i>	340–470 FW	90
Walleye, <i>Stizostedium vitreum vitreum</i>	22–34 FW	90
Fish, 11 species, Lake Texoma, Texas and Oklahoma, 1979, total chlordanes, whole fish	(ND–24) FW	22
Fish, Mississippi River, 1984–86, total chlordanes		
Shovelnose sturgeon, <i>Scaphirhynchus platorynchus</i>		
Muscle	325–2285 FW	75
Eggs	163–1926 FW	75
Common carp, muscle	55–556 FW	75
Channel catfish, <i>Ictalurus punctatus</i> , muscle	322–1389 FW	25
Fish, Mississippi River, 4 species of catfish, summer 1987, whole, total chlordanes	11–170 FW; 154–3121 LW	91
Fish, Mississippi River, 1988, total chlordanes, muscle		
Channel catfish	Max. 853 FW	75
Common carp	Max. 614 FW	75
Fresh water drum, <i>Aplodinotus grunniens</i>	Max. 19 FW	75
Flathead catfish, <i>Pylodictis olivaris</i>	Max. 272 FW	75
River carpsucker, <i>Carpoides carpio</i>	Max. 160 FW	75
Smallmouth buffalo, <i>Ictiobus bubalus</i>	Max. 200 FW	75
Sauger, <i>Stizostedion canadense</i>	Max. 19 FW	75
Paddlefish, <i>Polyodon spathula</i>	Max. 93 FW	75
Blue catfish, <i>Ictalurus furcatus</i>	Max. 895 FW	75
Bigmouth buffalo, <i>Ictiobus cyprinellus</i>	Max. 360 FW	75
White bass, <i>Morone chrysops</i>	Max. 436 FW	75
Fish, Missouri River, 1984–86, total chlordanes, 3 locations		
Shovelnose sturgeon		
Muscle	146–860 FW	75
Eggs	921–6735 FW	75
Channel catfish, muscle	205–777 FW	75
Common carp, muscle	118–548 FW	75
Fish, Missouri River, 1988, muscle		
Near Rockport, 6 species		
Total chlordanes	Max. 438 FW	75
Heptachlor epoxide	Max. 15 FW	75
Heptachlor	ND	75

Table 13.2 (continued) Chlordane Concentrations in Field Collections of Selected Animals (Values shown are in micrograms per kg [parts per billion] fresh weight [FW], dry weight [DW], or lipid weight [LW].)

Birds, 4 species, eastern and southern United States, 1972–74, egg, total chlordanes	<100 FW	36
Birds, New York State, 1982–86, found dead or debilitated, brain tissue, chlordane implicated as primary cause of distress		
Cooper's hawk, <i>Accipiter cooperii</i>		
Oxychlordane	Max. 5800 FW	79
Heptachlor epoxide	Max. 4300 FW	79
<i>trans</i> -Nonachlor	Max. 1300 FW	79
Sharp-shinned Hawk, <i>Accipiter striatus</i>		
Oxychlordane	Max. 4300 FW	79
Heptachlor epoxide	Max. 3500 FW	79
<i>trans</i> -Nonachlor	Max. 1000 FW	79

Table 13.2 (continued) Chlordane Concentrations in Field Collections of Selected Animals (Values shown are in micrograms per kg [parts per billion] fresh weight [FW], dry weight [DW], or lipid weight [LW].)

Taxonomic Group, Organism, Chlordane Isomer, and Other Variables	Concentration ^a (g/kg)	Reference ^b
Great blue heron		
Oxychlordane	Max. 2400 FW	79
Heptachlor epoxide	Max. 600 FW	79
Great horned owl, <i>Bubo virginianus</i>		
Oxychlordane	Max. 8700 FW	79
Heptachlor epoxide	Max. 7700 FW	79
trans-Nonachlor	Max. 2300 FW	79
Blue jay, <i>Cyanocitta cristata</i>		
Oxychlordane	Max. 5000 FW	79
Heptachlor epoxide	Max. 3700 FW	79
trans-Nonachlor	Max. 2000 FW	79
Eastern screech-owl, <i>Otus asio</i>		
Oxychlordane	Max. 2600 FW	79
Heptachlor epoxide	Max. 1800 FW	79
trans-Nonachlor	Max. 1800 FW	79
Common grackle, <i>Quiscalus quiscula</i>		
Oxychlordane	Max. 10,800 FW	79
Heptachlor epoxide	Max. 9100 FW	79
Eastern bluebird, <i>Sialia sialis</i>		
Oxychlordane	Max. 3000 FW	79
Heptachlor epoxide	Max. 2200 FW	79
European starling, <i>Sturnus vulgaris</i>		
Oxychlordane	Max. 7700 FW	79
Heptachlor epoxide	Max. 5000 FW	79
trans-Nonachlor	Max. 500 FW	79
American robin, <i>Turdus migratorius</i>		
Oxychlordane	Max. 1300 FW	79
Heptachlor epoxide	Max. 2700 FW	79
trans-Nonachlor	Max. 1900 FW	79
Cackling Canada geese, <i>Branta canadensis minima</i> , 1973–74, carcass, breeding areas, total chlordanes		
Uncontaminated sites	<1 FW	37
Contaminated (OR, CA)		
Immature male	<0.2 FW	37
Adult male	1.7 FW	37
Adult female	2.0 FW	37
Common goldeneye, <i>Bucephala clangula</i> , fat, oxychlordane		
On arrival at wintering grounds, New York		
Juveniles	40 (10–300) LW	38
Adults	220 (120–370) LW	38
Just prior to spring migration, adults	250 (190–320) LW	38
Dunlin, <i>Calidris alpina</i> , Washington State, 1980, whole, total chlordanes	Max. 60 FW	39
Prairie falcon, <i>Falco mexicanus</i> ; eggs, California, 1986–89		
trans-Nonachlor	(11–60) FW	99
cis-Nonachlor	4 (1–11) FW	99
Heptachlor epoxide	13 (10–18) FW	99
Oxychlordane	30 (18–50) FW	99
Total chlordanes	120 (79–180) FW	99
Peregrine, <i>Falco peregrinus</i>		
Alaska, 1979–84, egg		
trans-Nonachlor	Max. 290 FW	40
Oxychlordane	130 FW; Max. 960 FW	40

Table 13.2 (continued) Chlordane Concentrations in Field Collections of Selected Animals (Values shown are in micrograms per kg [parts per billion] fresh weight [FW], dry weight [DW], or lipid weight [LW].)

Taxonomic Group, Organism, Chlordane Isomer, and Other Variables	Concentration ^a (g/kg)	Reference ^b
1986–89, eggs		
East coast, U.S.		
<i>trans</i> -Nonachlor	330 (130–810) FW	99
<i>cis</i> -Nonachlor	290 (100–800) FW	99
Heptachlor epoxide	230 (140–390) FW	99
Oxychlordane	530 (310–890) FW	99
Total chlordanes	1800 (940–3300) FW	99
Total chlordanes		
California	580 (240–1400) FW	99
Colorado	560 (490–640) FW	99
Atlantic puffin, <i>Fratercula arctica</i> , Norway 1982–83, Hornoy, oxychlordane plus <i>trans</i> -nonachlor		
Adults		
Uropygial gland	1429 (48–2815) LW	41
Liver	93 (262–1531) LW	41
Chicks		
Brain	833 (445–1289) LW	41
Chicken, <i>Gallus</i> sp.		
Contaminated through use of former chlordane container to hold cage disinfectants, Australia		
Egg	300 DW	42
Pullets, fat		
30-weeks-old	920 DW	42
80-weeks-old	670 DW	42
Nationwide, U.S., egg		
<i>cis</i> -Chlordane	1 FW	9

13.5 LETHAL AND SUBLETHAL EFFECTS

13.5.1 General

Chlordane has been applied extensively to control pestiferous soil invertebrates, usually at rates between 0.6 and 2.24 kg/ha. Within this range, sensitive nontarget species, especially earthworms, were adversely affected. Nominal water concentrations between 0.2 and 3.0 µg/L were harmful to various species of fish and aquatic invertebrates. Effects included a reduction in survival, immobilization, impaired reproduction, histopathology, and elevated chlordane accumulations. *Cis*-chlordane, when compared to *trans*-chlordane, was more toxic, preferentially stored, and concentrated to a greater degree. In aquatic organisms, *cis*-chlordane photoisomers were frequently more toxic than the parent form. Oxychlordane was not a major metabolite in aquatic fauna. Sensitive bird species had reduced survival after consumption of diets as low as 1.5 mg chlordane/kg ration, or after a single oral dose as low as 14.1 mg/kg BW. Accumulations were documented in tissues following consumption of diets containing 0.1 to 0.3 mg chlordane/kg feed. Oxychlordane was the most persistent metabolite in avian brain tissue.

Concern for the continued widespread use of chlordane centers on its ability to cause liver cancer in domestic mice. Other adverse effects in mammals, such as elevated tissue residues and growth inhibition, were frequently associated with diets containing between 0.76 and 5.0 mg chlordane/kg feed. Metabolism of technical chlordane by mammals results primarily in oxychlordane, a metabolite that is about 20 times more toxic than the parent compound and the most persistent metabolite stored in adipose tissues. Chlordane interactions with other agricultural chemicals produced significant biological effects in warm-blooded organisms, indicating a need for additional research on this subject.

13.5.2 Terrestrial Invertebrates

Chlordane has been used extensively to control grubs, ants, snails, and other terrestrial invertebrates. Chlordane applied to wheat crops in India at 0.6 kg/ha and higher controlled infestation by two species of termites (*Odontotermes obesus*, *Microtermes obesi*) and increased grain yield; chlordane applications of 0.4 kg/ha and lower were ineffective (Khan and Singh 1985). Chlordane has been used to control the imported fire ant (*Solenopsis invicta*), although registration for this purpose by the USEPA has now been withdrawn (Williams and Lofgren 1983). Application of 4.5 g of chlordane per ant mound, applied as an emulsifiable concentrate, resulted in 83 to 94% control 4 to 5 weeks posttreatment (Williams and Lofgren 1983). Cricket (*Acheta pennsylvanicus*) nymphs died within 1 minute of contact with technical chlordane. Dead crickets showed cellular disruption of the caecal lining, the malpighian tubules, and the digestive tract (Greenhalgh 1986).

Chlordane, at 1.12 to 2.24 kg/ha, was lethal to fly and beetle larvae and also caused reductions in populations of various species of soil invertebrates (WHO 1984). Among nontarget soil species, earthworms were especially sensitive. Significant reductions in earthworm populations were recorded following application of 2.2 kg/ha. Metabolism was adversely affected in 2 weeks at 13 kg/ha, and remained depressed for at least 5 years; at 80 kg/ha, 46% died in 4 days (NRCC 1975). In soil, chlordane effects decreased with increasing soil temperature and organic content; the heptachlor component in technical chlordane had the greatest biological activity to soil fauna (NRCC 1975).

13.5.3 Aquatic Organisms

Signs of chlordane poisoning in fish included hyperexcitability, increased respiration rate, erratic swimming, loss of equilibrium, and convulsions; death frequently occurred within 12 h of exposure (NRCC 1975). Chlordane adversely affected sensitive species of fish and aquatic invertebrates at

nominal water concentrations between 0.2 and 3.0 µg/L (Table 13.3). Specifically, reduced survival was measured in shrimp and crabs at water concentrations of 0.2 to 2.0 µg/L, and in freshwater and marine fishes between 1.7 and 3.0 µg/L; immobilization, impaired reproduction, and histopathology were recorded in shrimp, fish, and planarians between 0.8 and 3.0 µg/L; and high accumulations were evident in fish, shrimp, and oysters between 0.2 and 4.2 µg/L. Growth stimulation and high residues were measured in resistant species of algae, such as *Scenedesmus quadricauda*, at media concentrations up to 100 µg chlordane/L. In sensitive algal species, however, growth was inhibited at water concentrations as low as 10 µg/L (Table 13.3).

Large intra- and inter-specific differences in sensitivity to chlordane were evident (Table 13.3). Some of this variability was attributed to variations in water temperature, salinity, and sediment loadings; some to the age, condition, and nutritional history of the test organism; and some to the chlordane formulation and isomer tested (NRCC 1975; USEPA 1980; Johnson and Finley 1980; McLeese and Metcalf 1980; Mayer and Ellersieck 1986; Rai and Mandal 1993). In general, granular chlordane formulations were most toxic; organisms at a young developmental stage and organisms with reduced lipid content were most sensitive; and adverse effects were most pronounced under conditions of elevated water temperatures, reduced salinities, decreased sediment loadings, and increased duration of exposure. Reduced bioavailability and lessened toxicity of chlordane to daphnids was associated with increasing concentrations (up to 200 mg/L) of suspended solids and their associated carbon content (Hall et al. 1986). Sediment loadings of 5.8 mg chlordane/kg were fatal to 50% of sandworms (*Nereis virens*) in 12 days (McLeese et al. 1982). Resistance or adaptation to chlordane has been reported in mosquitofish (*Gambusia affinis*) collected from ditches near treated cotton fields. These fish were up to 20 times more resistant than newly exposed fish (NRCC 1975).

Residues of *cis*-chlordane were preferentially stored and magnified over *trans*-chlordane by freshwater fish and invertebrates in ponds treated with technical chlordane at concentrations up to 1.14 µg/L. The *cis*-isomer, with an estimated Tb 1/2 of 46 days, persisted longer than did the *trans*-isomer (Johnson and Finley 1980). Tissue concentrations of 106,000 µg total chlordanes/kg, on a lipid weight basis, were associated with reduced survival of estuarine invertebrates (Zitko 1978). Moribund amphipods (*Hyalella azteca*), for example, contained 137,000 to 2,180,000 µg/kg lipid of various chlordanes, heptachlors, and chlordenes (Zitko 1978). In fish, chlordane concentrations of 300,000 to 4,000,000 µg/kg lipid weight in tissues were lethal (Zitko 1978).

Cis-chlordane was 8 times more toxic to bluegill (*Lepomis macrochirus*) than was *trans*-chlordane (Johnson and Finley 1980). *Cis*-chlordane was also more toxic to goldfish (*Carassius auratus*) than was *trans*-chlordane because of its comparatively rapid uptake from the medium and lengthy storage in body tissues, estimated at 99% after 25 days (Feroz and Khan 1979b). The elimination rate of *cis*-chlordane from a cichlid (*Cichlasoma* sp.) was estimated at 2.9% weekly over a 20-week period, with a Tb 1/2 of about 17 weeks. Metabolites accounted for 12.5% (dichlorochlordene, oxychlordane, chlordene chlorhydrin, dihydroxyheptachlor, dihydroxydihydrochlordene, plus four unidentified compounds) and unchanged *cis*-chlordane for 87.5% (Feroz and Khan 1979a). The assemblage of chlordane-related compounds present in lake trout (*Salvelinus namaycush*) from the Great Lakes is substantially different from technical chlordane, and is 3 to 5 times more toxic to mosquito larvae than the technical mixture. The increased toxicity is attributed to the presence of the stable metabolites oxychlordane and heptachlor epoxide (Gooch et al. 1990).

Photoisomers seem to be more toxic than the parent form. For example, *cis*-photochlordane was about twice as lethal to bluegills and goldfish as *cis*-chlordane (Sudershan and Khan 1980). Bluegills exposed to 5 µg/L of radiolabeled *cis*-photochlordane or *cis*-chlordane for 48 h accumulated *cis*-chlordane from the medium by a factor of 78, and *cis*-photochlordane by a factor of 140 (Sudershan and Khan 1980). During the next 6 weeks, 20% of the *cis*-chlordane was eliminated in a linear pattern, and about 50% was eliminated in 46 days. Elimination of *cis*-photochlordane followed a biphasic pattern and was most rapid during the first 3 weeks: 40% was eliminated in

the first 6 weeks, and 50% was eliminated in 15 weeks. Less than 7% of the radioactivity retained in *cis*-chlordane-treated bluegills was in the form of two conjugates, compared to 16% in the form of 14 metabolites for *cis*-photochlordane. No oxychlordane was found in bluegill tissues after treatment; this compound is one of the predominant metabolites found in chlordane-treated rodents and cockroaches. Thus, absence of epoxidation and presence of a mechanism of hydroxylation followed by conjugation seems to be the most active mode of chlordane metabolism in bluegill (Sudershan and Khan 1980).

Cis-photochlordane was about 10 times less toxic to *Daphnia pulex* than *cis*-chlordane (Podowski et al. 1979). This is in sharp contrast to the pattern shown in bluegill and goldfish (Sudershan and Khan 1980). Further, *cis*-photochlordane and *cis*-chlordane toxicity to mice and houseflies was about the same (Podowski et al. 1979), which demonstrates the difficulty in generalizing about the comparative toxicity of chlordane isomers.

Table 13.3 Chlordane Effects on Selected Aquatic Organisms (Compound tested was technical chlordane, unless indicated otherwise.)

Organism and Concentration in Medium (g/L)	Effect	Reference ^b
ALGAE		
Alga, <i>Chlamydomonas</i> sp.		
0.1–50	Stimulatory to growth	1
>100	Inhibitory to growth	1
Estuarine phytoplankton, mixed species		
5	No effect on growth in 5 days	2
10	Daily additions of 10 µg/L for 8 days reduced algal growth rate and carbon uptake; inhibition persisted for 2–48 h and did not affect community composition	2
Marine dinoflagellate, <i>Exuviaella baltica</i>		
50	Exposure for 7 days resulted in disintegration of many cells, reduced cell density, and reduced carbon fixation; particle size distribution altered, and this could affect availability of food for particle-feeding herbivores	3
Green alga, <i>Scenedesmus quadricauda</i>		
0.1–100	Stimulatory to respiration and growth; bioconcentration factor (BCF) ranged from 6000–15,000 in 24 h for all doses, and from 6700–103,000 in 5 days	1, 4
>1000	Growth inhibition	4
INVERTEBRATES		
Blue crab, <i>Callinectes sapidus</i>		
260	50% immobilization in 48 h	5
Dungeness crab, <i>Cancer magister</i>		
0.015	No effect on survival or molting	6
0.15	LC50 (37 days), molting inhibited	6
1.3	LC50 (96 h), zoeae	6
220	LC50 (96 h), adults	6
Chironomid, <i>Chironomus tentans</i>		
5.8	LC50 (48 h)	27
Sand shrimp, <i>Crangon septemspinosa</i>		
2	LC50 (96 h)	7
American oyster, <i>Crassostrea virginica</i>		
4.2	8% reduction in shell growth in 96 h, BCF of 2619 in soft parts	8
6.2–10	50% reduction in shell growth in 96 h, BCF of 3200–8300	5, 6, 8
100	BCF of 7300 after exposure for 10 days	9

Table 13.3 (continued) Chlordane Effects on Selected Aquatic Organisms (Compound tested was technical chlordane, unless indicated otherwise.)

Organism and Concentration in Medium (g/L)	Effect	Reference ^b
Daphnid, <i>Daphnia magna</i>		
12.1–21.6	Maximum acceptable toxicant concentration (MATC) ^a	6
28	50% immobilization in 96 h	10
97	LC50 (48 h) for chlorinated chlordane	11
152	LC50 (48 h) for chlorinated emulsifiable concentrate	11
270	LC50 (48 h)	12
813	LC50 (48 h) for dechlorinated chlordane	11
1174	LC50 (48 h) for dechlorinated emulsifiable concentrate	11
Daphnid, <i>Daphnia pulex</i>		
2.3	50% immobilization in 48 h for <i>trans</i> -nonachlor	13
24	LC50 (48 h)	14, 15
57	LC50 (96 h) for <i>cis</i> -chlordane	16
269	LC50 (96 h) for <i>trans</i> -chlordane	16
550	LC50 (96 h) for <i>cis</i> -photochlordane	16
930	LC50 (96 h) for oxychlordane	16
Planarian, <i>Dugesia dorotocephala</i>		
0.2	No deaths in 5 days	17
>1.0	Impaired reproduction after 10-day exposure	17
3.0	LC50 (10 days), many survivors with head lesions	17
7.0	LC50 (5 days)	17
10.0	LC100 (10 days)	17
Amphipod, <i>Gammarus fasciatus</i>		
40	LC50 (96 h), 95% confidence interval of 21–60 µg/L	14, 15
Amphipod, <i>Hyalella azteca</i>		
61	LC50 (48 h)	27
97	50% immobilization in 168 h	10
Freshwater bivalve mollusc, <i>Lamellidens marginalis</i> , exposed to 0.12 mg technical chlordane/L for up to 30 days		
2 days	Residues (in mg/kg FW) were 5.0 in gill, 3.6 in foot, 3.1 in muscle, and 2.2 in intestine	26
8 days	Residues, in mg/kg FW, ranged from 2.4 in gill to 1.1 in muscle	26
30 days	Residues, in mg/kg FW, were 1.0 in gill, 1.0 in foot, 0.4 in intestine, and 0.1 in muscle	26
Sandworm, <i>Nereis virens</i>		
220	LC50 (12 days), but no deaths in 96 h; at 96 h, signs of stress included everted proboscis, loss of equilibrium, emergence from sediments, and failure to burrow	18
Crayfish, <i>Orconectes nais</i>		
31.6	LC50 (35 days)	14
50	LC50 (96 h)	14
Korean shrimp, <i>Palaemon macrodactylus</i>		
11	LC50 (96 h)	15
Grass shrimp, <i>Palaemonetes pugio</i>		
4.2	LC15 (19 h), BCF about 1070	8
4.8	LC50 (96 h), BCF of 1900–2300	8
Brown shrimp, <i>Penaeus aztecus</i>		
2.4	50% immobilization in 48 h	5
Pink shrimp, <i>Penaeus duorarum</i>		
0.24	LC10 (96 h), whole-body BCF of 2960 in survivors	8
0.4	BCF of 4000–6000 in 96 h	8
4.4	LC50 (48 h)	8

Table 13.3 (continued) Chlordane Effects on Selected Aquatic Organisms (Compound tested was technical chlordane, unless indicated otherwise.)

Organism and Concentration in Medium (g/L)	Effect	Reference ^b
Stonefly, <i>Pteronarcys californica</i> 15	LC50 (96 h), 95% confidence interval of 9–24 µg/L	14, 15
Daphnid, <i>Simocephalus serrulatus</i> 20	LC50 (48 h)	14, 15
FISH		
Goldfish, <i>Carassius auratus</i> 13	LC50 (96 h) for <i>cis</i> -photochlordane	16
15	LC50 (96 h) for oxychlordane	16
26	Exposed for 24 h to <i>cis</i> -chlordane; whole-body BCF at 10 and 25 days after exposure were 2280 and 1820, respectively	19
27	LC50 (96 h) for <i>cis</i> -chlordane	16
82	LC50 (96 h)	6
440	LC50 (96 h) for <i>trans</i> -chlordane	16
Sheepshead minnow, <i>Cyprinodon variegatus</i> 0.5 and 0.8	MATC ^a	20
0.8	Reduced hatch during continuous exposure	20
1.7	Some deaths in second-generation fish during continuous exposure	20
2.8	Some deaths in adult fish during exposure for 189 days	20
3.3	No deaths in 28 days, whole-body BCF of 3333	8
7.1	Equilibrium loss in fry after exposure for 10 days	8
12.5–24.5	LC50 (96 h)	8, 20
15	LC25 (96 h), BCF up to 18,700 in survivors	8
36	No effect on fertilization success or embryo survival after adults exposed for 28 days	8
Common carp, <i>Cyprinus carpio</i> 3.0	LC50 (96 h)	6
Threespine stickleback, <i>Gasterosteus aculeatus</i> 90–160	LC50 (96 h)	6, 15
Indian catfish, <i>Heteropneustes fossilis</i> 150	No deaths in 96 h	21
247	Muscle glycogenolysis and hyperglycemia in 2–12 h	21
275	LC50 (96 h)	21
3500	LC100 (96 h)	21
Channel catfish, <i>Ictalurus punctatus</i> 7–46	LC50 (96 h)	14
Pinfish, <i>Lagodon rhomboides</i> 5.4	LC30 (94 h), whole-body BCF of 3070	8
6.4	LC50 (96 h), BCF up to 7500	8
Bluegill, <i>Lepomis macrochirus</i> 1.2 and 2.2	MATC ^a	10
9.2	LC50 (96 h) for oxychlordane	16
12	LC50 (48 and 96 h) for <i>cis</i> -photochlordane	16, 22
7.1–17	LC50 (96 h) for <i>cis</i> -chlordane	14, 16
19–85	LC50 (96 h)	6, 10, 14, 15
41	LC50 (96 h) for chlorinated technical chlordane	11
62	LC50 (96 h) for chlorinated emulsifiable concentrate	11
50.5–140	LC50 (96 h) for <i>trans</i> -chlordane	14, 16
582	LC50 (96 h) for dechlorinated technical chlordane	11
800	LC50 (96 h) for dechlorinated emulsifiable concentrate	11

Table 13.3 (continued) Chlordane Effects on Selected Aquatic Organisms (Compound tested was technical chlordane, unless indicated otherwise.)

Organism and Concentration in Medium (g/L)	Effect	Reference ^b
Largemouth bass, <i>Micropterus salmoides</i> 3.0	LC50 (96 h)	14
Striped bass, <i>Morone saxatilis</i> 11.8	LC50 (96 h)	6
Striped mullet, <i>Mugil cephalus</i> 3.2	LC50 (48 h)	5
Cutthroat trout, <i>Oncorhynchus clarki</i> 27	LC50 (96 h)	14
Coho salmon, <i>Oncorhynchus kisutch</i> 14–56	LC50 (96 h)	6, 14, 15
Rainbow trout, <i>Oncorhynchus mykiss</i> 8–47	LC50 (96 h)	6, 14, 15, 24
Chinook salmon, <i>Oncorhynchus tshawytscha</i> 57	LC50 (96 h)	15
Sea lamprey, <i>Petromyzon marinus</i> 1000	LC100 (14 h)	9
Fathead minnow, <i>Pimephales promelas</i> 21	LC50 (49 h)	27
25–115	LC50 (96 h)	10, 14, 15
Indian carp, <i>Saccobranchus fossilis</i> 420	LC50 (96 h)	23
Brown trout, <i>Salmo trutta</i> 11	LC50 (96 h)	14
Brook trout, <i>Salvelinus fontinalis</i> 0.32	Adverse effects during chronic exposure	10
22	No deaths in 96 h	25
30–47	LC50 (96 h)	6, 10, 25

^a MATC = Maximum Acceptable Toxicant Concentration. Lower value in each MATC pair indicates highest concentration tested producing no measurable effect on growth, survival, reproduction, and metabolism during chronic exposure; higher value indicates lowest concentration tested producing a measurable effect.

13.5.4 Amphibians and Reptiles

Shortly after chlordane was applied to wooden huts in Australia for termite control, large numbers of dead skinks (*Morethia boulengeri*, *Lerista pectorittata*) and frogs (*Litoria caerulea*, *L. peronii*) were discovered, presumably killed by the chlordane (Henle 1988). Toad (*Bufo arenarium*) embryos survived 0.5 mg technical chlordane/L for 8 days, but died by day 20; all embryos held in 15 mg/L were dead by day 15 (Juarez and Guzman 1984). For tadpoles of the common toad (*Bufo bufo*), a 48-h LC50 of 2 mg/L was reported (WHO 1984).

13.5.5 Birds

Signs of chlordane intoxication in birds include sluggishness, drooped eyelids, fluffed feathers, low crouching on perch, reduced food intake, and weight loss. Later, afflicted animals rested on their breast, wings spread, quivering and panting rapidly, back arched, neck arched over the back, and sometimes convulsing (Stickel et al. 1983). Signs of intoxication appeared within 5 min, and

death usually occurred in the first 8 days of exposure. Remission took up to 4 weeks in some birds (Hudson et al. 1984).

The most sensitive avian species tested against technical chlordane were California quail (*Callipepla californica*), with an acute oral LD₅₀ of 14.1 mg/kg BW; the ring-necked pheasant (*Phasianus colchicus*), with an acute oral LD₅₀ of 24 to 72 mg/kg BW; and European starlings (*Sturnus vulgaris*) fed diets containing 1.5 mg/kg ration for 57 days or 6.25 mg/kg for 24 days (Table 13.4). Accumulations of various chlordane isomers and metabolites were evident in chickens (*Gallus* sp.) fed diets containing as little as 0.1 mg technical chlordane/kg feed for 6 weeks, or 0.3 mg/kg for 4 weeks (NRCC 1975). Vapor toxicity of chlordane is persistent. In one instance, a room used for housing pigeons was sprayed with a chlordane solution; walls and floors were then scrubbed and the room left unoccupied for 2 months. When pigeons were returned to the room, enough chlordane remained to be lethal to all birds (Ingle 1965). Similar cases were reported for mice, presumably after use of very concentrated chlordane solutions (Ingle 1965).

Reproductive impairment was reported in several species of waterfowl from a marsh treated with 1.12 kg technical chlordane/ha (Table 13.4). Studies by Lundholm (1988) with two species of ducks (*Anas* spp.) and the domestic chicken (*Gallus* sp.) demonstrated that various organochlorine compounds, including chlordane, interfered (in a dose-dependent manner) with reproduction by reducing the binding of progesterone to its cytoplasmic receptor in the shell gland mucosa of birds, especially ducks.

The lethal effect of technical chlordane in birds is attributed primarily to chlordane metabolites, especially oxychlordane and, to a lesser extent, heptachlor epoxide (Stickel et al. 1983). Oxychlordane was the most persistent chlordane component in avian brain tissues. The half-time persistence of oxychlordane in brain was 63 days, and 95% loss was estimated in 280 days. The Tb 1/2 for heptachlor epoxide was 29 days, and for *trans*-nonachlor it was 19 days (Stickel et al. 1979). Oxychlordane residues in brain tissue approaching 5 mg/kg FW were considered within the lethal hazard zone to birds (Stickel et al. 1979).

Technical heptachlor contains about 15% *cis*-chlordane and 2.5% *trans*-chlordane. Diets containing 50 mg technical heptachlor/kg fed to brown-headed cowbirds (*Molothrus ater*), red-winged blackbirds (*Agelaius phoeniceus*), common grackles (*Quiscalus quiscula*), and European starlings produced 50% mortality in 9 to 24 days. Birds that died contained 9.2 to 27 mg oxychlordane/kg FW brain, and survivors contained 2.7 to 7.8 mg/kg (Stickel et al. 1979). Red-winged blackbirds fed diets containing 10 mg technical chlordane/kg for 84 days, 50 mg/kg for 42 days, or 100 mg/kg for 21 days, all contained about 17% of the total diet fed as *cis*-chlordane, with whole-body residues in mg/kg FW of 1.8, 9.2, and 14.8, respectively; accumulations of *trans*-chlordane were negligible (Stickel et al. 1983).

Chlordane interactions with other agricultural chemicals are significant and merit additional research. In one study, male Japanese quail (*Coturnix japonica*) pretreated for 8 weeks with 10 mg chlordane/kg diet had increased resistance to parathion, but not to paraoxon, as judged by cholinesterase activity (Ludke 1977). In another study, northern bobwhites (*Colinus virginianus*) treated with 10 mg chlordane/kg diet for 10 weeks, followed by endrin stress, had greater accumulations of chlordane in the brain than did birds treated only with chlordane (Ludke 1976).

Table 13.4 Chlordane Effects on Selected Birds

Organism and Other Variables	Effect and Reference
RED-WINGED BLACKBIRD, <i>Agelaius phoeniceus</i>	
Fed diets containing 10 mg/kg for 84 days	Residue of 1.8 mg <i>cis</i> -chlordane/kg body weight (BW), fresh weight (FW) (Stickel et al. 1983)
Diet containing 50 mg/kg for 42 days	Whole-body <i>cis</i> -chlordane content of 9.2 mg/kg FW (Stickel et al. 1983)
Diet containing 100 mg/kg for 21 days	Whole-body <i>cis</i> -chlordane content of 14.8 mg/kg FW (Stickel et al. 1983)
As above, plus 3 or 7 days off dosage 200 mg/kg diet	Whole-body <i>cis</i> -chlordane content of 5.4 and 2.6 mg/kg, FW respectively (Stickel et al. 1983) LD ₅₀ within 9 days (Stickel et al. 1983)

Table 13.4 (continued) Chlordane Effects on Selected Birds

Organism and Other Variables	Effect and Reference
MALLARD, <i>Anas platyrhynchos</i>	
Single oral dose, age 4–5 months 1200 mg/kg BW	LD50 (Hudson et al. 1984)
858 mg/kg diet for 5 days followed by 3 days of clean diet, ducklings age 10 days	LD50 (Hill et al. 1975)
709 mg/kg diet	LD50 (NRCC 1975)
BIRDS, 4 species , from marsh treated with 1.12 kg chlordane/ha	No reproduction in blue-winged teal (<i>Anas discors</i>) and northern shovelers (<i>Anas clypeata</i>); reproduction inhibited by 60% in coots (<i>Fulica americana</i>) and red-winged blackbirds (<i>Agelaius</i> <i>phoeniceus</i>); disruption of food cycles in marsh was probable cause (NRCC 1975)
BIRDS, 4 species , fed diets containing 71% <i>cis</i> -chlordane and 23% <i>trans</i> - chlordane at 50–500 mg/kg diet	Oxychlordane concentrations in brain of dead birds ranged from 9.4–22.1 mg/kg FW in cowbirds (<i>Molothrus ater</i>), grackles (<i>Quiscalus</i> <i>quiscula</i>), and red-winged blackbirds; in European starlings (<i>Sturnus</i> <i>vulgaris</i>), oxychlordane ranged from 5.0–19.1 mg/kg FW in birds that died, and from 1.4–10.5 mg/kg FW in sacrificed birds (Stickel et al. 1983)
BIRDS, 3 species , fed diets containing 150 mg technical chlordane/kg	LD50 reached in 6–7 days for starlings, cowbirds, and red-winged blackbirds (Stickel et al. 1979)
CALIFORNIA QUAIL, <i>Callipepla</i> <i>californica</i>	
Single oral dose of 14.1 mg/kg BW	LD50 (Hudson et al. 1984)
NORTHERN BOBWHITE, <i>Colinus</i> <i>virginianus</i>	
10–120 mg/kg diet for 14 weeks	LD50 (NRCC 1975; WHO 1984)
250 mg/kg diet for 10 days, juveniles	LD50 (WHO 1984)
250 mg/kg diet for 100 days, adults	LD50 (WHO 1984)
JAPANESE QUAIL, <i>Coturnix japonica</i>	
25 mg/kg diet, 4 weeks	No effect on survival, weight gain, or activity (NRCC 1975)
200 mg/kg diet, 7 days	LD100 (NRCC 1975)
14-day-old chicks fed treated diets for 5 days, then untreated diets for 3 days	No effect on survival or food consumption (Hill and Camardese 1986)
203 mg/kg diet	LD50 (Hill and Camardese 1986)
308 mg/kg diet	LD73, reduced food consumption (Hill and Camardese 1986)
370 mg/kg diet	LD93, reduced food consumption (Hill and Camardese 1986)
500 mg/kg diet	
CHICKEN, <i>Gallus</i> sp.	
Fed diet containing 0.1 mg/kg for 6 weeks	Egg chlordane residue about 0.2 mg/kg FW, and fat residue about 0.33 mg/kg FW (NRCC 1975)
Adults fed diet containing 0.3 mg/kg for 4 weeks	No adverse effects on growth, hatchability, or chick growth (NRCC 1975)
Fed diet containing 10 mg/kg for 5 days	Egg chlordane residue about 4 mg/kg FW (NRCC 1975)
220–230 mg/kg BW	Acute oral LD50 (NRCC 1975)
RING-NECKED PHEASANT, <i>Phasianus colchicus</i>	
Single oral dose of 24–72 mg/kg BW	LD50 (Hudson et al. 1984)
50 mg/kg diet for 100 days, juveniles	LD50 (WHO 1984)
318 mg/kg diet	LD50 (NRCC 1975)
430 mg/kg diet for 5 days, then clean diet for 3 days, juveniles	LD50 (Hill et al. 1975)
EUROPEAN STARLING, <i>Sturnus</i> <i>vulgaris</i>	
Fed diet containing 1.5, 6.25, 25, or 100 mg chlordane/kg	Time for 50% mortality was 57 days for 1.5 mg/kg diet, 24 days for 6.25 mg/kg diet, 6.5 days for the 25 mg/kg diet, and 3.25 days for the 100 mg/kg diet (Stickel et al. 1979)
Fed diet containing 100 mg nonachlor/kg for 35 days	8% dead (Stickel et al. 1983)

Table 13.4 (continued) Chlordane Effects on Selected Birds

Organism and Other Variables	Effect and Reference
200 mg chlordane/kg diet	LD50 usually within 14 days (Stickel et al. 1983)
500 mg chlordane/kg diet	LD50 in 5 days (Stickel et al. 1983)
BARN OWL, <i>Tyto alba</i>, adults	
Fed diets containing 75 mg/kg until 50% died; survivors sacrificed and residues measured	Mortality reached 50% on day 40; maximum residues in brains of birds dying during exposure (or sacrificed), in mg/kg FW, were 6.5 (9.0) for <i>cis</i> -chlordane, 4.5 (9.0) for <i>trans</i> -nonachlor, 3.2 (9.0) for <i>trans</i> -chlordane, and 1.0 (2.0) for <i>cis</i> -nonachlor (Dr. O.H. Pattee, Patuxent Wildlife Research Center, personal communication)
Fed diets containing 150 mg/kg until 50% died; survivors sacrificed and residues measured	Mortality reached 50% on day 17; maximum residues in brains of owls dying during exposure (or sacrificed), in mg/kg FW, were 5.1 (1.8) for <i>cis</i> -chlordane, 3.6 (1.8) for <i>trans</i> -chlordane, 3.2 (2.1) for <i>trans</i> -nonachlor, and 0.9 (0.4) for <i>cis</i> -nonachlor (Dr. O.H. Pattee, Patuxent Wildlife Research Center, personal communication)

13.5.6 Mammals

Concern for the continued widespread use of chlordane is centered around its carcinogenicity in mice, *Mus* sp. (Ewing et al. 1985). Chlordane produced liver cancer in both sexes of two different strains of domestic mice (USEPA 1980; WHO 1984; Tojo et al. 1986) (Table 13.5). A dose-dependent incidence of hepatocellular carcinoma was evident in mice fed chlordane in their diets. Frequency of liver carcinomas was not significantly different from controls at dietary levels of 5 mg/kg and lower, but was greatly elevated (i.e., >70% frequency) at dietary levels of 50 mg/kg and higher (USEPA 1980). In contrast to mice, chlordane was not a hepatic carcinogen in rats at dietary levels up to 64 mg/kg ration (WHO 1984; USEPA 1988); however, dose-related increases in follicular cell thyroid neoplasms and malignant fibrous histiocytomas were recorded in chlordane-exposed rats (Ohno et al. 1986). In humans, no increased evidence of cancer was proven among employees in chlordane manufacturing facilities, although there is a statistically significant increase in death rate from cerebrovascular disease in that group (Klaassen et al. 1986).

Human toxicity data for chlordane is usually obtained after accidental exposure through spillage onto clothing or ingestion (Ingle 1965; NRCC 1975; USEPA 1980). In one case, a 15-month-old girl accidentally swallowed a mouthful of chlordane suspension and within 3 h displayed tremors and incoordination. Repeated seizures developed and she was treated with ethyl chloride, amobarbitol, and gastric lavage with magnesium sulfate; ataxia and excitability disappeared in about 3 weeks. At age 26 years, she was in excellent health and seemed not to have experienced latent effects from the childhood incident (WHO 1984). Other cases of accidental chlordane poisoning in children are documented, and all appear to have recovered completely after treatment (WHO 1984).

Symptoms of acute chlordane poisoning in humans include irritability, salivation, labored respiration, muscle tremors, brain wave abnormalities, incoordination, convulsions, deep depression, and sometimes death (IARC 1979; USEPA 1980, 1988). Signs of acute chlordane intoxication in other mammal species are similar to those in humans and may also include aplastic anemia and acute leukemia; cyanosis; pathology of gastrointestinal tract, liver, kidney, lung, and heart; pulmonary congestion; degenerative changes in the central nervous system; impaired uptake and utilization of glucose; interference with immunocompetence response; diarrhea; avoidance of food and water; enhanced estrone metabolism; increased production of hepatic mixed function oxidase enzymes; altered enzyme activity in brain and in kidney cortex; enlarged liver; hair loss; abdominal distension; hunched appearance; inhibited oxidative phosphorylation in liver mitochondria; and thyroid carcinoma (Saxena and Karel 1976; IARC 1979; Reuber and Ward 1979; WHO 1984; Barnett et al. 1985; Johnson et al. 1986, 1987; Klaassen et al. 1986; USEPA 1988; Suzaki et al. 1988).

Acute oral LD50 values for technical chlordane and sensitive mammals usually ranged between 25 and 50 mg/kg BW (Table 13.5). Chlordane-related compounds (i.e., *cis*-chlordane, *trans*-chlordane, heptachlor, heptachlor epoxide) stimulate superoxide (O_2^-) generation in guinea pig leukocytes,

alter membrane potential, and increase intracellular calcium concentration; toxicity of individual compounds seems to be related to superoxide generation (Suzuki et al. 1988). Metabolism of chlordane isomers results in oxychlordane, a metabolite that is about 20 times more toxic to rats than is the parent compound and is the most persistent metabolite stored in rat adipose tissue (Menzie 1978; USEPA 1980). Oxychlordane accounted for 53% in females and 63% in males of all chlordane isomers in fat of rats killed 24 h after a single oral dose of 1.0 mg/kg BW technical chlordane (Nomeir and Hajjar 1987). Acute oral LD₅₀ values in the rat, in mg/kg BW, were 19.1 for oxychlordane; 89 to 392 for *cis*-chlordane; 200 to 590 for technical chlordane; 327 for *trans*-chlordane; >4600 for chlordene, 3-chlordene, 1-hydroxychlordene, chlordene epoxide, 1-hydroxy, and 2,3-epoxy chlordene; and >10,000 for 2-chlorochlordanne ([Table 13.5](#)).

Chlordane adversely affects growth and fertility of laboratory animals (Talamantes and Jang 1977; IARC 1979; Klaassen et al. 1986; USEPA 1988) ([Table 13.5](#)). Neonatal exposure of mice to chlordane retards growth, as judged by lowered body weights during the first 12 weeks (Talamantes and Jang 1977). No fetotoxic or teratogenic effects were observed in rats born to dams fed chlordane in their diets for 2 years at levels up to 300 mg/kg diet. However, pups nursed by dams consuming chlordane at 150 or 300 mg/kg diet developed signs of toxicity (USEPA 1988). In uterine mucosa of the rabbit, chlordane isomers (as well as isomers of DDE and polychlorinated biphenyls) reduced the binding of progesterone to its cytoplasmic receptor in a dose-dependent manner, which suggests a pathway to account for chlordane-induced reproductive impairment (Lundholm 1988).

Chlordane tends to accumulate in adipose tissues and, to a lesser extent, in liver ([Table 13.5](#)). In general, animals given a single oral dose of chlordane eliminated 80 to 90% of the dose within 7 days, usually via the feces; the *cis*-isomer is eliminated more rapidly than the *trans*-isomer and results in preferential accumulations of *trans*-chlordane (Nomeir and Hajjar 1987). In rats, *trans*-chlordane is rapidly absorbed and distributed to liver and kidney at single oral dosages as low as 0.05 mg/kg BW (Ohno et al. 1986). Rabbits fed *trans*-chlordane for 10 weeks excreted 70% of accumulated chlordane during the following 2 weeks on a chlordane-free diet (Menzie 1974). Treatment with *trans*-chlordane resulted in a greater percentage of oxychlordane in fat than did treatment with *cis*-chlordane. When chlordane was removed from the diet of treated animals, levels in fat declined 60% at a relatively steady rate over 4 weeks, but then only slightly thereafter. Accumulations in liver, kidney, brain, and muscle were much lower than in fat, but excretion kinetics were similar (Nomeir and Hajjar 1987).

Results of chronic feeding studies show that dietary concentrations of chlordane between 0.76 and 5 mg/kg ration did not affect survival but did produce adverse effects on various species of laboratory animals and livestock ([Table 13.5](#)). Dietary concentrations of 0.76 mg/kg (equivalent to 0.09 mg/kg BW daily) were associated with enlarged livers in mice, 1.0 mg/kg produced elevated residues in cow's milk, 2.5 mg/kg resulted in liver pathology in rats, 3 mg/kg (equivalent to 0.075 mg/kg BW daily) produced high residues in fat of dogs, and 5 mg/kg caused liver pathology in mice ([Table 13.5](#)).

Negative results for mutagenicity of *cis*-chlordane and *trans*-chlordane were reported in various strains of bacteria and in hepatocyte cultures of small mammals. But technical chlordane proved mutagenic to selected strains of *Salmonella typhimurium* and induced gene conversions in certain strains of the yeast, *Saccharomyces cervisiae* (IARC 1979; USEPA 1980, 1988; WHO 1984).

Chlordane interacts with other chemicals to produce additive or more-than-additive toxicity. For example, chlordane increased hepatotoxic effects of carbon tetrachloride in the rat (USEPA 1980; WHO 1984), and in combination with dimethylnitrosamine acts more than additively in producing liver neoplasms in mice (Williams and Numoto 1984). Chlordane in combination with either endrin, methoxychlor, or aldrin is additive or more-than-additive in toxicity to mice (Klaassen et al. 1986). Protein deficiency doubles the acute toxicity of chlordane to rats (WHO 1984). In contrast, chlordane exerts a protective effect against several organophosphorus and carbamate insecticides (WHO 1984), protects mouse embryos against influenza virus infection, and mouse newborns against oxazolone delayed hypersensitivity response (Barnett et al. 1985). More research seems warranted on interactions of chlordane with other agricultural chemicals.

Table 13.5 Chlordane Effects on Selected Mammals

Organism, Dose, and Other Variables	Effects and Reference
COW, <i>Bos bovis</i>	
Oral doses equivalent to 1, 10, or 100 mg/kg diet for 60 days, then no dose for 30 days	At 1 mg/kg diet equivalent, total chlordane in fat increased from 0.24 mg/kg at day 30 to 0.47 at day 60; 30 days later, residues remained elevated at 0.45 mg/kg. The same pattern was seen at higher dose levels but residues were higher at 1.2–1.5 mg/kg in the 10-mg/kg diet group, and 2.6–4.0 in the 100-mg/kg group (Nomeir and Hajjar 1987) Milk contained less than 50 µg/L (NRCC 1975)
Fed diets containing 10 mg/kg for 10 days	Milk contained less than 200 µg/L (NRCC 1975)
Fed diets containing 20 mg/kg for 150 days	
25–90 mg/kg body weight (BW)	Acute oral LD ₅₀ (WHO 1984)
DOG, <i>Canis familiaris</i>	
Fed diets containing 0.3, 3, 15, or 30 mg chlordane/kg food for 2 years	Liver abnormalities in 15- and 30-mg/kg groups; no adverse effects at lower doses on behavior, appearance, survival, weight gain, or blood chemistry. In the 3-mg/kg group, equivalent to 0.075 mg/kg BW daily, maximum residue in fat was 3.6 mg/kg (NRCC 1975; WHO 1984; USEPA 1988)
Daily oral dose ranging between 5 and 200 mg/kg BW	Dose-dependent mortality. All died between 25 days and 93 weeks (WHO 1984)
Single oral dose of 200–700 mg/kg BW	No deaths (WHO 1984)
GOAT, <i>Capra</i> sp.	
180 mg/kg BW	Acute oral LD ₅₀ (WHO 1984)
GUINEA PIG, <i>Cavia</i> spp.	
Males exposed daily for 90 days to 67 mg/kg BW through dermal painting	Mild degenerative changes in skin and testes (WHO 1984)
HAMSTER, <i>Cricetus</i> spp.	
1720 mg/kg BW	Acute oral LD ₅₀ (USEPA 1980; WHO 1984)
HUMANS, <i>Homo sapiens</i>	
100 µg/L	Reduced growth and altered cell morphology in human cell cultures (USEPA 1980)
25–50 mg/kg BW	Acute lethal oral dose (WHO 1984)
100 mg/kg BW	Fatal (IARC 1979)
Suicidal female swallowed 6 g chlordane, equivalent to 104 mg/kg BW	Death in 9 days (WHO 1984)
Contamination of water supply in Chattanooga, Tennessee, by up to 1.2 g chlordane/L	Gastrointestinal/neurological symptoms in 13 reported cases (WHO 1984)
MONKEY, <i>Macaca fascicularis</i>	
1 or 10 mg/kg BW of <i>trans</i> -chlordane given once weekly for 5 weeks by subcutaneous injection. Adipose tissue, blood, and skin lipids analyzed for up to 20 weeks after the last injection	<i>trans</i> -Chlordane and oxychlordane were detected in all tissues. In blood and adipose tissue, <i>trans</i> -chlordane decreased rapidly and oxychlordane increased gradually until a plateau was reached. Good correlations were determined for all chemicals between blood and adipose tissue, regardless of collection time and dose level, and between skin lipids and adipose tissue. At the high dose, <i>trans</i> -chlordane reached a maximum of 35 mg/kg FW in adipose tissue, but was not detectable after 20 weeks. The oxychlordane concentration in adipose tissue of the high-dose group was 25 mg/kg FW after the last injection, and 18 mg/kg FW after 20 weeks (Sasaki et al. 1992)

Table 13.5 (continued) Chlordane Effects on Selected Mammals

Organism, Dose, and Other Variables	Effects and Reference
CYNOMOLGUS MONKEY, <i>Macaca</i> spp.	
Inhalation for 90 days of air containing 10 µg technical chlordane/L	No measurable effect (Khasawinah et al. 1989)
INDIAN DESERT GERBIL, <i>Meriones hurrianae</i>	
Males dosed intramuscularly at 2.5 mg/kg BW every 3 days for 45 days	Hyperproteinemia, hyperglycemia, and enhanced serum alkaline and acid phosphatase activities (WHO 1984)
Single intramuscular injection of 25, 50, or 75 mg/kg BW	Dose-dependent hyperglycemia, due to increased production of liver glucose, in blood of treated animals, reaching a maximum glucose level about 1 h post-injection, persisting for up to 3 days, and approaching control levels within 1 week (Saxena and Karel 1976)
MOUSE, <i>Mus</i> spp.	
On days 2, 3, and 4 of life, each received 0.075 or 0.15 mg of either <i>cis</i> -chlordane or <i>trans</i> -chlordane	Depressed growth and delayed development in eye and vaginal opening during first 12 weeks; all normal at necropsy after 15 weeks (Talamantes and Jang 1977)
Oral doses of 0.08 or 0.25 mg daily for 30 days, equivalent to 100 and 300 mg/kg BW	Dose-related reduction in size of seminiferous tubules and in percentage of damaged tubules. High-dose group experienced 24–58% reduction in spermatogenesis (and high death rate); low-dose group 11–21% reduction; and controls 0.5–6.1% reduction (Balash et al. 1987)
0.09 mg/kg BW daily for 2 years, equivalent to 0.76 mg/kg diet	Increased liver to BW ratios in both sexes. At higher dietary concentrations equivalent to 0.43 and 1.1 mg/kg BW daily, liver necrosis was observed in males (USEPA 1988)
Daily oral doses for 14 days of 0.1, 4, and 8 mg <i>trans</i> -chlordane/kg BW	Significant dose-related increase in liver weight and leukocytes; no effect on immunocompetence (Johnson et al. 1986)
Pregnant females treated with 0.16 or 8 mg/kg BW throughout gestation	Decreased immune competence in offspring of high-dose group challenged with oxazolone at age 101 days (WHO 1984)
Single oral dose of <i>cis</i> -chlordane of 1.0 mg/kg BW	Peak tissue concentrations reached (in µg/kg FW) were 1180 in liver, 880 in fat, 349 in kidney, 248 in lungs, 164 in muscle, 92 in testes, and 68 in brain. Peak concentration in blood of 113 µg/L reached in 8 h; 34% of total dose excreted in feces by 12 h after treatment. After 14 days, measurable residues detected in gonad, muscle, fat, and kidney (Ewing et al. 1985)
Offspring from parents given 1.0 or 2.5 mg/kg BW for 7 consecutive days	Impaired conditioned avoidance response behavior and hyperactivity (WHO 1984)
Fed diets containing 5, 25, or 50 mg technical chlordane/kg ration for 18 months	Dose-related incidence of hepatic nodular hyperplasias in the 25 and 50 mg/kg diets and an increased incidence of hepatomas in the male 5- and 25-mg/kg groups. Controls experienced a high incidence of premature deaths (Epstein 1976)
Females injected intraperitoneally with 25 mg/kg BW once weekly for 3 weeks	Fertility reduced by about 50% (USEPA 1988)
Fed diets containing 25 to 100 mg chlordane/kg food for six generations	At 100 mg/kg, decreased viability in first and second generations and no offspring in third generation. At 50 mg/kg, viability was reduced in fourth and fifth generations. No significant effects in the 25-mg/kg group, even after six generations (WHO 1984)
Males fed diets containing 29.9 or 56.2 mg technical chlordane/kg for 80 weeks	Frequency of liver tumors was 88% in high-dose group, 33% in low-dose group, and 19% in controls (USEPA 1980)
Females fed diets containing 30 or 64 mg technical chlordane/kg for 80 weeks	Frequency of liver tumors was 70% in high-dose group, 6% in low-dose group, and 4% in controls (USEPA 1980)
Males given single dose of 50 or 100 mg/kg BW, then mated with untreated females	No dominant lethal changes produced (USEPA 1980)
390–430 mg/kg BW	Acute oral LD ₅₀ (IARC 1979; USEPA 1980)

Table 13.5 (continued) Chlordane Effects on Selected Mammals

Organism, Dose, and Other Variables	Effects and Reference
RABBIT, <i>Oryctolagus</i> sp.	
Oral doses of 1, 5, or 15 mg/kg BW daily on days 6–18 of gestation	Some miscarriages in 1 and 15 mg/kg groups; no changes in behavior, appearance, or body weight; no teratogenic effects observed (WHO 1984).
Dosed orally with 14.3 mg of radiolabeled <i>trans</i> -chlordane daily for 10 weeks and killed 2 weeks after the last dose	Residues were highest in abdominal and subcutaneous fat (235 mg/kg FW), followed by heart and spleen (75–91 mg/kg), then liver, brain, and blood (25–44 mg/kg) (Nomeir and Hajjar 1987)
20 mg/kg BW, single intravenous injection	LD74 (Ingle 1965)
Dermal exposure for 90 days equivalent to 20–40 mg/kg BW	LD50 (WHO 1984)
Dosed orally with <i>cis</i> -chlordane at 67 mg/kg BW, or <i>trans</i> -chlordane at 30 mg/kg BW every 4 days for a total of 4 doses, then killed 5 days after the last dose	Residues in the <i>trans</i> -chlordane group were higher (17–77 mg/kg) than in the <i>cis</i> -chlordane group (8–67 mg/kg), although <i>trans</i> -chlordane was given at a much lower dose. Fat and kidney usually contained the highest concentrations, and brain the lowest. Oxychlordane was found in all tissues at 0.1 mg/kg in brain, 11 mg/kg in fat, and 0.5–2 mg/kg in liver, muscle, and kidney (Nomeir and Hajjar 1987)
100–500 mg/kg BW	Acute oral LD50 (Ingle 1965; USEPA 1980)
780–1200 mg/kg BW	Acute dermal LD50; death preceded by skin irritation, tremors, and convulsions (WHO 1984)
SHEEP, <i>Ovis aries</i>	
Single oral dose of 500 mg/kg BW	Incoordination and partial blindness; full recovery in 5–6 days (WHO 1984)
Single oral dose of 1000 mg/kg BW	Severe respiratory and nervous signs in 16 h, and death in 48 h (WHO 1984)
BABOON, <i>Papio anubis</i>	
Fed diets containing chlordane, equivalent to 0.1–1.0 mg/kg BW daily, for 2 years	At 1.0 mg/kg BW, cytochrome P-450 activity was significantly increased, but no other significant effects were recorded on general health or on any major organ system (WHO 1984)
RAT, <i>Rattus</i> spp.	
Inhalation of air containing technical chlordane	
0.1 µg/L, 90 days	Adverse biological response (Khasawinah et al. 1989)
5.8 or 28.2 µg/L, 28 days	No measurable difference from controls at low dose; impaired liver function at high dose (Khasawinah et al. 1989)
154 µg/L, 5 days	Death (Khasawinah et al. 1989)
413 µg/L, 2 days	Death (Khasawinah et al. 1989)
Fed technical chlordane at dietary levels of 1, 5, or 25 mg/kg, equivalent to daily doses of 0.045, 0.229, and 1.175 mg/kg BW, respectively, for 130 weeks (2.5 years)	No significant effects on hematology, clinical chemistry, body weight, or survival rate. Dose-dependent hepatocellular necrosis (34% in high-dose group); liver adenomas in males and hepatocellular swelling in females from the high-dose group (USEPA 1988)
0.05 mg radiolabeled <i>trans</i> -chlordane/kg BW, single oral dose, residues measured over 96 h after exposure	Maximum residues (in mg/kg FW) and time post-administration were: liver, 0.1, 2 h; fat tissue, 0.09, 96 h; kidney, 0.07, 4 h; skin, 0.03, 8 h; brain, 0.01, 4 h; muscle, 0.008, 4 h; and blood 0.003, 4 h. Half-time persistence was 6.5–13 h for the rapidly decreasing phase, and 4.8–8.9 days for the slowly decreasing phase (Ohno et al. 1986)
Daily intraperitoneal injections of technical chlordane at 0.15, 1.75, or 25 mg/kg daily for 42 days	Dose-dependent alterations of brain potentials without behavioral signs of chronic toxicity (USEPA 1980)
Single oral dose of 0.2 mg/kg BW of <i>cis</i> -chlordane, <i>trans</i> -chlordane, or oxychlordane	Maximum residues in fat after 24 h, in mg/kg FW, were 0.3 for <i>cis</i> -chlordane, 0.7 for <i>trans</i> -chlordane, and 0.5 for oxychlordane (Nomeir and Hajjar 1987)
Single oral dose of 0.2 or 1.0 mg/kg BW technical chlordane	Maximum residues in fat at 24 h (in mg/kg FW) were 0.5 for the low-dose group, and 3.7 for the high-dose group (Nomeir and Hajjar 1987)

Table 13.5 (continued) Chlordane Effects on Selected Mammals

Organism, Dose, and Other Variables	Effects and Reference
Fed diets containing 0.3, 3, 15, 30, or 60 mg technical chlordane/kg diet for 3 generations	Levels up to and including 30 mg/kg diet had no measurable effect on fertility, number of young produced, growth, or mortality rate; no gross or microscopic differences between the groups. At 60 mg/kg the second F ₃ generation litters had elevated mortality (11%) during the latter part of the nursing period; these animals also showed gross and microscopic pathology (NRCC 1975; WHO 1984)
Single oral dose of 1.0 mg <i>cis</i> -chlordane/kg BW	Peak tissue concentrations (in mg/kg FW) were noted within 4 h after treatment: liver, 1.9; fat, 1.2; kidney, 0.7; lung, 0.3; brain 0.2; testes, 0.1; muscle, 0.1; and blood, 0.08. After 12 h, 7% was excreted, and after 3 days, 83% was voided (Ewing et al. 1985)
Single oral dose of 1.0 mg/kg BW	About 50% excreted in feces after 1 day and >90% in 7 days; only 2–3% of the dose was detected in the urine (Nomeir and Hajjar 1987)
Fed oxychlordane in diets for 90 days at rate equivalent to 2.0 mg/kg BW daily	No gross pathology or histological lesions (NRCC 1975; WHO 1984)
Fed 2.5, 25, or 75 mg technical chlordane per kg of diet for 2 years	Severe toxic signs at 25 and 75 mg/kg; liver damage at 2.5 mg/kg diet (WHO 1984)
Long-term feeding studies at dietary concentrations between 5 and 320 mg technical chlordane/kg	Reduced survival and growth at dietary levels >150 mg/kg; liver enlargement and micropathology at >20 mg/kg; no effect on reproduction at 150 mg/kg diet; no adverse effects at 5 mg/kg diet (Ingle 1965)
Fed <i>cis</i> -chlordane at dietary levels of 0, 5, 15, 25, or 35 mg/kg	Increased mortality and growth retardation in 4–5 months at 35-mg/kg diet; growth normal in other groups; some liver damage in 25- and 35-mg/kg groups (WHO 1984)
Daily oral dose of 6.5–25 mg technical chlordane/kg BW, for 15 days	No tremors or convulsions; however, dose-related liver pathology was noted (WHO 1984)
Single oral dose of 10 mg radiolabeled <i>trans</i> -chlordane/kg BW	Maximum residues, in mg/kg FW and time after administration were: liver, 21, 4 h; kidney, 18, 4 h; adipose tissue, 11, 16 h; skin, 5, 8 h; brain, 3.4, 4 h; muscle 1.4, 4 h; and blood, 0.6, 4 h. Tb 1/2 of 5–12 h for the fast component, and 4.3–7.3 days for the slow component (Ohno et al. 1986)
Fed diets containing 15 or 25 mg/kg of <i>cis</i> -chlordane for 78 weeks	No adverse effects on liver at 15-mg/kg diet; some effects at 25-mg/kg (NRCC 1975)
Fed <i>trans</i> -chlordane at dietary levels of 15, 25, 35, or 75 mg/kg diet	Decreased survival, liver damage, and growth retardation of males in 8 months at 75-mg/kg diet; growth normal at other doses (WHO 1984)
19.1 mg oxychlordane/kg BW	Acute oral LD50 (WHO 1984)
20 mg technical chlordane/kg diet for 350 days	Residues (in mg/kg FW) were about 20 for adipose tissue, 0.8 for liver, and 0.2 for heart (NRCC 1975)
Daily oral doses of 25 mg/kg BW for 15 days	No toxic signs (USEPA 1980)
Fed diets containing 35 mg/kg <i>trans</i> -chlordane for 78 weeks	No adverse effects on liver (NRCC 1975)
Daily oral dose of 50 mg technical chlordane/kg BW for 15 days	2 of 5 rats died; toxic signs in survivors (WHO 1984)
83–392 mg/kg BW	Acute oral LD50 for <i>cis</i> -chlordane (USEPA 1980, 1988)
Fed diets containing 100 or 200 mg/kg ration of <i>cis</i> -chlordane or <i>trans</i> -chlordane for 11–15 days	Maximum residues, in mg/kg lipid, in females fed 100 mg/kg <i>cis</i> -chlordane were 23 for <i>cis</i> -chlordane and 100 for oxychlordane; for the 200 <i>cis</i> -chlordane group, levels were 48 for <i>cis</i> -chlordane and 182 for oxychlordane. Females fed 100 mg/kg <i>trans</i> -chlordane had 10 mg/kg lipid of <i>trans</i> -chlordane and 201 of oxychlordane; for the 200 mg/kg group, residues were 23 mg/kg lipid of <i>trans</i> -chlordane and 470 of oxychlordane; for all groups, residues in males were 6–21 times lower than in females (Nomeir and Hajjar 1987)
Fed diets averaging 121 and 241 mg/kg feed (females) and 203 and 407 mg technical chlordane/kg diet (males) for 80 weeks	Increased mortality, tremors, growth reduction; elevated incidence of thyroid neoplasms and malignancies in all treated animals, but no hepatocellular carcinomas (IARC 1979; USEPA 1988)
137 mg/kg BW	Acute oral LD50 for rats fed a low protein diet (USEPA 1980)
200–590 mg technical chlordane/kg BW	Acute oral LD50 (NRCC 1975; USEPA 1980; WHO 1984)

Table 13.5 (continued) Chlordane Effects on Selected Mammals

Organism, Dose, and Other Variables	Effects and Reference
205 mg technical chlordane/kg BW	Acute dermal LD50 for females (WHO 1984)
Fed diets containing 300, 500, or 1000 mg technical chlordane/kg	75% dead at 300 mg/kg diet after 100 days; all dead in 70 days at 500 mg/kg, or in 10 days at 1000 mg/kg (WHO 1984)
311 mg/kg BW	Acute oral LD50 for rats fed a normal protein diet (USEPA 1980)
Fed diets containing 320 mg technical chlordane/kg from weaning	Reduced sexual activity, reduction in number of viable litters, increased rate of death of progeny prior to weaning (WHO 1984)
327 mg <i>trans</i> -chlordane/kg BW	Acute oral LD50 (USEPA 1980; WHO 1984)
335 mg/kg BW	Acute oral LD50 for males IARC 1979
343 mg/kg BW	Acute intraperitoneal (IP) LD50 for adults (USEPA 1980)
350 mg/kg BW	IP injection produced mild tremors and disorientation within a few minutes, and death within 1 h (USEPA 1980)
530–690 mg/kg BW	Acute dermal LD50 for females (USEPA 1980; WHO 1984)
539 mg/kg BW	Acute IP LD50 for newborns pretreated with 40 mg/kg BW phenobarbital (USEPA 1980)
840 mg/kg BW	Acute dermal LD50 for males (USEPA 1980)
1121 mg/kg BW	Acute IP LD50 for newborns (USEPA 1980)
Oral administration (in mg/kg BW) of 4600 chlordene, 4600 3-chlorochlordanne, 4600 1-hydroxychlordanne, 4600 chlordene epoxide, 4600 1-hydroxy, 2, 3-epoxy chlordanne, or 10,200 2-chlorochlordanne	Less than 50% dead (WHO 1984)
PIG, <i>Sus</i> spp.	
Fed diet containing 300 mg/kg of <i>cis</i> -chlordanne or <i>trans</i> -chlordanne for 60–90 days	Residues of total chlordanes in fat ranged from 9 mg/kg to 72 mg/kg; values were highest for <i>trans</i> -chlordanne and lowest for <i>cis</i> -chlordanne (NRCC 1975)

13.6 RECOMMENDATIONS

All use of chlordane was banned in Norway in 1967 (Ingebrigtsen et al. 1984). In August 1975, the USEPA issued its intent to suspend registrations and prohibit production of all pesticides containing heptachlor or chlordane, based on evidence of carcinogenicity (Glooschenko and Lott 1977). On July 1, 1983, chlordane use was prohibited in the United States for any purpose except to control underground termites. A similar situation exists in Japan (Ohno et al. 1986; Tojo et al. 1986).

The continued use of chlordane, coupled with its general persistence in the environment, suggests that extreme caution be taken in all stages of its manufacture, transport, storage, and application (Greenhalgh 1986). In particular, chlordane use near marine environments is not recommended because of chlordane's high toxicity to marine life (USEPA 1988). At elevated risk of chlordane toxicity in the human population are children, as a result of the milk they consume; fishermen and their families, because of high consumption of fish and shellfish; people living downwind from fields treated with chlordane; and individuals residing in houses treated with chlordane-containing pesticides (USEPA 1980).

The proposed criterion for marine life protection of 0.004 µg/L as a 24-h mean, not to exceed 0.09 µg/L at any time (Table 13.6), seems to offer a reasonable degree of protection. But the proposed freshwater criterion of 0.0043 µg/L, 24-h average, not to exceed 2.4 µg/L at any time (Table 13.6), overlaps the range of 0.2 to 3.0 µg/L shown earlier to be harmful to sensitive species of fish and aquatic invertebrates. Accordingly, the maximum permissible freshwater value should

be adjusted downward. "Safe" residues in tissues of aquatic biota require clarification, and probably additional research effort. Criteria on chlordane for protection of mammalian wildlife are missing, and those formulated for birds are incomplete and require data on no-observable-effect levels from lifetime exposures (Table 13.6). Until this information becomes available, it seems prudent to use criteria developed for human health protection as temporary guidelines for the protection of vertebrate wildlife. Specifically, daily intake should not exceed 0.001 mg total chlordane, including *cis*-chlordane, *trans*-chlordane, and oxychlordane/kg BW; and food items should not exceed 0.3 mg/kg FW (Table 13.6).

Table 13.6 Proposed Chlordane Criteria for Protection of Natural Resources and Human Health

Resource	Criterion or Effective Chlordane Concentration	Reference ^a
AQUATIC LIFE		
Water concentration, safe level		
Freshwater	<0.0043 µg/L, 24 h average; not to exceed 2.4 µg/L at any time	1
Saltwater	<0.004 µg/L, 24 h average; not to exceed 0.09 µg/L at any time	1
Tissue concentrations		
Fish		
Reduced survival	>300 mg/kg tissue, lipid weight (LW) basis	2
No observed adverse effect level (NOEL)	<0.1 mg/kg fresh weight (FW) tissue	3
Estuarine invertebrates, lethal	>106 mg/kg tissue LW	2
BIRDS		
Concentration in brain		
Joint lethal range	1.1–5.5 mg/kg FW for oxychlordane and 3.4–8.3 mg/kg FW for heptachlor epoxide	4, 12
Single lethal range	6 mg/kg FW for oxychlordane or 9 mg/kg FW for heptachlor epoxide	4, 12
Diet, acceptable range, but producing slight elevation in tissue concentrations	0.1–0.3 mg/kg diet	6
MAMMALS		
Dog, <i>Canis familiaris</i> , NOEL	<3 mg/kg diet, equivalent to <0.075 mg/kg body weight (BW) daily	5, 6
Rat, <i>Rattus</i> sp., NOEL	<5 mg/kg diet, equivalent to 0.25 mg/kg BW daily	5
Livestock water use, USA	<3 µg/L	7
HUMAN HEALTH		
Drinking water		
Worldwide	<0.3 µg/L	5, 15
Canada, United States	<3.0 µg/L	1, 7
Chronic, child, U.S.	<0.5 µg/L	7, 15
Maximum 1-day exposure, adult, U.S.	63.0 µg/L	7
Increased lifetime risk of cancer, 70-kg adult, 2 liters daily ^b		
10 ⁻⁴	2.7 µg/L	7
10 ⁻⁵	0.27 µg/L	7
10 ⁻⁶	0.027 µg/L	7
Acceptable daily intake ^c , 70-kg adult	<70 µg, equivalent to <0.001 mg/kg BW	1, 3, 5, 6, 8, 14, 15
Diet		
U.S. Food and Drug Administration "action level"	0.3 mg/kg FW	3, 8-10, 13
Australia	<0.05 mg/kg FW in meats, including oxychlordane	11

Table 13.6 (continued) Proposed Chlordane Criteria for Protection of Natural Resources and Human Health

Resource	Criterion or Effective Chlordane Concentration	Reference ^a
Worldwide	Usually <0.3 mg/kg FW, but residue tolerances vary between 0.02 and 0.5 mg/kg FW, based on the sum of <i>cis</i> -chlordane, <i>trans</i> -chlordane, and oxychlordane	5, 8
Air		
USSR	Maximum allowable concentration of 0.01 mg/m ³	5
Romania	<0.3 mg/m ³ , maximum allowed is 0.6 mg/m ³	5
Belgium, Finland, U.S., Japan, the Netherlands	<0.5 mg/m ³	1, 5, 7, 8, 15
15-min exposure limit, United States	<2 mg/m ³	1

^a 1, USEPA 1980; 2, Zitko 1978; 3, Arruda et al. 1987; 4, Blus et al. 1983; 5, WHO 1984; 6, NRCC 1975; 7, USEPA 1988; 8, IARC 1979; 9, Ingle 1965; 10, Wood et al. 1986; 11, Petterson et al. 1988; 12, Stickel et al. 1979; 13, Kennish and Ruppel 1997; 14, Rai and Mandal 1993; 15, USPHS 1994.

^b One excess cancer per million (10^{-6}) is associated with lifetime exposure to chlordane in drinking water at concentrations as low as 0.027 µg/L, the most conservative estimate. A lifetime health advisory computation was not possible because chlordane is a probable human carcinogen (USEPA 1988).

^c Consumed fish are considered to be the only source of chlordane; up to 98% of chlordane exposure results from aquatic organisms with high (up to 14,100X) bioconcentration potential (USEPA 1980). Urban residents should not consume more than 8 ounces (227 mg) of fish daily containing 0.03 mg total chlordanes/kg FW, and nonurban residents up to 1135 mg of fish daily containing 0.03 mg/kg FW (Arruda et al. 1987). The value of 0.001 mg/kg BW daily is based on the no-observed-effect level of 5 mg/kg in the diet of the rat, equivalent to 0.25 mg/kg BW, and 3 mg/kg in the diet of the dog, equivalent to 0.075 mg/kg BW (WHO 1984).

Additional research on chlordane is recommended in nine general areas:

1. Monitoring of background concentrations of oxychlordane in wildlife, since this metabolite is more toxic and persistent than the parent chemical (Kawano et al. 1988)
2. Interpretation of the biological significance of residue levels found in wildlife
3. Adoption of improved uniform methods of quantitation so that residue levels can be compared, and so that a time estimate of their environmental significance can be made (NRCC 1975; USEPA 1988)
4. Reexamination of aquatic toxicity data wherein concentrations tested exceeded the solubility of chlordane in water of 6 to 9 µg/L (WHO 1984)
5. Evaluation of interaction of chlordane with other agricultural chemicals, including heptachlor, to clearly delineate any additive, synergistic, or antagonistic effects (WHO 1984)
6. Reevaluation of the cancer risk of chlordane to experimental animals (WHO 1984)
7. Measurement of chronic exposures of fish and wildlife to realistic environmental levels (WHO 1984)
8. Measurement of effects of depleted soil fertility from chlordane-induced earthworm suppression on migratory birds and other wildlife (NRCC 1975; WHO 1984)
9. Continuance of epidemiological studies on workers who have been exposed to chlordane (WHO 1984).

13.7 SUMMARY

Technical chlordane is an organochlorine compound first introduced into the United States in 1947 in a variety of formulations for use as a broad-spectrum pesticide. By 1974, about 9.5 million kg of chlordane were being produced annually. Concern over the potential carcinogenicity of chlordane has led to sharply curtailed production. Since 1983, chlordane use in the United States has been prohibited, except for control of underground termites.

Technical chlordane consists of about 45 components, primarily *cis*-chlordane (19%), *trans*-chlordane (24%), heptachlor (10%), *cis*- and *trans*-nonachlor (7%), and various chlordane isomers (22%). Chemical analysis of technical chlordane is difficult because of analytical interferences from other organochlorine compounds, nonstandardization of analytical techniques, variations in the number and relative composition of components in weathered chlordane, and uncertainty of the structural formulas and other properties of several compounds present.

Past chlordane use, coupled with atmospheric transport as the major route of dissemination, produced global contamination of fish and wildlife resources and human populations. The chemical and its metabolites were frequently detected in all species examined, but usually at low concentrations. Residues in fish muscle sometimes exceeded the U.S. Food and Drug Administration action level of 0.3 mg/kg fresh weight recommended for human health protection. In general, chlordane in animals is highest near areas where the chemical has been applied to control termites; concentrations are highest in fat and liver, especially in predatory species.

The half-life of chlordane in water is comparatively short. *cis*-Chlordane, for example, usually persists less than 18 h in solution. In soils, however, some chlordane isomers persist for 3 to 14 years because of low solubility in water, high solubility in lipids, and relatively low vapor pressure. There seems to be little accumulation of chlordane in crops grown in contaminated soils.

Chlordane is readily absorbed by warm-blooded animals via skin, diet, and inhalation, and distributed throughout the body. In general, residues of chlordane and its metabolites are not measurable in tissues 4 to 8 weeks after exposure, although metabolism rates varied significantly between species. Food chain biomagnification is usually low, except in some marine mammals. In most mammals, the metabolite oxychlordane has proven much more toxic and persistent than the parent chemical.

Many species of aquatic organisms are adversely affected at concentrations in water between 0.2 and 3.0 µg/L technical chlordane. Sensitive bird species had reduced survival on diets containing 1.5 mg chlordane per kilogram ration, or after a single oral dose as low as 14.1 mg chlordane per kilogram body weight. Chlordane has produced liver cancer in laboratory strains of domestic mice, but carcinogenicity has not been established in other mammals.

Chlordane criteria for protection of marine life (0.004 µg/L, 24-h mean; not to exceed 0.09 µg/L) appear satisfactory. Proposed criteria for freshwater life protection (0.0043 µg/L, 24-h mean; not to exceed 2.4 µg/L), however, overlap the range of 0.2 to 3.0 µg/L shown to adversely affect certain fish and aquatic invertebrates, suggesting that some downward modification in the maximum permissible level is needed. Chlordane criteria for protection of birds and mammals are inadequate because the database is incomplete. Until these data become available, a reasonable substitute is the criteria proposed for human health protection — namely, daily intake not to exceed 0.001 mg chlordane per kilogram body weight, and diet not to exceed 0.3 mg chlordane per kilogram fresh weight.

Most authorities agree that more studies are needed in several areas:

- Monitoring of oxychlordane concentrations in wildlife
- Interpretation of the biological significance of residue levels found in wildlife
- Standardization of analytical extraction and other techniques for quantitation of chlordane and its metabolites
- Reexamination of aquatic toxicity data where test concentrations exceeded the solubility of chlordane in water (6 to 9 µg/L)
- Interaction effects with other agricultural chemicals
- Reevaluation of the cancer risk of chlordane on representative organisms at realistic environmental levels
- Effects of depleted soil fertility from chlordane-induced earthworm suppression
- Continuance of epidemiological studies on exposed workers.

CHAPTER 14

Chlorpyrifos

14.1 INTRODUCTION

Chlorpyrifos (phosphorothioic acid *O,O*-diethyl *O*-(3,5,6-trichloro-2-pyridinyl) ester), also commonly known as Dursban and Lorsban, was first registered as a broad-spectrum insecticide in 1965, and subsequently used widely to control a variety of pests such as fire ants, turf and ornamental plant insects, cockroaches, mosquitoes, leatherjackets, termites, hornflies, lice, and fleas (U.S. Environmental Protection Agency [USEPA] 1986; Hughes et al. 1991; Clements et al. 1992; U.S. Public Health Service [USPHS] 1995; Ryals et al. 1998). In 1982, total agricultural use of chlorpyrifos was estimated at 2.2 to 3.2 million kg, and industrial uses ranged between 0.68 and 1.04 million kg (USEPA 1982). In 1984, about 0.15 million kg (0.33 million pounds) of chlorpyrifos were applied to about 600,000 ha (1.48 million acres) of wetlands in the United States for mosquito control (Odenkirchen 1987). More than 1.1 million kg chlorpyrifos were used in California in 1990 (Menconi and Paul 1994). Atmospheric transport of chlorpyrifos from California's Central Valley to the Sierra Nevada mountains in California was estimated at 27 kg annually in 1995 and 1996 (McConnell et al. 1998). Treatment programs in which chlorpyrifos concentrations suitable for mosquito control and other insect pests were used have been shown to be detrimental to nontarget species, including aquatic organisms, waterfowl, and terrestrial organisms from surrounding ecosystems (Linn 1968; Hurlbert et al. 1970, 1972; Atkins 1972; Streu and Cruz 1972; Nelson and Evans 1973; Butcher et al. 1977; Thirugnanam and Forgash 1977; Tagatz et al. 1982; Goodman et al. 1985a; McEwen et al. 1986; Mayer 1987; Odenkirchen 1987; Smith 1987; Odenkirchen and Eisler 1988). Domestic use of chlorpyrifos has resulted in the death of an 11-day-old infant (Center for Disease Control [CDC] 1980) and the poisoning of office workers (Hodgson et al. 1986). Prophylactic use of chlorpyrifos on farm animals has caused reproductive impairment of livestock (Everett 1982). Chlorpyrifos-resistant strains of insects have been detected; they include the German cockroach (*Blattella germanica*) in Florida and Nebraska (Milio et al. 1987) and the sawtoothed grain beetle (*Oryzaephilus surinamensis*) in Australia (Collins 1985).

14.2 ENVIRONMENTAL CHEMISTRY

Formulations of chlorpyrifos include emulsifiable concentrates, wettable powders, granules, pellets, microencapsulates, and impregnated materials. Suggested diluents for concentrates include water and petroleum distillates, such as kerosene and diesel oil. Carrier compounds include synthetic clays with alkyl/aryl sulfonates as wetting agents (Table 14.1). Little information is available to assess the influence of various use formulations on toxicity, dispersal, decomposition, and bioavailability. Chemical and other properties of chlorpyrifos are summarized in Table 14.2 and Figure 14.1.

Table 14.1 Selected Chlorpyrifos Formulations and Carriers

Compound ^a	Formulation	Carrier
Dursban 2E	Emulsifiable concentrate of 0.285 kg/L (2.4 lb/gal)	Solution in aromatic distillate with anionic/nonionic emulsifier blend and residual chlorinated solvent
Dursban M	Emulsifiable concentrate of 0.57 kg/L (4.8 lb/gal)	As above
Dursban 6	Solution of 0.855 kg/L (7.2 lb/gal)	Solution in an aromatic distillate
Dursban 2 1/2	Granular, 2.5%	Absorbed onto stabilized clay with release agents added
Lorsban 4C	Emulsifiable concentrate of 0.479 kg/L (4.0 lb/gal)	Solution in aromatic naphtha with emulsifiers
Lorsban 25W	Wettable powder, 25%	Dispersion on blended clays with alkyl/aryl sulfonates as wetting agents

^a Dursban and Lorsban are registered trademarks of the Dow Chemical Company.

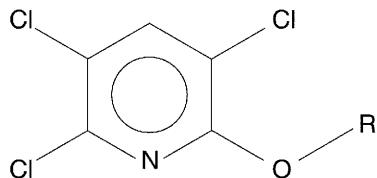

Modified from Marshall, W.F. and J.R. Roberts. 1978. *Ecotoxicology of Chlorpyrifos*. Natl. Res. Coun. Canada, Assoc. Comm. Sci. Crit. Environ. Qual., Publ. 16059, Ottawa, Ontario, Canada. 314 pp.

Table 14.2 Chemical and Other Properties of Chlorpyrifos

Variable	Datum
Chemical name	Phosphorothioic acid O,O-diethyl O-(3,5,6-trichloro-2-pyridinyl) ester
Alternate names	CAS 2921-88-2; Dursban; Lorsban; 27311; Trichlorpyrophos; Brodan; Pyrinex; Chlorpyriphos-ethyl
Primary uses	Insecticide, acaricide
Producers	Dow Chemical Company; India Medical Corp.; Makhteshim-Agan (Israel); Planters Products, Inc.
Empirical formula	C ₉ H ₁₁ Cl ₃ NO ₃ PS
Molecular weight	350.57
Physical state at 25°C	White granular crystalline solid
Melting point	41.5–43.5°C
Vapor pressure	
25°C	1.87 × 10 ⁻⁵ mmHg
35°C	8.87 × 10 ⁻⁵ mmHg
Heat of sublimation	26,800 cal/mol
Percent by weight	
Carbon	30.83
Hydrogen	3.16
Chlorine	30.34
Nitrogen	4.00
Oxygen	13.69
Phosphorus	8.83
Sulfur	9.15
Solubility	
Water, 23–25°C	0.4–2.0 mg/L
Isooctane, 23°C	790.0 g/kg
Methanol, 23°C	450.0 g/kg
Log K _{ow}	5.2
Soil organic carbon/water partition coefficient	13,600

Data from Brust 1966; Rigerink and Kenaga 1966; Kenaga 1971; Windholz 1976; Menconi and Paul 1994.

The degradation half-life time (T_b 1/2) of chlorpyrifos is 7.1 days in seawater (Schimmel et al. 1983), and 53 days in distilled water (Freed et al. 1979). Degradation is usually through hydrolysis to produce 3,5,6-trichloro-2-pyridinol and phosphorothioic acid (Brust 1966; Smith 1966, 1968; Marshall and Roberts 1978). Temperature, pH, radiation, and metal cations all significantly affect chlorpyrifos T_b 1/2 in water: half-life is decreased with increasing water pH, temperature, sunlight, and metal cation concentrations (Brust 1966; Mortland and Raman 1967; Smith 1968; Schaefer and Dupras 1969, 1970; Meikle and Youngson 1970; Menconi and Paul 1994).

Figure 14.1 Structures of chlorpyrifos and some of its metabolites. (Modified from Barron, M.G., S.M. Plakas, and P.C. Wilga. 1991. Chlorpyrifos pharmacokinetics and metabolism following intravascular and dietary administration in channel catfish. *Toxicol. Appl. Pharmacol.* 108:474-482.)

In soil, Tb 1/2 values for chlorpyrifos range from less than 1 week to more than 24 weeks, depending on soil moisture, microbial activity, clay and organic content, and temperature. In 411 soils studied, increasing temperature resulted in decreased Tb 1/2 values (Miles et al. 1983). Degradation was more rapid in sandy loam than in organic muck soils, more rapid in moist than in dry soils, and more rapid in clay than in other soil types (Getzin 1981; Miles et al. 1983, 1984). The major routes of chlorpyrifos loss from soils are chemical hydrolysis in moist soils, clay-catalyzed hydrolysis in dry soils, and microbial degradation and volatilization (Marshall and Roberts 1978). Chlorpyrifos is poorly metabolized by soil bacteria and frequent treatments of agricultural soils may result in accumulation with occasional adverse effects (Gonzalez-Lopez et al. 1997). For example, at 2 to 10 kg/ha, chlorpyrifos significantly reduces the growth and dinitrogen fixation of heterotrophic nitrogen-fixers. The negative effects of chlorpyrifos on nitrogen-fixing bacteria are important because root colonization by microorganisms such as *Azospirillum*, *Azotobacter*, and *Rhizobium* is positive for plant growth (Gonzalez-Lopez et al. 1997).

The half-life of chlorpyrifos in sediments is comparatively long; it was 24 days in a sediment–water slurry (Schimmel et al. 1983). In a pond treated with chlorpyrifos, total water-borne residues decreased by a factor of more than 10, while total sediment residues rose by about 3 (Hurlbert et al. 1970). Similar results were noted in an artificial lake treated with chlorpyrifos: lake water concentrations peaked 1 day after treatment at 0.9 µg/L and plateaued near 0.2 µg/L after 3 weeks (Mulla et al. 1973).

Chlorpyrifos inhibits substrate-borne reception and emission of sex pheromone in *Trichogramma brassicae*, an entomophagous insect massively used as a biological control agent of corn borers, among survivors of an LC20 dose. Inhibition was probably due to nervous system effects and was not specific to pheromone communication (Delpuech et al. 1998).

Fish rapidly absorb, metabolize, and excrete chlorpyrifos from the diet (Barron et al. 1991). The mechanism of action of chlorpyrifos occurs via phosphorylation of the active site of acetyl-cholinesterase after initial formation of chlorpyrifos oxon by oxidative desulfurization. In studies with channel catfish (*Ictalurus punctatus*), the oral bioavailability of chlorpyrifos was 41%, substantially higher than in mammals. Catfish muscle contained less than 5% of the oral dose with an

elimination half-life (T_b 1/2) of 3.3 days. Chlorpyrifos residues in whole catfish were more than 95% chlorpyrifos, while bile and urine primarily contained metabolites. The dephosphorylated metabolite trichloropyridinol (TCP) was the major metabolite in the blood, while the glucuronide conjugate of TCP was the major metabolite in urine and bile. The toxic metabolite chlorpyrifos oxon was not detected in blood, tissues, or excreta. Extensive metabolism resulted in a low potential for chlorpyrifos to accumulate in catfish from dietary exposure. In both fish and mammals, TCP is a major biotransformation product (Barron et al. 1991). Channel catfish rapidly distribute water-borne chlorpyrifos into the blood and more slowly to peripheral tissues, with concentrations highest in fat and lowest in muscle (Barron et al. 1993). As was true with dietary chlorpyrifos, TCP was the major metabolite in blood, and the glucuronide conjugate of TCP was the major metabolite in urine and bile. Pharmacokinetics and metabolism of water-borne chlorpyrifos in channel catfish were similar to the disposition of chlorpyrifos in other vertebrates (Barron et al. 1993; USPHS 1995).

14.3 LABORATORY INVESTIGATIONS

14.3.1 Aquatic Organisms

During 96-h toxicity tests, several species of freshwater and marine invertebrates and fishes died at chlorpyrifos concentrations between 0.04 and 0.6 µg/L. LC₅₀ (96-h) values, in µg chlorpyrifos/L, for sensitive species tested were 0.04 for mysid shrimp, *Mysidopsis bahia*; 0.11 for amphipod, *Gammarus lacustris*; 0.38 for stonefly, *Pteronarcella badia*; and 0.6 for striped bass, *Morone saxatilis*; (Mayer and Ellersieck 1986) (Table 14.3). Toxicity was usually greater at elevated temperatures and at increasing pH levels (Johnson and Finley 1980). Aquatic invertebrates were usually more sensitive to chlorpyrifos than were vertebrates (Moore et al. 1998). Significant differences in genotype frequencies of the glucose phosphate isomerase (P_{gi}) locus were observed between chlorpyrifos-susceptible and chlorpyrifos-tolerant groups of mosquitofish, *Gambusia affinis* (Hughes et al. 1991). In general, arthropods were the most sensitive group assayed and molluscs the most tolerant (Borthwick and Walsh 1981) (Table 14.3). Adult newts (*Triturus vulgaris*) had normal survival and activity patterns during exposure to 96 µg chlorpyrifos/L for 96 h (van Wijngaarden et al. 1993). The bullfrog (*Rana catesbeiana*) also appears to be comparatively tolerant to chlorpyrifos, as judged by a single oral LD₅₀ value of >400 mg/kg body weight (Hudson et al. 1984).

Sublethal effects of chlorpyrifos exposure have been documented for many species of freshwater and marine fauna. They include inhibition of cholinesterase (ChE) activity levels in brain and hematopoietic organs, reduction in blood glucose levels, sluggishness, motor incoordination, delayed maturation and growth, renal histopathology, reproductive impairment, and reduced feed intake (Rongsriyam et al. 1968; Thirugnanam and Forgash 1977; Marshall and Roberts 1978; Tagatz et al. 1982; Jarvinen et al. 1983; USEPA 1985, 1986; Goodman et al. 1985b; Norberg and Mount 1985; Hansen et al. 1986; Jarvinen et al. 1988; Srivastava et al. 1990; Jimenez and Pocsido et al. 1994; Holladay et al. 1996). Reproductive impairment, for example, was observed in *Daphnia magna* at 0.08 µg chlorpyrifos/L (USEPA 1985). Reduction in setting rate was shown in oyster larvae after exposure to 0.1 µg/L for 8 days (Tagatz et al. 1982). Equilibrium loss was documented in 50% of brown shrimp (*Penaeus aztecus*) after exposure to 0.32 µg chlorpyrifos/L for 24 hours (Marshall and Roberts 1978). Growth of the California grunion (*Leuresthes tenuis*) was reduced 20% in an early life stage during immersion in 0.5 µg chlorpyrifos/L for 35 days and 26% in fry after exposure to 1.0 µg/L for 26 days (Goodman et al. 1985b). Nile tilapia (*Oreochromis niloticus*) exposed to 1 µg/L for 3 months had renal pathology and disrupted immune function (Holladay et al. 1996). Larvae of fathead minnows exposed to 2.1 µg/L for 30 days had increased deformities at day 30, as did larvae exposed to 122 µg/L for 5 h (Jarvinen et al. 1988). Guppies exposed to 3 µg/L for 2 weeks had 80 to 90% inhibition of acetylcholinesterase within 2 weeks; partial recovery occurred after

4 days in clean water, but cholinesterase levels were still 56% inhibited after 14 days (van der Wel and Welling 1989). In fathead minnows exposed to 120 µg chlorpyrifos/L for 200 days, ChE activity was significantly reduced, fecundity was reduced, maturation delayed, and, in second-generation fish, growth and maturation were reduced (Jarvinen et al. 1983). Chlorpyrifos was associated with deformities in fathead minnows. Additional data on sublethal effects of chlorpyrifos to aquatic biota are listed elsewhere (USEPA 1986; Odenkirchen and Eisler 1988; Menconi and Paul 1994).

Bioconcentration factors for tilapia (*Oreochromis aureus*) for individual tissues ranged from 85 in muscle to 939 in liver; gills (497) and bile (517) were intermediate (Herzberg 1987). Bioconcentration of chlorpyrifos from the medium varied substantially among five species of fishes, but generally paralleled ambient levels of chlorpyrifos (Table 14.4). Increases in bioconcentration factors (BCF) in chlorpyrifos-exposed teleosts may be associated with three variables: increased metabolic rate, as indicated by hyperventilation, hyperactivity, and decreased growth; increased bioavailability of chlorpyrifos as a result of solvent-induced supersaturation or increased food availability; and decreased depuration rates due to possible physiological dysfunction (Goodman et al. 1985a, 1985b; Hansen et al. 1986). At high BCFs, adverse effects on growth and survival were observed in sheepshead minnow (*Cyprinodon variegatus*) by Cripe et al. (1986) and in Gulf toadfish (*Opsanus beta*) by Hansen et al. (1986). Chlorpyrifos is excreted rapidly from fish; the estimated Tb 1/2 for many species is 8.7 h, and equilibration occurs with the surrounding medium in 24 to 72 h (Smith et al. 1966; Blau and Neely 1975; Marshall and Roberts 1978). Higher Tb 1/2 values of 13.4 to 69.3 h were recorded for various species of freshwater fishes (Welling and de Vries 1992; Deneer 1994; Tsuda et al., 1994), with slow excretion rates associated with high BCF values (Tsuda et al. 1994) and impaired metabolic breakdown (Welling and de Vries 1992). No detectable chlorpyrifos residues were found after 12 days in 10 species of estuarine invertebrates — including oligochaete annelids, molluscs, and crustaceans — after treatment with 0.046 kg chlorpyrifos/ha (Marganian and Wall 1972).

14.3.2 Birds and Mammals

Signs of chlorpyrifos intoxication, as summarized by Hudson et al. (1984), include excessive blinking, hypoactivity, hyperexcitability, excessive drinking, muscular incoordination, rapid breathing, muscular weakness, tremors, piloerection (mammals) or fluffed feathers (birds), salivation, lacrimation, diarrhea, excessive urination, prostration, loss of righting reflex, spasms, tetany, coma, and convulsions. Death usually occurs between 1 h and 9 days after exposure. Chlorpyrifos oxon (*O,O*-diethyl-*O*-(3,5,6-trichloro-2-pyridyl) phosphate) is the active oxygen analog of chlorpyrifos and is probably responsible for most of the anticholinesterase mode of action of chlorpyrifos; the oxon is extensively and rapidly detoxified in mammalian liver via enzymatic hydrolysis by at least two microsomal esterases (Sultatos and Murphy 1983; USPHS 1995). Significant accumulations of chlorpyrifos were not detected in domestic turkeys (*Meleagris gallopavo*) and chickens. In birds kept in pens on soil treated with 4.5 to 9.0 kg active ingredients chlorpyrifos/ha, tissue residues were 0.16 mg/kg after 1 week; these decreased thereafter, although birds remained on the treated soil (Kenaga 1974).

LD50 values, based on a single oral dose, ranged from 5 to 157 mg chlorpyrifos/kg body weight (BW) in birds, and from 151 to 1000 in mammals. However, 7 of 14 avian species had reported LD50 values of <25.0 mg/kg BW (Table 14.5). As little as 2 mg/kg BW to nestling red-winged

blackbirds (*Agelaius phoeniceus*) was associated with reduced survival during the first 24-h post-exposure interval; however, nestling European starlings had normal survival when given a single oral dose of 2 mg/kg BW (Meyers et al. 1992). Many species of birds that survived chlorpyrifos poisoning showed gross pathological changes (Tucker and Crabtree 1970). Furthermore, the slope of the acute dose-response curve was low (Hudson et al. 1984). These findings suggest that decreasing dosage levels did not produce proportional decreases in response, and indicate a reduced safety margin for chlorpyrifos owing to mortalities that occur frequently at levels much lower than the calculated LD₅₀ values (Hudson et al. 1984).

^a 1, Schafer 1972; 2, Tucker and Haegle 1971; 3, Tucker and Crabtree 1970; 4, Hudson et al. 1984; 5, Hill and Camardese 1984; 6, Hudson et al. 1972; 7, Smith 1987; 8, Meyers et al. 1992; 9, Clements et al. 1992.

Reduction in cholinesterase activity levels of various tissues (blood, brain) is one of the earliest signs of chlorpyrifos intoxication. Cholinesterase reductions have been demonstrated in turkeys fed diets containing 50 mg chlorpyrifos/kg (estimated daily dose of 0.7 mg/kg BW) for 20 days (Schlinke et al. 1969); in chickens fed diets of 25 mg/kg (estimated daily dose of 0.94 mg/kg BW) for 20 days (Schlinke 1970); in quail (*Coturnix coturnix*) given a single (sublethal) esophageal

intubation of 13 mg/kg BW (Solar-Rodriguez et al. 1998); and in mallard (*Anas platyrhynchos*) ducklings fed 75 mg chlorpyrifos/kg diet for 14 days (Herin et al. 1978). Brain cholinesterase activity in quail was normal after 11 days despite 81% inhibition 8 h postadministration (Solar-Rodriguez et al. 1998). Low temperatures (27.5°C vs. 35°C) potentiated dose-related cholinesterase depression in juvenile northern bobwhite (*Colinus virginianus*), suggesting a need for more research on cold stress interactions between acute oral chlorpyrifos exposure (Maguire and Williams 1987). In adult female rats, brain cholinesterase activity was inhibited by as much as 96% following subcutaneous injection of 280 mg/kg BW; all survived without extensive signs of toxicity, but weight loss was evident 2 to 7 days after treatment (Liu and Pope 1998).

Dietary concentrations of 30 to 100 mg chlorpyrifos/kg feed produce some deaths in birds, and 136 to about 500 mg/kg feed usually kills at least 50% (Table 14.6). In chickens fed diets of 100 mg chlorpyrifos/kg — equivalent to an estimated daily dose of 6.8 mg/kg BW — egg fertility was reduced by 15% and hatchability by 17% (Schom et al. 1973). Dietary levels lethal to mallard ducklings were 136 to 180 mg/kg feed, equivalent to 10 mg/kg BW fed daily for 5 days (Kenaga 1974). In adult mallards given diets containing 80 mg chlorpyrifos/kg for 60 to 84 days, body weight, food consumption, brain cholinesterase activity levels, and egg production were all reduced. Moreover, egg weight and eggshell thickness were reduced, the resultant ducklings weighed less than controls, and survival was comparatively poor at age 7 days. No effect on any variable was observed at diets of 8 mg/kg (Gile and Meyers 1986; Meyers and Gile 1986).

Table 14.6 Dietary Toxicity of Chlorpyrifos to Selected Species of Birds

Species and Age (days)	Duration of Dietary Exposure (days)	Minimum Lethal Concentration (mg/kg diet)	LD50 (mg/kg diet)	Reference ^a

^a 1, Kenaga, 1974; 2, Hill et al. 1975; 3, Hill and Camardese 1986.

Dermal application routes are also toxic. Some deaths were recorded in turkeys from dermal treatments of 15 to 20 mg chlorpyrifos/kg BW (Schlinke et al. 1969). Higher levels applied to feathers killed turkeys within 8 h (Marshall and Roberts 1978). Newborn piglets (*Sus* spp.) were especially more sensitive than those 30 to 36 h old to cutaneous applications of chlorpyrifos;

newborns showed clinical signs consistent with organophosphorus toxicosis after a 2.5% aerosol preparation (dosage unknown) was applied to the tail and umbilicus (Long et al. 1986). Accidental poisoning of cattle (*Bos* spp.) by chlorpyrifos through dermal application to control ticks resulted in some deaths. Among bulls that survived, sperm production was reduced 43% in seriously affected animals and 12% in those with no outward signs of poisoning (Everett 1982).

Chlorpyrifos is not mutagenic, as judged by mitotic recombination assays (Poole et al. 1976), and did not increase sister chromatid exchange above background in tests with chick (*Gallus* spp.) embryos and Chinese hamster (*Cricetus* spp.) ovary cells (Muscarella et al. 1984). Chlorpyrifos altered serum cortisol and decreased thyroxine concentrations in sheep given oral doses of 12.5 mg chlorpyrifos/kg BW twice weekly for 43 days (Rawlings et al. 1998), indicating a need for more research on the role of chlorpyrifos in hormone metabolism.

Chlorpyrifos-impregnated ear tags are under development to control horn flies (*Haematobia irritans*) in U.S. cattle (Byford et al. 1986). Cattle fitted with ear tags (0.96 g chlorpyrifos per tag/365 kg animal, or about 2.6 mg chlorpyrifos/kg BW) had slightly elevated tissue residues (0.13 mg/kg fat) after 12 weeks, but residues were well within acceptable tolerance levels of 2.0 mg chlorpyrifos/kg fresh weight cattle fat, meat, or meat by-products (Byford et al. 1986). In dogs (*Canis familiaris*), chlorpyrifos-impregnated collars provided effective control of adult fleas (*Ctenocephalides* spp.) for up to 11 months, with no significant adverse reactions regardless of canine coat length, size, or age (Higgins and Jarvis 1986).

14.4 FIELD INVESTIGATIONS

There have been many accidental spills of chlorpyrifos, but little quantitative assessment of its environmental effects. One exception is a spill in April 1985 in England (Boreham and Birch 1987). In that instance, a truck overturned, spilling 205 L chlorpyrifos into an adjacent stream that drained into the Roding River. A resulting sharp decrease in the number and type of macroinvertebrate benthic organisms in affected parts of the river, compared to unaffected areas, lasted 6 months. In addition, certain chlorpyrifos-resistant benthic organisms were unusually abundant.

Chlorpyrifos controls mosquito larvae at applied dosages between 0.028 and 0.056 kg/ha, equivalent to 9 to 18 µg chlorpyrifos/L in 152 mm (6 inches) of water (Marshall and Roberts 1977; Eaton et al. 1985). In 1984 alone, chlorpyrifos was used for this purpose on about 600,000 ha (Odenkirchen 1987). Surface waters of ponds on golf courses in North Carolina often contain 7.2 to 11.5 µg chlorpyrifos/L as a result of turf treatment with chlorpyrifos (Ryals et al. 1998). At this time, no obvious deleterious effects of chlorpyrifos have been recorded in mammals, amphibians, or reptiles under field conditions of current use (Table 14.7). For example, bullfrogs (*Rana catesbeiana*) from an Iowa pond that received runoff from a 16-ha cornfield treated with the label rate of Lorsban 15G, when compared to a reference pond, had the same level of plasma activity and reactivation for total cholinesterase, acetylcholinesterase, and butylcholinesterase (Richards et al. 1999). However, at recommended dosage application rates for control of mosquitoes and other pestiferous insects (usually 0.028 to 0.056 kg/ha), adverse effects have been documented on survival, reproduction, metabolism, and species diversity of a variety of fishes, terrestrial and aquatic invertebrates, freshwater flora, waterfowl, and horned larks (*Eremophila alpestris*), and on the marketability of various crops (Mulla et al. 1971, 1973; Hurlbert et al. 1972; Macek et al. 1972; Nelson and Evans 1973; Hoy and Shea 1981) (Table 14.7). For example, field populations of daphnids (*Daphnia pulex*) were reduced 50% by 0.38 µg chlorpyrifos/L after 2 days and by 0.25 µg/L in 7 days; similar values were found in laboratory populations of this species (van der Hoeven and Gerritsen 1997). It is emphasized that the effectiveness of chlorpyrifos under field conditions, like that of other organophosphorus pesticides, is significantly modified by numerous variables such as formulation, route of administration, pond substrate, dose, and water temperature (Macek et al. 1969; Bailey et al. 1970; Rawn et al. 1978; Odenkirchen 1987).

Table 14.7 Chlorpyrifos Effects on Selected Ecosystems

Ecosystem and Other Information	Application Rate and Other Variables	Effects and Reference
AQUATIC		
Lake	0.004 kg/ha, emulsifiable concentrate, oil diluent single application	After 24 h, aquatic insect populations reduced 14–40% and snails reduced 10% (Moore and Breeland 1967)
Freshwater ponds, (8 m × 17 m × 0.3 m deep)	Individual applications of 0.011, 0.056, 0.11, or 1.11 kg/ha; 4 applications at 2-week intervals	Initial population inhibition of mosquitofish (<i>Gambusia</i> sp.), but reproduction resumed except for 1.11 kg/ha group. Fish whole-body residues in 0.056 kg/ha group, in mg/kg body weight, were 2.8 at 4 h, 1.7 at 24 h, and 0.1 after 2 weeks. Insect and zooplankton populations reduced >92%; little recovery was evident after third treatment. The 0.056 kg/ha treatment regimen, at 4 h, resulted in residues of 10 µg/L in water, 375 µg/kg in vegetation, and nondetectable levels in mud; at 14 days, all residues were nondetectable (Hurlbert et al. 1970)
Freshwater ponds (8 m × 17 m × 0.3 m deep)	Individual applications of 0.011, 0.056, 0.11 and 1.11 kg/ha; 4 applications at 2-week intervals	High mortality (>42%) of mallard (<i>Anas platyrhynchos</i>) ducklings on all treated ponds, vs. none dead on control ponds (Hurlbert et al. 1970)
Freshwater lake	0.014 kg/ha (equivalent to about 1.2 µg/L), single application	Freshwater algae (<i>Ankistrodesmus</i> sp., <i>Tetraedron</i> sp.) reduced 30–90% 7 days posttreatment; reduced population growth evident 1 year postapplication (Brown et al. 1976)
Flooded rice field	Individual applications of 0.014–0.019 kg/ha, emulsifiable concentrate, oil diluent, 3 applications at 5-week intervals	Mortality after 72 h, 32% in caged bluegills (<i>Lepomis macrochirus</i>), 50 to 70% in mayfly nymphs (<i>Siphlonurus</i> sp.), and 32% in predatory diving beetles (Washino et al. 1972)
Artificial lake	0.02 kg/ha, granular formulation, single application	Chironomid larvae population remained >90% depressed for 5 months (Mulla et al. 1971)
Salt marsh	0.025 kg/ha, single application	No gross effects on wildlife (Ludwig et al. 1968)
Salt marsh	0.028 kg/ha (0.025 lbs/acre), single aerial application, mosquito larvicide granules	No observable effects on caged blue crabs (<i>Callinectes sapidus</i>), penaeid shrimp, or fishes; some fiddler crabs (<i>Uca</i> sp.) dead (USFWS 1968)
Salt marsh	Individual applications of 0.028 kg/ha, 4 applications at 2-week intervals	In killifish (<i>Fundulus heteroclitus</i>), convulsions, ChE depression, and deaths noted. ChE remained depressed for about 10 weeks after final application (Thirugnanam and Forgash 1977)
Shallow pond, mean depth 0.25 m, surface area 0.11 ha, high vegetation	Individual applications of 0.056 kg/ha technical grade, 2 applications at 34-day interval	After 63 days, 46–55% mortality in centrarchid populations, and 75% reduction in insect populations of caddisflies, mayflies, and midges (Macek et al. 1972)
Shallow ponds	0.056 kg/ha, emulsifiable concentrate, oil diluent single application	All caged green sunfish (<i>Lepomis cyanellus</i>) died (Linn 1968)
Woodland pools	Single application of 0.056 kg/ha, granular formulation	Increased algal growth on leaf litter observed months after treatment, attributed to reduction in grazing stress by mosquito larvae (Hagmann and Porteus 1972)
Woodland pools	0.056 kg/ha, granular formulation, single application	Isopod populations reduced 90–95% (Cooney and Pickard 1974)
Salt marsh, 202 ha (500 acres)	0.56 kg/ha (0.5 lb/acre), single application applied as aerial spray, to kill mosquito larvae	Killed significant numbers of fishes and crustaceans (USFWS 1968)
Salt marsh, 78 ha plot	0.56 kg/ha, emulsifiable concentrate, once, aerially	After 48 h, mortality was 35% in caged fish and 84% in caged shrimp; no other adverse effects were noted during the next 27 days (Wall and Marganian 1971)

Table 14.7 (continued) Chlorpyrifos Effects on Selected Ecosystems

Ecosystem and Other Information	Application Rate and Other Variables	Effects and Reference
Salt marsh estuary, Bay St. Louis, Mississippi, 408 ha site (1008 acres)	0.56 kg/ha (0.5 lb/ acre), granular, single aerial application, for mosquito control	After spraying, all caged fiddler crabs died, white shrimp (<i>Penaeus setiferus</i>) populations were reduced, and large numbers of blue crabs were found dead. No observable effects on terrestrial organisms, including insects. One month after spraying, shrimp and blue crab populations seemed normal, although fiddler crabs were absent (USFWS 1967)
Artificial streams, each 520 m long, 0.14 ha of surface area, with pools 30.5 m long × 3.6 m wide × 81 cm deep	Continuous treatment stream received 0.22 µg chlorpyrifos/L for days 1 to 41, and 1.0 µg/L from days 41–100. Intermittent treatment stream received dosage 14 times higher than continuous treatment stream, but dosage was confined to 24 h every 14 days. Chlorpyrifos administered as emulsifiable concentrate in petroleum derivative solvent	When compared to control stream, no effect on total abundance of benthic organisms. However, in both treated streams, species diversity decreased by equal amounts and was still decreasing at day 100. Adverse sublethal effects were noted in fathead minnow, <i>Pimephales promelas</i> (spinal deformities) and bluegills (cholinesterase inhibition, signs of organophosphorus poisoning) only in the pulse-dosed stream. In all streams, however, fish survived, grew, and reproduced equally well (Eaton et al. 1985)
Outdoor ponds, Minnesota, June	Single dose of 0.5, 5, or 20 µg/L; observed for 30 days	Larvae of fathead minnows had dose-dependent growth inhibition (controls grew 8.3% and high-dose group 3.1%) and seemed related to reductions in crustacean and rotifer populations in the treated enclosures. Chlorpyrifos in high-dose enclosure was <3 µg/L at 96 h and <0.16 µg/L at day 30 (Brazner and Kline 1990)
Temporary woodland pool	Average maximum water concentration of 1.6 µg chlorpyrifos/L	No obvious adverse effects on wildlife (i.e., 3 spp. of rodents, 1 sp. frog, 1 sp. turtle (Nelson and Evans 1973)
Freshwater ponds	Single dose of chlorpyrifos, equivalent to 4, 10, or 1000 µg/L	Increased algal bloom duration in treated ponds, possibly due to loss of grazing fauna (Butcher et al. 1977)
Freshwater pond	Single application of pelletized 10.6% chlorpyrifos to obtain theoretical water concentrations of 250 µg/L and higher	Species diversity of diatoms reduced >50% in 6 weeks, vs. 12% increase in controls (Nelson et al. 1976)
TERRESTRIAL		
Rice field area	0.029 kg/ha, single application	All honeybees (<i>Apis</i> sp.) within 0.4 km downwind of spray area were dead; 95% were dead at 0.8 km and 89% at 1.2 km (Atkins 1972)
Savannah region of Senegal; 1989	0.27 and 0.39 kg/ha to control desert locust (<i>Schistocerca gregaria</i>) and Senegalese grasshopper (<i>Oedaleus senegalensis</i>)	Total bird numbers on treated plots decreased. Some of the decrease (2–3%) was due to death, but most represented movements of birds in reaction to a reduction in their arthropod food. Brain cholinesterase levels in several avian species were depressed 1 week posttreatment (Mullie and Keith 1993)
New Mexico ranchlands	Dust formulations of 0.48 and 1.97 kg/ha, to control wildlife flea populations	No observable deleterious effects in rodents and rabbits 3–4 weeks posttreatment (Miller et al. 1970)
Wheat fields	0.56 and 1.0 kg/ha, to control pale western cutworm (<i>Agrotis orthogonia</i>)	Horned larks (<i>Eremophila alpestris</i>) had brain cholinesterase activity levels depressed 22% at 3 days posttreatment, and 8% at 16 days. No sick or dead birds found; however, no systematic searches were made for the small lark carcasses, nor were specific observations for toxic signs conducted (McEwen et al. 1986)

Table 14.7 (continued) Chlorpyrifos Effects on Selected Ecosystems

Ecosystem and Other Information	Application Rate and Other Variables	Effects and Reference
Perennial rye (<i>Lolium perenne</i>) grasslands in United Kingdom infested with 3–6 million leatherjackets (<i>Tipula</i> spp.)/ha	0.72 kg active ingredients per hectare; single application; posttreatment effects on earthworms, birds, and mammals measured up to 14 days after spraying	Almost all leatherjackets were dead 14 days after spraying; maximum chlorpyrifos residues in leatherjackets was 1.2 mg/kg FW at day 10 postspray vs. 0.02 in controls. All earthworms were alive and active when collected. No adverse effects on nesting or feeding territorial birds including carrion crows (<i>Corvus corone</i>), ring-necked pheasant (<i>Phasianus colchicus</i>), magpies (<i>Pica pica</i>), blackbirds (<i>Turdus merula</i>), wood pigeons (<i>Columba palumbus</i>), and buzzards (<i>Buteo buteo</i>). Mammals seemed normal, including brown hares (<i>Lepus capensis</i>), rabbits (<i>Oryctolagus cuniculus</i>), and roe deer (<i>Capreolus capreolus</i>) (Clements and Bole 1988)
Pasturelands where Brent geese (<i>Branta bernicla</i>) and Canada geese (<i>Branta canadensis</i>) were grazing	Single application of 0.72 kg/ha	No perceptible effect on goose behavior (activity, pecking rate) after spraying. Maximum residues in herbage were 20.4 mg/kg 3 days after spraying and 10 mg/kg FW in goose feces 4 days after spraying; residues were <0.05 mg/kg within 10 days (Clements et al. 1992)
Iraqi date palm (<i>Phoenix</i> sp.) orchards	Emulsifiable concentrate applied once after fruiting and infestation with high-pressure ground sprayers at 0.98 kg/ha to control insect pests	Chlorpyrifos residues in dates decreased from 1.28 mg/kg fresh weight at day 1 postapplication to 0.2 mg/kg on day 15, to 0.05 on day 29, and to nondetectable concentrations on day 71. Concentrations of the chlorpyrifos oxygen analog, however, after reaching a peak of 0.5 mg/kg on day 15, were still detectable (0.1 mg/kg) at day 85, suggesting that dates should be harvested at least 8 weeks after chlorpyrifos treatment (Mansour 1985)
Turf	1.12 kg/ha, emulsifiable concentrate, single application, to control chinch bug (<i>Blissus leucopterus listus</i>)	Most arthropods in turf killed immediately after application. Target pest populations remained depressed for 1 year posttreatment, but other insect populations recovered to levels greater than controls after 3.5 months (Streu and Cruz 1972)
Citrus groves; 3 blocks of 4 groves each	One block received up to 3.93 kg/ha of Lorsban 4E postbloom; a second block received up to 6.73 kg/ha postpetal; the third block was not treated	A total of 58 dead vertebrate animals (birds, amphibians, reptiles, mammals) were found on the first block, 39 on the second block, and 50 from the reference site. Authors concluded that risk to wildlife is low (Mortenson et al. 1999)

14.5 RECOMMENDATIONS

Water quality criteria formulated for chlorpyrifos (USEPA 1986; USPHS 1995) and aquatic life protection seem to afford a reasonable degree of safety, at least during short-term exposure. Specifically, the proposed criteria for freshwater are 0.041 µg/L (4-day average concentration) and 0.083 µg/L (1-h average concentration), neither of which should be exceeded more than once every 3 years. For saltwater, these criteria are 0.0056 µg/L and 0.011 µg/L, respectively. Levels of chlorpyrifos in the Sacramento–San Joaquin River system proposed by the state of California to protect aquatic life during chronic exposure are <0.02 µg/L in freshwater and <0.01 µg/L in saltwater (Menconi and Paul 1994). However, concentrations of chlorpyrifos in the San Joaquin River during 1991 to 1993 ranged between 0.01 and 1.6 µg/L (Menconi and Paul 1994) and suggest that California's stringent water quality criteria proposed for chlorpyrifos should be reexamined. Proposed chlorpyrifos drinking water criteria by some agencies to protect human health are significantly higher than those recommended

for aquatic life protection: 21 µg/L in Vermont, 30 µg/L to protect children in lifetime exposure in the United States, 90 µg/L in Canada, and 100 µg/L to protect adults in the United States (USPHS 1995).

The acceptable tolerance level of chlorpyrifos in meat and meat by-products destined for human consumption is 2.0 mg/kg fresh weight (Byford et al. 1986), and for agriculture products it usually ranges between 0.05 and 15.0 mg/kg FW and up to 25.0 mg/kg for citrus oil (USPHS 1995). The significance of these concentrations to animal health, or to consumers other than man, is unknown. More research is needed to establish maximum tolerable chlorpyrifos limits in tissues of sensitive fish and wildlife. Proposed air criteria for chlorpyrifos and human health include 200 µg/m³ in the workplace, and much lower concentrations of 0.48 to 3.3 µg/m³ in nonoccupational settings (USPHS 1995). No air criteria are currently available or proposed for protection of wildlife.

Information is lacking on the effectiveness of chlorpyrifos in large-scale (>40 ha) coldwater ecosystems, typical of those found in Alaska or northern-tier states. Accordingly, initiation of long-term studies in these potential problem areas are recommended. As judged by the available literature, three courses of action now seem warranted.

1. Restrict the use of chlorpyrifos for mosquito control in wetlands, estuaries, and waterfowl breeding areas because recommended treatment levels are demonstrably harmful to nontarget species, including mallard ducklings. The unsuitability of chlorpyrifos for mosquito control is further supported by the finding that certain mosquito populations in California are showing signs of chlorpyrifos resistance, and thus may require more aggressive future treatment programs (Reisen et al. 1984).
2. Curtail agricultural use of chlorpyrifos in watershed areas pending acquisition of additional data on its transport, fate, and effects, including data on chlorpyrifos flux rates from soils and sediments and its resultant bioavailability.
3. Develop suitable replacements for chlorpyrifos in mosquito control programs. These replacement compounds should exhibit a relatively long half-life in aquatic environments while avoiding the broad-spectrum toxicity typical of chlorpyrifos to large numbers of nontarget organisms.

14.6 SUMMARY

Chlorpyrifos (phosphorothioic acid *O,O*-diethyl-*O*-(3,5,6,-trichloro-2-pyridinyl) ester), an organophosphorus compound with an anticholinesterase mode of action, is used extensively in a variety of formulations to control a broad spectrum of agricultural and other pestiferous insects. Domestic use of chlorpyrifos in 1982 was about 3.6 million kg; the compound is used mostly in agriculture, but also to control mosquitoes in wetlands (0.15 million kg applied to about 600,000 ha) and turf-destroying insects on golf courses (0.04 million kg). Accidental or careless applications of chlorpyrifos have resulted in the death of many species of nontarget organisms such as fish, aquatic invertebrates, birds, and humans. Applications at recommended rates of 0.028 to 0.056 kg/surface ha for mosquito control have produced mortality, bioaccumulation, and deleterious sublethal effects in aquatic plants, zooplankton, insects, rotifers, crustaceans, waterfowl, and fish. Adverse effects were also noted in bordering invertebrate populations.

Degradation rate of chlorpyrifos in abiotic substrates varies, ranging from about 1 week in seawater (50% degradation) to more than 24 weeks in soils under conditions of dryness, low temperatures, reduced microbial activity, and low organic content. Intermediate degradation rates reported have been 3.4 weeks for sediments and 7.6 weeks for distilled water. In biological samples, degradation time is comparatively short — usually less than 9 h in fishes and probably the same in birds and invertebrates.

Chlorpyrifos is acutely toxic to some species of aquatic invertebrates and teleosts at nominal water concentrations ranging between 0.04 and 1.1 µg/L. Acute single-dose oral LD₅₀ values of chlorpyrifos to susceptible avian species ranged from 5 to 13 mg/kg body weight. Mammals were comparatively tolerant of chlorpyrifos: acute oral LD₅₀ values were reported to be 151 mg/kg body weight and higher. Lethal dietary concentrations for sensitive species of birds ranged from 30 to

50 mg chlorpyrifos/kg food. Sublethal effects were recorded in all species of organisms examined at concentrations below those causing mortality. These effects included bioconcentration from the medium by teleosts (410 to 1000); cholinesterase activity reduction in brain and hematopoietic tissues; reduced growth; impaired reproduction, including sterility and developmental abnormalities; motor incoordination; convulsions; and depressed population densities of aquatic invertebrates.

Three courses of action are recommended:

1. Restrict the use of chlorpyrifos for mosquito control in wetlands, estuaries, and waterfowl breeding areas because recommended treatment levels are demonstrably harmful to nontarget resident biota.
2. Curtail agricultural use in watershed areas pending acquisition of additional data on chlorpyrifos toxicokinetics.
3. Develop suitable replacements for chlorpyrifos in mosquito control programs; specifically, pesticides with more specificity to target organisms and lower toxicity to nontarget biota.

CHAPTER 15

Cyanide

15.1 INTRODUCTION

The origin of terrestrial life probably depended on the presence and reactivity of hydrogen cyanide and its derivatives. Paradoxically, hydrogen cyanide is toxic to the majority of living matter (Marrs and Ballantyne 1987). Cyanide is a general respiratory poison — although uptake can also occur through ingestion or dermal absorption — producing reactions within seconds and death within minutes (Towill et al. 1978; U.S. Environmental Protection Agency [USEPA] 1980). The toxic mechanism of cyanide primarily involves the inhibition of cytochrome oxidase, the terminal oxidative enzyme of the mitochondrial electron transport chain, producing blockage of aerobic ATP synthesis (Egekeze and Oehme 1979; Younes and Strubelt 1988). Because of their highly effective lethal potency, cyanides were used for genocidal programs in Germany in World War II, in mass suicides by members of the People's Temple religious sect in Guyana, and in the substitution of medication in Tylenol® capsules in drugstores in various cities in the United States. In fact, cyanides are responsible for more human deaths than any other chemicals known, owing to their deliberate use in suicide, murder, chemical warfare, genocide, and judicial execution (Way 1981, 1984; Ballantyne and Marrs 1987; Gee 1987; Marrs and Ballantyne 1987; Yamamoto 1989). High sublethal doses of cyanide are rapidly detoxified, and accidental acute cyanide poisonings in humans are uncommon (Towill et al. 1978).

Cyanide compounds are useful to society in terms of their key role in synthetic and industrial processes, for certain fumigation and agricultural uses, and for some therapeutic applications (Ballantyne and Marrs 1987). Cyanides are present in effluents from iron and steel processing plants, petroleum refineries, and metal-plating plants, and constitute a hazard to aquatic ecosystems in certain waste-receiving waters (Smith et al. 1979) and to livestock (USEPA 1980; Towill et al. 1978). Cyanide serves no useful purpose in the human body, yet it is present in our food, air, and water (Becker 1985).

Natural sources of cyanide include various species of bacteria, algae, fungi, and higher plants that form and excrete cyanide (Way 1984). The most widely distributed major food crop with a high content of cyanogenic glycosides is cassava (*Manihot esculenta*), also known as manioc. Cassava is a food staple in human diets in over 80 countries, and it is sometimes added to animal feeds as a substitute for more expensive cereal grains (Gomez et al. 1988). In humans, chronic cyanide intoxication caused by consumption of cassava is the main etiological factor in the debilitating tropical ataxic neuropathy (Egekeze and Oehme 1980). Other plants having comparatively elevated cyanide content include fruit pits, sweet potatoes (*Ipomoea batatas*), corn (*Zea mays*), bamboo shoots (*Bambos* spp.), linseed (*Linum* sp.), lima beans (*Phaseolus lunatus*), and millet (*Panicum millaceum*) (Way 1984). In higher plants that contain cyanogenic glycosides, at least 20 of these compounds have been identified (USEPA 1980). Amygdalin — one of the more intensively

studied cyanogenic glycosides — is found in seeds of the cherry (*Prunus* spp.), plum (*Prunus* spp.), peach (*Prunus persica*), apricot (*Prunus armeniaca*), apple (*Malus malus*), pear (*Pyrus communis*), and many parts of the cherry laurel (*Prunus laurocerasus*) (USEPA 1980). Apricot seeds and peach kernels are food delicacies in Turkey and have caused at least nine poisonings (two fatal) in children from that country (Gee 1987). Acute cyanide poisoning has occurred in the United States from the ingestion of almond-flavored milkshakes prepared from apricot kernels (Way 1984). Amygdalin is also the chief ingredient in laetrile, a medication prescribed by some physicians to control tumors. Both laetrile and amygdalin-containing fruit pits have been implicated as the causes of acute cyanide poisoning in humans (USEPA 1980). Another naturally occurring group of organic cyanides (nitriles) is the highly toxic pseudocyanogenic glycosides, especially cycasin, and these have been implicated in a variety of tropical diseases of the nervous system, and partial or total blindness (USEPA 1980). Other nitriles found in plants include the lathyrogenic compounds, glucosinolates, and the cyanopyridine alkaloids (USEPA 1980).

The recognition that certain plants, such as bitter almonds (*Amygdalus communis*), cherry laurel leaves, and cassava, are poisonous if consumed in sufficient quantities has been known for at least 2000 years. But it was not until the 1700s that cyanide was recognized as the basis for their lethal toxicity. The first account of an experimental administration of extract of bitter almonds and other poisons to dogs (*Canis familiaris*) dates from 1679, as reviewed by Sykes (1981) and Ballantyne (1987a). In 1731, two fatal cases of human poisoning in Ireland were caused by drinking cherry laurel water, in this instance used as a flavoring agent in cooking and to dilute brandy. In that same year, it was shown that cherry laurel water administered to dogs by various routes proved rapidly fatal. By 1781, it was well established that mammals, birds, reptiles, amphibians, fish, and insects could all be killed with small doses of laurel water, and that death was more rapid than that produced by other poisons tested. It was also at this time that cyanide was first implicated as a homicidal agent in England. In 1782, hydrocyanic acid was isolated from Prussian blue (a dye) by the Swedish chemist Scheele. In 1786, Scheele accidentally broke a vial of the material and died from vapor poisoning. In 1787, it was determined that hydrocyanic acid contained hydrogen, carbon, and nitrogen, but did not contain oxygen, formerly believed to be an essential component of all acids. Between 1802 and 1815, hydrocyanic acid was found to be lethal in small quantities to birds and dogs, and to act rapidly when given orally, intravenously, or applied to the eye surface. By 1803, it was known that cyanide occurred naturally and could be extracted from apricots or almonds. In 1815, hydrocyanic acid was prepared in a semipure form. Between 1817 and 1948, cyanide, in appropriate doses, was used therapeutically in England for the treatment of pulmonary diseases, tuberculosis, and as a sedative. By 1830, cyanogenic glycosides containing HCN were isolated from cassava. Today, more than 800 species of cyanogenic plants have been identified. In 1876, it was first demonstrated that cyanide inhibited tissue oxidation. In 1894, cobalt compounds were suggested as antidotes due to their marked cyanide-binding capacity. Studies on cyanide detoxification conducted between 1877 and 1894 showed that thiosulfate administration caused the formation of thiocyanate — a relatively harmless metabolite. By the late 1800s, cyanide was regarded as a common plant metabolite rather than as an unusual poison. In 1929, it was conclusively demonstrated that cyanide combines with the trivalent iron atom in cytochrome oxidase, a respiratory enzyme that links the tricarboxylic acid cycle and formation of metabolic water. Many reviews have been published on cyanide in the environment. Particularly useful were those by Doudoroff (1976), Towill et al. (1978), Smith et al. (1979), Egekeze and Oehme (1980), USEPA (1980, 1989), Vennesland et al. (1981), Leduc et al. (1982), Leduc (1984), Way (1984), Ballantyne and Marrs (1987), Evered and Harnett (1988), Eisler (1991), Smith and Mudder (1991), U.S. Public Health Service [USPHS] (1995); Hill and Henry (1996), and Ripley et al. (1996).

Cyanide hazards to fish, wildlife, and livestock are well documented. Massive kills of freshwater fish by accidental discharges of cyanide wastes are fairly common (Holden and Marsden 1964; Leduc 1978; Towill et al. 1978; USEPA 1980; Albersworth et al. 1989; Ripley et al. 1996). In one case, cyanide-containing mine effluents from a Canadian tailings pond released into a nearby creek

killed more than 20,000 steelhead (*Oncorhynchus mykiss*) (Leduc et al. 1982). Many species of birds were found dead near burrows of the black-tailed prairie dog (*Cynomys ludovicianus*) after the burrows had been treated with calcium cyanide to control prairie dog populations; dead birds included the burrowing owl (*Athene cunicularia*), the bald eagle (*Haliaeetus leucocephalus*), and the golden eagle (*Aquila chrysaetos*) (Wiemeyer et al. 1986). An endangered California condor (*Gymnogyps californianus*) found dead in Kern County, California, in November 1983 had particles of a yellow fluorescent tracer in its mouth; these particles were similar to those mixed with sodium cyanide (NaCN) in M-44 spring-loaded ejector mechanism devices used in a U.S. Fish and Wildlife Service Animal Damage Control Program in that vicinity, suggesting that cyanide was a possible cause of death (Krynnitsky et al. 1986). M-44 devices are known to have caused the death of magpies (*Pica* spp.), ravens and crows (*Corvus* spp.), wild turkeys (*Meleagris gallopavo*), and various unidentified species of hawks and vultures (Wiemeyer et al. 1986). Between 1980 and 1989, 519 mammals — mostly rodents (35%) and bats (34%) — were found dead at cyanide-extraction, gold-mine leach ponds in California, Nevada, and Arizona. The list included coyote (*Canis latrans*), foxes, skunks, badger (*Taxidea taxus*), weasels, rabbits, deer, and beavers (Clark and Hothem 1991). Also found dead at these same leach ponds were 38 reptiles, 55 amphibians, and 6997 birds, including many species of waterfowl and songbirds (Allen 1990; Clark and Hothem 1991; Henny et al. 1994; Hill and Henry 1996).

The major threat of cyanide poisoning to livestock and terrestrial mammalian wildlife is through ingestion of plants containing high levels of cyanogenic glycosides (Towill et al. 1978; Marrs and Ballantyne 1987). Plants implicated in cyanide poisoning of animals include the sorghums (Johnson grass, *Sorghum halepense*; Sudan grass, *Sorghum alnum*), arrowgrass (*Triglochin* spp.), elderberry (*Sambucus* spp.), wild cherry (*Prunus* spp.), and the pits of several common fruits, such as apple, peach, and apricot. These plants and fruit pits have the potential of releasing cyanide upon ingestion (Egekeze and Oehme 1980). Domestic goats (*Capra* spp.) died of cyanide poisoning after eating leaves and fruit of the crab apple (*Malus sylvestris*). The crab apple contains cyanogenic glycosides in its leaves and fruit (Shaw 1986). Cyanide poisoning of cattle (*Bos* spp.) by forage sorghums and various hybrid cultivars has been reported in India (Bapat and Abhyankar 1984) and elsewhere (Cade and Rubira 1982; Biehl 1984). Cattle appear to be more vulnerable to cyanide poisoning than sheep (*Ovis aries*), horses (*Equus cabalus*), and pigs (*Sus* spp.) (Cade and Rubira 1982). Equine sorghum cystitis ataxia is a condition observed in horses grazing *Sorghum* or hybrid Sudan grass pastures; it is characterized by urinary incontinence, posterior incoordination, and degenerative central nervous system lesions (Egekeze and Oehme 1980). Grazing cyanogenic plants can induce sulfur deficiency in sheep, presumably because sulfur detoxifies the released cyanide (Towill et al. 1978). The increasing use of cassava and other cyanogenic plants in animal feeding portends a greater exposure to dietary cyanides (Davis 1981).

15.2 CHEMICAL PROPERTIES

The chemical speciation of cyanides varies according to their source. Specific terms used to describe cyanide include free cyanide, cyanide ion, simple cyanides, complex cyanides, nitriles, cyanogens, and total cyanide. The most common forms of cyanide in the environment are free cyanide, metallocyanide complexes, and synthetic nitriles. A brief description of each cyanide species follows (Smith et al. 1978, 1979; Towill et al. 1978; Egekeze and Oehme 1980; USEPA 1980, 1989; Davis 1981; Leduc 1981, 1984; Leduc et al. 1982; Simovic and Snodgrass 1985; Ballantyne 1987a; Homan 1987; Marrs and Ballantyne 1987).

Free cyanide is the primary toxic agent in the aquatic environment. Free cyanide refers to the sum of molecular HCN and the cyanide anion (CN^-), regardless of origin. In aqueous solution with pH 9.2 and lower, the majority of the free cyanide is in the form of molecular HCN. The chemical names for HCN include hydrogen cyanide, hydrocyanic acid, cyanohydric acid, and prussic acid.

Table 15.1 Some Properties of Potassium Cyanide, Hydrogen Cyanide, and Sodium Cyanide

Property	Potassium Cyanide	Hydrogen Cyanide	Sodium Cyanide
CAS number	151-50-8	74-90-8	143-33-9
Chemical formula	KCN	HCN	NaCN
Molecular weight	65.12	27.03	49.01
Physical state	Solid	Gas or liquid	Solid
Boiling point (°C)	—	25.7	1496
Melting point (°C)	634.5	-13.21	563.7
Specific gravity	1.5	0.7 (liquid)	1.6
Solubility in water (g/L)	716 at 20°C	Miscible	480 at 10°C

Data from U.S. Environmental Protection Agency (USEPA). 1989. Cyanide. *Rev. Environ. Contam. Toxicol.* 107:53-64.

Hydrogen cyanide (Table 15.1) is a colorless, flammable liquid or gas that boils at 25.7°C and freezes at minus 13.2°C. The gas rarely occurs in nature, is lighter than air, and diffuses rapidly. It is usually prepared commercially from ammonia and methane at elevated temperatures with a platinum catalyst. It is miscible with water and alcohol, but is only slightly soluble in ether. In water, HCN is a weak acid with the ratio of HCN to CN⁻ about 100 at pH 7.2, 10 at pH 8.2, and 1 at pH 9.2. HCN can dissociate into H⁺ and CN⁻. Cyanide ion, or free cyanide ion, refers to the anion CN⁻ derived from hydrocyanic acid in solution, in equilibrium with simple or complexed cyanide molecules. Cyanide ions resemble halide ions in several ways and are sometimes referred to as "pseudohalide" ions. For example, silver cyanide is almost insoluble in water, as are silver halides. Cyanide ions also form stable complexes with many metals.

Simple cyanides typically refer to alkali water-soluble salts, such as NaCN, KCN, Ca(CN)₂, and Hg(CN)₂, but also include several cyanide salts of alkali, alkaline earth, or heavy metals, that is, Zn(CN)₂, Cd(CN)₂, Ni(CN)₂, and AgCN, of varying degrees of solubility. In water, NaCN and KCN will completely dissociate to give free cyanide. All simple cyanides ionize in water to release cyanide ion which, depending on pH, will form hydrocyanic acid. For sodium cyanide, the reaction proceeds as follows:

Increased pH will maintain a larger fraction of the cyanide as CN⁻, and acidification will cause the reverse. At pH 7, about 99% of the free cyanide is in the form of HCN; whereas at pH 9.3, HCN composes 50%. Since HCN is extremely water soluble and is also one of the most toxic cyanide species, it is noteworthy that the toxicity of simple cyanides will not be affected measurably below pH 8.3.

Complex cyanides are compounds in which the cyanide anion is incorporated into a complex or complexes. These compounds are different in chemical and toxicologic properties from simple cyanides. In solution, the stability of the cyanide complex varies with the type of cation and the complex that it forms. Some of these are dissociable in weak acids to give free cyanide and a cation, while other complexes require much stronger acidic conditions for dissociation. The least-stable complex metallocyanides include Zn(CN)₄²⁻, Cd(CN)₃⁻, and Cd(CN)₄²⁻; moderately stable complexes include Cu(CN)₂⁻, Cu(CN)₃²⁻, Ni(CN)₄²⁻, and Ag(CN)₂⁻; and the most stable complexes include Fe(CN)₆⁴⁻, and Co(CN)₆⁴⁻. The toxicity of complex cyanides is usually related to their ability to release cyanide ions in solution, which then enter into an equilibrium with HCN; relatively small fluctuations in pH significantly affect their biocidal properties.

Cyanogen [$(CN)_2$] is the simplest compound containing the cyanide group. Cyanogen is an extremely toxic, flammable gas that reacts slowly with water to form HCN, cyanic acid, and other compounds. It is rapidly degraded in the environment. Cyanogen and its halide derivations are comparable to hydrogen cyanide in toxicity.

Nitriles are defined as organic compounds (RCN) containing the cyanide group. Cyanide bound to carbon as nitriles (other than as cyanogenic glycosides) are comparatively innocuous in the environment, are low in chemical reactivity, and are biodegradable. For simple mononitriles, there is a clear progression, with more cyanide being released as chain length increases. A similar pattern exists in dinitriles, but corresponding compounds require a longer carbon chain than mononitriles before free cyanide is produced. Based on studies with chicken liver homogenates (Davis 1981), mononitriles were more toxic than dinitriles, and within each group the order of toxicity was $CH_3 > C_2H_5 > C_3H_7 > C_4H_9 > C_5H_{11} > C_7H_{15}$. Cyanohydrins [$R_2C(OH)CN$] and cyanogenic glycosides [$R_1R_2C(OR_3)CN$] are special classes of nitriles, in that under appropriate conditions they will decompose to HCN and cyanide ions. Cyanogens (not to be confused with cyanogen), such as acrylonitrile, priopionitrile, and succinonitrile, are nitrile-containing materials of varying complexity and lability, and can liberate free and toxicologically available amounts of cyanide. But the non-nitrile portion of the cyanogen molecule may exert an independent or interactive toxicity, causing a complex response.

Cyanates contain the OCN group. Inorganic cyanates that are formed industrially by the oxidation of cyanide salts hydrolyze in water to form ammonia and bicarbonate ion. Alkyl cyanates are insoluble in water and form cyanurates. Alkyl isocyanates contain the OCN radical, are formed from cyanates, and, like cyanates, are readily hydrolyzed. Thiocyanates (SCN group) are formed from cyanides and sulfur-containing materials and are relatively stable.

Total cyanides refers to all cyanide-containing compounds, including simple and complex cyanides, cyanoglycosides, and free cyanide. Total cyanides is a chemical measurement of free cyanide present in solution or released by acidification or digestion. Only free cyanide is considered to be a biologically meaningful expression of cyanide toxicity. Under most circumstances, the concentration of total cyanide will exceed that of HCN. In some waters, however, the total cyanide concentration may consist almost entirely of free cyanide, or it may contain cyanides that readily photodecompose or dissociate to yield HCN. The relation between total cyanide and free cyanide in natural waters varies with receiving-water conditions, type of cyanide compounds present, degree of exposure to daylight, and presence of other chemical compounds.

Hydrogen cyanide has frequently been associated with the odor of bitter almonds (Ballantyne 1983; Gee 1987). The threshold odor for olfactory detection of atmospheric HCN is 1 mg/L, but the odor may not be detected for various reasons, including the presence of other odors and the fact that only 20 to 40% of those tested could detect a cyanide odor.

Analytical methods for determining free and bound cyanide and cyanogenic compounds in biological materials are under revision. Procedures include chromatography; enzymic postcolumn cleavage; electrochemical detection; and ultraviolet, infrared, proton, and carbon-13 nuclear magnetic resonance spectroscopies (Brimer 1988). Proposed newer analytical methodologies include chemiluminescence (Wu et al. 1989); deproteinization techniques (Krynnitsky et al. 1986); thin-film dissociation coupled with preferential ultraviolet irradiation (Kelada 1989); differential pulse polarography (Westly 1988); and modified spectrophotometric (Blago 1989; Ohno 1989), colorimetric (Lundquist and Sorbo 1981), and ion chromatographic determinations (Nonomura and Hobo 1989). Analysis of cyanide and cytochrome oxidase is usually conducted with samples of whole blood, serum, plasma, brain, or ventricular myocardium tissues. Samples should be obtained as soon as possible after cyanide exposure and analyzed immediately; otherwise, erroneous analytical values will result (Towill et al. 1978; Ballantyne 1983). Brain and liver are recommended for cyanide analysis if removed and analyzed within a week (Ballantyne et al. 1974). Cyanide measurements are further confounded by the presence of various antidotal agents (Ballantyne 1983); by various tissue preservatives, such as formaldoxime (Knocke 1981) and sodium fluoride (Curry

et al. 1967); and by the spontaneous postmortem production of cyanide in various tissues (e.g., sterile blood, brain, liver, kidney, uterus, intestines) over time in cases of non-cyanide death (Curry et al. 1967; Ballantyne et al. 1974).

15.3 MODE OF ACTION

Cyanide is a potent and rapid-acting asphyxiant. At lethal doses, inhalation or ingestion of cyanide produces reactions within seconds and death within minutes. Cyanide's toxic effect is due to its affinity for the ferric heme form of cytochrome a_3 , also known as cytochrome c oxidase, the terminal oxidase of the mitochondrial respiratory chain (Towill et al. 1978; Egekeze and Oehme 1980; Solomonson 1981; Way 1981, 1984; Leduc et al. 1982; Biehl 1984; Ballantyne 1987a; Marrs and Ballantyne 1987; Yamamoto 1989; Chew and Ip 1992). Inhibition of the enzyme cytochrome c oxidase is thought to involve a two-step reaction: initial penetration of cyanide into a protein crevice, followed by binding to heme iron. Formation of a stable cytochrome c oxidase-CN complex in the mitochondria produces a blockage of electron transfer from cytochrome oxidase to molecular oxygen and cessation of cellular respiration, causing cytotoxic hypoxia in the presence of normal hemoglobin oxygenation. Tissue anoxia induced by the activation of cytochrome oxidase causes a shift from aerobic to anaerobic metabolism, resulting in the depletion of energy-rich compounds such as glycogen, phosphocreatine, and adenosine triphosphate, and the accumulation of lactate with decreased blood pH. The combination of cytotoxic hypoxia with lactate acidosis depresses the central nervous system — the most sensitive site of anoxia — resulting in respiratory arrest and death. If the absorption rate is significantly greater than the detoxification rate, there will be a rapid accumulation of free cyanide in tissues and body fluids, resulting in the prompt onset of signs of acute cyanide poisoning. Acute cyanide poisoning is frequently encountered as a relatively massive overdose, where the amount of cyanide greatly exceeds the minimal concentration necessary to inhibit cytochrome c oxidase. In such cases, many enzymes and biological systems are disrupted, including various metalloenzymes, nitrate reductase, nitrite reductase, myoglobin, various peroxidases, catalase, and ribulose diphosphate carboxylase, resulting in severe signs of toxicity and rapid death.

The great majority of the absorbed cyanide reacts with thiosulfate in the presence of enzymes to produce thiocyanate, which is excreted in the urine over a period of several days. Owing to this rapid detoxification, animals can ingest high sublethal doses of cyanide over extended periods without harm (Towill et al. 1978; Egekeze and Oehme 1980; USEPA 1980; Davis 1981; Solomonson 1981; Leduc 1984; Ballantyne 1987a; Oh et al. 1987; Marrs and Ballantyne 1987; Westley 1988; Mengel et al. 1989). Authorities are also in general agreement on several points:

- Thiosulfate is usually low in the body, and higher levels can significantly protect against cyanide toxicity.
- Species vary considerably in both the extent to which thiocyanate is formed and the rate at which it is eliminated from the body.
- Thiocyanate metabolites resulting from the transulfuration process are about 120 times less toxic than the parent cyanide compound.
- Thiocyanate can accumulate in tissues and has been associated with developmental abnormalities and other adverse effects.
- The two enzyme systems responsible for the transulfuration process are thiosulfate-cyanide sulfurtransferase — also known as rhodanese — and beta-mercaptopyruvate cyanide sulfurtransferase.

Rhodanese is widely distributed in the body, but activity levels in mammals are highest in the mitochondrial fraction of liver. Rhodanese activity levels in catalyzing the transformation of thiosulfate to thiocyanate are limited by the availability of sulfur. Minor detoxification pathways for cyanide include exhalation in breath as HCN, and as CO₂ from oxidative metabolism of formic

acid; conjugation with cystine to form 2-iminothiazolidene-4-carboxylic acid or 2-aminothiazoline-4-carboxylic acid; combining with hydroxocobalamin (B_{12}) to form cyanocobalamin, which is excreted in urine and bile; and binding by methemoglobin in the blood (Towill et al. 1978; USEPA 1980; Ballantyne 1987a; Marrs and Ballantyne 1987).

Absorption of hydrogen cyanide liquid or gas readily occurs through inhalation, ingestion, or skin contact (Towill et al. 1978; Egekeze and Oehme 1980; USEPA 1980; Homan 1987). Inhalation and skin absorption are the primary hazardous routes in cyanide toxicity in occupational exposure. Skin absorption is most rapid when the skin is cut, abraded, or moist. Inhalation of cyanide salts is also potentially hazardous because the cyanide dissolves on contact with moist mucous membranes. Regardless of route of exposure, cyanide is readily absorbed into the bloodstream and distributed throughout the body. Cyanide concentrates in erythrocytes through binding to methemoglobin (Towill et al. 1978; USEPA 1980), and free cyanide concentrations in plasma are now considered one of the better indicators of cytotoxicity (Ballantyne 1987a). Because of the affinity of cyanide for the mammalian erythrocyte, the spleen may contain elevated cyanide concentrations when compared to blood. Accordingly, spleen should always be taken for analysis in cases of suspected cyanide poisoning (Ballantyne 1975). Cyanide also accumulates in various body cells through binding to metalloproteins or enzymes such as catalase and cytochrome *c* oxidase (USEPA 1980). The brain is probably the major target organ of cytotoxic hypoxia, and brain cytochrome oxidase may be the most active site of lethal cyanide action, as judged by distribution of cyanide, thiosulfate, and rhodanese (Solomonson 1981; Ballantyne 1987a). Significant positive correlations exist between cyanide concentrations in plasma, cerebrospinal fluid, and brain (Ballantyne 1987a). These correlations need further exploration.

Hydrogen cyanide formation may contribute to the toxicity of snake venom, owing to the high levels of L-amino acid oxidase in some snake venoms (Vennesland et al. 1981a). This enzyme is harmless on injection, but the tissue destruction caused by other venom components probably provides the required substrate and cofactor for HCN production. Cyanide inhibits ion transport mechanisms in amphibian skin, gall bladder, and proximal renal tubules (Bello-Reuss et al. 1981). Measurable changes in cell membrane potentials of isolated gall bladder epithelium cells, for example, were induced by NaCN in a salamander (*Necturus maculosus*) (Bello-Reuss et al. 1981). Cyanide-induced hyperpolarization was caused primarily by an increase in permeability of the cell membrane to potassium, which, in turn, was mediated by an elevation of intracellular calcium ion activity, attributable to release from mitochondrial sources. The binding rate of CN to hemeproteins, specifically hemoglobin components III and IV, is 370 to 2300 times slower in a marine polychaete annelid (*Glycera dibranchiata*), when compared to guinea pig (*Cavia* spp.), soybean (*Glycine max*), and sperm whale (*Physeter macrocephalus*). The significance of this observation is unclear but warrants further exploration (Mintorovitch et al. 1989).

15.4 CLINICAL FEATURES

Accidental exposure to cyanides or cyanogens through inhalation, skin exposure, and swallowing occurs in agricultural fumigation, laboratories, industrial operations, domestic abuse, and products of combustion (Ballantyne and Marrs 1987b). Intentional exposure is reported from homicides, suicides (usually uncommon), judicial executions, chemical warfare, and covert activities (Ballantyne and Marrs 1987b). Diagnosis of lethal cyanide poisoning is difficult because of the absence of gross pathology or histology, nonspecific congestion of viscera, and cerebral or pulmonary edema. Sometimes, the blood is bright red, and sometimes the odor of bitter almonds is detected, but neither is sufficiently consistent for diagnostic purposes (Ballantyne and Marrs 1987b). At low lethal doses of cyanide, the effects are principally on cytochrome oxidase in the central nervous system. At higher doses, cardiovascular signs and changes in electrical activity of the brain are among the most consistent changes measured (Way 1981, 1984). Acute and subacute

toxic effects of poisoning with cyanide can vary from convulsions, screaming, vomiting, and bloody frothing to less dramatic events, such as a slow, quiet onset to coma and subsequent death (Way 1981). In the first stage of cyanide poisoning, victims exhibit headache, vertigo, weak and rapid pulse, nausea, and vomiting. In the second stage, there are convulsions, falling, dilated pupils, clammy skin, and a weaker and more rapid pulse. In the final stage, heartbeat becomes irregular and slow, body temperature falls, there is cyanosis of lips, face, and extremities, coma, frothy bloody saliva flow from the mouth, and death (Way 1981). If acute exposure is to a sublethal dose of cyanide, this may lead to signs of toxicity; but as detoxification proceeds, these signs will become less obvious and eventually vanish, and cyanide will be excreted as thiocyanate without accumulating (Ballantyne 1987a).

Chronic cyanide poisoning may develop in individuals who ingest significant quantities of cyanide or cyanide precursors in their diets. Effects are exacerbated by dietary deficiencies in Vitamin B₁₂, iodine, and sulfur amino acids, as well as by low levels and insufficient distribution of detoxifying enzymes such as rhodanese (Solomonson 1981). Cyanide toxicity of dietary origin has been implicated in acute animal deaths and as a major etiologic factor in toxic ataxic neuropathy in man, and as a cause of blindness in humans suffering from tobacco amblyopia and Leber's hereditary optic atrophy (Egekeze and Oehme 1980). An increase in blood plasma cyanide is observed in healthy individuals who smoke cigarettes (Cailleux et al. 1988). An increase in blood plasma thiocyanate is also seen in smokers and in hemodialysis patients just before dialysis (Cailleux et al. 1988). Continuous intake of cyanide causes high levels of plasma thiocyanate and goiters in mammals; the antithyroid action (goiters) results from cyanide interference with iodine transport and thyroxine synthesis (Solomonson 1981; Leduc 1981, 1984). Signs of chronic cyanide poisoning include demyelination, lesions of the optic nerve, decrease in sulfur-containing amino acids, increase in thiocyanate, goiter, ataxia, hypertonia, and depressed thyroid function (Solomonson 1981). These effects are common in areas that depend on cyanogenic plants — such as cassava — as a major dietary component (Solomonson 1981).

Biochemically, cyanide affects the citric acid cycle, strongly inhibits catalases and proteinases, induces glycolysis in protozoans, fish, and mammals, produces Vitamin B₁₂ deficiency, and modifies the phosphorylation mechanism of respiratory mitochondrial enzymes, causing arrested respiration due to inability to use oxygen (Leduc 1984). Cyanide biomagnification or cycling has not been reported, probably because of cyanide's high chemical reactivity and rapid biotransformation (Towill et al. 1978; Marrs and Ballantyne 1987). There is no evidence that chronic exposure to cyanide results in teratogenic, mutagenic, or carcinogenic effects (USEPA 1980). Cyanide possibly has antineoplastic activity, as judged by a low therapeutic success against rat sarcomas (USEPA 1980), but this requires additional documentation.

Confirmatory evidence of cyanide poisoning includes elevated blood thiocyanate levels — except, perhaps, when death was rapid — and reduced cytochrome oxidase activity in brain and myocardium, provided that all tissues were taken within a day or so of death, frozen quickly, and analyzed shortly thereafter (Biehl 1984; Marrs and Ballantyne 1987). Evaluation of cyanide poisoning and metabolism includes signs of toxicity, LD₅₀ values, measurement of cyanide and thiocyanate concentrations, cytochrome *c* oxidase activity, metabolic modification of *in vivo* cyanogenesis, rate of cyanide liberation *in vitro*, and influence of modifying factors such as the animal species, dose, rate and frequency of administration, route of exposure, differential distribution of cyanide, detoxification rates, circadian rhythm interactions, age of the organism, and presence of antidotes (Ballantyne 1987a). For example, the concentration of cyanide measured in body fluids and tissues in man and other animals following lethal administration of cyanide depends on several factors (Ballantyne and Marrs 1987b):

- Route of exposure, with oral route yielding highest residues and inhalation route the lowest
- Amount and duration of exposure
- Nature of the material, with HCN and CN⁻ being most toxic

- Time to death
- Antidotes used; time to autopsy, with marked loss documented from simple evaporation, thiocyanate formation, hydrolysis, and polymerization
- Time from autopsy to sample analysis, wherein cyanide concentrations may increase due to microbial action

15.5 ANTIDOTES

The antagonism of cyanide intoxication has been under investigation for at least 150 years. In 1840, cyanide lethality was reported to be antagonized by artificial respiration. In 1888, amyl nitrite was reported effective in antagonizing lethal effects of cyanide in dogs. In 1894, cobalt was shown to form a stable metal complex with cyanide and was used to antagonize cyanide. In 1933, the use of sodium thiosulfate as the sulfur donor was described (Way 1984). Many compounds are used today as cyanide antidotes, including cobalt salts, rhodanese, sulfur donors, methemoglobin producers, carbohydrates, drugs used to treat acidosis, oxygen, methylene blue, 4-dimethylaminophenol, various aromatic amino- and nitro-compounds (such as aniline, *p*-aminopropiophenone, nitrobenzene), carbonyl compounds, and sodium pyruvate (Egekeze and Oehme 1980; USEPA 1980; Solomonson 1981; Way 1981, 1984; Biehl 1984; Becker 1985; Ballantyne 1987b; Marrs 1987; Marrs and Ballantyne 1987; Way et al. 1988). Different antidotes are preferred in different countries: in the United States, a mixture of sodium nitrite and sodium thiosulfate; in France and the United Kingdom, cobaltedetate, also known as Kelocyanor; and in Germany, a mixture of 4-dimethylaminophenol and sodium thiosulfate.

The classic nitrite-thiosulfate treatment of cyanide poisoning, developed almost 60 years ago, is one of the antidotal combinations still employed (Way 1981). Excess oxygen improves this antidotal combination by potentiating the effectiveness of the nitrite–thiosulfate combination, as confirmed by studies in sheep and rats (Way 1984), although, theoretically, oxygen should serve no useful purpose (Way et al. 1988). This therapeutic regimen protected rats against 20 LD₅₀ doses of cyanide (Towill et al. 1978). Nitrite converts hemoglobin to methemoglobin, which has a high affinity for cyanide. The methemoglobin–HCN complex then slowly releases cyanide, which is converted to thiocyanate by way of rhodanese (Solomonson 1981). Sodium nitrite, administered intravenously, is now considered one of the more rapid therapeutic methods (Way 1984). The injection of sodium thiosulfate provides sulfur for the enzyme rhodanese to mediate the biotransformation of cyanide to the much less toxic thiocyanate (Egekeze and Oehme 1980). Multiple injections of sodium thiosulfate protected mice against death by organic cyanides and were more effective than sodium nitrite (Willhite and Smith 1981). The nitrite–thiosulfate antidotal combination is one of the most effective treatments of cyanide poisoning, although the specific mechanism of action of these two compounds is now being questioned, and concerns have been raised because of the toxicity of nitrite (Way 1981, 1984). One accepted therapy is an intravenous combination of sodium nitrite (1 mL of 20% solution) and sodium thiosulfate (3 mL of 20% solution), giving 4 mL of this mixture per 45 kg of body weight (Egekeze and Oehme 1980). For maximal effectiveness in treating cyanide intoxication in sheep, large doses of sodium thiosulfate (660 mg/kg BW) are given in combination with conventional doses of sodium nitrite (6.6 mg/kg BW) (Egekeze and Oehme 1980). Livestock treatment in cases of suspected cyanide intoxication consists of intravenous administration of 10 to 20 mg sodium nitrite/kg BW followed by 30 to 40 mg sodium thiosulfate/kg BW. However, a sodium thiosulfate dose of 500 mg/kg BW, or more, may be more efficacious (Biehl 1984). Once clinical signs have abated, 1 g of activated charcoal/kg BW may be administered as a drench via a stomach tube (Biehl 1984). A 30-kg female goat (*Capra* sp.) was successfully treated after eating the leaves and fruit of the crab apple (*Malus sylvestris*), a plant that contains high levels of cyanogenic glycosides in leaves and fruits (Shaw 1986). Treatment consisted of four hourly treatments of 100 g of animal charcoal and bismuth subnitrate in water

as a drench, followed by 300 mg sodium nitrite as a 1% aqueous solution, then 25 g of sodium thiosulfate. Another goat died despite identical treatment (Shaw 1986).

Cobalt compounds, such as hydroxocobalamin and its derivatives (i.e., cobalt histidine, cobalt chloride, dicobalt ethylenediamine tetracetic acid) have been used to treat cyanide poisoning for more than 100 years. Their efficacy was confirmed in pigeons (*Columba* sp.) and rabbits (*Oryctolagus* sp.), but cobalt compounds did not receive wide support as cyanide antagonists because of the inherent toxicity of cobalt ion (Way 1981, 1984). Nevertheless, proponents of the use of cobalt compounds (i.e., the United Kingdom, Scandinavia, much of Europe) stress the rapidity of action in forming a stable metal complex with cyanide, thereby preventing its toxic effect (Towill et al. 1978; Way 1984). One of the more frequently used cobalt compounds in cyanide treatment is hydroxocobalamin, which reverses cyanide toxicity by combining with cyanide to form cyanocobalamin (Vitamin B₁₂) (USEPA 1980; Solomonson 1981). Hydroxocobalamin has been used in guinea pigs and baboons (*Papio anubis*) to lower blood cyanide levels, and in humans after inhalation or ingestion of cyanide compounds (Egekeze and Oehme 1980).

Dimethylaminophenol (DMAP) forms methemoglobin by setting up a catalytic cycle inside the erythrocyte, in which oxygen oxidizes the DMAP to *N,N*-dimethylquinoneimine, the latter oxidizing the hemoglobin to methemoglobin (Marrs 1987). Dogs poisoned with KCN and given DMAP intravenously had restored respiration and decreased plasma cyanide levels. The 4-dimethylaminophenol induced ferrihemoglobin production, which combined with the cyanide in the red cells to form ferrihemoglobin cyanide (Christel et al. 1977).

No usable cyanide prophylactic therapy now exists for humans, although sodium thiosulfate, hydroxocobalamin, and other compounds have been used to protect against cyanide toxicity in laboratory animals (Mengel et al. 1989). For example, pyridoxal 5-phosphate, the active form of Vitamin B₆, readily forms complexes with cyanides, and was effective in providing significant protection to rats (Keniston et al. 1987). Fructose fed prior to insult lessens cyanide-induced hepatotoxicity in rats (Younes and Strubelt 1988). L-ascorbic acid and dehydroascorbic acid probably act as protectants against cyanide toxicity by way of nontoxic cyanohydrin formation (Sprine et al. 1982). Carbon tetrachloride pretreatment was effective in protecting mice against death from most nitriles (Willhite and Smith 1981), and pretreatment with *p*-aminopropiophenone serves to protect against cyanide toxicity (D'Mello 1987).

15.6 SOURCES AND USES

Production of cyanides in the United States increased from about 136 million kg in 1963 to 318 million kg in 1976 (Towill et al. 1978; Way 1981; Marrs and Ballantyne 1987). Cyanide consumption in North America was 64 million kg in 1988 and 98 million kg in 1989; about 80% of these amounts was used in gold mining (Knudson 1990). In Canada, more than 90% of the mined gold is extracted from ores with the cyanidation process. This process consists of leaching gold from the ore as a gold–cyanide complex, and recovering the gold by precipitation (Simovic and Snodgrass 1985; Eisler et al. 1999). Heap leaching occurs when crushed ore is stacked on an impermeable plastic pad on the ground surface, with spraying or dripping of an NaCN solution on the flattened top. Large leach heaps may include 272,000 metric tons of ore and tower 100 meters or more (Albersworth et al. 1989). In the milling of gold ores, an NaCN solution is percolated through the crushed ores to dissolve the gold particles (Ripley et al. 1996). In both leaching and milling processes, after the gold is chemically precipitated, the solution is adjusted for pH and cyanide concentration, and recycled to precipitate more gold. Eventually, the remaining solution must be treated to recycle the cyanide or to destroy it to prevent escape into the environment (Ripley et al. 1996). Milling and heap leaching require cycling of millions of liters of alkaline water containing high concentrations of potentially toxic NaCN, free cyanide, and metal cyanide complexes that are frequently accessible to wildlife. Some milling operations result in tailings ponds

of 150 ha and larger. Heap leach operations that spray or drip cyanide solutions onto the top of the ore heap require solution processing ponds of about 1 ha in surface area. Although not intentional or desired, puddles of various sizes may occur on the top of heaps where the highest concentrations of NaCN are found. Exposed solution recovery channels are usually constructed at the base of leach heaps. All of these cyanide-containing water bodies are hazardous to wildlife if not properly managed (Henny et al. 1994; Eisler et al. 1999).

About 84% of domestic HCN production is used to produce organic cyanides, also known as nitriles, including acrylonitriles, methyl methacrylate, and adiponitrile (Towill et al. 1978). Nitriles tend to polymerize, which is the basis for their use in the manufacture of synthetic fibers, resins, plastics, dyestuffs, vitamins, solvents, elastomers, agricultural insecticides, and high-pressure lubricants (Willhite and Smith 1981). The widespread usefulness of HCN is related to its strong tendency and that of its inorganic salts to form complexes with metals. For example, sodium cyanide is used in metallurgy for the extraction of gold and silver from ores and in electroplating baths because it forms stable soluble complexes. Similar behavior makes alkali cyanide solutions excellent for cleaning silverware and other precious metals and is responsible for their general use in industry as metal cleaners (Towill et al. 1978). In Canada, more than 90% of the gold mined is extracted from ores with the cyanidation process. This process consists of leaching gold from the ore as a gold–cyanide complex, and gold being precipitated with the addition of zinc dust. A variety of cyanide compounds are produced during gold cyanidation (Simovic and Snodgrass 1985; Ripley et al. 1996; Eisler et al. 1999). In addition to their primary use in the metals and electroplating industries, and in the manufacture of synthetic fibers and plastics, various cyanide compounds have been used directly or as an intermediate to produce synthetic rubber, fumigants, rodenticides, insecticides, predator control agents, rocket fuels, paints and paint finishes, paper, nylon, pharmaceuticals, photographic chemicals, mirrors, cement, perfume, bleaches, soaps and detergents, riot control agents, fertilizers, and weedicides (Towill et al. 1978; Way 1981; Willhite and Smith 1981; Leduc 1984; Homan 1987).

Hydrogen cyanide vapor, because of its high and rapid acute lethal toxicity and ready diffusion, has been used widely to fumigate buildings, ships, and warehouses; to exterminate rabbits, rodents, and large predators; and in horticultural practice, to control insect pests that have developed resistance to other pesticides (Homan 1987; Ballantyne 1988). Typically, fumigation powders containing either calcium cyanide, Ca(CN)₂, or sodium cyanide, NaCN, are blown into burrows or scattered over the floor in greenhouses. On coming into contact with water, such powders liberate HCN vapor (Ballantyne 1988). Hydrogen cyanide released from Ca(CN)₂ is registered for use on almonds, dried beans, citrus, cocoa beans, grains, nuts, and spices (Towill et al. 1978). Cyanide-containing compounds are used for a variety of agricultural and pesticidal agents. These compounds include cyanogen (NCCN), as an intermediate in the production of some commercial fertilizers; cyanogen chloride (CNCI), in the manufacture of triazine herbicides; cyanogen bromide (CNBr), as a pesticidal fumigant; hydrogen cyanide, in the synthesis of methionine for animal feeds; ammonium thiocyanate (NH₄SCN), as a cotton defoliant; sodium thiocyanate (NaSCN), as a weedkiller; and calcium cyanamide (CaNCN), as a plant fertilizer, herbicide, pesticide, and defoliant of cotton and tomatoes (Homan 1987). Cyanide compounds have also been used as preservatives for raw vegetables (Towill et al. 1978).

Sodium cyanide has been used for about 50 years by the U.S. Fish and Wildlife Service against coyote in attempts to protect livestock, especially sheep. The Service has made extensive use of two NaCN ejector devices: “the coyote getter,” from the late 1930s to 1970; and the M-44, from about 1968 to the present, except for the period 1972 to 1974, when all uses of NaCN for predator control were canceled (USEPA 1976a; Connolly and Simmons 1984). Although both ejectors dispense toxicant when pulled, they differ in the way ejection is achieved. In the coyote getter, the toxicant is in a 0.38-caliber cartridge case and is expelled by the explosive force of the primer plus a small powder charge. The M-44 uses a spring-driven plunger to push out its toxic contents. M-44 capsules weigh about 0.94 grams, and consist of about 89% NaCN, 6% Celatom MP-78 (mostly

diatomaceous silica), 5% potassium chloride, and 0.25% FP Tracerite yellow — used as a fluorescent marker (Connolly and Simmons 1984). Coyote getters and M-44s are set into the ground with only their tops protruding. Fetid scent or lure stimulates a coyote to bite and pull, whereupon a lethal dose of NaCN is ejected into its mouth; coma and death follow in 30 to 60 s. Although coyote getters were about 99% effective against coyotes, compared to 73% for M-44s, the Service decided that spring-driven plungers were less hazardous to operators than were explosive-driven plungers (Connolly and Simmons 1984). The coyote getter was generally much more selective than the trap for the capture of coyotes. It was less destructive than traps to small mammals, birds of prey, ground-nesting birds, deer, antelope, and domestic sheep, but more destructive to dogs, bears, and cattle (Robinson 1943). In a 1-year test period (1940/41) in Colorado, Wyoming, and New Mexico, the following numbers of animals were killed by the coyote getter: 1107 coyotes, 2 bobcats (*Lynx rufus*), 24 dogs, 14 black-billed magpies (*Pica pica*), 7 foxes (*Vulpes* sp.), 8 unidentified skunks, 2 badgers, 2 unidentified eagles, 2 bears (*Ursus* sp.), and 1 each of hawk (unidentified), rockchuck (*Ochotona* sp.), and cow (Robinson 1943).

Cyanide compounds have been used to collect various species of freshwater fish. In England and Scotland, cyanides are used legally to control rabbits, and illegally to obtain Atlantic salmon (*Salmo salar*) and brown trout (*Salmo trutta*) from rivers, leaving no visible evidence of damage to the fish (Holden and Marsden 1964). Sodium cyanide has been applied to streams in Wyoming and Utah to collect fish through anesthesia. Mountain whitefish (*Prosopium williamsoni*) were sensitive to cyanide and died at concentrations that were tolerable to salmon and trout (Wiley 1984). Sodium cyanide was also used as a fish control agent in Illinois, Nebraska, South Dakota, Missouri, and in the lower Mississippi River valley, but was never registered for this use because of human safety concerns (Lennon et al. 1970). The widespread use of NaCN to collect exotic marine fishes is associated with high mortality in aquarium fish stocks in the Philippine Islands and elsewhere (Hall and Bellwood 1995). Cyanide fishing is banned in many Asia-Pacific countries; however, widespread illegal fishing continues, with significant adverse effects on coral reef ecosystems (Jones and Hoegh-Guldberg 1999).

Cyanide compounds have been prescribed by physicians for treatment of hypertension and cancer (Sprine et al. 1982). Sodium nitroprusside ($\text{Na}_2\text{Fe}(\text{CN})_5\text{NO} \cdot 2\text{H}_2\text{O}$) was widely used for more than 30 years to treat severe hypertension and to minimize bleeding during surgery (Solomonson 1981; Vesey 1987). Laetile, an extract of ground apricot kernels, has been used for cancer chemotherapy and, in deliberate high intakes, as an attempted suicide vehicle (Gee 1987).

Road salt in some areas may contribute to elevated cyanide levels in adjacent surface waters (Ohno 1989). In climates with significant snowfall, road salt is applied as a deicing agent. Road salts are commonly treated with anticaking agents to ensure uniform spreading. One anticaking agent, sodium hexacyanoferrate, decomposes in sunlight to yield the highly toxic free cyanide that contaminates surface waters by runoff (Ohno 1989). Another anticaking agent, yellow prussiate of soda (sodium ferrocyanide), has been implicated in fish kills when inadvertently used by fish culturists (Barney 1989).

The military uses of HCN were first realized by Napoleon III, but it was not until World War I (WW I) that this application received widespread consideration. About 3.6 million kg of hydrogen cyanide were manufactured by France as a chemical weapon and used in WW I in various mixtures called Manganite and Bincennite, although its use was not highly successful because of limitations in projectile size and other factors. During WW II, the Japanese were armed with 50-kg HCN bombs, and the United States had 500-kg bombs. More than 500,000 kg of HCN chemical weapons were produced during WW II by Japan, the United States, and the Soviet Union, but it is not known to what extent these weapons were used in that conflict (Way 1981).

Cyanides are widely distributed among common plants in the form of cyanogenic glycosides (Egekeze and Oehme 1980; Solomonson 1981; Way 1981; Biehl 1984; Homan 1987; Marrs and Ballantyne 1987). Their toxicity following ingestion is primarily related to the hydrolytic release of HCN. Ingestion of cyanogenic plants probably has accounted for most instances of cyanide

exposure and toxicosis in man and range animals. Of chief agricultural importance among plants that accumulate large quantities of cyanogenic glycosides are the sorghums, Johnson grass, Sudan grass, corn, lima beans, flax, pits of stone fruits (cherry, apricot, peach), vetch, linseed, sweet potatoes, bamboo shoots, southern mock orange, millet, almonds, and cassava. Factors favoring cyanide buildup in cyanogenic plants include high nitrogen and low phosphorus in soils (Biehl 1984). The potential for high glycoside levels is greatest in immature and rapidly growing plants (Egekeze and Oehme 1980). At present, more than 28 different cyanoglycosides have been measured in about 1000 species of higher plants (Leduc 1984). In cassava, for example, more than 90% of the cyanide is present as linamurin, a cyanogenic glycoside, and the remainder occurs as free (nonglycoside) cyanide (Gomez et al. 1983). Laetrile, a preparation made from apricot kernels, contains high levels of amygdalin, a cyanogenic glycoside that can be degraded in the gut to cyanide and benzaldehyde. Several cases of cyanide poisoning in humans have been reported from intake of laetrile, either orally or anally (Solomonson 1981; Homan 1987). Cyanide formation in higher plants and microorganisms can also occur with compounds other than cyanogenic glycosides, such as glycine, glyoxylate plus hydroxylamine, or histidine (Solomonson 1981; Vennesland et al. 1981a). In some cases, plants may contain cyanide residues resulting from fumigation with HCN (Way 1981).

Many species of plants, including some fungi, bacteria, algae, and higher plants, produce cyanide as a metabolic product (Leduc et al. 1982; Leduc 1984). Some species of soil bacteria suppress plant diseases caused by soil-borne pathogens by producing metabolites with antibiotic activity. Certain strains of *Pseudomonas fluorescens*, a soil bacterium, suppress black root rot of tobacco caused by the fungus *Thielaviopsis basicola* by excreting several metabolites, including HCN (Voisard et al. 1989). A wide variety of bacteria and fungi can degrade cyanide compounds and may be useful in the treatment of cyanide wastes (Towill et al. 1978). For example, several species of fungi known to be pathogens of cyanogenic plants can degrade cyanide by hydration to formamide; dried mycelia of these species are now sold commercially to detoxify cyanide in industrial wastes (Knowles 1988).

Anthropogenic sources of cyanide in the environment include industrial processes, laboratories, fumigation operations, cyanogenic drugs, fires, cigarette smoking, and chemical warfare operations (Marrs and Ballantyne 1987). Cyanides are present in many industrial wastewaters, especially those of electroplaters, manufacturers of paint, aluminum, and plastics, metal finishers, metallurgists, coal gasification processes, certain mine operations, and petroleum refiners (Towill et al. 1978; Egekeze and Oehme 1980; Way 1981, 1984). Electroplaters are a major source. In the United States alone, electroplaters discharge about 9.7 million kg of cyanide wastes annually into the environment from 2600 electroplating plants (Marrs and Ballantyne 1987). Paint residues annually contribute an additional 141,300 kg of cyanide wastes into the environment, and paint sludges 20,400 kg (Way 1981; Marrs and Ballantyne 1987). Cyanide can also originate from natural processes, such as cyanide production by bacteria, algae, and fungi, and from many terrestrial plants that release free HCN when their cellular structure is disrupted (Leduc 1981). Hospital wastewaters usually contain no detectable cyanide, but concentrations up to 64 µg CN⁻/L have been measured after alkali chlorination treatment (Tatsumoto and Hattori 1988). It seems that various compounds common in hospital wastewaters will produce 15 to 25 µg CN⁻/L after alkali chlorination. These compounds include hydantoin (an antiepilepsy agent) and related nitrogenous compounds, such as hydantonic acid, 5,5-diphenylhydantoin, imidazole, and 2-imidazolidinone (Tatsumoto and Hattori 1988).

Free hydrogen cyanide occurs only rarely in nature because of its high reactivity. The gas is sometimes found in the atmosphere, however, as a result of emissions from the petrochemical industry, malfunctioning catalytic converters on automobiles, fumigation of ships and warehouses, incomplete combustion of nitrogen-containing materials, and from tobacco smoke (Towill et al. 1978; Way 1981, 1984). Hydrogen cyanide is known to be produced in fires involving nitrogen-containing polymers and is probably the most important narcotic fire product other than carbon monoxide (Purser et al. 1984). Cyanide-related fire deaths and injuries, as judged by elevated blood

cyanide and thiocyanate concentrations, have been documented in airplanes, jails, and high-rises (Becker 1985; Ballantyne 1987b; Lundquist and Sorbo 1989). In a study of fire victims in Scotland, elevated blood cyanide levels were found in 78% of fatalities, and 31% had blood levels considered to be toxic (Purser et al. 1984). Major factors that influence HCN release include the chemical nature of the material, temperature, oxygen availability, and burning time (Ballantyne 1987b). Substantial quantities of free HCN and organic cyanides are known to be produced in fire settings involving horsehair, tobacco, wool, silk, and many synthetic polymers, such as polyurethane and polyacrylonitriles (Egekeze and Oehme 1980; Purser et al. 1984; Becker 1985; Ballantyne 1987b). Polyacrylonitrile, for example, is used in fabrics, upholstery covers, paddings, and clothing; about 50% of the mass of the polymer is theoretically available as HCN under thermal decomposition (Purser et al. 1984; Homan 1987).

15.7 CONCENTRATIONS IN FIELD COLLECTIONS

The reactivity of HCN, and its ability to condense with itself and other compounds, was probably responsible for the prebiotic formation of the majority of biochemical compounds required for life (Marrs and Ballantyne 1987). Cyanide is now known to be present in a number of foodstuff and forage plants, as a metabolite of certain drugs, in various industrial pollutants, and may be formed by the combustion of cyanide-releasing substances, such as plastics in airplane fires, and tobacco in smoking (Robinson et al. 1985). Hydrogen cyanide production may occur in hepatopancreas of mussels, *Mytilus edulis* (Vennesland et al. 1981a), in rat liver (Solomonson 1981), and in green and blue-green algae during nitrate metabolism (Leduc et al. 1982). Except for certain naturally occurring organic cyanide compounds in plants, it is uncommon to find cyanide in foods consumed in the United States (USEPA 1980).

The cyanide anion is found in a variety of naturally occurring plant compounds as cyanogenic glycosides, glycosides, lathyrogenic compounds, indoleacetonitrile, and cyanopyridine alkaloids. Plants that contain cyanogenic glycosides are potentially poisonous because bruising or incomplete cooking can result in glycoside hydrolysis and release of HCN (Towill et al. 1978). Cyanide concentrations in cyanogenic plants are usually highest in leaves of young plants. Levels drop rapidly after pollination (Biehl 1984). There are about 20 major cyanogenic glycosides, of which usually only one or two occur in any plant. They are synthesized from amino acids and sugars and are found in many economically important plants, such as sorghum, flax, lima bean, cassava, and many of the stone fruits (Table 15.2) (Towill et al. 1978; Shaw 1986). Cassava contains linamurin and lotaustralin, whereas the main cyanogenic glycoside in cereals is dhurrin; consumption of foods containing toxic cyanogens (primarily cassava) has been associated with death or morbidity — on an acute basis — or goiter and tropical ataxic neuropathy on a chronic consumption basis (Okolie and Ugochukwu 1989). Cassava is a perennial shrub, native to the neotropics, grown for its tuberous starchy roots, and a traditional dietary staple of many indigenous populations in Amazonia, especially the Tukanoan Indians in northwestern Amazonia (Dufour 1988). Cassava is one of the few food plants in which the cyanide content may create toxic problems. All varieties of cassava contain cyanogenic glycosides capable of liberating HCN, but amounts vary greatly depending on variety and environmental conditions. Bitter cultivars of cassava provide over 70% of the Tukanoan's food energy, appearing in the diet as bread, meal, a starch drink, and boiled cassava juice. The greatly elevated total cyanide content in bitter varieties (Table 15.2) may contain 5.1 to 13.4% of the total as the toxic free cyanide (Dufour 1988).

The production of HCN by animals is almost exclusively restricted to various arthropods: 7 species of about 3000 species of centipedes; 46 of 2500 species of polydesmid millipedes; and 10 of 750,000 species of insects, including 3 species of beetles, 4 moths, and 3 butterflies (Duffey 1981). Millipedes — which are eaten frequently by toads and starlings — secrete cyanide for

defensive purposes in repelling predators. In zygaenid moths, cyanide seems to be localized in eggs ([Table 15.2](#)) (Duffey 1981).

Cyanide concentrations in fish from streams that were deliberately poisoned with cyanide ranged between 10 and 100 µg total cyanide/kg whole-body FW (Wiley 1984). Total cyanide concentrations in gill tissues of salmonids under widely varying conditions of temperature, nominal water concentrations, and duration of exposure ranged from about 30 µg/kg FW to >7000 µg/kg (Holden and Marsden 1964). Unpoisoned fish usually contained <1 µg/kg FW in gills, although values up to 50 µg/kg occurred occasionally. Lowest cyanide concentrations in gill occurred at elevated (summer) water temperatures. At lower temperatures, survival was greater and residues were higher (Holden and Marsden 1964). Fish retrieved from cyanide-poisoned environments, dead or alive, can probably be consumed by man because muscle cyanide residues were considered to be low (i.e., <1000 mg/kg FW) (Leduc 1984).

Cyanide pollution is likely to occur in many places, ranging from industrialized urban areas to gold mines in the western United States and Northwest Territories of Canada ([Table 15.2](#)). Cyanides are ubiquitous in industrial effluents, and their increasing generation from power plants and from the combustion of solid wastes is expected to result in elevated cyanide levels in air and water (Leduc 1984). However, data are scarce on background concentrations of cyanides in various nonbiological materials. In soils, for example, high concentrations are unusual and are nearly always the result of improper waste disposal (Towill et al. 1978). Cyanides in soils are not absorbed or retained. Under aerobic conditions, microbial metabolism rapidly degrades cyanides to carbon dioxide and ammonia; under anaerobic conditions, cyanides are converted by bacteria to gaseous nitrogen compounds that escape to the atmosphere (Towill et al. 1978). Heat treatment wastes from metal processing operations may contain up to 200 g CN/kg, mostly as NaCN, and are frequently hauled to landfills for disposal (Lagas et al. 1982). The presence of cyanide in landfill waste is potentially hazardous because of the possibility that cyanide may leach to soil and groundwater, release HCN, and disturb natural microbiological degradation of organic materials. Measurements at landfills in England and the Netherlands showed total cyanide levels up to 560 g/kg in soil and 12 µg/L in groundwater (Lagas et al. 1982). However, 7-month-long experimental studies of cyanide in heat treatment wastes in landfills showed that between 72 and 82% of the cyanide was converted, mostly to ammonium and organic nitrogen compounds; between 4 and 22% of the cyanide leached as free or complex cyanide; and up to 11% remained in the landfill (Lagas et al. 1982).

Hydrogen cyanide (HCN) is a common industrial pollutant and frequently occurs in water at concentrations between 0.1 and several mg/L of free HCN (Leduc 1978; Leduc et al. 1982). Total cyanides is the most-often cited measurement in aqueous solutions, owing to limitations in analytical methodologies (Leduc et al. 1982). Cyanides have been identified in freshwaters of rural and wilderness areas in Canada and Germany. Concentrations ranging between 30 and 60 µg total cyanides/L seem related to runoff, with cyanide peaks more frequent in fall and winter during periods of minimal runoff (Leduc et al. 1982). In larger rivers, cyanide was low in winter owing to dilution by high runoff, but peaked in summer because of cyanide production by plants (Leduc 1984). Cyanides do not seem to persist in aquatic environments. In small, cold oligotrophic lakes treated with 1 mg NaCN/L, acute toxicity was negligible within 40 days. In warm shallow ponds, toxicity disappeared within 4 days after application of 1 mg NaCN/L. In rivers and streams, toxicity rapidly disappeared on dilution (Leduc 1984). Cyanide was not detectable in water and sediments of Yellowknife Bay, Canada, between 1974 and 1976, although the bay receives liquid effluents containing cyanides from an operating gold mine. Nondetection was attributed to rapid oxidation (Moore 1981). Several factors contribute to the rapid disappearance of cyanide from water. Bacteria and protozoans may degrade cyanide by converting it to carbon dioxide and ammonia. Chlorination of water supplies can result in conversion to cyanate (USEPA 1980). An alkaline pH favors oxidation by chlorine, and an acidic pH favors volatilization of HCN into the atmosphere (USEPA 1980).

15.8 PERSISTENCE IN WATER, SOIL, AND AIR

In water, cyanides occur as free hydrocyanic acid, simple cyanides, easily degradable complex cyanides such as $Zn(CN)_2$, and sparingly decomposable complex cyanides of iron and cobalt; complex nickel and copper cyanides are intermediate between the easily decomposable and sparingly degradable compounds (Towill et al. 1978). Cyanide has relatively low persistence in surface waters under normal conditions but may persist for extended periods in groundwater (Way 1981). Volatilization is the dominant mechanism for removal of free cyanide from concentrated solutions and is most effective under conditions of high temperatures, high dissolved oxygen levels, and at increased concentrations of atmospheric carbon dioxide (Leduc et al. 1982; Simovic and Snodgrass 1985). Loss of simple cyanides from the water column is primarily through sedimentation, microbial degradation, and volatilization (Leduc et al. 1982; Marrs and Ballantyne 1987). Water-soluble strong complexes, such as ferricyanides and ferrocyanides, do not release free cyanide unless exposed to ultraviolet light. Thus, sunlight may lead to cyanide formation in wastes containing iron–cyanide complexes (Towill et al. 1978; Leduc et al. 1982; Simovic and Snodgrass 1985; Marrs and Ballantyne 1987).

Alkaline chlorination of wastewaters is one of the most widely used methods of treating cyanide wastes. In this process, cyanogen chloride, $CNCl$, is formed, which at alkaline pH is hydrolyzed to the cyanate ion, CNO^- . If free chlorine is present, CNO^- can be further oxidized (Way 1981; Leduc et al. 1982; Simovic and Snodgrass 1985; Marrs and Ballantyne 1987). The use of sulfur dioxide in a high dissolved oxygen environment with a copper catalyst reportedly reduces total cyanide in high cyanide rinsewaters from metal plating shops to less than 1 mg/L. This process may have application in cyanide detoxification of tailings ponds (Robbins 1996). Other methods used in cyanide waste management include lagooning for natural degradation, evaporation, exposure

to ultraviolet radiation, aldehyde treatment, ozonization, acidification–volatilization–reneutralization, ion exchange, activated carbon absorption, electrolytic decomposition, catalytic oxidation, and biological treatment with cyanide-metabolizing bacteria (Towill et al. 1978; USEPA 1980; Way 1981; Marrs and Ballantyne 1987; Smith and Mudder 1991). Additional cyanide detoxification treatments include the use of FeSO_4 , FeSO_4 plus CO_2 , H_2O_2 , $\text{Ca}(\text{OCl})_2$ (Henny et al. 1994), dilution with water, FeSO_4 plus H_2O_2 , and $(\text{NH}_4)\text{HSO}_3$ (Eisler et al. 1999). In Canadian gold-mining operations, the primary treatment for cyanide removal is to retain gold mill wastewaters in impoundments for several days to months. Removal occurs through volatilization, photodegradation, chemical oxidation, and, to a lesser extent, microbial oxidation. Microbial oxidation of cyanide is not significant in mine tailing ponds, which typically have $\text{pH} > 10$, a low number of microorganisms, low nutrient levels, large quiescent zones, and cyanide concentrations $>10 \text{ mg/L}$ (Simovic and Snodgrass 1985).

Cyanide seldom remains biologically available in soils because it is either complexed by trace metals, metabolized by various microorganisms, or lost through volatilization (Towill et al. 1978; Marrs and Ballantyne 1987). Cyanide ions are not strongly adsorbed or retained on soils, and leaching into the surrounding groundwater will probably occur. Under aerobic conditions, cyanide salts in the soil are microbially degraded to nitrites or form complexes with trace metals. Under anaerobic conditions, cyanides denitrify to gaseous nitrogen compounds that enter the atmosphere.

Volatile cyanides occur only occasionally in the atmosphere, due largely to emissions from plating plants, fumigation, and other special operations (Towill et al. 1978). Under normal conditions, cyanide has relatively low persistence in air, usually between 30 days and 1 year (Way 1981), although some atmospheric HCN may persist for up to 11 years (Marrs and Ballantyne 1987). Data are lacking on the distribution and transformation of cyanide in the atmosphere (Towill et al. 1978) and should be acquired.

15.9 LETHAL AND SUBLETHAL EFFECTS

15.9.1 Terrestrial Flora and Invertebrates

Bacteria exposed to cyanide may exhibit decreased growth, altered cell morphology, decreased motility, mutagenicity, and altered respiration (Towill et al. 1978). Mixed microbial populations capable of metabolizing cyanide and not previously exposed to cyanide were adversely affected at 0.3 mg HCN/kg; however, these populations can become acclimatized to cyanide and can then degrade wastes with higher cyanide concentrations (Towill et al. 1978). Acclimatized populations in activated sewage sludge can often completely convert nitriles to ammonia, sometimes at concentrations as high as 60 mg total cyanides/kg (Towill et al. 1978). Cyanide can be degraded by various pathways to yield a variety of products, including carbon dioxide, ammonia, beta-cyanoalanine, and formamide (Knowles 1988). Several species of fungi can accumulate and metabolize cyanide, but the products of cyanide metabolism vary. For example, carbon dioxide and ammonia are formed as end products by *Fusarium solani*, whereas alpha-aminobutyronitile is a major cyanide metabolite of *Rhizoctonia solani* (Towill et al. 1978). Significant amounts of cyanide are formed as secondary metabolites by many species of fungi and some bacteria by decarboxylation of glycine (Knowles 1988). Rhizobacteria may suppress plant growth in soil through cyanide production. In one case, volatile metabolites — including cyanide — from fluorescent pseudomonad soil bacteria prevented root growth in seedlings of lettuce, *Lactuca sativa* (Alstrom and Burns 1989). Not all cyanogenic isolates inhibited plant growth. Some strains promoted growth in lettuce and beans by 41 to 64% in 4 weeks vs. 49 to 53% growth reduction by inhibitory strains (Alstrom and Burns 1989).

In higher plants, elevated cyanide concentrations inhibited respiration (through iron complexation in cytochrome oxidase) and ATP production and other processes dependent on ATP, such as

ion uptake and phloem translocation, eventually leading to death (Towill et al. 1978). Cyanide produces chromosomal aberrations in some plants, but the mode of action is unknown (Towill et al. 1978). At lower concentrations, effects include inhibition of germination and growth, but cyanide sometimes enhances seed germination by stimulating the pentose phosphate pathway and inhibiting catalase (Towill et al. 1978; Solomonson 1981). The detoxification mechanism of cyanide is mediated by rhodanese. This enzyme is widely distributed in plants (Solomonson 1981; Leduc 1984). The rate of production and release of cyanide by plants to the environment through death and decomposition is unknown (Towill et al. 1978).

Free cyanide is not found in intact plant cells. Many species of plants, such as cassava, sorghum, flax, cherries, almonds, and beans, contain cyanogenic glycosides that release HCN when hydrolyzed (Towill et al. 1978). Cyanide poisoning of livestock by forage sorghums, such as Sudan grass and various hybrid cultivars, is well known (Cade and Rubira 1982) and has led to the development of several variations of sorghums that have a reduced capability of producing cyanide poisoning (Egekeze and Oehme 1980). Cyanogenesis has an important role in plant defense against predatory herbivores. This herbivore–plant interaction is not simple; the degree of selectivity by herbivores varies among individuals and by differences in hunger and previous diet (Jones 1988).

Cyanide metabolism in higher plants involves amino acids, *N*-hydroxyamino acids, aldoximes, nitriles, and cyanohydrins (Halkier et al. 1988). Cyanide is a coproduct of ethylene synthesis in higher plants. The increase in ethylene production that occurs during the senescence of certain flowers and the ripening of fruits is accompanied by a rise in beta-cyanoalanine activity. The activity of this enzyme correlates closely with that of ACC (1-aminocyclopropane-1-carboxylic acid) oxidase, the last enzyme in the ethylene pathway. Manning (1988) suggested that ACC oxidase reacts with various amino acids to liberate cyanide. Cyanide added to isolated castorbean (*Ricinus communis*) mitochondria significantly enhanced the rate and amount of protein synthesis. Cyanide stimulated mitochondrial protein synthesis in a dose-dependent manner, with an optimal stimulation of over twofold at 26 µg/L; but at this concentration, mitochondrial respiration was inhibited by 90% (Kaderbhai et al. 1989). Cyanide is a weak competitive inhibitor of green bean (*Phaseolus vulgaris*) lipoxygenase, an enzyme that catalyzes the formation of hydroperoxides from polyunsaturated fatty acids (Adams 1989). Because degradation of hydroperoxides causes unacceptable changes in bean flavor and color, compounds that inhibit lipoxygenase may enjoy wide application in the frozen vegetable industry (Adams 1989). Corn seedlings from cold-resistant cultivars were more resistant to 65 mg KCN/L at low temperatures (13°C) than were seedlings from cold-susceptible cultivars (25°C), as judged by respiratory activity of mitochondria (Van De Venter 1985). Results suggest that cyanide-resistant respiration may play a role in cold resistance in maize seedlings, although more evidence is needed to demonstrate that cold-resistant plants actually use their greater potential for alternative respiration at low temperatures (Van De Venter 1985).

The cyanogenic system comprising cyanogenic glycosides, cyanohydrins, beta-glucosidases, and nitrile lyases is widespread in plants but also occurs in several species of arthropods, including the tiger beetle (*Megacephala virginica*), leaf beetle (*Paropsis atomaria*), zygaenid moths, and certain butterflies (Nahrstedt 1988). In *Zygaena trifolii*, cyanide compounds seem to function as protection against predators (Nahrstedt 1988). Defensive secretions of cyanide have also been reported in polydesmid millipedes, and these organisms seem to be more tolerant than other species when placed in killing jars containing HCN (Towill et al. 1978). In a millipede (*Apheloria* sp.), cyanide is generated in a two-compartment organ by hydrolysis of mandelonitrile; cyanide generation occurs outside the gland when the components of the two compartments are mixed during ejection (Towill et al. 1978).

Highly toxic substances, such as cyanides, are sometimes feeding cues and stimulants for specialized insects. For example, instar larvae of the southern armyworm (*Spodoptera eridania*) strongly prefer cyanogenic foods, such as foliage of the lima bean, a plant with comparatively elevated cyanide content — up to 31 mg/kg in some varieties — in the form of linamurin (Brattsten et al. 1983). Feeding was stimulated in southern armyworms at dietary levels up to 508 mg KCN/kg

(208 mg HCN/kg) for first to fourth instar larval stages, and between 1000 and 10,000 mg KCN/kg diet for fifth and sixth instar larvae (Brattsten et al. 1983). Sixth instar larvae preexposed to diets containing 5000 mg KCN/kg showed no adverse effects at dietary levels of 10,000 mg KCN/kg. However, previously unexposed larvae showed reversible signs of poisoning at 10,000 mg/kg diet, including complete inhibition of oviposition and 83% reduction in adult emergence (Brattsten et al. 1983). Experimental studies with southern armyworm larvae and thiocyanate — one of the *in vivo* cyanide metabolites — showed that 5000 mg thiocyanate/kg diet reduced pupation by 77%, completely inhibited oviposition, and reduced adult emergence by 80% (Brattsten et al. 1983), strongly suggesting that thiocyanate poisoning is the primary effect of high dietary cyanide levels in southern armyworms.

Resistant species, such as southern armyworms, require injected doses up to 800 mg KCN/kg BW (332 mg HCN/kg BW) or diets of 3600 mg KCN/kg for 50% mortality (Brattsten et al. 1983), but data are scarce for other terrestrial invertebrates. Exposure to 8 mg HCN/L air inhibits respiration in the granary weevil (*Sitophilus granarius*) within 15 min and kills 50% in 4 h; some weevils recover after cessation of 4-h exposure (Towill et al. 1978).

15.9.2 Aquatic Organisms

Numerous accidental spills of sodium cyanide or potassium cyanide into rivers and streams have resulted in massive kills of fishes, amphibians, aquatic insects, and aquatic vegetation. Sources of poisonings were storage reservoirs of concentrated solutions, overturned rail tank cars, or discharge of substances generating free HCN in the water from hydrolysis or decomposition (Leduc 1984). Data on the recovery of poisoned ecosystems are scarce. In one case, a large amount of cyanide-containing slag entered a stream from the reservoir of a Japanese gold mine as a result of an earthquake (Yasuno et al. 1981). The slag covered the stream bed for about 10 km from the point of rupture, killing all stream biota; cyanide was detected in the water column for only 3 days after the spill. Within 1 month, flora was established on the silt covering the above-water stones, but there was little underwater growth. After 6 to 7 months, populations of fish, algae, and invertebrates had recovered, although species composition of algae was altered (Yasuno et al. 1981). Short-term exposure of 12 days to 10 µg HCN/L — a level frequently encountered in freshwater aquatic ecosystems — has produced cyanide-induced hormonal and physiological balance in sexually mature rainbow trout. Female trout had reduced plasma estradiol levels and reduced oocyte growth and yolk deposition within the ovary (Ruby et al. 1993a). Males had decreased numbers of spermatocytes and selective loss of Type I basophils in the pituitary gland (Ruby et al. 1993b).

Fish were the most sensitive aquatic organisms tested (Eisler 1991). Significant adverse non-lethal effects, including reduced swimming performance and inhibited reproduction, were observed in the range of 5.0 to 7.2 µg free cyanide/L; deaths were recorded for most species between 20 and 76 µg free cyanide/L (Table 15.3). Among invertebrates, adverse nonlethal effects were documented between 18 and 43 µg/L, and lethal effects between 30 and 100 µg/L — although some deaths were recorded in the range 3 to 7 µg/L for the amphipod *Gammarus pulex* (Table 15.3). Algae and macrophytes were comparatively tolerant; adverse effects were reported at >160 µg free cyanide/L (Table 15.3). The high tolerance of mudskippers (*Boleophthalmus boddaerti*), and perhaps other species of fishes, to HCN (LC50 of 290 µg/L in 96 h) is a result of a surplus of cytochrome oxidase and inducible cyanide-detoxifying mechanisms and not to a reduction in metabolic rate or an enhanced anaerobic metabolism (Chew and Ip 1992).

Adverse effects of cyanide on aquatic plants are unlikely at concentrations that cause acute effects to most species of freshwater and marine fishes and invertebrates (USEPA 1980; Eisler 1991). Water hyacinth (*Eichhornia crassipes*) can survive for at least 72 h in nutrient solution containing up to 300 mg CN/L and can accumulate up to 6.7 g/kg DW plant material. On this basis, 1 ha of water hyacinths has the potential to absorb 56.8 kg of cyanide in 72 h, and this property may be useful in reducing the level of cyanide in untreated wastewater from various

electroplating factories, where concentrations generally exceed 200 mg CN/L (Low and Lee 1981). Large-scale use of water hyacinths for this purpose has not yet been implemented, possibly due to disagreement over appropriate disposal mechanisms. Cyanide may also affect plant community structure. Some algae, for example, metabolized cyanide at water concentrations <1 mg CN/L; but at concentrations of 1 to 10 mg/L, algal activity was inhibited, leaving a biota dominated by *Actinomycetes* — a filamentous bacterium (Knocke 1981).

Cyanide adversely affects fish reproduction by reducing the number of eggs spawned, and the viability of the eggs by delaying the process of secondary yolk deposition in the ovary (Lesniak and Ruby 1982; Ruby et al. 1986). Vitellogenin, a glycolipophosphoprotein present in plasma of fish during the process of yolk formation, is synthesized in liver under stimulation of estrogen and subsequently sequestered in the ovary; it is essential for normal egg development. Exposure of naturally reproducing female rainbow trout to as little as 10 µg HCN/L for 12 days during the onset of the reproductive cycle caused a reduction in plasma vitellogenin levels and a reduction in ovary weight. The loss of vitellogenin in the plasma would remove a major source of yolk (Ruby et al. 1986). Reproductive impairment in adult bluegills (*Lepomis macrochirus*) has been reported following exposure to 5.2 µg CN/L for 289 days (USEPA 1980). Fertilized fish eggs are usually resistant to cyanide prior to blastula formation, but delayed effects occur at 60 to 100 µg HCN/L, including birth defects and reduced survival of embryos and newly hatched larvae (Leduc et al. 1982). Concentrations as low as 10 µg HCN/L caused developmental abnormalities in embryos of Atlantic salmon after extended exposure (Leduc 1978). These abnormalities, which were absent in controls, included yolk sac dropsey and malformations of eyes, mouth, and vertebral column (Leduc 1984).

Other adverse effects of cyanide on fish include delayed mortality, pathology, impaired swimming ability and relative performance, susceptibility to predation, disrupted respiration, osmoregulatory disturbances, and altered growth patterns. Free cyanide concentrations between 50 and 200 µg/L were fatal to the more-sensitive fish species over time, and concentrations >200 µg/L were rapidly lethal to most species of fish (USEPA 1980). Cyanide-induced pathology in fish includes subcutaneous hemorrhaging, liver necrosis, and hepatic damage. Exposure of fish for 9 days to 10 µg HCN/L was sufficient to induce extensive necrosis in the liver, although gill tissue showed no damage. Intensification of liver histopathology was evident at dosages of 20 and 30 µg HCN/L and exposure periods up to 18 days (Leduc 1984). Cyanide has a strong, immediate, and long-lasting inhibitory effect on the swimming ability of fish (Leduc 1984). Free cyanide concentrations as low as 10 µg/L can rapidly and irreversibly impair the swimming ability of salmonids in well-aerated water (Doudoroff 1976). Osmoregulatory disturbances recorded at 10 µg HCN/L may affect migratory patterns, feeding, and predator avoidance (Leduc et al. 1982; Leduc 1984). In general, fish experience a significant reduction in relative performance (based on osmoregulation, growth, swimming, and spermatogenesis) at 10 µg HCN/L. And, although fish can survive indefinitely at 30 µg HCN/L in the laboratory, the different physiological requirements necessary to survive in nature could not be met (Leduc 1978, 1981, 1982) (Figure 15.1). Increased predation by green sunfish (*Lepomis cyanellus*) on fathead minnows (*Pimephales promelas*) was noted at sublethal concentrations of HCN, but it was uncertain if fatheads became easier prey or if green sunfish had greater appetites (Smith et al. 1979).

Sodium cyanide has stimulatory effects on oxygen-sensitive receptors in lungfish, amphibians, reptiles, birds, and mammals (Smatresk 1986). Facultative and aquatic air breathers appear to rely on air breathing when external chemoreceptors are stimulated, whereas obligate air-breathing fish are more responsive to internal stimuli (Smatresk 1986). Gill ventilation frequency of longnose gar (*Lepisosteus osseus*), for example, was little affected by external cyanide application but responded strongly when cyanide was administered internally by injection (Smatresk 1986). Cyanide, like many other chemicals, can stimulate growth of fish during exposure to low sublethal levels. This phenomenon, referred to as hormesis, is little understood and warrants additional research (Leduc 1984).

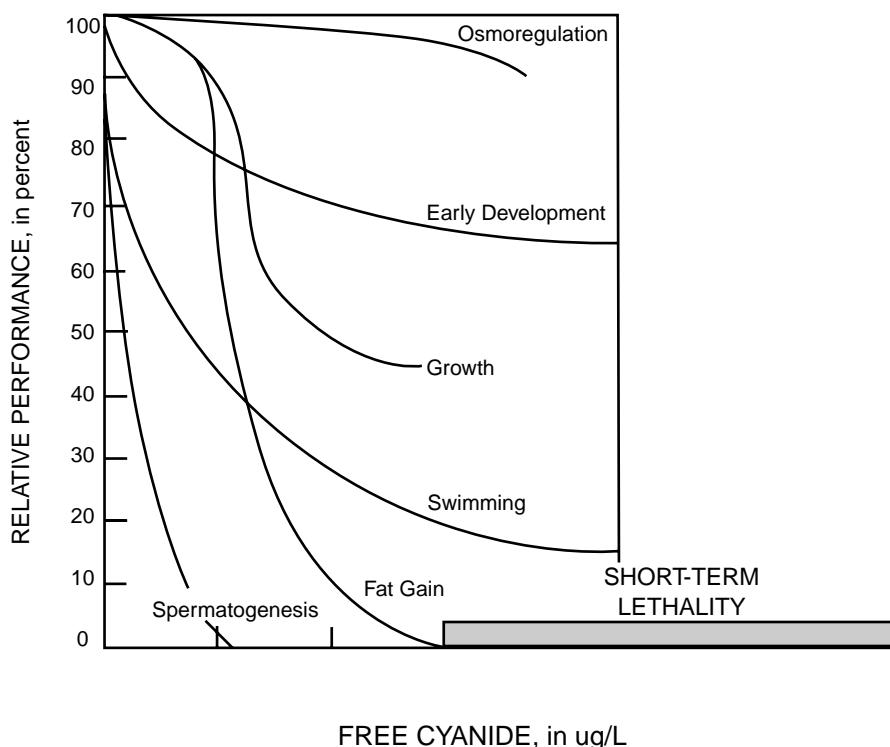

Figure 15.1 Summary of lethal and sublethal effects of free cyanide on freshwater fish. (Modified from Leduc, G., R.C. Pierce, and I.R. McCracken. 1982. The Effects of Cyanides on Aquatic Organisms with Emphasis upon Freshwater Fishes. Natl. Res. Coun. Canada, Publ. NRCC 19246. 139 pp. Avail. from Publications, NRCC/CNRC, Ottawa, Canada K1A OR6.)

The observed toxicity to aquatic life of simple and complex cyanides was attributed almost entirely to molecular (undissociated) hydrocyanic acid (HCN) derived from ionization, dissociation, and photodecomposition of cyanide-containing compounds. The toxicity of the cyanide ion, CN^- , which is a minor component of free cyanide ($\text{HCN} + \text{CN}^-$) in waters that are not exceptionally alkaline is of little importance (Doudoroff 1976; Towill et al. 1978; Smith et al. 1979; USEPA 1980). The acute toxicity of stable silver cyanide and cuprocyanide complex anions is much less than that of molecular HCN, but is nevertheless important. These ions can be the principal toxicants, even in some very dilute solutions. The much lower toxicities of the ferrocyanide and ferricyanide complexes — which are of high stability but subject to extensive and rapid photolysis, yielding free cyanide on direct exposure to sunlight — and the nickelocyanide ion complex are not likely to be of practical importance (Doudoroff 1976). Toxicity to aquatic organisms of organic cyanide compounds, such as lactonitrile, is similar to that of inorganic cyanides because they usually undergo rapid hydrolysis in water to free cyanide (Towill et al. 1978). There is general agreement that total cyanide concentrations in water in most cases will overestimate the actual cyanide toxicity to aquatic organisms, and that the analytically determined HCN concentration in cyanide-polluted waters is considered to be the most reliable index of toxicity (Doudoroff 1976; Smith et al. 1979; USEPA 1980; Abel and Garner 1986).

Cyanide acts rapidly in aquatic environments, does not persist for extended periods, and is highly species selective. Organisms usually recover quickly on removal to clean water. The critical sites for cyanide toxicity in freshwater organisms include the gills, egg capsules, and other sites where gaseous exchange and osmoregulatory processes occur. On passing through a semipermeable membrane, the HCN molecules are usually distributed by way of the circulatory system to various receptor sites where toxic action or detoxification occurs (Leduc 1984). Once in the general

circulation, cyanide rapidly inhibits the electron transport chain of vital organs. Signs of distress include increased ventilation, gulping for air at the surface, erratic swimming movements, muscular incoordination, convulsions, tremors, sinking to the bottom, and death with widely extended gill covers (Leduc 1981, 1989). The acute mode of action of HCN is limited to binding those porphyrins that contain Fe³⁺, such as cytochrome oxidase, hydroperoxidases, and methemoglobin. At lethal levels, cyanide is primarily a respiratory poison and one of the most rapidly effective toxicants known (Leduc et al. 1982). The detoxification mechanism of cyanide is mediated by thiosulfate sulfur transferase, also known as rhodanese. This enzyme is widely distributed in animals, including fish liver, gills, and kidney. Rhodanese plays a key role in sulfur metabolism, and catalyzes the transfer of a sulfane–sulfur group to a thiophilic group (Leduc 1984). Thiosulfate administered in the water with cyanide reduced the toxicity of cyanide to fish, presumably by increasing the detoxification rate of cyanide to thiocyanate (Towill et al. 1978).

Additive or more-than-additive toxicity of free cyanide to aquatic fauna has been reported in combination with ammonia (Smith et al. 1979; Leduc et al. 1982; Alabaster et al. 1983; Leduc 1984) or arsenic (Leduc 1984). However, conflicting reports on the toxicity of mixtures of HCN with zinc or chromium (Towill et al. 1978; Smith et al. 1979; Leduc et al. 1982; Leduc 1984) require clarification. Formation of the nickelocyanide complex markedly reduces the toxicity of both cyanide and nickel at high concentrations in alkaline pH. At lower concentrations and acidic pH, solutions increase in toxicity by more than 1000-fold, owing to dissociation of the metallo-cyanide complex to form hydrogen cyanide (Towill et al. 1978). Mixtures of cyanide and ammonia may interfere with seaward migration of Atlantic salmon smolts under conditions of low dissolved oxygen (Alabaster et al. 1983). The 96-h toxicity of mixtures of sodium cyanide and nickel sulfate to fathead minnows is influenced by water alkalinity and pH. Toxicity decreased with increasing alkalinity and pH from 0.42 mg CN/L at 5 mg CaCO₃/L and pH 6.5, to 1.4 mg CN/L at 70 mg CaCO₃/L and pH 7.5; to 730 mg CN/L at 192 mg CaCO₃/L and pH 8.0 (Doudoroff 1956).

Numerous biological and abiotic factors are known to modify the biocidal properties of free cyanide, including water pH, temperature, and oxygen content; life stage, condition, and species assayed; previous exposure to cyanide compounds; presence of other chemicals; and initial dose tested. There is general agreement that:

- Cyanide is more toxic to freshwater fish under conditions of low dissolved oxygen (Doudoroff 1976; Towill et al. 1978; Smith et al. 1979; USEPA 1980; Leduc 1984)
- pH levels within the range 6.8 to 8.3 had little effect on cyanide toxicity but enhanced toxicity at acidic pH (Smith et al. 1979; USEPA 1980; Leduc et al. 1982; Leduc 1984)
- Juveniles and adults were the most sensitive life stages tested, and embryos and sac fry the most resistant (Smith et al. 1978, 1979; USEPA 1980; Leduc 1984)
- Substantial interspecies variability exists in sensitivity to free cyanide (Smith et al. 1979; USEPA 1980).

Initial dose and water temperature both modify the biocidal properties of HCN to freshwater teleosts. At slowly lethal concentrations (i.e., <10 µg HCN/L), cyanide was more toxic at lower temperatures; at high, rapidly lethal HCN concentrations, cyanide was more toxic at elevated temperatures (Kovacs and Leduc 1982a, 1982b; Leduc et al. 1982; Leduc 1984). By contrast, aquatic invertebrates were most sensitive to HCN at elevated water temperatures, regardless of dose (Smith et al. 1979). Season and exercise modify the lethality of HCN to juvenile rainbow trout (McGeachy and Leduc 1988); higher resistance to cyanide correlated with higher activity induced by exercise and higher temperatures, suggesting a faster detoxification rate or higher oxidative and anaerobic metabolisms. Low levels of cyanide that were harmful when applied constantly may be harmless under seasonal or other variations that allow the organism to recover and detoxify (Leduc 1981). Acclimatization by fish to low sublethal levels of cyanide through continuous exposure might enhance their resistance

to potentially lethal concentrations (Leduc 1981, 1984), but studies with Atlantic salmon and rainbow trout indicate otherwise. Prior acclimatization of Atlantic salmon smolts to cyanide increased their resistance only slightly to lethal concentrations (Alabaster et al. 1983). Juvenile rainbow trout previously exposed to low sublethal concentrations showed a marked reduction in fat synthesis and swimming performance when challenged with higher cyanide doses. Effects were most pronounced at low water temperatures (Kovacs and Leduc 1982a). Experimental evidence is lacking on exposure to lethal concentrations after prior exposure to high sublethal concentrations. Some investigators predict decreased resistance (Leduc 1984), and others increased survival (Towill et al. 1978).

Table 15.3 Cyanide Effects on Selected Species of Aquatic Organisms (All concentrations are shown as g HCN/L [ppb] of medium at start unless indicated otherwise.)

Species, Concentration, and Other Variables	Effect	Reference ^a
ALGAE AND MACROPHYTES		
Alga, <i>Chlorella</i> sp.		
7300	Inhibition of photosynthesis	3
30,000	Enzyme inhibition	2
Water hyacinth, <i>Eichhornia crassipes</i>		
300,000	Nonphytotoxic in 72 h; plants contained 6.7 g total CN/kg dry weight (DW), equivalent to bioconcentration factor (BCF) of 22	5
Freshwater aquatic plants, 9 species, 65,000, 30-min exposure	No effect on respiratory oxygen uptake in 6 species of angiosperms (<i>Myriophyllum</i> sp., <i>Potamogeton</i> spp., <i>Elodea</i> sp., <i>Ruppia</i> sp., <i>Cabomba</i> sp.); some effect on two species of bryophytes (<i>Rhynchostegium ripariooides</i> , <i>Fontinalis antipyretica</i>) and one species of alga (<i>Cladophora glomerata</i>)	4
Alga, <i>Microcystis aeruginosa</i>		
7990	90% kill	2
Alga, <i>Prototricha zopfi</i>		
3000	Inhibition of respiration	2
Alga, <i>Scenedesmus quadricauda</i>		
160, as CN-	Toxic	1
INVERTEBRATES		
Copepod, <i>Acartia clausi</i>		
30	LC50 (96 h)	2
Isopod, <i>Asellus communis</i>		
29–40	MATC ^b	2, 8
1834	LC50 (11 days)	2
Oyster, <i>Crassostrea</i> sp.		
150	Motor activity suppressed after 10 min	2
Daphnid, <i>Daphnia magna</i>		
160	LC50 (96 h)	10
Daphnid, <i>Daphnia pulex</i>		
83	LC50 (96 h)	2
Amphipod, <i>Gammarus pseudolimnaeus</i>		
16–21	MATC ^b	
58	LC50 (96 h) at 20°C	8
184	LC50 (96 h) at 5.2°C	8
Amphipod, <i>Gammarus pulex</i>		
3	LC50 (15 h); 50% dead in 14 days after exposure for only 5 h	6
7.5	LC50 (9 h); exposure for 66 min results in 50% mortality 14 days after exposure	6

Table 15.3 (continued) Cyanide Effects on Selected Species of Aquatic Organisms (All concentrations are shown as g HCN/L [ppb] of medium at start unless indicated otherwise.)

Species, Concentration, and Other Variables	Effect	Reference ^a
15	LC50 (6 h); exposure for 45 min causes 50% mortality 14 days after exposure	6
75	LC50 (3 h); exposure for 18 min results in 50% kill 14 days after exposure	6
Mussel, <i>Mytilus edulis</i>		
18	After exposure for 14 days, growth was reduced and uptake of glycine was inhibited	9
100	LC20 (14 days)	9
Mysid shrimp, <i>Mysidopsis bahia</i>		
11, 20, 43, or 70	Life-cycle (29 days) exposure produced adverse effects on survival at 70 µg/L, and on reproduction at 43 µg/L; no measurable effects at lower doses of 11 and 20 µg/L	7
93–113	LC50 (96 h)	2, 7
Snail, <i>Physa heterostropha</i>		
432	LC50 (96 h)	3, 10
Fiddler crab, <i>Uca tangeri</i>		
Isolated perfused gills subjected to 26,000 CN-/L, as KCN	Inhibited sodium chloride absorption across gill epithelium; effect reversible if exposure <5 min and nonreversible if >30 min; salt absorption effect regulated by (Na ⁺ + K ⁺) ATPase	11
FISHES		
Mudskipper, <i>Boleophthalmus boddarti</i>		
290.0	LC50 (96 h) for adults	33
Mormyrid fishes, <i>Gnathonemus</i> spp.		
5.0–25.0	Significant dose-dependent effect on electric organ activity within 60 min	37
Brown bullhead, <i>Ictalurus nebulosus</i>		
Subjected to steadily increasing concentrations of waterborne cyanide over a 9-h period: 200 at 1 h, 600 at 3 h, 1000 at 5 h, and 1800 at 9 h	Increased heart beat rate at lower concentrations and decreased rate at higher concentrations; hyperventilation in first 3 h, followed by decrease in ventilation rate; oxygen consumption paralleled changes in heart and ventilatory rates; death in 9 h	21
Longnose gar, <i>Lepisosteus osseus</i>		
12 µg CN-/kg BW, as sodium cyanide, equivalent to 10.7 µg CN or 20 µg NaCN, single injection	Hypoxic response and bradycardia; effects appear earlier when administered into the ventral aorta or conus than into the dorsal aorta	27
Bluegill, <i>Lepomis macrochirus</i>		
5.0	Inhibited spawning following chronic exposure	22
5.2	Complete inhibition of spawning after exposure for 57–289 days	2, 8
9.3–19.8	MATC	2
19.4	Reduced survival of fry in 57-day exposure which began with eggs	8
50	Tolerated concentration at higher temperatures, but no reproduction	8
56–227	LC50 (96 h) for juveniles	8, 22
109–218	LC50 (96 h) for fry	8
232–365	LC50 (96 h) for eggs	22
535–690	LC50 (96 h) for eggs at hatching	8
Largemouth bass, <i>Micropterus salmoides</i>		
101	LC50 (96h) for juveniles	8
Cutthroat trout, <i>Oncorhynchus clarkii</i>		
1000 for 20 min	All fish recovered within 12 min and fed and grew normally during the next 6 months	31

Table 15.3 (continued) Cyanide Effects on Selected Species of Aquatic Organisms (All concentrations are shown as g HCN/L [ppb] of medium at start unless indicated otherwise.)

Species, Concentration, and Other Variables	Effect	Reference ^a
Coho salmon, <i>Oncorhynchus kisutch</i>		
7.0	Reduction of 50% in swimming performance during 8-day exposure	13
10	Swimming speed reduced after exposure for 2 h	2
Rainbow trout, <i>Oncorhynchus mykiss</i>		
0.1 or 1.0	No effect on sperm motility or on fertilization rate at lower dose; some effect on sperm motility at higher dose	12
5.0	Reduction of 50% in swimming performance in 20-day exposure	13
10	No effect on growth during 20-day exposure at 6°C	13
10	Increased respiration rate in 4 days, growth reduction and liver damage in 9 days, abnormal oocyte development and reduced spermatogonia production in 18–20 days	2
10	After exposure for 12 days, sexually mature females had significant declines in plasma levels of reproductive and metabolic hormones, and sexually mature males had decreased spermatocytes and selective cell loss in pituitary gland	34, 35
10, 20, or 30 for 7 days, sexually mature females	Exposure to 10 or 20 µg/L caused a reduction in serum calcium to levels insufficient for the production of exogenous yolk; this was not observed in the 30 µg/L group	14
10, 20, or 30 for 18 days, juveniles	Degenerative necrosis of liver hepatocytes at all concentrations in a dose-dependent pattern. Severe initial growth repression at all concentrations followed by a significant increase, but growth remained depressed 40% and 95% in the 20 and 30 µg/L groups, respectively, at 18 days	15
10 or 20, exposure for 20 days during midsummer, sexually maturing females	Both concentrations resulted in abnormal oocytes, delayed development, and significantly reduced the number of eggs for spawning	16
15	No effect on growth during 20-day exposure at 12°C	13
18	No deaths in 96 h at 6°C	13
20	65% reduction in weight gain after 21 days	2
28	LC50 (96 h) at 6°C	10,13,17
30	No effect on growth during 20-day exposure at 18°C	13
32	No deaths in 96 h at 12°C	13
42	LC50 (96 h) at 12°C	13,17
43	LC50 (96 h) for nonexercised juveniles during winter	18
46–75	LC50 (96 h) for juveniles	8,19
52	LC50 (96 h) for exercised juveniles during winter	18
60	No deaths in 96 h at 18°C	13
68	LC50 (96 h) at 18°C	10,13,17
70 for 24 h	Increased susceptibility to mycotic dermal infections by <i>Saprolegnia parasitica</i>	36
96	LC50 (144 h)	20
Subjected to steadily increasing concentrations of waterborne cyanide: 0 at start, 200 at 1 h, 600 at 3 h, 1000 at 5 h, and 1800 at 9 h	Reduction in heart rate, hyperventilation, increased oxygen consumption, death in 9 h	21
Chinook salmon, <i>Oncorhynchus tshawytscha</i>		
10	After 64 days, increased growth rate and production when compared to controls	13
20	Growth reduced 27% after exposure for 64 days	2

Table 15.3 (continued) Cyanide Effects on Selected Species of Aquatic Organisms (All concentrations are shown as g HCN/L [ppb] of medium at start unless indicated otherwise.)

Species, Concentration, and Other Variables	Effect	Reference ^a
Yellow perch, <i>Perca flavescens</i>		
76–108	LC50 (96 h) for juveniles	8, 22
288–>389	LC50 (96 h) for eggs and fry	8, 22
Fathead minnow, <i>Pimephales promelas</i>		
12.9–19.6	MATC ^b	8, 22
18–58	Reduction in RNA content in larva in 96 h at 18–36 µg HCN/L, and in DNA and protein at 18–58 µg/L	28
19	Egg reduction of 59% after exposure for 265 days at 25°C	13
35	Reduction in growth rate during chronic exposure	5
44	Hatching reduced 83% after chronic exposure	13
47	Growth reduction in 30 days	28
58	Toxicosis occurred in yolk-sac larvae within 24 h, as judged by significant reductions in content of RNA and protein; however, effects were not measurable in 96 h, suggesting development of partial tolerance	29
>61	Adverse effects on growth and survival during life-time exposure	13
82–113	LC50 (96 h) for fry at 25°C	8
83–137	LC50 (96 h) for juveniles	8, 22
99	LC50 (96 h) for fry at 20°C	8
107	Reduced survival in 96 h	28
121–202	LC50 (96 h) for eggs at 25°C	8
121–352	LC50 (96 h) for eggs; more toxic at low dissolved oxygen	22
122	LC50 (96 h) for fry at 15°C	8
Mixture of NaCN plus CdSO ₄ , equivalent to 170 µg CN/L	LC50 (96 h) for adults	30
Mixture of NaCN plus ZnSO ₄ , equivalent to 180 µg CN/L	LC50 (96 h) for adults	30
230, as NaCN	LC50 (96 h) for adults	30
273	LC50 (96 h) for eggs at 20°C	8
352	LC50 (96 h) for eggs at 15°C	8
Mixture of NaCN plus NiSO ₄ , equivalent to 650 µg CN/L	LC50 (96 h) for adults	8
Black crappie, <i>Pomoxis nigromaculatus</i>		
60	Some deaths in <24 h	3
101	LC50 (96 h) for juveniles	8
Plainfin midshipman, <i>Porichthys notatus</i>		
Isolated photophores exposed to 2600, as KCN	Maximal luminescence induced by KCN; effect inhibited by d-glucose, d-glyceraldehyde 3-phosphate, and 3-phosphoglycerate	32
Atlantic salmon, <i>Salmo salar</i>		
5.0 for 12 days, adult females	Decline in plasma and gonad vitellogenin levels	23
10	Abnormal embryonic development after 58-day exposure	2
10, 80, or 100; newly fertilized eggs continually exposed for 5 months to end of sac-fry stage	Hatching delayed 6–9 days at 80 and 100 µg/L. Hatching success reduced 15–40% at all test concentrations, but no measurable effects on growth or survival after hatching. Abnormalities (mostly defects of eye, mouth, vertebral column) were 6% at 10 µg/L, and 19% at 100 µg/L	24
24	LC50 (24 h) at dissolved oxygen of 3.5 mg/L	25
73	LC50 (24 h) at dissolved oxygen of 10 mg/L	25
5000, 10,000, 25,000, 50,000, or 125,000 for 30 min	Total cyanide residues in gills ranged from 1.0–6.6 mg/kg fresh weight (FW) in a dose-dependent manner	26

Table 15.3 (continued) Cyanide Effects on Selected Species of Aquatic Organisms (All concentrations are shown as g HCN/L [ppb] of medium at start unless indicated otherwise.)

Species, Concentration, and Other Variables	Effect	Reference ^a
50,000 for 10, 15, 20, 25, or 30 min	Residues in gills, in mg total CN/kg FW, ranged from 1.3 (10 and 15 min) to 1.9 (15 and 20 min) to 4.5 (30 min)	26
Brown trout, <i>Salmo trutta</i>		
90	LC50 (96 h)	10
5000, 10,000, 25,000, 50,000, 75,000, or 100,000, as CN ⁻ for 30 min	Residues in gills ranged in a dose-dependent manner from 0.6 mg CN/kg FW in the 5 mg/L group to 3.4 mg/kg FW in the 100 mg/L group	26
50,000 for 10, 15, 20, or 25 min	Residues in tissues, in mg/kg FW, ranged from 0.7–1.8 in gill, 0.6–2.3 in brain, and 1.3–2.5 in liver; concentrations were directly related to length of exposure	26
Brook trout, <i>Salvelinus fontinalis</i>		
5.0	Reduction of 50% in swimming performance in 29-day exposure	13
5.7–11.2	MATC ^b	8, 22
10	75% reduction in swimming endurance after exposure for 26 min	2
10–50	Swimming ability reduced 98% after exposure for 29 days	20
11	Continuous exposure of mature females for 144 days before spawning resulted in 50% reduction in number of eggs produced and 15% reduction in egg viability; however, 90 days after hatch, trout were 18% heavier and 10% longer than controls	13
25	Inhibited oxygen intake after 5 h	2
33	Adverse effects on juvenile growth rate during exposure for 90 days	2, 8
56–112	LC50 (96 h) range for swimup fry and juveniles	8, 22
108–518	LC50 (96 h) for sac-fry	8, 22
>212	LC50 (96 hours) for eggs	8, 22

^b Maximum acceptable toxicant concentration. Lower value in each pair indicates highest concentration tested producing no measurable effect on growth, survival, reproduction, or metabolism during chronic exposure; higher value indicates lowest concentration tested producing a measurable effect.

15.9.3 Birds

Free cyanide levels associated with high avian death rates include 0.12 mg/L in air, 2.1 to 4.6 mg/kg body weight (BW) via acute oral exposure, and 1.3 mg/kg BW administered intravenously (Table 15.4). In cyanide-tolerant species, such as the domestic chicken (*Gallus domesticus*), dietary levels of 135 mg total cyanide/kg ration resulted in growth reduction of chicks, but 103 mg total cyanide/kg ration had no measurable effect on these chicks (Eisler 1991; Hill and Henry 1996). First signs of cyanide toxicosis in sensitive birds appeared between 0.5 and 5 min after exposure and included panting, eye blinking, salivation, and lethargy (Wiemeyer et al. 1986). In domestic chickens, signs of cyanide toxicosis began 10 min after exposure. At higher doses, breathing in all species tested became increasingly deep and labored, followed by gasping and shallow intermittent

breathing. Death usually followed in 15 to 30 min, although birds alive at 60 min frequently recovered (Wiemeyer et al. 1986). Elevated cyanide concentrations were found in blood of chickens that died of cyanide poisoning. However, these concentrations overlapped those in survivors. Despite this variability, blood is considered more reliable than liver as an indicator of cyanide residues in exposed birds (Wiemeyer et al. 1986). No gross pathological changes in chickens related to cyanide dosing were observed at necropsy. The rapid recovery of some birds exposed to cyanide may be due to the rapid metabolism of cyanide to thiocyanate and its subsequent excretion. Species sensitivity to cyanide was not related to body size but seemed to be associated with diet (Wiemeyer et al. 1986). Birds that feed predominantly on flesh, such as vultures, kestrels, and owls, were more sensitive to cyanide than were species that feed mainly on plant material — with the possible exception of mallard (*Anas platyrhynchos*) — as judged by acute oral LD₅₀ values (Table 15.4). Mallards given single oral doses of KCN (1.0 mg KCN/kg BW) at cyanide concentrations and amounts similar to those found at gold-mining tailings ponds (40 mg CN⁻/L) had elevated concentrations of creatinine kinase in serum, suggesting tissue damage (Pritsos and Ma 1997). At 0.5 mg KCN/kg BW, mitochondrial function (an indicator of oxygen consumption) and ATP concentrations were significantly depressed in heart, liver, and brain (Ma and Pritsos 1997). Rhodanese and 3-mercaptopyruvate sulfurtransferase — two enzymes associated with cyanide detoxification — were induced in brain but not in heart of KCN-dosed mallards. Although cyanide concentrations as high as 2.0 mg KCN/kg BW (at 80 mg CN⁻/L) were not acutely toxic to mallards, the long-term effects of such exposures were not determined and may have serious consequences for migratory birds exposed sublethally to cyanide at gold-mine tailings ponds.

Many species of migratory birds — including waterfowl, shorebirds, passerines, and raptors — were found dead in the immediate vicinity of gold-mine heap-leach extraction facilities and tailings ponds, presumably as a result of drinking the cyanide-contaminated (>200 mg total cyanide/L) waters (Clark and Hothem 1991; Henny et al. 1994; Hill and Henry 1996). About 7000 dead birds — mostly waterfowl and songbirds — were recovered from cyanide-extraction, gold-mine leach ponds in the western United States between 1980 and 1989. No gross pathological changes related to cyanide were observed in these birds at necropsy (Allen 1990; Clark and Hothem 1991). No gross pathology was evident in cyanide-dosed captive birds (Wiemeyer et al. 1986), and this is similar to the findings of laboratory studies with cyanide and other animal orders that were tested and examined (Eisler 1991). Migratory bird mortality from cyanide toxicosis may be eliminated at these facilities by screening birds from toxic solutions (Hallock 1990) or lowering the cyanide concentrations with hydrogen peroxide to <50 mg total cyanide/L (Allen 1990), although the latter procedure requires verification (Clark and Hothem 1991). Chemical bird repellents used at cyanide ponds with some success against European starlings (*Sturnus vulgaris*) include O-aminoacetophone and 4-ketobenztriazine (Clark and Shah 1993).

Some birds may not die immediately after drinking lethal cyanide solutions. Sodium cyanide rapidly forms free cyanide in the avian digestive tract (pH 1.3 to 6.5), whereas formation of free cyanide from metal cyanide complexes is comparatively slow (Huiatt et al. 1983). A high rate of cyanide absorption is critical to acute toxicity, and absorption may be retarded by the lower dissociation rates of metal-cyanide complexes (Henny et al. 1994). In Arizona, a red-breasted merganser (*Mergus serrator*) was found dead 20 km from the nearest known source of cyanide, and its pectoral muscle tissue tested positive for cyanide (Clark and Hothem 1991). A proposed mechanism to account for this phenomenon involves weak-acid dissociable (WAD) cyanide compounds. Cyanide bound to certain metals, usually copper, is dissociable in weak acids such as stomach acids. Clark and Hothem (1991) suggested that drinking of lethal cyanide solutions by animals may not result in immediate death if the cyanide level is sufficiently low; these animals may die later when additional cyanide is liberated by stomach acid. More research is needed on WAD cyanide compounds.

Cyanide-nutrient interactions are reported for alanine, which appears to exacerbate cyanide toxicity, and for cystine, which seems to alleviate toxicity (Davis et al. 1988). Dietary cyanide — at levels that do not cause growth depression — alleviates selenium toxicity in chickens, but not the reverse (Davis et al. 1988; Elzubier and Davis 1988a). For example, dietary selenium, as selenite, at 10 mg/kg for 24 days, reduced growth, food intake, and food utilization efficiency, and produced increased liver size and elevated selenium residues. The addition of 45 mg CN/kg diet (100 mg sodium nitroprusside/kg) eliminated all effects except elevated selenium residues in liver. The mechanism of alleviation is unknown and may involve a reduction of tissue selenium through selenocyanate formation, or increased elimination of excess selenium by increasing the amount of dimethyl selenide exhaled (Elzubier and Davis 1988a). At dietary levels of 135 mg CN/kg plus 10 mg selenium/kg, chick growth was significantly decreased (Elzubier and Davis 1988a). This interaction can be lost if there is a deficiency of certain micronutrients or an excess of Vitamin K (Davis et al. 1988).

Table 15.4 Cyanide Effects on Selected Species of Birds

Species, Dose, and Other Variables	Effect	Reference ^a
MALLARD, <i>Anas platyrhynchos</i>		
Single oral dose of NaCN		
0.53 mg CN kg body weight (BW), equivalent to 1 mg NaCN/kg BW	No deaths	7
1.1 mg CN/kg BW (2.0 mg NaCN/kg BW)	About 6% dead	7
1.27 mg/CN kg BW (2.4 mg NaCN/kg BW)	About 33% dead	7
1.43 mg CN/kg BW (2.7 mg NaCN/kg BW)	LD50; 95% confidence interval (CI) of 2.2 and 3.2 mg NaCN/kg BW	7, 8
TURKEY VULTURE, <i>Cathartes aura</i>		
Single oral dose of 19.1 mg CN/kg BW, equivalent to 36 mg NaCN/kg BW	Up to 80% of the cyanide in blood was present as free cyanide, and the remainder as bound cyanide	1
Single oral dose of 19.1 mg CN/kg BW, equivalent to 36 mg NaCN/kg BW	Average time to death was about 19 min and ranged between 8 and 41 min. Cyanide residues postmortem, in mg CN/kg fresh weight (FW), were 6.7 in blood (Max. 21) and 0.6 in liver (Max. 2.8)	2
ROCK DOVE, <i>Columba livia</i>		
0.12 mg CN/L air, as HCN	All dead in 10 min	2
1.6 mg CN/kg BW, equivalent to 4.0 mg KCN/kg BW	Minimum lethal dose when administered intravenously or intramuscularly	2
BLACK VULTURE, <i>Coragyps atratus</i>		
Single oral dose, as NaCN		
1.6 mg CN/kg BW	No deaths in 60 min. Mean and maximum blood CN concentrations, in mg/kg FW, were 0.7 and 0.9, respectively	2
2.4 mg CN/kg BW	Some deaths within 30 min.; mean blood CN residues in mg/kg FW, were 0.7 in dead birds vs. 1.2 in those surviving 60 min	2
2.54 mg CN/kg BW	Acute oral LD50; 95% (CI) of 2.3 and 2.8 mg CN/kg BW (4.4–5.3 mg NaCN/kg BW)	2
3.7 and 19.1 mg CN/kg BW	All dead within 16 min; maximum blood CN levels postmortem were 2.1 mg/kg FW in the low-dose group and 4.2 in the high-dose group	2

Table 15.4 (continued) Cyanide Effects on Selected Species of Birds

Species, Dose, and Other Variables	Effect	Reference^a
JAPANESE QUAIL, <i>Coturnix japonica</i>		
Single oral dose, as NaCN 4.5 mg CN/kg BW	Acute oral LD ₅₀ for adult females; 95% CI of 3.1 and 6.5 mg CN/kg BW	2
5.5 mg CN/kg BW	Acute oral LD ₅₀ for adult males; 95% CI of 4.0 and 7.5 mg CN/kg BW	2
AMERICAN KESTREL, <i>Falco sparverius</i>		
2.12 mg CN/kg BW, as NaCN	Acute oral LD ₅₀ , 95% CI of 1.6 and 2.8 mg CN/kg BW	2
DOMESTIC CHICKEN, <i>Gallus domesticus</i>		
Intravenous route 0.01 µg/kg BW	Most of dose recovered in urine as thiocyanate in 6 h; excretion limited by availability of transferable sulfur	3
0.6 mg CN/kg BW, equivalent to 1.5 mg KCN/kg BW	Lethal	2
0.78 mg CN/kg BW, as KCN	Sublethal. Thiocyanate excretion increased 10X after 10 min and returned to normal levels after 3.5 h; the total thiocyanate collected was equivalent to 85% of the administered dose	4
1.3 mg CN/kg BW, as KCN	Lethal	4
Inhalation route 0.12 mg HCN/L air	All survived for at least 60 min	2
Single oral dose, as NaCN 3.2 mg CN/kg BW, equivalent to 6.0 mg NaCN/kg BW	No deaths in 30 min; maximum CN levels, in mg/kg FW, were 1.1 in blood and 0.06 in liver	2
6.4 mg CN/kg BW	Some deaths in 30 min; maximum CN levels, in mg/kg FW, were 1.6 in blood and 0.12 in liver	2
11.1 mg CN/kg BW	Acute oral LD ₅₀ , 95% CI of 6.4 and 19.1 mg CN/kg BW	2
25.4 mg CN/kg BW	Advanced signs of acute poisoning; death probable within 30 min. Maximum CN levels, in mg/kg FW, were 1.5 in blood and 0.6 in liver	2
Dietary route Fed cassava diets containing 4, 37, 70, or 103 mg total cyanide/kg ration to day-old chicks for 8 weeks	At all dietary levels, there was no significant effect on survival, growth, histology, hemoglobin, hematocrit, or lymphocyte number; however, serum thiocyanate levels increased in a dose-dependent manner	5
Fed diets containing 135 mg HCN/kg Chicks, 20-day exposure	Growth and food intake significantly depressed; plasma thiocyanate concentration increased	6
Adults, 14-day exposure	Urinary excretion of thiocyanate increased 5X in laying hens	6
CALIFORNIA condor, <i>Gymnogyps californianus</i>		
Juvenile (8.4 kg), found dead, presumably of cyanide poisoning	No evidence of injuries or disease. Yellow fluorescent particles found in mouth appeared like those placed in NaCN ejector mechanisms used in predator control. However, blood cyanide concentration was similar to that found in nonexposed vultures, including two captive California condors	2
EASTERN SCREECH-OWL, <i>Otus asio</i>		
4.6 mg CN/kg BW, equivalent to 8.6 mg NaCN/kg BW	Acute oral LD ₅₀ , 95% CI of 3.8 and 5.4 mg CN/kg BW	2

Table 15.4 (continued) Cyanide Effects on Selected Species of Birds

Species, Dose, and Other Variables	Effect	Reference^a
CANARY, <i>Serinus canarias</i>		
0.12 mg HCN/L air	All dead in 3 min	2
EUROPEAN STARLING, <i>Sturnus vulgaris</i>		
9.0 mg CN/kg BW, as NaCN	Acute oral LD50, 95% CI of 4.8 and 17 mg CN/kg BW	2
ANDEAN CONDOR, <i>Vultur gryphus</i>		
Single oral dose of 19.1 mg CN/kg BW (36 mg NaCN/kg BW)	Blood sampled immediately after death contained 1.2 mg free CN/L and 0.5 mg bound CN/L	1

15.9.4 Mammals

Microgold and silver mining are probably the most widespread sources of anthropogenic cyanides in critical wildlife habitat, such as deserts in the western United States (Hill and Henry 1996). Many species of mammals, mostly rodents and bats, were found dead at cyanide-extraction gold-mine tailings and heap leach ponds in California, Nevada, and Arizona, including 10 endangered, threatened, or otherwise protected species of mammals (Clark and Hothem 1991). A similar situation was documented for a vat-leach gold mine in South Carolina with a large tailings pond (Clark 1991).

Much of the toxicological interest in cyanide relating to mammals has focused on its rapid lethal action. However, its most widely distributed toxicologic problems are due to its toxicity from dietary, industrial, and environmental factors (Way 1981, 1984; Gee 1987; Marrs and Ballantyne 1987; Eisler 1991). Chronic exposure to cyanide is correlated with specific human diseases: Nigerian nutritional neuropathy, Leber's optical atrophy, retrobulbar neuritis, pernicious anemia, tobacco amblyopia, cretinism, and ataxic tropical neuropathy (Towill et al. 1978; Way 1981; Sprine et al. 1982; Berninger et al. 1989; Ukhun and Dibie 1989). The effects of chronic cyanide intoxication are confounded by various nutritional factors, such as dietary deficiencies of sulfur-containing amino acids, proteins, and water-soluble vitamins (Way 1981).

Most authorities now agree on five points (Towill et al. 1978; USEPA 1980; Way 1984; Ballantyne and Marrs 1987a; Eisler 1991; Hill and Henry 1996; Eisler et al. 1999) ([Table 15.5](#)):

1. Cyanide has low persistence in the environment and is not accumulated or stored in any mammal studied.
2. Cyanide biomagnification in food webs has not been reported, possibly due to rapid detoxification of sublethal doses by most species, and death at higher doses.
3. Cyanide has an unusually low chronic toxicity, but chronic intoxication exists and, in some cases, can be incapacitating.
4. Despite the high lethality of large single doses or acute respiratory exposures to high vapor concentrations of cyanide, repeated sublethal doses seldom result in cumulative adverse effects.
5. Cyanide, in substantial but sublethal intermittent doses, can be tolerated by many species for long periods, perhaps indefinitely.

The toxicity of cyanogenic plants is a problem for both domestic and wild ungulates. Poisoning of herbivorous ungulates is more prevalent under drought conditions, when these mammals become

less selective in their choice of forage; dry growing conditions also enhance cyanogenic glycoside accumulations in certain plants (Towill et al. 1978). Animals that eat rapidly are at greatest risk, and intakes of 4 mg HCN/kg BW can be lethal if consumed quickly (Egekeze and Oehme 1980). In general, cattle are most vulnerable to cyanogenic plants; sheep, horses, and pigs — in that order — are more resistant than cattle (Cade and Rubira 1982). Deer (*Odocoileus* sp.) and elk (*Cervus* sp.) have been observed to graze on forages that contain a high content of cyanogenic glycosides; however, cyanide poisoning has not been reported in these species (Towill et al. 1978). Ruminant and nonruminant ungulate mammals that consume forage with high cyanogenic glycoside content, such as sorghums, Sudan grasses, and corn, may experience toxic signs due to microbes in the gut that hydrolyze the glycosides, releasing free hydrogen cyanide (Towill et al. 1978). Signs of acute cyanide poisoning in livestock usually occur within 10 min and include initial excitability with muscle tremors, salivation, lacrimation, defecation, urination, and labored breathing, followed by muscular incoordination, gasping, and convulsions; death can occur quickly, depending on the dose administered (Towill et al. 1978; Cade and Rubira 1982). Thyroid dysfunction has been reported in sheep grazing on star grass (*Cydonia plectostachyum*), a plant with high cyanogenic glycoside and low iodine content. Sheep developed enlarged thyroids and gave birth to lambs that were stillborn or died shortly after birth (Towill et al. 1978). Cyanogenic foods can exacerbate selenium deficiency, as judged by the increased incidence of nutritional myopathy in lambs on low-selenium diets (Elzubier and Davis 1988a). A secondary effect from ingesting cyanogenic glycosides from forage is sulfur deficiency as a result of sulfur mobilization to detoxify the cyanide to thiocyanate (Towill et al. 1978).

Cyanide poisonings of livestock by forage sorghums and other cyanogenic plants are well documented (Cade and Rubira 1982). Horses in the southwestern United States grazing on Sudan grass and sorghums developed posterior muscle incoordination, urinary incontinence, and spinal cord histopathology. Offspring of mares that had eaten Sudan grass during early pregnancy developed musculoskeletal deformities (Towill et al. 1978). Salt licks containing sulfur (8.5%) have been used to treat sheep after they failed to gain weight when grazing on sorghum with high HCN content (Towill et al. 1978). Sugar gum (*Eucalyptus cladocalyx*) and manna gum (*Eucalyptus viminalis*) contain high levels of cyanogenic glycosides, and both have been implicated as the source of fatal HCN poisoning in domestic sheep and goats that had eaten leaves from branches felled for drought feeding, or after grazing sucker shoots on lopped stumps (Webber et al. 1984). In one case, 10 goats died and 10 others were in distress within 2 h after eating leaves from a felled sugar gum. Dead goats had bright red blood that failed to clot and subepicardial petechial hemorrhages. Rumens of dead goats contained leaves of *Eucalyptus* spp. and smelled of bitter almonds. The 10 survivors were treated intravenously with 3 mL of a 1-L solution made to contain 20 g sodium nitrite and 50 g sodium thiosulfate; four recovered and six died. Of 50 afflicted goats, 24 died within 24 h and the remainder recovered (Webber et al. 1984). In rare instances, HCN poisoning occurs when animals are exposed to chemicals used for fumigation or as a fertilizer (Webber et al. 1984), but there is general agreement that ingestion of plants containing high levels of cyanogenic glycosides is the most frequent cause of cyanide poisoning in livestock.

Cassava, also known as manioc, tapioca, yucca, or guacamate, is one of the very few — and, by far, the most important — food crops in which the cyanide content creates toxic problems (Cooke and Coursey 1981). Cassava is a major energy source for people and livestock in many parts of the world. It accounts for an average of 40% of the human caloric intake in Africa (Casadi et al. 1984) and ranges to more than 70% in some African diets (Way 1984). In comparison to other tropical crops, it produces the highest yield per hectare (Okeke et al. 1985). Cassava is native to tropical America from southern Mexico to northern Argentina and probably has been under cultivation there for 4000 to 5000 years. It has been introduced to east Africa, Indian Ocean islands, southern India, and the Far East (Cooke and Coursey 1981). The global production of cassava roots was estimated at 50 million tons in 1950, and 100 million tons in 1980; about 44.2 million tons are grown annually in Africa, 32.7 in tropical America, and 32.9 in Asia (Cooke and Coursey 1981).

Linamurin is the principal cyanogenic glycoside in cassava; its toxicity is due to hydrolysis by intestinal microflora releasing free cyanide (Padmaja and Panikkar 1989). Rabbits (*Oryctolagus cuniculus*) fed 1.43 mg linamurin/kg BW daily (10 mg/kg BW weekly) for 24 weeks showed effects similar to those of rabbits fed 0.3 mg KCN/kg BW weekly. Specific effects produced by linamurin and KCN included elevated lactic acid in heart, brain, and liver; reduced glycogen in liver and brain; and marked depletion in brain phospholipids (Padmaja and Panikkar 1989).

The use of cassava in animal feed presents two major problems: the presence of cyanogenic glycosides in the tuber, and the remarkably low protein levels in fresh and dried cassava. Pigs fed low-protein cassava diets for 8 weeks had reduced food consumption and lowered liver weight; addition of protein supplement to the diet reversed these trends (Tewe 1982a). Removal of cyanogenic glycosides from cassava tubers, mash, peels, and root meal is accomplished with several techniques. Usually, the cassava root is dried in the sun for several weeks, and this process removes most of the cyanogenic glycosides. However, under conditions of famine or food shortage, this process cannot be carried out properly (Cliff et al. 1984). Long fermentation periods, especially under conditions of high moisture content, may be effective in substantial detoxification of cassava mash (Ukhun and Dibie 1989). Cassava peels containing as much as 1061 mg HCN/kg FW can be rendered suitable for feeding to livestock (4 to 625 mg/kg) by boiling for 7 min, roasting for 30 min, soaking for 15 h, or drying in the sun for 7.6 days (Okeke et al. 1985). Cassava root meal (up to 40% of cassava meal) is satisfactory as a diet supplement for domestic pigs, provided that cyanide content is <100 mg/kg ration (Gomez et al. 1983).

Neuropathies associated with cassava ingestion (i.e., cyanide intoxication) can develop into a syndrome in humans and domestic animals, characterized by nerve deafness, optic atrophy, and an involvement of the sensory spinal nerve that produces ataxia. Other symptoms include stomatitis, glossitis, and scrotal dermatitis (Way 1981). Potentially more serious are long-term effects such as ataxic neuropathy, goiter, and cretinism, which have been attributed to high cassava content in diets. Thiocyanate — one of the detoxification products — inhibits iodine absorption and promotes goiter, a common ailment in tropical countries (Cooke and Coursey 1981). At high dietary cyanide intakes, there is an association with diabetes and cancer (Cliff et al. 1984), but this requires verification. The first case of cassava toxicity occurred almost 400 years ago (Cooke and Coursey 1981). The toxic principle was later identified as a cyanogenic glycoside, shown to be identical with flax linamurin (2-(beta-D-glucopyranosyloxy)-isobutyronitrile). All parts of the plant, except possibly the seeds, contain the glycoside together with the enzyme linamarase. This enzyme affects hydrolysis of the nitrile to free HCN when the tissue cellular structure is damaged (Cooke and Coursey 1981). Mantakassa disease is related to chronic cyanide intoxication associated with a diet consisting almost exclusively of cassava. In times of famine and sulfur-poor diets, Mantakassa effects were more pronounced (Casadi et al. 1984). Symptoms of Mantakassa disease include the sudden onset of difficulty in walking, increased knee and ankle reflexes, elevated serum thiocyanate levels, fever, pain, headache, slurred speech, dizziness, and vomiting. Women of reproductive age and children were the most seriously affected. Symptoms persisted for up to 4 months after treatment with hydroxycobalamin, vitamin supplements, and a high-protein, energy-rich diet (Cliff et al. 1984). Mantakassa was reported in 1102 victims in Mozambique in 1981 from a drought-stricken cassava staple area; from Zaire in 1928, 1932, 1937, and again in 1978 to 1981; in Nigeria; and in the United Republic of Tanzania. The mean serum thiocyanate level in patients with Mantakassa is 2.6 times higher than in non-Mantakassa patients in Nigeria, and 3.5 times higher than in Tanzanian patients. Pesticides, infection, viruses, and consumption of food other than cassava were eliminated as possible causative agents in Mantakassa disease. Still unresolved is whether the disease is triggered when a threshold level of thiocyanate is reached, or when a critical combination of cyanide intoxication plus nutritional deficiency occurs (Cliff et al. 1984).

Routes of administration other than dietary ingestion should not be discounted. Livestock found dead near a cyanide disposal site had been drinking surface water runoff from the area that contained up to 365 mg HCN/L (USEPA 1980). The use of cyanide fumigant powder formulations may be

hazardous by contact of the powder with moist or abraded skin, contact with the eye, swallowing, and inhalation of evolved HCN (Ballantyne 1988). In rabbits, lethal systemic toxicity was produced by contamination of the eye, moist skin, or abraded skin (but not dry skin) with cyanide powder formulations (40% NaCN plus 60% kaolin) administered at 1 to 5 g powder/m³ (Ballantyne 1988). Hydrogen cyanide in the liquid state can readily penetrate the skin, and skin ulceration has been reported from splash contact with cyanides among workers in the electroplating and gold extraction industries — although effects in those instances were more likely due to the alkalinity of the aqueous solutions (Homan 1987). In one case, liquid HCN ran over the bare hand of a worker wearing a fresh air respirator; he collapsed into unconsciousness in 5 min, but ultimately recovered (USEPA 1980).

Use of poisons in livestock collars is both specific and selective for animals causing depredations, as is the case for cyanide collars to protect sheep against coyotes (Steiner 1979) (**Table 15.5**). These collars contain a 33% NaCN solution and are usually effective against coyotes. However, field results indicate that some coyotes kill by means other than neck attack, and some exhibit great wariness in attacking collared sheep (Savarie and Sterner 1979).

Calcium cyanide in flake form was used in the 1920s to kill black-tailed prairie dogs and pocket gophers (*Geomys bursarius*) in Kansas, and various other species of rodents in Nova Scotia (Wade 1924). For prairie dog control, the usual practice was to place 43 to 56 g calcium cyanide 0.3 to 0.7 m below the rim of the burrow and close to the entrances. The moisture in the air liberated HCN gas, which remained in the burrow for several hours, producing 100% kill. A lower dose of 28 g per burrow was only about 90% effective (Wade 1924). Control of prairie dogs with cyanide sometimes resulted in the death of burrowing owls that lived in the prairie dog burrows (Wade 1924). Some animals can develop an aversion to food associated with sodium cyanide-induced illness (Clapperton et al. 1996). For example, sodium cyanide-containing baits used in New Zealand against the brushtail possum (*Trichosurus vulpecula*) produced bait shyness through conditioned food aversion induced by sublethal (4 to 5 mg NaCN/kg BW) cyanide ingestion, effectively reducing NaCN poisoning operations in that country (Warburton and Drew 1994; O'Connor and Matthews 1995; Clapperton et al. 1996).

Clinical signs of acute cyanide poisoning in mammals last only a few minutes after ingestion and include rapid and labored breathing, ataxia, cardiac irregularities, dilated pupils, convulsions, coma, and respiratory failure. Death may occur quickly, depending on the dose administered (Towill et al. 1978; Egekeze and Oehme 1980; Cade and Rubira 1982; Ballantyne 1983). Despite the high lethality of large single exposures, repeated sublethal doses — especially in diets — are tolerated by many species for extended periods, perhaps indefinitely (Eisler 1991). Cyanide poisoning causes cardiovascular changes as well as its better known effects on cellular respiration. Cyanide increases cerebral blood flow in rabbits and cats, and disrupts systemic arterial pressure in dogs (Robinson et al. 1985). Cyanide affects mammalian behavior, mostly motor functions, although these effects have not been quantified. Cyanide-induced motor alterations observed in rats and guinea pigs include muscular incoordination, increased whole-body locomotion, disrupted swimming performance, and altered conditioned avoidance responses (D'Mello 1987). As a consequence of the cytotoxic hypoxia in acute cyanide poisoning, there is a shift from aerobic to anaerobic metabolism, and the development of lactate acidosis. A combination of rapid breathing, convulsions, and lactate acidosis is strongly suggestive of acute cyanide poisoning (Ballantyne 1983). As with other chemical asphyxiants, the critical organs that are most sensitive to oxygen depletion are the brain and heart (Egekeze and Oehme 1980). The only consistent postmortem changes found in animals poisoned by cyanide are those relating to oxygenation of the blood. Because oxygen cannot be utilized, venous blood has a bright-red color and is slow to clot (Egekeze and Oehme 1980). Bright-red venous blood is not a reliable indicator of cause of death, however, because it is also associated with chemicals other than cyanide (Ballantyne 1983).

Cyanide poisoning is associated with changes in various physiological and biochemical parameters. The earliest effect of cyanide intoxication in mice seems to be inhibition of hepatic rhodanese

activity, due to either blockage by excess binding to the active site or to depletion of the sulfane–sulfur pool. These changes do not seem to occur in blood, where rhodanese functions at its maximal rate, thus preventing cyanide from reaching the target tissues and causing death (Buzaleh et al. 1989). Cyanide causes dose- and species-dependent responses on vascular smooth muscle. Studies with isolated aortic strips indicate that rabbits are 80 times more sensitive than dogs or ferrets (*Mustela putorius*) (Robinson et al. 1985). Rabbits killed with HCN had higher concentrations of cyanide in blood and other tissues and lower tissue cytochrome oxidase activities than did those killed with KCN (Ballantyne et al. 1972). Cyanide promotes dose- and calcium-dependent release of dopamine from tissues in the domestic cat, and reductions in adenosine triphosphate (ATP) content of the carotid body (Obeso et al. 1989). Cyanide-induced hypoxia is believed to produce decreases in the ATP content of Type I glomus cells. The decrease in the phosphate transfer potential is a crucial step in the overall transduction process, that is, the activation of the transmitter release from Type I cells, with resultant release and activation of sensory nerve endings (Obeso et al. 1989). Studies with isolated heart of the domestic ferret demonstrate that cyanide affects intracellular ionic exchange of H⁺, Na⁺, and Ca²⁺ (Fry et al. 1987); inhibits cardiac action potential (Elliott et al. 1989); and inhibits oxidative phosphorylation accompanied by an intracellular acidosis, a decrease in phosphocreatinine, and a rise in inorganic phosphate (Eisner et al. 1987). When oxidative phosphorylation is inhibited in cardiac muscle, there is a rapid decrease of developed force or pressure. Most of the decrease of developed pressure produced by cyanide in ferret heart is not produced by intracellular acidosis and may result from increased inorganic phosphate (Eisner et al. 1987). Observed changes in rat cerebral oxidative responses to cyanide may be due to redistribution of intracellular oxygen supply to mitochondria respiring in an oxygen-dependent manner or by branching effects within brain mitochondria (Lee et al. 1988). Hyperammonemia and the increase of neutral and aromatic amino acids may also be important in loss of consciousness induced by cyanide (Yamamoto 1989). Rats exposed for 30 days to 100 or 500 mg KCN/L drinking water had mitochondrial dysfunction, depressed ATP concentrations in liver and heart, and a depressed growth rate. Little effect was observed at 50 mg KCN/L (Pritsos 1996). The adverse effect on growth is consistent with the biochemical indicators of energy depletion. However, the concentrations should be viewed with caution as CN may have volatilized from the water solutions prior to ingestion by the rats, due to presumed neutral pH (Pritsos 1996).

Organic cyanide compounds, or nitriles, have been implicated in numerous human fatalities and signs of poisoning — especially acetonitrile, acrylonitrile, acetone cyanohydrin, malonitrile, and succinonitrile. Nitriles hydrolyze to carboxylic acid and ammonia in either basic or acidic solutions. Mice (*Mus sp.*) given lethal doses of various nitriles had elevated cyanide concentrations in liver and brain; the major acute toxicity of nitriles is CN release by liver processes (Willhite and Smith 1981). In general, alkyl nitriles release CN much less readily than aryl alkyl nitriles, and this may account for their comparatively low toxicity (Davis 1981).

No human cases of illness or death due to cyanide in water supplies are known (USEPA 1980). Accidental acute cyanide poisonings in man are uncommon (Towill et al. 1978). However, a man accidentally splashed with molten sodium cyanide died about 10 h later (Curry 1963). Human cyanide deaths usually involve suicides, where relatively large amounts of sodium cyanide or potassium cyanide are ingested and the victims die rapidly in obvious circumstances. Recovery after oral ingestion is rare. In one case, a spouse emptied capsules containing medicine and repacked them with 40% solid NaCN. The victim took one capsule and ingested about 0.05 g, but vomited and recovered completely (Curry 1963). Human deaths are increasing from gas or smoke inhalation from urban fires, possibly owing to the increased toxicity of fire atmospheres caused by the use of organocyanide plastics in modern construction and furnishings (Egekeze and Oehme 1980). Hydrogen cyanide may be important in some fires in producing rapid incapacitation, causing the victims to remain in the fire and die from carbon monoxide or other factors, although HCN concentrations of 60 mg/L air and lower had minimal effects (Purser 1984). Exposure to the mixture of HCN and carbon monoxide, with accompanying changes in cerebral blood flow during attempts to escape

from fires, may be a cause of collapse and subsequent death (Purser 1984). For example, cynomolgus monkeys (*Macaca* spp.) exposed to pyrolysis products of polyacrylonitrile (PAN) and to low-level HCN gas had similar physiological effects in both atmospheres: specifically, hyperventilation, followed by loss of consciousness after 1 to 5 min; and bradycardia, with arrhythmias and T-wave abnormalities. Recovery was rapid following cessation of exposure (Purser et al. 1984). Because HCN is the major toxic product formed by the pyrolysis of PAN, Purser et al. (1984) suggested that HCN may produce rapid incapacitation at low blood levels of cyanide in fires, while death may occur later due to carbon monoxide poisoning or other factors.

Finally, cyanide does not appear to be mutagenic, teratogenic, or carcinogenic in mammals (USEPA 1980; Ballantyne 1987a). In fact, there has been a longstanding hypothesis for an anticancer effect of the cyanogenic glycoside amygdalin (also called laetrile). The hypothesis is based on amygdalin's selective hydrolysis by a beta glucosidase, liberating cyanide and benzaldehyde at the neoplastic site. The cyanide then selectively attacks the cancer cell, which is presumed to be low in rhodanese, whereas normal cells are assumed to possess sufficient rhodanese and sulfur to detoxify the cyanide (Way 1981). However, many tumors are neither selectively enriched in beta glucosidase nor low in rhodanese (Way 1981).

Table 15.5 Cyanide Effects on Selected Species of Mammals

Species, Dose, and Other Variables	Effect	Reference ^a
CATTLE, <i>Bos</i> sp.		
Fed hybrid sorghum Sudan grass cross 988 at 15–20 kg/animal daily for 3–8 days	Of 180 cows, 21 were affected and 13 died; toxic cyanide levels were measured in fodder, and in liver and ruminal contents of dead cows	44
DOG, <i>Canis familiaris</i>		
Administered doses up to 2 mg NaCN/kg body weight (BW), once or twice daily for 15 months	Acute toxic signs evident after each administration, but complete recovery within 30 min; no measurable adverse effects after 15 months	1
5.4 mg NaCN/kg BW, single subcutaneous injection	LD50	2
24 mg KCN/kg BW, single oral or slow intravenous injection route	Lethal. At time of respiratory arrest, blood plasma concentration was 1.0 mg total CN/L or about 0.4 mg free cyanide/L	3
Fed diets containing 150 mg NaCN/kg for 30 days	No measurable effect on food consumption, blood chemistry, behavior, or organ histology	1
COYOTE, <i>Canis latrans</i>		
Single forced oral dose of NaCN, in mg/kg BW		
4	Immobilized in 13 min, but all survived for at least 30 days. Some sacrificed after 30 min: NaCN residues in mg/kg fresh weight (FW) were 0.03 in blood and 0.9 in stomach	2
4.1 (2.1–8.3)	LD50	2
8	Immobilization in 9 min, death within 41 min	2
16, 32, or 64	All immobilized in less than 1 min and all died in less than 8 min; maximum NaCN residues were 0.14 mg/L in blood and 13.0 mg/L FW in stomach	2
"Toxic" collars attached to neck of sheep and camouflaged with wool. Each collar contained 50 mL of a 33% NaCN solution. Toxic action commences when coyote attacks sheep and punctures collar. All coyotes tested were known to attack sheep in laboratory pens	Of three coyotes tested, one was immobilized in 1 min and died within 18 min; the other two coyotes recovered. The dead coyote had mouthed the collar for about 2 s: residues, in mg NaCN/kg, were 0.026 in blood and <0.1 in stomach. The other two coyotes had mouthed the collar for 3–15 s and had NaCN	

Table 15.5 (continued) Cyanide Effects on Selected Species of Mammals

Species, Dose, and Other Variables	Effect	Reference^a
Toxic collar, as above. Each coyote tested was known to have fatally attacked at least 3 domestic sheep within a 30-day period	levels, in mg/kg FW, of 0.014 and 0.029 in blood, and 0.6 and <0.1 in stomach Of the 12 coyotes that attacked the neck region of the sheep and punctured the collar, 9 received lethal doses and became immobilized in 1–3 min and died 3–25 min later. The mean time to death was 11.6 min. One of the three sublethally dosed coyotes survived at last three successful attacks in which the collar was punctured, and two survived two attacks. In all cases, contact with NaCN produced shaking of the head, pawing at the mouth, rubbing the snout on the ground, and ataxia	2 4
AFRICAN GIANT RAT, <i>Cricetomys gambianus</i>		
Weanlings fed diets for 16 weeks containing zero mg HCN/kg (maize), 110 mg HCN/kg (cassava pulp), 150 mg HCN/kg (cassava tuber), or 597 mg HCN/kg (cassava peel)	Food consumption was similar in all diets. No pathology was observed in any organ of animals on all treatments. Rats on maize and cassava pulp diets had significantly increased growth rate, feed efficiency, and protein efficiency. Rats on cassava peel and tuber diets had significantly increased thiocyanate levels in serum, organs, and urine	5
Juveniles, age 10–14 weeks, fed cassava peel diets for 2 weeks containing 720 mg HCN/kg Weanlings fed 1000 mg CN/kg diet, as KCN, for 12 weeks	Adverse effects on growth when cassava peel exceeds 7.8% of the ration Reduction in feed intake, reduced body weight, elevated thiocyanate concentrations in serum (37.4 mg/L vs. 12.6), urine (341 mg/L vs. 25), liver (1.7 g/kg FW vs. 0.4), kidney (2.4 g/kg FW vs. 0.4), and spleen (2.1 g/kg FW vs. 0.3)	6 7
HUMAN, <i>Homo sapiens</i>		
Intentional oral ingestion of unknown amount of NaCN or KCN, three cases	Death between 5 and 30 min; stomach cyanide concentrations ranged between 100 and 164 mg; tissue residues postmortem, in mg cyanide/kg FW, were 0.3–1.1 in blood, 0.3–1.0 in liver, and 0.2–0.3 in brain	8
Found dead, four cases, time to death unknown	Maximum cyanide burden in stomach was 230 mg; maximum tissue residues, in mg cyanide/kg FW were 3.5 in blood, 6.3 in liver, and 0.5 in brain	8
Attempted suicide by 39-year-old male, unknown amount of NaCN	Severe tremors and progressive loss of muscle tone — representing the first case of cyanide intoxication with delayed onset of symptoms	9
Inhalation of HCN gas, in mg/m ³ , for various time intervals		
140 for 60 min	Calculated LC50	10
220 for 30 min	Calculated LC50	10
504 for 10 min	Calculated LC50	10
680 for 5 min	Calculated LC50	10
1500 for 3 min	Calculated LC50	10
4400 for 1 min	Calculated LC50	10
Inhalation of 2000 mg HCN/L	First breath results in deep, rapid breathing, with collapse, convulsions, and death within 1 min	11
Inhalation of cyanogen chloride, in mg/L, for various time intervals		
1, 10 min	Irritant	1
48, 30 min	Fatal	1
159, 10 min	Fatal	1

Table 15.5 (continued) Cyanide Effects on Selected Species of Mammals

Species, Dose, and Other Variables	Effect	Reference^a
Inhalation of cyanogen bromide, in mg/L, for various time intervals		
1.4, no time given	Irritant to eyes and nose	1
92, 10 min	Fatal	1
Single oral dose		
0.5–3.5 mg HCN/kg BW	Lethal	12, 41
0.7–3.5 mg KCN/kg BW, equivalent to 50–250 mg KCN/adult	Fatal	10
2 mg HCN/kg BW, or total of about 150 mg HCN	Acute LD ₅₀ for adults	13
1–5 g NaCN or KCN, equivalent to 0.2 g/adult or 3 mg/kg BW	Minimum lethal dose	14
Tissue residues		
Whole blood, 1–2 mg free cyanide/L	Usually lethal	42
Whole blood, 2.6–3.1 mg total CN/L	Minimum cyanide concentration associated with death in an otherwise healthy individual	13
Whole blood, 4–45 mg total CN/L	Levels measured in known suicides	13
Whole body, 7 mg HCN/kg BW	Residue associated with minimum lethal dose	11
Daily dietary intake of 15–31.5 mg hydrogen cyanide from cassava	Mantakassa disease (see text for discussion)	15
100 mg HCN/kg BW applied to skin surface	LD ₅₀	11
Clothing inundated with 10% NaCN solution, pH 11.4	Clinical signs of toxicity within 25 min and death in about 60 min	13
LIVESTOCK		
>200 mg HCN/kg plant materials in diet	Potentially dangerous	13
CYNOMOLGUS MONKEYS, <i>Macaca</i> spp.		
Given multiple sublethal doses of KCN (5–18 mg) for 23 days	Brain histopathology	3
Exposed to HCN gas produced from combustion of polyacrylonitrile materials at various temperatures		
300°C, 87–170 mg HCN/L air	Incapacitated in 16–30 min, blood cyanide of 4.3 mg/L	16
600°C, 120–174 mg HCN/L air	Incapacitated between 6 and 24 min; blood cyanide of 2.96 mg/L	16
900°C, 166–196 mg HCN/L air	Incapacitated between 2 and 13 min; blood cyanide concentration of 3.1 mg/L	16
Exposed to HCN gas at air concentrations of 60, 80, or 150 mg HCN/L for 30 min	At 60 mg/L, HCN had only a slight depressive effect on the central nervous system; at 80 and 150 mg/L, severe CNS depression and incapacitation occurred	17
Exposed to HCN gas at air concentrations of 100, 102, 123, 147, or 156 mg HCN/L air	Incapacitated in 8 min at higher doses, to 19 min at lowest dose tested. Blood cyanide after 30 min exposure ranged between 1.7 mg/L at 100 mg HCN/L and 3.2 mg/L at 156 mg HCN/L; after recovery for 60 min, blood CN ranged between 2.0 and 2.9 mg/L	16
HOUSE MOUSE, <i>Mus musculus</i>		
Single oral dose of 8.7 (8.2–9.3) mg NaCN/kg BW, equivalent to 4.6 mg CN/kg BW	LD ₅₀	45
DOMESTIC MOUSE, <i>Mus</i> spp.		
Single intraperitoneal injection		
HCN, 2.8 mg/kg BW	LD ₅₀	10
NaCN, 4.6–5.9 mg/kg BW	LD ₅₀	10

Table 15.5 (continued) Cyanide Effects on Selected Species of Mammals

Species, Dose, and Other Variables	Effect	Reference^a
KCN, 5.3–6.7 mg/kg BW	LD50	10
Acetone cyanohydrin, $(\text{CH}_3)_2\text{C}(\text{OH})\text{CN}$, 8.7 mg/kg BW	LD50 (7 days); first death in 5 min	18
Malononitrile, NCCH_2CN , 18 mg/kg BW	LD50 (7 days); first death in 4.8 h	18
Propiononitrile, $\text{CH}_3\text{CH}_2\text{CN}$, 28 mg/kg BW	LD50 (7 days); first death in 21 h	18
N-butyronitrile, 38 mg/kg BW	LD50 (7 days); first death in 2.2 h	18
Acrylonitrile, $\text{CH}_2=\text{CHCN}$, 46 mg/kg BW	LD50 (7 days); first death in 2.3 h	18
Succinonitrile, $\text{NCCH}_2\text{CH}_2\text{CN}$, 62 mg/kg BW	LD50 (7 days); first death in 5.1 h	18
Acetonitrile, CH_3CN , 175 mg/kg BW	LD50 (7 days); first death in 7.1 h	18
Single subcutaneous injection		
HCN, 7.8–12.0 mg/kg BW	LD50	10
KCN, 10 mg/kg BW	Loss of consciousness in 100%; blood ammonia levels increased 2.5X; brain amino acid levels (i.e., leucine, isoleucine, tyrosine, phenylalanine) increased by 1.5–3.0X. Alpha ketoglutarate, at 500 mg/kg BW by intraperitoneal injection, completely blocked the development of cyanide-induced loss of consciousness and hyperammonemia	19
Single oral dose		
8.5 mg KCN/kg BW, equivalent to 3.4 mg CN ⁻ /kg BW	LD50	10, 20
Drinking water, 1000 mg KCN/L, exposure for 40 days	Marked inhibition of cytochrome oxidase activity in liver, brain, and blood; increased cyanide concentrations in all tissues; inhibition of rhodanese activity; diminished labile sulfur tissue levels	43
LITTLE BROWN BAT, <i>Myotis lucifugus</i>		
Single oral dose of NaCN of 8.4 (5.9–11.9) mg/kg BW, equivalent to 4.4 (3.1–6.3) mg CN/kg BW	LD50	45
RABBIT, <i>Oryctolagus</i> spp.		
Isolated aorta strips, 0.00014 µg NaCN/L–140 µg/L	Small contractions measured at lowest dose tested, ED50 at 70 µg/L, and maximum response at 140 µg/L. Higher doses up to 14 mg/L produced relaxation	21
Single intramuscular injection, in mg/kg BW		
0.5–1.5	LD50 for HCN	10
1.6	LD50 for NaCN	10
3.1–3.3	LD50 for KCN	10
8.0		
Killed with KCN	Cyanide concentrations, in mg/kg FW, were 1.6 in serum, 5.3 in blood, and <0.4 in other tissues sampled	22
Killed with HCN	Cyanide concentrations, in mg/kg FW, were 9.3 in blood, 2.1 in brain, 2.0 in serum, 0.5 in myocardium, and <0.4 in other tissues	22
Single intravenous injection, in mg/kg BW		
0.6	LD50 for HCN	10
1.2	LD50 for NaCN	10
1.9	LD50 for KCN	10
Single dose administered to eye surface, in mg/kg BW		
1.0	LD50 for HCN	10
4.5–5.1	LD50 for NaCN	10
7.9	LD50 for KCN	10
11.2	Signs of NaCN poisoning in 3 min; death in 7 min	23

Table 15.5 (continued) Cyanide Effects on Selected Species of Mammals

Species, Dose, and Other Variables	Effect	Reference^a
Single intraperitoneal injection, in mg/kg BW		
1.7–2.0	LD50 for HCN	10
2.8–2.9	LD50 for NaCN	10
3.6–4.0	LD50 for KCN	10
Administered as solution to skin, in mg/kg BW		
2.3	LD50 for HCN and abraded skin	10
6.9	LD50 for HCN and intact skin	10
14.3	LD50 for KCN and abraded skin	10
19.3	Abraded skin. Signs of NaCN poisoning evident in 25 min, death in 41 min	23
22.3	LD50 for KCN and intact skin	10
29.5	Moist skin. Signs of NaCN poisoning evident in 79 min, death in 117 min	23
>110	Dry skin. No signs of NaCN poisoning, no deaths	23
Single oral dose, in mg/kg BW		
2.5	LD50 for HCN	10
5.1	LD50 for NaCN	10
5.8	LD50 for KCN	10
12.8	Signs of NaCN poisoning in 4 min, death in 22 min	23
Single oral dose, NaCN, 10–15 mg/kg BW	All dead in 14–30 min; blood cyanide ranged between 3.7 and 5.4 mg/L	24
Inhalation of HCN from combustion of 20 g polyacrylonitrile	All dead in 12–16 min; blood cyanide ranged between 1.6 and 3.1 mg/L	24
Interval between death and removal of tissues for analysis in rabbits killed by KCN		
Brain	Concentrations dropped from 1.6 mg/kg FW immediately after death to 1.2 in 1 day, 0.92 in 3 days, and 0.04 in 7 days	25
Blood	Residues, in mg/kg FW, were 5.7 immediately after death, and 2.3 after 21 days	25
Lung	Cyanide concentrations dropped from 2.0 mg/kg FW just after death, to 0.8 in 7 days	25
DOMESTIC SHEEP, <i>Ovis aries</i>		
Intravenous or intraarterial injection, fetal lambs 80% through gestation (120 days), NaCN, 50–400 µg	Slowing of fetal heart rate, disruption of respiratory movements, significant but inconsistent changes in arterial blood pressure	26
Single intramuscular injection of 10 mg KCN/kg BW	All dead within 17 min; cyanide concentrations postmortem, in mg/kg FW, were 3.3 in blood, 1.5 in plasma, 1.6 in serum, 1.4 in cerebrospinal fluid, 0.9 in brain grey matter, and 1.0 in brain white matter	3, 10, 27
WHITE-FOOTED MOUSE, <i>Peromyscus leucopus</i>		
Single oral dose of 28 mg NaCN/kg BW, equivalent to 14.8 mg CN/kg BW	LD50	45
LABORATORY WHITE RAT, <i>Rattus</i> spp.		
Single intraperitoneal injection		
0.1–10 mg CN/kg BW	LD50	28
5 mg NaCN or KCN/kg BW	50% decrease in brain cytochrome oxidase activity within 5–10 min	14
5 mg KCN/kg BW	Reversible intracellular metabolic changes including acidosis and increased lactate levels — typical of cellular anoxia	29

Table 15.5 (continued) Cyanide Effects on Selected Species of Mammals

Species, Dose, and Other Variables	Effect	Reference^a
Intravenous injection, constant infusion of 0.15–0.20 mg CN/kg BW per min	LD50 in about 20 min; rapid progressive reduction in cerebrocortical cytochrome oxidase (cytochrome aa ₃) concomitant with increases up to 200% in cerebral blood flow	30
Single intracarotid artery injection of KCN 1–2 mg/kg BW	Modest acute clinical dysfunction and incomplete suppression of brain electroencephalographic (EEG) activity	31
2.5 mg/kg BW	Some deaths. Survivors showed rapid abolition of brain EEG activity, 52% reduction in brain cytochrome oxidase activity, 600% increase in lactate, 85% decrease in glycogen, 32% reduction in ATP, and 73% increase in ADP. All values returned to normal in 6–24 h, and remained normal for balance of 7-day observation period	31
3.5–5 mg/kg BW	High incidence of cardiovascular collapse and death within minutes	31
Tissue residues 2.6–2.9 mg HCN/kg FW	Minimum lethal concentrations in rats poisoned orally with KCN	13
Inhalation exposure route, HCN vapor, in mg/m ³ , for various periods 3778 for 10 s 1128 for 1 min 493 for 5 min 151–173 for 30–60 min	LC50 LC50 LC50 LC50	10 10 10 10
Single oral dose 3.4 mg KCN/kg BW 3.6–4.2 mg HCN/kg BW 5.1–5.7 mg NaCN/kg BW 5.7 mg KCN/kg BW 6, 10, or 14 mg KCN/kg BW	LD25 LD50 LD50 LD50 Some deaths in all groups; all dead at higher doses within 60 min. Those killed 10 min postadministration had higher blood CN concentrations than those killed near death or at survival at 60 min	32 10 10 32 13
6.4 mg NaCN/kg BW 7.5–10 mg KCN/kg BW 8.6 mg KCN/kg BW 10 mg KCN/kg BW, equivalent to 4 mg HCN/kg BW 13.2 mg NaCN/kg FW or 7 mg HCN/kg BW	LD50 LD50 LD98 LD50 Dead in 10.3 min. Tissue cyanide levels, in mg/kg FW, were 8.9 in liver, 5.9 in lung, 4.9 in blood, 2.1 in spleen, and 1.5 in brain	13 10, 13 32 20 33
40 mg NaCN/kg BW, equivalent to 21 mg HCN/kg BW	Dead in 3.3 min	33
Drinking water exposure Equivalent to 8 mg CN/kg BW daily for 21 days Equivalent to 21 mg CN/kg BW daily for 21 days 200 mg CN/L for 4 weeks Drinking water of adults contained 150 mg CN/L, as KCN, for 2 weeks, followed by injection with radioselenium-75 and observed for 15 days	Liver normal Significantly increased liver weight Reduced growth Cyanide-treated rats excreted significantly more radioselenium in urine than did controls. Half-time persistence of radioselenium in treated group was 28 days vs. 38 days in controls	20 20 34 35
Drinking water of weanling males contained 150 mg CN/L for 9 weeks	Significant reduction in glutathione activity, and in selenium concentrations in blood, kidney, liver, and muscle	35

Table 15.5 (continued) Cyanide Effects on Selected Species of Mammals

Species, Dose, and Other Variables	Effect	Reference ^a
Dietary exposure		
Fed 12 mg CN/kg BW daily for 2 years, equivalent to 300 mg HCN/kg ration	No measurable adverse effects on blood chemistry, growth, survival, or histology; elevated thiocyanate levels in liver and kidneys	1
Fed 500 mg HCN/kg ration to pregnant rats through gestation and lactation	No effect on reproduction	20
Weanlings fed diets of raw lima beans containing 727 mg CN/kg for 3 weeks, or 727 mg CN/kg diet as KCN for 3 weeks	Lima bean diet alone increased hepatic glutamate dehydrogenase (GLDH) and decreased isocitrate dehydrogenase (ICDH) activities. But KCN diet had no effect on GLDH and increased ICDH activity, emphasizing the importance of dietary components when evaluating CN-containing diets	36
750 mg CN/kg diet (1875 mg KCN/kg diet) for 8 weeks, adequate protein	No measurable effect on food consumption or growth rate. Significantly increased serum and urinary thiocyanate concentrations	37
As above, protein-deficient diet	Reduction in body weight gain, reduction in serum thiocyanate concentration	37
Weanling males fed diets containing 1500 mg KCN/kg, or 2240 potassium thiocyanate (KSCN) for 50 weeks	No deaths or clinical signs of toxicity. Both groups had decreased thyroid gland activity. Cyanide, but not thiocyanate, caused reduction in growth rate	38
Isolated liver segments from starved rats exposed to 100 mg KCN/L	Oxygen consumption reduced 80%, and evidence of hepatotoxicity as judged by enzyme release, glutathione depletion, and calcium accumulation in liver. Hepatotoxicity prevented by feeding rats fructose	39
DOMESTIC PIG, <i>Sus</i> spp.		
Fed diet containing 96 mg CN/kg ration, as cassava peel, for 72 days	No effect on food consumption or protein metabolism	40

15.10 RECOMMENDATIONS

Proposed free cyanide criteria suggest that sensitive species of aquatic organisms are protected at <3 µg/L; birds and livestock at <100 mg/kg diet; and human health at concentrations of <10 µg/L drinking water, <50 mg/kg diet, and <5 mg/m³ air (Eisler 1991) ([Table 15.6](#)). In aquatic systems, research is needed in several areas:

1. Long-term effects of cyanide on life cycles, growth, survival, metabolism, and behavior of a variety of aquatic organisms and microorganisms in addition to fish (Towill et al. 1978; Leduc et al. 1982)
2. Effects of seasonal pulses of cyanide on aquatic organisms in rural and wilderness areas (Leduc 1984)

3. Influence of various environmental parameters (e.g., oxygen, pH, temperature), if any, on adaptive resistance to cyanide (Leduc 1981, 1984)
4. Usefulness of various biochemical indicators of cyanide poisoning, such as cytochrome oxidase inhibition (Gee 1987), estradiol and thyroxine levels in fish plasma (Ruby et al. 1986, 1993a), and pituitary gland histology (Ruby et al. 1993b)

To protect vertebrate wildlife from mine water poisoning with certainty, it is necessary to exclude them from cyanide solutions or to reduce cyanide concentrations to nontoxic levels (Henny et al. 1994). More research is needed on chemical repellents and physical screening methods. Mortality of avian and terrestrial wildlife from cyanide toxicosis may be curtailed at small ponds associated with leach heaps by screening wildlife from toxic solutions (Hallock 1990) or covering small solution ponds with polypropylene netting, provided that the fencing and netting are properly maintained (Henny et al. 1994). Some mines in Nevada are now covering surfaces of small ponds with 4-inch (10.2-cm) diameter high-density polyethylene balls; birds are no longer attracted to these ponds as water sources (Eisler et al. 1999). Gold mine operators in southern California and Nevada used plastic sheeting to cover the cyanide leach pond, resulting in a cessation of wildlife mortality. The comparatively high cost of this process was soon recouped through reduced evaporation of water and cyanide (Eisler et al. 1999). To reduce the potential for puddling on ore heaps, more research is recommended on physical exclusionary devices, chemical repellents, and monitoring of solution application rates (Henny et al. 1994; Hill and Henry 1996; Eisler et al. 1999).

Analytical methodologies need to be developed that differentiate between free cyanide (HCN and CN^-) and other forms of cyanide, and that are simple, sensitive (i.e., in the $\mu\text{g/L}$ range), and accurate (Smith et al. 1979; Leduc et al. 1982). Procedures need to be standardized that ensure prompt refrigeration and analysis of all samples for cyanide determination because some stored samples generate cyanide, while others show decreases (Gee 1987). Periodic monitoring of cyanide in waterways is unsatisfactory for assessing potential hazards because of cyanide's rapid action, high toxicity, and low environmental persistence. A similar case is made for cyanide in the atmosphere. Development of a continuous monitoring system of cyanides in waterways and air is recommended, with emphasis on point source dischargers, such as industrial and municipal facilities (Towill et al. 1978; Egekeze and Oehme 1980; Leduc et al. 1982). Information is needed on the fate of cyanide compounds in natural waters, relative contributions of natural and anthropogenic sources, and critical exposure routes for aquatic organisms (Leduc et al. 1982). Additional research is needed on the origin of cyanide in wilderness and rural watershed areas, specifically the roles of organic wastes and their associated bacterial flora, aquatic vegetation induced by nutrient enrichment, and terrestrial plant cover in the watershed (Leduc 1984).

The use of M-44 sodium cyanide capsules for predator control was suspended and canceled by the U.S. Environmental Protection Agency on March 9, 1972. M-44 use was again permitted by the U.S. Environmental Protection Agency beginning on February 4, 1976, provided that "each authorized or licensed applicator shall carry an antidote kit on his person when placing or inspecting M-44 devices. The kit shall contain at least 6 pearls of amylnitrite and instructions on their use. Each authorized or licensed applicator shall also carry on his person instructions for obtaining medical assistance in the event of accidental exposure to sodium cyanide" (USEPA 1976a, b). The use of cyanide-containing paste baits to control pestiferous mammals is practiced widely in New Zealand; however, some species are repelled by these baits and more research is needed to improve their effectiveness (Warburton and Drew 1994).

Farmers need to be aware of factors that influence the cyanogenic potential of forage crops and conduct regular inspections of grazing fields for cyanogenic plants. Moreover, hay and silage should be properly cured in order to minimize cyanide content before feeding to livestock (Egekeze and Oehme 1980). Selective breeding of plants with low cyanide content will help reduce livestock

poisoning, but the most advisable prevention method at present is to prohibit grazing on fields where cyanogenic plants are present (Egekeze and Oehme 1980). More research seems needed on:

1. Effects of drought and other factors that may increase the concentration of cyanogenic glycosides in livestock forage plants
2. Mechanisms of cyanide liberation by plants
3. Effects of cyanide on wildlife and range animals that graze foliage with high cyanogenic glycoside content (Towill et al. 1978)

Research is needed on low-level, long-term cyanide intoxication in mammals by oral and inhalation routes in the vicinities of high cyanide concentrations, especially on the incidence of skin dermatitis, nasal lesions, and thyroid dysfunction, and on urinary thiocyanate concentrations. These types of studies may provide a more valid rationale in establishing standards and threshold limit values for HCN and inorganic cyanide (Towill et al. 1978; Egekeze and Oehme 1980). Data are scarce on the carcinogenic, teratogenic, and mutagenic properties of cyanide, and on the distribution and transformation of cyanides in air, land, or water. Additional analysis of available information and more research in these areas are recommended. Finally, more research is needed on cyanide toxicokinetics because cyanide is a very reactive nucleophile that distributes widely through the body, is permeable to cell membranes, and may accumulate in the fetus (Towill et al. 1978; Eisler et al. 1999).

Table 15.6 Proposed Free Cyanide Criteria for the Protection of Living Resources and Human Health

Resource, Criterion, and Other Variables	Concentration	Reference ^a
FRESHWATER ORGANISMS (g/L medium)		
Minimal impairment, most species of fish		
Reduced survival, amphipods	3–5	1–6
Safe, most fish species	>3–34	1, 7
Significant impairment, most species of fish	3.5 (24-h average, not to exceed 52.0 at any time)	7
Hazardous	8–16, exposure for at least 20 days	6, 7
Most fish species	>11	1, 4
Microorganisms	>300	8
Reduced survival, chronic exposure		
Bivalve molluscs, larvae	>14	1
Fish, many species	30–150	1, 5
Impaired reproduction, sensitive species of fish	>25	2
Impaired swimming ability, growth, development, and behavior	>100	3, 6
Lethal to rapidly lethal, acute exposure	300–1000	5
Great Lakes		
Acute exposure, safe	<22	23
Chronic exposure, safe	<5.2	23
MARINE ORGANISMS (g/L seawater)		
Acceptable		
Acute	<1.0	23
Chronic	<1.0	23
Adverse effects, chronic exposure	>2	7
Minimal risk	<5	1
Hazardous	>10	1
Lethal	>30	7

15.11 SUMMARY

Cyanides are used widely and extensively in the manufacture of synthetic fabrics and plastics, in electroplating baths and metal mining operations, as pesticidal agents and intermediates in agricultural chemical production, and in predator control devices. Elevated cyanide levels are normally encountered in more than 1000 species of food plants and forage crops, and this probably

represents the greatest source of cyanide exposure and toxicosis to humans and to range animals. Anthropogenic sources of cyanide in the environment include certain industrial processes, laboratories, fumigation operations, cyanogenic drugs, fires, cigarette smoking, and chemical warfare. Although cyanide is ubiquitous in the environment, levels tend to be elevated in the vicinity of metal processing operations, electroplaters, gold-mining facilities, oil refineries, power plants, and solid waste combustion.

Many chemical forms of cyanide are present in the environment, including free cyanide, metallocyanide complexes, and synthetic organocyanides, also known as nitriles. But only free cyanide (i.e., the sum of molecular hydrogen cyanide, HCN, and the cyanide anion, CN⁻) is the primary toxic agent, regardless of origin. Cyanides are readily absorbed through inhalation, ingestion, or skin contact and are readily distributed throughout the body via blood. Cyanide is a potent and rapid-acting asphyxiant. It induces tissue anoxia through inactivation of cytochrome oxidase, causing cytotoxic hypoxia in the presence of normal hemoglobin oxygenation. Diagnosis of acute lethal cyanide poisoning is difficult because signs and symptoms are nonspecific, and numerous factors modify its biocidal properties, such as dietary deficiencies in Vitamin B₁₂, iodine, and sulfur amino acids. Among the more consistent changes measured in acute cyanide poisoning are inhibition of brain cytochrome oxidase activity, and changes in electrical activity in heart and brain. At sublethal doses, cyanide reacts with thiosulfate in the presence of rhodanese to produce the comparatively nontoxic thiocyanate, most of which is excreted in the urine. Rapid detoxification enables animals to ingest high sublethal doses of cyanide over extended periods without harm. Antidotes in current use to counteract cyanide poisoning include a combination of sodium nitrite and sodium thiosulfate (United States), cobalt edetate (United Kingdom, Scandinavia, France), or a mixture of 4-dimethylaminophenol and sodium thiosulfate (Germany).

All available evidence suggests that cyanides are neither mutagenic, teratogenic, nor carcinogenic. Moreover, there are no reports of cyanide biomagnification or cycling in living organisms, probably owing to its rapid detoxification. Cyanide seldom persists in surface waters and soils owing to complexation or sedimentation, microbial metabolism, and loss from volatilization. More data are needed on cyanide distribution and transformation in the atmosphere. Analytical methods for the determination of free and bound cyanides and cyanogenic compounds in biological materials are under constant revision. Further, unless tissue samples are obtained promptly after cyanide exposure and analyzed immediately, erroneous analytical values will result.

Higher plants are adversely affected by cyanide through cytochrome oxidase inhibition; the rate of production and release of cyanide by plants to the environment through death and decomposition is unknown. Nonacclimatized soil bacteria are adversely affected at 0.3 mg HCN/kg; acclimatized populations, however, can degrade wastes containing up to 60 mg total cyanide/kg. In some cases, soil bacteria and fungi produce cyanides as secondary metabolites, with adverse effects on certain plants. Several species of arthropods normally contain elevated whole-body cyanide concentrations, and these confer protection against predators and allow consumption of cyanogenic plants.

Fish were the most sensitive aquatic organisms tested. Adverse effects on swimming and reproduction were observed between 5 and 7.2 µg free cyanide/L; lethal effects usually occurred between 20 and 76 µg/L. Biocidal properties of cyanide in aquatic environments were significantly modified by water pH, temperature, and oxygen content; life stage, condition, and species assayed; previous exposure to cyanides; presence of other chemicals; and initial dose tested. Birds that feed predominantly on flesh were more sensitive to cyanide than were herbivores. Free cyanide levels associated with high avian death rates include 0.12 mg/L in air, 2.1 to 4.6 mg/kg body weight (BW) via acute oral exposure, and 1.3 mg/kg BW administered intravenously. Dietary levels of 135 mg total cyanide/kg ration resulted in growth reduction of chicks, but 103 mg total cyanide/kg ration had no measurable effect on domestic chickens. Cyanogenic plants represent a problem for various range animals and wildlife, primarily among species that eat rapidly. Intakes of 4 mg HCN/kg BW are lethal to these species if it is consumed quickly. Cassava (*Manihot esculenta*) is a cyanogenic plant that accounts for up to 70% of human caloric intake in some areas, and this is

associated with serious, long-term toxic effects including ataxia, optic nerve lesions, altered thyroid function, demyelination, and increases in tissue thiocyanate levels. Acute oral LD₅₀ values for representative species of mammals ranged between 2 and 3.6 mg HCN/kg BW. Despite the high lethality of large single exposures, repeated sublethal doses — especially in diets — can be tolerated by many species for extended periods, perhaps indefinitely. Mammalian deaths were also recorded at air concentrations of 140 mg HCN/m³ (exposure for 60 min) and 4400 mg HCN/m³ (exposure for 1 min), and at dermal applications between 2.3 mg HCN/kg BW for abraded skin and 100 mg HCN/kg BW for intact skin. Adverse nonlethal effects were noted at drinking water concentrations >150 mg HCN/L and at dietary concentrations >720 mg HCN/kg ration.

Free cyanide criteria currently proposed for natural resource protection include <3 µg/L medium for aquatic life, and <100 mg/kg diet for birds and livestock. For human health protection, free cyanide values are <10 µg/L drinking water, <50 mg/kg diet, and <5 mg/m³ air.

CHAPTER 16

Diazinon

16.1 INTRODUCTION

Diazinon, an organophosphorus compound with an anticholinesterase mode of action, was released for experimental evaluation in the early 1950s. Diazinon is now used extensively by commercial and home applicators in a variety of formulations to control flies, cockroaches, lice on sheep, insect pests on ornamental plants and food crops (especially corn, rice, onions, and sweet potatoes), forage crops such as alfalfa, and nematodes and soil insects in turf, lawns, and croplands (Anonymous 1972; Meier et al. 1976; Allison and Hermanutz 1977; Berg 1984; Stone and Gradoni 1985; Eisler 1986; Wan 1989; Menconi and Cox 1994; Moore and Waring 1996). Diazinon is the most widely used organophosphorus pesticide in Pakistan to control cabbage root fly and carrot fly (Alam and Maughan 1992). In 1992, more than 612,000 kg diazinon were used in California on alfalfa, nuts, stone fruits, vegetables, and other crops (Menconi and Cox 1994).

Avian and terrestrial wildlife can acquire diazinon by drinking contaminated water, by absorbing it through legs and feet, by consuming treated grass or grain, or by ingesting pesticide-impregnated carrier particles (Stone and Knoch 1982; Stone and Gradoni 1985). Diazinon was detected at low concentrations (<0.2 mg/kg) in tissues of 29% of loggerhead shrikes (*Lanius ludovicianus*) collected in Virginia between 1985 and 1988 (Blumton et al. 1990). Diazinon poisonings of birds — involving 54 incidents in 17 states — have been recorded for at least 23 species, especially among waterfowl feeding on recently treated turfgrass. Incidents involving agricultural applications may be less conspicuous, and thus not as well-documented (Stone and Gradoni 1985). Kills of Canada geese (*Branta canadensis*), brant (*Branta bernicla*), mallard (*Anas platyrhynchos*), American black duck (*Anas rubripes*), American wigeon (*Anas americana*), other species of waterfowl, and songbirds have all been associated with consumption of grass or grain shortly after diazinon application (Schobert 1974; Zinkl et al. 1978; Stone 1980; Stone and Knoch 1982; Anderson and Glowa 1985; Littrell 1986; Stone and Gradoni 1986; Brehmer and Anderson 1992; Kendall et al. 1992, 1993). Fatal diazinon poisonings have also been recorded in humans (Soliman et al. 1982; Lox 1983), domestic chickens (*Gallus gallus*) (Sokkar et al. 1975), domestic ducklings (*Anas* spp.) and goslings (*Anser* spp.) (Egyed et al. 1974, 1976), in laboratory monkey colonies of the tamarin (*Saguinus fuscicollis*) and the common marmoset (*Callithrix jacchus*) (Brack and Rothe 1982), and the honeybee (*Apis mellifera*) (Anderson and Glowa 1984). Mammals seem to be less sensitive than birds to diazinon poisoning (Stone and Gradoni 1985). The lack of reported mammalian mortalities (only one suspected case of a pocket gopher, *Thomomys* sp., found dead in a park at Yakima, Washington, following aerial spraying of diazinon on shade trees) is consistent with the general findings of Grue et al. (1983) for organophosphorus insecticides. Sublethal effects such as reduced food consumption and egg production in the ring-necked pheasant (*Phasianus colchicus*) (Stromborg 1977), and behavioral modifications, reduced food intake, alterations in liver enzyme activities,

reductions in vitamin concentrations, reduced body temperature, and lowered resistance to cold stress in white-footed mice (*Peromyscus leucopus*) (Montz and Kirkpatrick 1985) have been noted at diazinon concentrations markedly lower than those causing acute mortality. It has been suggested — but not proven — that wildlife partially disabled in the field as a result of diazinon poisoning would be more likely to die of exposure, predation, starvation, or dehydration, or face behavioral abnormalities, learning impairments, and reproductive declines than would similarly treated domestic or laboratory animals (Montz 1983; Montz and Kirkpatrick 1985). Sublethal effects of diazinon on fish populations include vertebral malformations, altered blood chemistry, inhibition of acetylcholinesterase activity, reduced larval and adult growth, impaired swimming, abnormal pigmentation, histopathology of muscle and gills, and reduction of liver RNA, DNA, and protein content (Allison and Hermanutz 1977; Eisler 1986; Moore and Waring 1996).

16.2 ENVIRONMENTAL CHEMISTRY

Diazinon is a broad-spectrum insecticide that is effective against a variety of orchard, vegetable, and soil pests, ectoparasites, flies, lice, and fleas. It exists as technical-grade product, wettable powder, emulsifiable concentrate, granules, and in a variety of other formulations (Negherbon 1959; Anonymous 1972; Eberle 1974; Berg 1984; Menconi and Cox 1994). The active ingredient in diazinon is phosphorothioic acid *O,O*-diethyl *O*-(6-methyl-2-1(methylethyl)-4-pyrimidinyl) ester (Figure 16.1). Its molecular formula and molecular weight are $C_{12}H_{21}N_2O_3PS$ and 304.35, respectively. The technical grade is light amber to dark brown and boils at 83° to 84°C. Diazinon is soluble in water to 60 mg/L and dissolves readily in aliphatic and aromatic solvents, alcohols, and ketones. Diazinon can be stored on the shelf for at least 3 years with negligible degradation. Diazinon is also known as G-24480, Sarolex, Spectracide (Anonymous 1972), AG-500, Alfa-tox, Basudin, Dazzel, Diazajet, Diazide, Diazol, ENT 19507, Gardentox, Neocidol, Nucidol, CAS 333-41-5 (Hudson et al. 1984), Diagran, Dianon, DiaterrFos, Diazatol, Dizinon, Dyzol, D.z.n., Fezudin, Kayazinon, Kayazol, Knox Out, and Nipsan (Berg 1984).

Some diazinon formulations contain 0.2 to 0.7% (2000 to 7000 mg/kg) of Sulfotep (tetraethyl dithiopyrophosphate) as a manufacturing impurity. Sulfotep is reportedly at least 100 times more toxic than diazinon to some organisms (Jarvinen and Tanner 1982). It seems that additional research is warranted on diazinon/Sulfotep interactions.

Diazinon degrades rapidly in plants, with half-time persistence usually less than 14 days. However, persistence increases as temperatures decrease, and is longer in crops with a high oil content (Table 16.1). In water, diazinon breaks down to comparatively nontoxic compounds with little known hazard potential to aquatic species (Meier et al. 1976; Jarvinen and Tanner 1982), although the degradation rate is highly dependent on pH (Table 16.1). The half-time persistence of

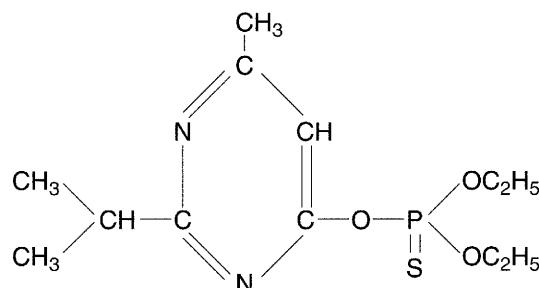

Figure 16.1 Structural formula of diazinon.

diazinon on sandy loam soil exposed to sunlight is 2.5 to 10 days (Menconi and Cox 1994). In most soils, diazinon seldom penetrates below the top 1.3 cm (Kuhr and Tashiro 1978; Branham and Wehner 1985). But diazinon may remain biologically available in soils for 6 months or longer at low temperature, low moisture, high alkalinity, and lack of suitable microbial degraders (Anonymous 1972; Bartsch 1974; Meier et al. 1976; Allison and Hermanutz 1977; Menzie 1978; Forrest et al. 1981; Branham and Wehner 1985). Bacterial enzymes, derived from *Pseudomonas* sp., can be used to hydrolyze diazinon in soil, although costs are prohibitive except in treating emergency situations involving spills of concentrated diazinon solutions. In one case, diazinon was enzymatically hydrolyzed within 24 h in an agricultural sandy soil at concentrations as high as 10,000 mg/kg (Barick and Munnecke 1982).

In almost every instance of diazinon poisoning, there has been a general reduction in cholinesterase activity levels, especially in brain and blood. Diazinon exerts its toxicity by binding to the neuronal enzyme acetylcholinesterase (AChE) for a considerable time postexposure (Montz 1983; Kendall et al. 1992; Decarie et al. 1993). It is emphasized that all organophosphorus pesticide compounds, in sufficient dose, inhibit AChE *in vivo*, and all share a common mechanism of acute toxic action (Murphy 1975). AChE inhibition results in the accumulation of endogenous acetylcholine in nerve tissues and effector organs, resulting in signs that mimic the muscarinic, nicotinic, and central nervous system (CNS) actions of acetylcholine. The immediate cause of death in fatal organophosphorus compound poisonings, including diazinon, is asphyxia resulting from respiratory failure. Contributing factors are the muscarinic actions of bronchoconstriction and increased bronchial secretions, nicotinic actions leading to paralysis of the respiratory muscles, and the CNS action of depression and paralysis of the respiratory center (Murphy 1975).

Diazinon is not a potent inhibitor of cholinesterase and must be converted to its oxygen analogues (oxons), especially diazoxon (diethyl-2-isopropyl-6-methylpyrimidin-4-yl phosphate) *in vivo* before poisoning can occur (Wahla et al. 1976). Diazoxon is about 10,000 times more effective in reducing cholinesterase activity levels than diazinon (Fog and Asaka 1982). At least eight diazinon metabolites have been identified in vertebrates, of which four are oxons (Machin et al. 1975; Menzie 1978; Seguchi and Asaka 1981). It is generally agreed that diazinon is metabolized to diazoxon through the action of liver mixed-function oxidases and nicotinic adenine nucleotide phosphate (Menzie 1978; McLean et al. 1984). Diazinon toxicity will depend to some extent on the relation between the rates of activation of diazinon to diazoxon, and of decomposition of the latter to harmless products (Fujii and Asaka 1982). Birds are more sensitive to diazinon than mammals, probably because mammalian blood enzymes hydrolyze diazoxon rapidly, whereas bird blood has virtually no hydrolytic activity. It seems that diazoxon stability in blood is a major factor affecting susceptibility of birds and mammals to diazinon poisoning (Machin et al. 1975).

Diazinon poisoning effects in animals can be delayed or prevented by treatment with a variety of compounds. For example, AChE in diazinon-stressed birds can be reactivated by pralidoxime (Egyed et al. 1976; Fleming and Bradbury 1981; Misawa et al. 1982). Furthermore, pretreatment of large white butterfly (*Pieris brassicae*) larvae with methylene dioxyphenyl compounds will inhibit the diazinon-to-diazoxon activation (Wahla et al. 1976). Added tryptophan and its metabolites may prevent teratogenic defects by maintaining nicotinic adenine nucleotide (NAD) levels in diazinon-treated chicken embryos; diazinon reportedly acts to decrease the availability of tryptophan to bird embryos, subsequently interfering with NAD metabolism and causing birth defects (Henderson and Kitos 1982). NAD metabolism in diazinon-stressed birds can also be maintained with nicotinamide (Misawa et al. 1982). In contrast to many other organophosphorus insecticides, organisms that survive diazinon-inhibited cholinesterase levels can undergo considerable spontaneous reactivation (dephosphorylation), indicating that its dephosphorylation occurs more readily than that of cholinesterase inhibited by other organophosphorus compounds (Fleming and Bradbury 1981).

16.3 LETHAL EFFECTS

16.3.1 General

Diazinon toxicity varies widely within and among species, and is modified by organism age, sex, body size, climatic conditions, pesticide formulation, chemistry of the environment, and other factors (Montz 1983). Nevertheless, several trends are apparent, as judged by available data. Among aquatic organisms, for example, freshwater cladocerans and marine shrimps were the most sensitive species tested, with LC50 (96 h) values of less than 5 µg/L; freshwater teleosts were more resistant, with the lowest LC50 (96 h) value recorded being 90 µg/L. Diazinon has considerable potential for causing acute avian poisoning episodes. Sensitive species of birds, including ducks, turkey (*Meleagris gallopavo*), and red-winged blackbird (*Agelaius phoeniceus*), died at single oral doses of 2 mg of diazinon/kg body weight. Mammals are more resistant than birds to diazinon; the lowest LD50 (acute oral) value recorded is 224 mg/kg body weight for female rats (*Rattus rattus*). Chronic oral toxicity tests with mammals suggest that daily intake exceeding 5 or 10 mg diazinon/kg body weight is probably fatal over time to swine (*Sus scrofa*) and dogs (*Canis familiaris*), respectively. Finally, 9 mg/kg of dietary diazinon fed during gestation to pregnant mice (*Mus musculus*) was associated with significant mortality of pups prior to weaning.

16.3.2 Aquatic Organisms

Freshwater cladocerans and marine crustaceans were the most sensitive groups tested, with LC50 (96 h) values of less than 2 µg/L for the more sensitive species (Table 16.2). European eels (*Anguilla anguilla*), rainbow trout (*Oncorhynchus mykiss*), and bluegills (*Lepomis macrochirus*) seemed to be the most sensitive freshwater teleosts tested, with LC50 (96 h) values between 80

and 120 µg/L; however, the postlarval and juvenile stages of the striped knifejaw (*Oplegnathus fasciatus*) — a marine fish cultured intensively in Japan — were unusually sensitive (Table 16.2). In general, technical grade formulations of diazinon seem to be more toxic than emulsifiable concentrates, dusts, and oil solutions (Table 16.2). Also, large variations in acute toxicity values were evident, even among closely related species (Table 16.2).

Outward signs of diazinon poisoning in fish included lethargy, forward extension of pectoral fins, darkened areas on posterior part of body, hyperexcitability when startled, sudden rapid swimming in circles, and severe muscular contractions (Goodman et al. 1979; Alam and Maughan 1992). Internally, physiological mechanisms in teleosts preceding death involved the following sequence: cholinesterase inhibition, acetylcholine accumulation, disruption of nerve functions, respiratory failure, and asphyxia (Sastry and Sharma 1980). Closely related species of fishes differ markedly in their sensitivity to diazinon. Guppies (*Poecilia reticulata*) are 5 times more sensitive to diazinon than are zebrafish (*Brachydanio rerio*), as judged by LC50 (96 h) values (Keizer et al. 1991, 1993). Differences of resistance and accumulation between guppies and zebrafish are related to the rate of oxidative metabolism. Preexposure of guppies to a high sublethal concentration of diazinon increases resistance to diazinon by a factor of 5 when compared to non-pretreated guppies; zebrafish similarly pretreated were not more resistant. Pretreatment of guppies resulted in a strong inhibition of diazoxon formation and pyrimidinol during incubations of diazinon with the hepatic postmitochondrial supernatant. It was concluded that toxicity of diazinon in the guppy is due to its metabolism to a highly toxic metabolite, likely diazoxon. And in zebrafish or pretreated guppies having low rates of diazinon metabolism, toxicity is due to the accumulation of the parent compound (Keizer et al. 1991, 1993). Limited data indicated that the yellowtail (*Seriola quinqueradiata*), a marine teleost, was 84 times more sensitive to diazinon than were four species of freshwater fishes, as judged by LC50 (48 h) values, and by its inability to biotransform diazinon to nontoxic metabolites within 1 h (Fujii and Asaka 1982). Diazinon has not been detected in marine waters, but the potential exists for contamination of estuarine areas from agricultural and urban runoff (Goodman et al. 1979).

16.3.3 Birds

Diazinon adversely affects survival of developing mallard embryos when the eggshell surface is subjected for 30 seconds to concentrations 25 to 34 times higher than recommended field application rates. Mortality patterns were similar for solutions applied in water or in oil (Table 16.3).

Table 16.3 Mortality of Mallard Embryos after Immersion for 30 seconds in Graded Strength Diazinon Solutions

Modified from Hoffman, D.J. and W.C. Eastin, Jr. 1981. Effects of malathion, diazinon, and parathion on mallard embryo development and cholinesterase activity. *Environ. Res.* 26:472-485.

This laboratory finding suggests that eggs of mallards, and probably other birds, are protected when diazinon is applied according to label directions. Chickens dipped in solutions containing 1000 mg of diazinon/L, an accidentally high formulation, experienced 60% mortality within 3 days; no other deaths occurred during the next 4 months (Sokkar et al. 1975). Results of 5-day feeding trials with 2-week-old Japanese quail (*Coturnix japonica*), followed by 3 days on untreated feed, showed an LD₅₀ of 167 mg diazinon/kg diet — a concentration considered “very toxic.” No deaths were observed at dietary levels of 85 mg diazinon/kg, but 53% died at 170 mg/kg, and 87% at 240 mg/kg (Hill and Camardese 1986).

Diazinon has a potential for causing acute avian poisoning episodes (Schafer et al. 1983). Ingestion of 5 granules of Diazinon 14G (14.3% diazinon) killed 80% of house sparrows (*Passer domesticus*), and all red-winged blackbirds to which they were administered (Balcomb et al. 1984). Ingestion of fewer than 5 granules of Diazinon 14G, each containing about 215 µg diazinon, could be lethal to sparrow-sized birds (i.e., 15 to 35 g body weight), especially juveniles of seed-eaters (Hill and Camardese 1984). Acute oral LD₅₀ values indicate that 15 mg diazinon/kg body weight is fatal to virtually all species tested, and that 2 to 5 mg/kg is lethal to the more sensitive species (Table 16.4). Signs of diazinon poisoning in birds included muscular incoordination, wing spasms, wing-drop, hunched back, labored breathing, spasmodic contractions of the anal sphincter, diarrhea, salivation, lacrimation (tear production), eyelid drooping, prostration, and arching of the neck over the back (Hudson et al. 1984). Most of these signs have been observed in birds poisoned by compounds other than diazinon; these compounds also act via an anticholinesterase mode of action (Hudson et al. 1984).

16.3.4 Mammals

Signs of diazinon poisoning in mammals included a reduction in blood and brain cholinesterase activity, diarrhea, sweating, vomiting, salivation, cyanosis, muscle twitches, convulsions, loss of reflexes, loss of sphincter control, and coma (Anonymous 1972). Other compounds that produce their toxic effects by inhibiting AChE, such as organophosphorus pesticides and many carbamates, show similar effects (Murphy 1975). Two species of marmoset accidentally poisoned by diazinon exhibited — prior to death — high-pitched voices, trembling, frog-like jumping, a stiff gait, and pale oral mucous membranes. Internally, bone marrow necrosis and hemorrhages in several organs were evident (Brack and Rothe 1982). Internal damage was also observed in swine and dogs that died following controlled administration of diazinon. Swine showed histopathology of liver and intestinal tract, and duodenal ulcers; dogs showed occasional rupture of the intestinal wall and testicular atrophy (Earl et al. 1971).

Results of acute oral toxicity tests indicated that the rat was the most sensitive mammalian species tested, with an acute oral LD50 of 224 mg diazinon/kg body weight (Table 16.4). It is clear that mammals are significantly more resistant to acute oral poisoning by diazinon than birds (Table 16.4). Diazinon was also toxic to mammals when administered dermally, through inhalation, and in the diet (Table 16.5). The lowest dermal LD50 recorded was 600 mg diazinon/kg body weight for rabbits (*Lepus* sp.) using an emulsifiable (4E) formulation. The single datum for inhalation toxicity indicated that 27.2 mg of diazinon/L of air killed 50% of test rabbits after exposure for 4 h (Table 16.5). Pregnant mice fed diets containing 9 mg of diazinon/kg during gestation all survived, but some pups died prior to weaning (Table 16.5). Results of chronic oral toxicity tests of diazinon indicated that death was probable if daily doses exceeded 5 mg/mg body weight for swine, or 10 mg/kg for dogs (Table 16.5).

16.3.5 Terrestrial Invertebrates

Accidental spraying of beehives in Connecticut with diazinon resulted in a complete kill of resident honeybees. Dead bees contained up to 3 mg diazinon/kg (Anderson and Glowa 1984). Diazinon is an effective insecticide. LD50 values for diazinon and adult houseflies (*Musca domestica*), applied topically, were 0.4 µg/insect, or 4.6 mg/kg body weight (Negherbon 1959). LD50 values for larvae of the large white butterfly, applied topically, were 8.8 mg/kg body weight for diazinon, and 11.0 mg/kg body weight for diazoxon (Wahla et al. 1976). Pretreatment of larvae

with methylene dioxyphenyl compounds antagonized the action of diazinon by a factor of about 2, but synergized the action of diazoxon by an order of magnitude (Wahla et al. 1976).

16.4 SUBLETHAL EFFECTS

16.4.1 General

Among sensitive species of aquatic organisms, diazinon was associated with reduced growth and reproduction in marine and freshwater invertebrates and teleosts, spinal deformities in fish, reduced emergence in stream insects, measurable accumulations in tissues, increased numbers of stream macroinvertebrates carried downstream by currents (drift), possible mutagenicity in fish, and interference with algal–invertebrate interactions. In birds, diazinon is a known teratogen. It is also associated with reduced egg production, decreased food intake, and loss in body weight. Diazinon fed to pregnant mice resulted in offspring with brain pathology, delayed sexual maturity, and adverse behavioral modifications that became apparent late in life. For all groups tested, diazinon directly or indirectly inhibited cholinesterase activity.

16.4.2 Aquatic Organisms

Atlantic salmon (*Salmo salar*) exposed to 0.3 to 45.0 µg diazinon/L for 120 h had reduced levels of reproductive steroids in blood plasma at all concentrations. Exposure to 2 µg/L for only 30 min produced a significant reduction in olfactory response to prostaglandin F_{2a} (Moore and Waring 1996). Carp and other species of freshwater teleosts that survived high sublethal concentrations of diazinon had impaired swimming and abnormal pigmentation (Alam and Maughan 1992). Spinal deformities, mostly lordosis and scoliosis, were among the more insidious effects documented for diazinon. Malformations were observed in fathead minnows (*Pimephales promelas*) after 19 weeks in water containing 3.2 µg diazinon/L (Allison and Hermanutz 1977), in yearling brook trout (*Salvelinus fontinalis*) within a few weeks at 4.8 µg/L (Allison and Hermanutz 1977), and in various species of freshwater teleosts after exposure for 7 days to 50 µg diazinon/L (Kanazawa 1978). Exposure of bluegills (*Lepomis macrochirus*) to 15 µg diazinon/L for only 24 h resulted in mild hyperplasia of the gills that increased in severity with increasing concentration (30 to 75 µg/L) and may lead to death (Dutta et al. 1993).

Diazinon is a noncarcinogen and reportedly has no significant mutagenic activity in microbial systems, yeast, and mammals, including humans (as quoted in Vigfusson et al. 1983). However, Vigfusson et al. (1983) have measured a significant increase in the frequency of sister chromatid exchange in central mud minnows (*Umbra limi*) that were exposed *in vivo* for 11 days to solutions containing 0.16 to 1.6 µg diazinon/L. This finding requires verification.

In general, diazinon does not bioconcentrate to a significant degree and is rapidly excreted after exposure (Menconi and Cox 1994; Tsuda et al. 1995). Diazinon in water is bioconcentrated by brook trout at levels as low as 0.55 µg/L, but tissue residues for all aquatic organisms seldom exceeds 213 times that of ambient water, even after months of continuous exposure (Table 16.6). Common carp (*Cyprinus carpio*) exposed to 1.5 to 2.4 µg/L for 168 h had bioconcentration factors of 12 in muscle, 12 in gallbladder, 50 in kidney, and 51 in liver; almost all was excreted in 72 h on transfer to clean water, except for kidney, which is the major organ for excretion (Tsuda et al. 1990). High bioconcentration factors of 800 in liver, 1600 in muscle, 2300 in gill, and 2730 in blood are reported for juvenile European eels (*Anguilla anguilla*) after exposure to 42 to 56 µg/L for 96 h. However, diazinon residues in tissues were usually not detected in tissues after 24 h in clean water (Sancho et al. 1992b, 1993a). The half-time persistence of diazinon in tissues of European eels was estimated at 17 to 31 h in liver, 32 to 33 h in muscle, and 27 to 38 h in gill

^b 1, Kanazawa 1978; 2, Seguchi and Asaka 1981; 3, Allison and Hermanutz 1977; 4, Goodman et al. 1979; 5, Tsuda et al. 1995.

(Sancho et al. 1992a, 1992b, 1993b). Whole guppies exposed to high sublethal concentrations of diazinon show bioconcentration factors of 59 after 48 h and 188 after 144 h; the half-time persistence of diazinon was 10 h after 48-h exposure and 23 h after 144-h exposure (Keizer et al. 1993). Diazinon and its metabolites are excreted rapidly posttreatment; the loss rate is approximately linear (Kanazawa 1978). The enzyme system responsible for diazinon metabolism in fish liver microsomes required NADPH and oxygen for the oxidative desulfuration of diazinon to diazoxon (Hogan and Knowles 1972). Fish with high fat content contained greater residues of diazinon in fatty tissues than did fish with comparatively low lipid content (Seguchi and Asaka 1981), and this could account, in part, for inter- and intraspecies variations in uptake and depuration. Some organisms, such as the sheepshead minnow (*Cyprinodon variegatus*), have measurable diazinon residues during initial exposure to 6.5 µg/L, but no detectable residues after lengthy exposure (Goodman et al. 1979), suggesting that physiological adaptation resulting in rapid detoxification is possible.

Freshwater and marine alga were unaffected at water diazinon concentrations that were fatal (i.e., 1000 µg/L) to aquatic invertebrates (Stadnyk and Campbell 1971; Shacklock and Croft 1981). However, diazinon at 1.0 µg/L induced extensive clumping of a freshwater alga (*Chlorella pyrenoidosa*) onto the antennae of *Daphnia magna* within 24 h (Stratton and Corke 1981). The affected daphnids were immobilized and settled to the bottom of the test containers. The causes of particulate matter adhesion are open to speculation, and additional research is merited.

Freshwater macroinvertebrates were comparatively sensitive to diazinon (Table 16.7). Results of large-scale experimental stream studies (Arthur et al. 1983) showed that dose levels of 0.3 µg diazinon/L caused a five- to eightfold reduction in emergence of mayflies and caddisflies within 3 weeks. After 12 weeks, mayflies, damselflies, caddisflies, and amphipods were absent from benthic samples. Elevated (and catastrophic) drift of stream invertebrates was also documented in diazinon-treated streams, especially for amphipods, leeches, and snails (Arthur et al. 1983). Short-term tests of 5-h duration with rotifers (*Brachionus calyciflorus*) show a 50% reduction in feeding

rate on alga (*Nannochloris oculata*) at 14.2 mg/L (Fernandez-Casalderry et al. 1992), with long-term implications to population stability.

Freshwater fish populations can be directly damaged by prolonged exposure to diazinon at concentrations up to several hundred times lower than those causing acute mortality (Sastry and Sharma 1980; Sastry and Malik 1982; Saker and Gabr 1992; Dutta et al. 1997; [Table 16.7](#)). Impaired reproduction and AChE inhibition occurs concurrently in teleosts during long-term exposure to diazinon, but reproduction can be impaired for at least 3 weeks after fish are placed in uncontaminated water, even though AChE is normal and they contained no detectable diazinon residues (Goodman et al. 1979). Furthermore, diazinon exposure during spawning caused complete, but temporary, inhibition of reproduction at concentrations that did not produce this effect in fish exposed since hatch (Allison 1977). This could severely impact aquatic species with a short reproductive period (Allison 1977).

16.4.3 Birds

Diazinon produces visible Type I and II teratisms when injected into chicken embryos (Misawa et al. 1981, 1982; Henderson and Kitos 1982; Wyttenbach and Hwang 1984). Type I teratisms (related to tissue NAD depression) included abnormal beaks, abnormal feathering, and shortened limbs. Type II teratisms, which included short and wry neck, leg musculature hypoplasia, and rumplessness were associated with disruptions in the nicotinic cholinergic system. The severity of effects depended on embryo age and was dose related. Chick embryos (age 48 h) receiving 25 µg or more of diazinon/embryo had cervical notochord and neural tube malformations at 96 h, and short neck at 19 days (Wyttenbach and Hwang 1984). Wry neck occurred at doses ranging from 6.2 to 100 µg/embryo, but was more frequent at higher doses. Type II teratisms were attributed to disruption of notochord sheath formation. Coinjection of 2-pyridinealdoxime methochloride (2-PAM) along with 200 µg diazinon/embryo markedly reduced notochord and neural tube deformations (Wyttenbach and Hwang 1984). Similarly, the co-presence of tryptophan — or its metabolites L-kynurenine, 3-hydroxyanthronilic acid, quinolinic acid — maintained NAD levels of diazinon-treated embryos close to, or above, normal, and significantly alleviated the symptoms of Type I teratisms (Henderson and Kitos 1982).

Reduced egg production, depressed food consumption, and loss in body weight have been observed in ring-necked pheasants at daily diazinon intakes greater than 1.05 mg/bird; a dose-related delay in recovery of egg laying was noted after termination of diazinon treatment (Stromborg 1977, 1979). Threshold levels in ring-necked pheasants of 1.05 and 2.1 mg diazinon daily corresponded to 1/16 and 1/8 of daily ration (70 g) treated at commercial application rates. Food consumption of ring-necked pheasants was reduced significantly when only food treated with diazinon was available; pheasants avoided diazinon-treated food if suitable alternatives existed (Stromborg 1977; Bennett and Prince 1981). Dietary levels above 50 mg/kg were associated with reduced food consumption, weight loss, and reduction in egg production in northern bobwhites (Stromborg 1981). If food reduction is important, then diets containing more than 17.5 mg diazinon/kg (based on empirical calculations) were potentially harmful to bobwhites (Stromborg 1981). The mechanisms accounting for reduction in egg deposition are not clear, but are probably related primarily to decreased food intake. They may also be associated with diazinon-induced pituitary hypofunction at the level of the hypothalamus, resulting in reduced synthesis and secretion of gonadotrophic, thyrotrophic, and adrenocorticotropic hormones (Sokkar et al. 1975).

16.4.4 Mammals

Diazinon exerts its toxic effects by binding to the neuronal enzyme acetylcholinesterase (AChE) for long periods after exposure. Diazinon, in turn, is converted to diazoxon, which has a higher affinity for AChE (and thus greater toxicity) than the parent compound. There is a latent period in

white-footed mice in reduction of cholinesterase activities, sometimes up to 6 h, until diazinon is converted to diazoxon (Montz 1983). Effects of multiple doses of diazinon to mammals are not clear; for example, rats exposed to a high dose of diazinon did not respond fully to a second dose until 1 month later (Kikuchi et al. 1981). It is difficult to ascertain when complete recovery of diazinon-poisoned animals has occurred. It is speculated, but not verified, that wildlife recovering from diazinon poisoning may face increased predation, aberrant behavior, learning disabilities, hypothermia, and reproductive impairments (Montz 1983). Data are lacking on recovery aspects of diazinon-poisoned native mammal populations (Montz and Kirkpatrick 1985).

Diazinon is rapidly biotransformed and excreted in mammals. Estimated half-times of diazinon persistence were 6 to 12 h in rats (Anonymous 1972) and dogs (Iverson et al. 1975). Most of the diazinon metabolites were excreted in the urine as diethyl phosphoric acid and diethyl phosphorothioic acid in dogs (Iverson et al. 1975), and as hydroxy diazinon and dehydrodiazinon in sheep (Machin et al. 1974).

Determination of AChE activity in selected tissues following diazinon exposure provided an estimate of potential toxicity, but tissue sensitivity varied widely between and among taxa. In sheep, brain cholinesterase inhibition was pronounced after diazinon insult, and metabolism of diazinon in, or close to, the brain was the most likely source of toxicologically effective diazoxon (Machin et al. 1974, 1975). In rat, diazinon effectively reduced blood cholinesterase levels, with inhibition significantly more evident in erythrocytes than in plasma (Tomokuni and Hasegawa 1985). All mammalian bloods hydrolyze diazoxon rapidly, whereas birds have virtually no hydrolytic activity in their blood, and, as a result, were more susceptible than mammals. The stability of diazoxon in the blood appears to be a primary factor in susceptibility to diazinon poisoning (Machin et al. 1975). In species lacking blood oxonases, the liver was probably the most important site of diazinon metabolism (Machin et al. 1975). Diazinon that accumulated in rat liver was biotransformed, usually within 24 h, by microsomal mixed-function oxidases and glutathione S-transferases. However, diazinon residues in rat kidney were almost 500 times those in liver (and 11 times brain), and were measurable in kidney but not in liver (Tomokuni and Hasegawa 1985). It now seems that diazinon residues in kidney and cholinesterase inhibition in erythrocytes are the most useful indicators of acute diazinon poisoning in mammals.

Sublethal effects of diazinon have been recorded in rodents, the most sensitive mammal group tested. Effects were measured at 0.5 mg diazinon/kg in diets of rats for 5 weeks, at 0.18 mg/kg body weight administered daily to pregnant mice, and at single doses of 1.8 mg/kg body weight for rat and 2.3 mg/kg body weight for white-footed mice (Table 16.8). Many variables modify diazinon-induced responses, including the organism's sex. For example, female rats and dogs were more sensitive to diazinon than males (Earl et al. 1971; Davies and Holub 1980a, 1980b; Kikuchi et al. 1981), but male swine were more sensitive than females (Earl et al. 1971).

Behavioral deficits observed in offspring of mice exposed to diazinon during gestation indicated that prenatal exposure may produce subtle dysfunctions not apparent until later in life (Spyker and Avery 1977). Pregnant mice given a daily dose of 0.18 or 9 mg diazinon per kg body weight throughout gestation gave birth to viable, overtly normal, offspring. But, pups born to mothers of the 9 mg/kg groups grew more slowly than controls and were significantly smaller at 1 month than controls (Spyker and Avery 1977). Offspring of mothers receiving 0.18 mg/kg body weight exhibited significant delays in the appearance of the contact placing reflex and in descent of testes or vaginal opening. Mature offspring of mothers exposed to either dose level displayed impaired endurance and coordination on rod cling and inclined plane tests of neuromuscular function (Table 16.8). In addition, offspring of the 9-mg/kg-dose group had slower running speeds and less endurance in a swimming test than controls. At 101 days, forebrain neuropathology was evident in the 9-mg/kg group but not in the 0.18-mg/kg group. The mechanisms responsible for these effects are unknown (Spyker and Avery 1977).

Diazinon is nonmutagenic to mammals, as judged by its inability to induce sister chromatid exchanges (SCE) in Chinese hamster ovary cells (CHOC) at 80 mg/kg culture medium. Most organophosphorus insecticides tested induced SCE in CHOC at this concentration (Nishio and

^a D = mg/kg diet; BW = mg/kg body weight daily.^b 1, Davies and Holub 1980a; 2, Kikuchi et al. 1981; 3, Davies and Holub 1980b; 4, Lox 1983; 5, Anonymous 1972; 6, Spyker and Avery 1977; 7, Barnett et al. 1980; 8, Montz 1983; 9, Montz and Kirkpatrick 1985; 10, Iverson et al. 1975; 11, Earl et al. 1971; 12, Dressel et al. 1982; 13, Wilkinson 1980; 14, Machin et al. 1974.

Uyeki 1981; Chen et al. 1982). Diazoxon, an oxygen analog of diazinon, did produce SCE at 304 mg/kg, but was 3 to 10 times less effective than oxygen analogues of other organophosphorus compounds screened (Nishio and Uyeki 1981).

16.4.5 Terrestrial Invertebrates

Tobacco hornworms (*Manduca sexta*) from a field sprayed with 840 mg diazinon/ha contained no detectable residues of diazoxon. Only one sample, collected about 4 h after spraying, exceeded 1.0 mg diazinon/kg body weight. No diazinon residues in these insects were detectable after 18 days.

It was concluded that the potential hazard to birds eating hornworms was minimal (Stromborg et al. 1982). In contrast, diazinon residues in molluscan slugs (*Agriolimax reticulatus*), collected from plats of spring wheat sprayed with 8000 mg diazinon/ha, increased linearly to about 200 mg/kg at 6 weeks postapplication, then declined to background levels after 16 weeks (Edwards 1976). During this same period, soil residues decreased from about 4 mg/kg immediately after application, to about 1 mg/kg at 6 weeks, and were not detectable after 12 weeks. The high residues observed in slugs may be due, in part, to physical adsorption of diazinon to slug mucus. Edwards (1976) concluded that slugs heavily contaminated by diazinon constituted a serious danger to birds and mammals feeding on them.

Depuration rates of diazinon differed significantly for two species of nematodes, *Panagrellus redivivus* and *Bursaphelenchus xylophilus* (Al-Attar and Knowles 1982). Both species showed maximum uptake of radiolabeled diazinon between 6 and 12 h, and both metabolized diazinon to diazoxon and pyrimidinol. By 96 h, 95% of the diazinon in *P. redivivus* had been metabolized, but only 26% was transformed in *B. xylophilus*, again demonstrating variability in diazinon metabolism between related species.

16.5 RECOMMENDATIONS

As shown earlier, certain aquatic organisms were impacted by diazinon water concentrations between 0.3 and 1.2 µg/L; effects included lowered emergence and elevated drift of stream insects (0.3 µg/L), reduced fecundity of marine minnows (0.47 µg/L), accumulations in freshwater teleosts (0.55 µg/L), and daphnid immobilization (1.0 µg/L) and death (1.2 µg/L). These comparatively low levels are of concern because transient peak water concentrations of 4 to 200 µg diazinon/L have been recorded near diazinon sheep-dipping sites in England (Moore and Waring 1996), and 36.8 µg/L in the Sacramento–San Joaquin River, California (Menconi and Cox 1994). For protection of sensitive aquatic organisms, Arthur et al. (1983) recommended that water diazinon levels should not exceed 0.08 µg/L. This value represents a safety factor of about 4 over the lowest recorded adverse effect level of 0.3 µg/L. For protection of freshwater aquatic life, Menconi and Cox (1994) recommend an average 4-day concentration of 0.04 µg diazinon/L provided that this value is not exceeded more than once every 3 years and the maximum 1-h concentration does not exceed 0.08 µg/L more than once every 3 years. Safety factors may require adjustment as additional data become available. Establishment of safe levels is complicated by the fact that diazinon can persist for many months in neutral or basic waters, including seawater (Kanazawa 1978), but hydrolyzes rapidly in acidic waters (Allison and Hermanutz 1977). Data on chronic effects of fluctuating and intermittent exposures of fishes and invertebrates to diazinon are also needed, and these will aid in the establishment of safe concentrations for this organophosphorus pesticide (Allison and Hermanutz 1977).

Granular formulations were especially hazardous to seed-eating birds; ingestion of fewer than 5 granules of a Diazinon 14G formulation could be lethal (Hill and Camardese 1984). A reduction in diazinon content of existing granular formulations may become necessary in application areas frequented by high densities of seed-eating birds. Stone and Gradoni (1985) recommend that diazinon should not be used in areas where waterfowl feed, especially turfgrass. Suggested alternatives to diazinon for turfgrass use include Dursban (*O,O*-diethyl *O*-(3,5,6-trichloro-2-pyridyl)-phosphorothioate), Dylox (dimethyl (2,2,2-trichloro-1-hydroxyethyl) phosphonate), Carbaryl (1-naphthyl *N*-methylcarbamate), and Lannate (*S*-methyl-*N*-((methylcarbamoyl)oxy)-thioacetimidate) (Stone 1980; Stone and Gradoni 1985). Diazinon should be used with caution in large-scale spray applications — such as grasshopper control — as judged by some deaths of horned larks (*Eremophila alpestris*), lark buntings (*Calamospiza melanocorys*), western meadowlarks (*Sturnella neglecta*), and chestnut-collared longspurs (*Calciarius ornatus*) when used for this purpose in Wyoming (McEwen et al. 1972). Diazinon applications to agricultural crops comprised a relatively

small percentage of the reported mortality incidents, but it is likely that this category is under-reported since such incidents were probably less conspicuous than those noted on lawns and golf courses (Stone and Gradoni 1985). Also, diazinon interactions with other agricultural chemicals, such as Captan (*cis*-*N*-((trichloromethyl)thio)-4-cyclohexene-1,2-dicarboximide), may produce more-than-additive (but reversible) adverse effects on food consumption and egg production of ring-necked pheasants (Stromborg 1977). More research is needed on complex mixtures of agricultural pesticides that contain diazinon.

In female rats, the no-observable-effect level (NOEL) is 0.1 mg/kg of dietary diazinon. At 0.5 mg/kg, there was a marked lowering of plasma cholinesterase activity in 5 weeks (Davies and Holub 1980a). But studies with male rats indicate that the NOEL is 2 mg/kg of dietary diazinon, or about 20 times higher than female rats (Davies and Holub 1980b). Accordingly, future studies should consider sex as a variable in toxicity evaluation of diazinon. It is generally agreed that mammals are more resistant than birds to diazinon owing, in part, to their ability to rapidly metabolize diazoxon. However, data are missing on the effects of diazinon on native mammals under field conditions, and this should constitute a priority research area. No diazinon criteria to protect human health have been proposed by the U.S. Food and Drug Administration or the state of California (Menconi and Cox 1994).

16.6 SUMMARY

Diazinon (phosphorothioic acid *O,O*-diethyl *O*-(6-methyl-2-(1-methylethyl)-4-pyrimidinyl) ester) is an organophosphorus compound with an anticholinesterase mode of action. It is used extensively to control flies, lice, insect pests of ornamental plants and food crops, as well as nematodes and soil insects in lawns and croplands. Diazinon degrades rapidly in the environment, with half-time persistence usually less than 14 days. But under conditions of low temperature, low moisture, high alkalinity, and lack of suitable microbial degraders, diazinon may remain biologically active in soils for 6 months or longer.

At recommended treatment levels, diazinon-related kills have been noted for songbirds, honeybees, and especially waterfowl that consume diazinon-treated grass. However, incidents involving agricultural applications may be underreported. Accidental deaths through misapplication of diazinon have also been recorded in domestic poultry, monkeys, and humans. It has been suggested, but not yet verified, that wildlife partially disabled in the field as a result of diazinon poisoning would be more likely to die of exposure, predation, starvation, or dehydration, or face behavioral modifications, learning impairments, and reproductive declines than would similarly treated domestic or laboratory animals.

Among sensitive aquatic organisms, LC50 (96 h) values of 1.2 to 2.0 µg/L were derived for freshwater cladocerans, and 4.1 to 5.9 µg/L for marine shrimps; freshwater teleosts were comparatively resistant, with all LC50 (96 h) values greater than 80 µg/L. Sublethal effects were recorded at 0.3 to 3.2 µg diazinon/L and included reduced emergence of stream insects (0.3 µg/L), reduced fecundity of a marine fish (0.47 µg/L), significant accumulations in freshwater teleosts (0.55 µg/L), daphnid immobilization (1.0 µg/L), potential mutagenicity in a freshwater fish (1.6 µg/L), and spinal deformities in teleosts (3.2 µg/L). Exposure to diazinon during spawning caused temporary, but complete, inhibition of reproduction at concentrations that did not produce this effect in fish exposed continuously since hatch.

Acute oral LD50 values of about 2500 to 3500 µg diazinon/kg body weight were determined for goslings (*Anser* spp.), ducks (*Anas* spp.), domestic turkey (*Meleagris gallopavo*), and the red-winged blackbird (*Agelaius phoeniceus*), the most sensitive birds tested. A dietary LD50 of 167,000 µg diazinon/kg was determined for Japanese quail (*Coturnix japonica*). Diazinon produced marked teratogenic effects in embryos of the domestic chicken (*Gallus gallus*) at 6.2 to 25 µg/embryo, reduced egg deposition in the ring-necked pheasant (*Phasianus colchicus*) at more

than 1050 µg/bird, and (empirically) decreased food consumption and increased weight loss in the northern bobwhite (*Colinus virginianus*) at greater than 17,500 µg diazinon/kg diet.

The rat (*Rattus rattus*) was the most sensitive mammal tested in acute oral toxicity screenings, with an LD₅₀ of 224,000 µg diazinon/kg body weight. Chronic oral toxicity tests with swine (*Sus scrofa*) indicated that death was probable if daily intakes were greater than 5000 µg diazinon/kg body weight. Measurable adverse effects of diazinon have been recorded in rodents, the most sensitive mammalian group tested: at 500 µg/kg in diets fed to rats for 5 weeks, causing blood cholinesterase inhibition; 180 µg/kg body weight administered daily to pregnant mice (*Mus musculus*) during gestation, inducing behavioral modifications and delayed sexual maturity of progeny; and single oral doses of 1800 and 2300 µg/kg body weight in rats and white-footed mice (*Peromyscus leucopus*), respectively, producing altered blood chemistry and brain cholinesterase inhibition.

For protection of sensitive aquatic organisms, diazinon concentrations in water should not exceed 0.08 µg/L. However, more data are needed on effects of fluctuating and intermittent chronic exposures of diazinon on reproduction of fish and aquatic invertebrates. Granular formulations of diazinon seem to be especially hazardous to seed-eating birds, suggesting a need to control or eliminate granular applications when these species are present. For additional protection of birds, diazinon should be used with extreme caution in areas where waterfowl feed, and in large-scale spray applications such as grasshopper control. Diazinon in combination with some agricultural chemicals produced more-than-additive adverse effects on bird growth and fecundity; accordingly, more research is needed on effects of complex mixtures of pesticides that contain diazinon. Most investigators agreed that mammals were less susceptible to diazinon than were birds, at least under controlled environmental regimens. Data are lacking on diazinon impacts to mammals under field conditions; acquisition of these data should constitute a priority research area.

CHAPTER 17

Diflubenzuron

17.1 INTRODUCTION

Compounds collectively known as insect growth regulators have been recognized in recent years as important new insecticides. These compounds include juvenile hormone mimics, antijuvenile hormone analogs, and chitin synthesis inhibitors. The most widely studied chitin synthesis inhibitor, and the only one currently registered for use against selected insect pests in the United States, is diflubenzuron (1-(4-chlorophenyl)-3-(2,6-difluorobenzoyl)urea), also known as dimilin (Christiansen 1986; Touart and Rao 1987; Eisler 1992). Chitin is a major component of the tough outer covering, or cuticle, of insects. As insects develop from immature larvae to adults, they undergo several molts, during which new cuticles are formed and old ones are shed. Diflubenzuron prevents successful development by inhibiting chitin synthetase, the final enzyme in the pathway by which chitin is synthesized from glucose (Marx 1977; Ivie 1978).

Diflubenzuron is highly effective against larval stages of many species of nuisance insects. It has been used extensively to control mosquitoes, midges, gnats, weevils (including the cotton boll weevil, *Anthonomus grandis*), various beetles, caterpillars of moths and butterflies (especially the gypsy moth, *Lymantria dispar*), flies, and rust mites (Marx 1977; Ivie 1978; Veech 1978; Schaefer et al. 1980; Opdycke et al. 1982a; Mazzarelli 1986). In Maryland, for example, more than 30,000 ha are sprayed annually to control gypsy moths (Swift et al. 1988a). In general, less than 140 g/ha (2 ounces/acre) of diflubenzuron is sufficient to control susceptible species, although affected larvae do not die until they molt (Marx 1977).

Most authorities agree that diflubenzuron has low mammalian toxicity, is not highly concentrated through vertebrate food chains or by absorption from water, remains stable on foliage, and seldom persists for extended periods in soil and water (Marx 1977; Ivie 1978; Schaefer et al. 1980). Chitin synthesis inhibitors, however, are not specific to insect pests. Beneficial insects also produce chitin, as do all arthropods, including spiders, crabs, crayfish, lobsters, shrimp, daphnids, mayflies, stoneflies, barnacles, copepods, and horseshoe crabs. All of these groups are adversely affected by diflubenzuron, including effects on survival, reproduction, development, limb regeneration, and population growth (Farlow 1976; Marx 1977; Christiansen 1986; Cunningham 1986; Mazzarelli 1986; Touart and Rao 1987; Weis et al. 1987; Eisler 1992; Fischer and Hall 1992).

17.2 ENVIRONMENTAL CHEMISTRY

17.2.1 General

Diflubenzuron breakdown by hydrolysis, soil degradation, or plant and animal metabolism initially yields 2,6-difluorobenzoic acid and 4-chlorophenylurea. Ultimately, the end products are

either conjugated into mostly water-soluble products or are biologically acylated and methylated. At extremely low doses, diflubenzuron selectively inhibits the ability of arthropods to synthesize chitin at the time of molting, producing death of the organism from rupture of the cuticle or starvation. Other organisms that contain chitin (i.e., some species of fungi and marine diatoms), or polysaccharides similar to chitin (i.e., birds and mammals), seem unaffected. Mobility and leachability of diflubenzuron in soils is low, and residues are usually not detectable after 7 days. Degradation is most rapid when small-particle (2 to 5 µm) formulations are applied and soil bacteria are abundant. In water, diflubenzuron usually persists for only a few days. Degradation is most rapid under conditions of high organic and sediment loadings, and elevated water pH and temperature.

17.2.2 Chemical and Biochemical Properties

Selected chemical properties of diflubenzuron are listed in [Table 17.1](#). Diflubenzuron degradative pathways are almost entirely through cleavage between the carbonyl and amide groups of the urea bridge. Ultimately, the end products are either conjugated into predominantly water-soluble products or are acylated and methylated biologically (Metcalf et al. 1975). Hydrolysis, soil degradation, and plant and animal metabolism of diflubenzuron yield the same initial products: 2,6-difluorobenzoic acid and 4-chlorophenylurea. Soil degradation and plant and animal metabolism involve further conversion of these compounds to 2,6-difluorobenzamide and 4-chloroaniline (Schaefer et al. 1980; Gartrell 1981) ([Figure 17.1](#)). Interspecies variations in ability to metabolize diflubenzuron are common, as judged by metabolic patterns in rat (*Rattus spp.*), cow (*Bos bovis*), and sheep (*Ovis aries*). In all three species, hydroxylation of either aromatic ring and scission of the ureido bridge constituted the main metabolic pathways. In cow and rat, the prevailing route was ring hydroxylation; in sheep, it was the scission reaction. In cow and sheep, about half the 2,6-difluorobenzoyl moiety excreted in urine was conjugated to glycine, but in rat the acid was excreted largely unchanged. In sheep, where cleavage-splitting of the diflubenzuron molecule was the primary metabolic route, there was no evidence of 4-chlorophenylurea or 4-chloroaniline in

Table 17.1 Chemical and Other Properties of Diflubenzuron

Variable	Data
Chemical names	1-(4-Chlorophenyl)-3-(2,6-difluorobenzoyl)urea; <i>N</i> -[(4-chlorophenyl)amino]carbonyl]-2,6-difluorobenzamide; 1-(2,6-difluorobenzoyl)-3-(4-chlorophenyl)urea
Alternate names	Deflubenzon, Diflubenzuron, Dimilin, DU, DU 112307, Duphar BV, ENT-29054, Largon, Micromite, OMS 1804, PDD 6040-I, PH 60-40, TH 6040, Vigilante
Action	Insecticide, larvicide, ovicide; insect growth regulator acting by interference with deposition of insect chitin
CAS number	35367-38-5
Empirical formula	C ₁₄ H ₉ ClF ₂ N ₂ O ₂
Molecular weight	310.68
Formulations	Granular; oil-dispersible concentrate; wettable powder
Manufacturing process and impurities	Produced by reaction of 2,6-difluorobenzamide with 4-chlorophenyl isocyanate. The technical product is 95% pure. Impurities are of low toxicological concern in terminal residues
Stability	Stable under sunlight and in neutral or mildly acidic solutions; unstable in strong basic solutions
Physical state	White crystalline solid
Melting point	210–230°C (technical); 230–232°C (pure)
Solubility	
Water	0.1–0.2 mg/L at 20°C; 1.0 mg/L at 25°C
Polar organic solvents	Moderate to good
K _{ow}	3500

Data from Metcalf et al. 1975; Farlow 1976; Johnson and Finley 1980; Gartrell 1981; Hudson et al. 1984; Mayer 1987; Poplyk 1989; Fischer and Hall 1992.

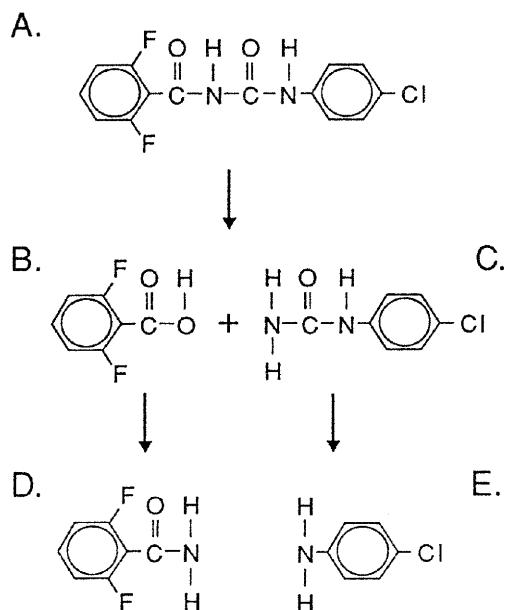

Figure 17.1 Generalized degradation pattern for diflubenzuron. Diflubenzuron (**A**) degrades initially to 2,6-difluorobenzoic acid (**B**) and 4-chlorophenylurea (**C**). 2,6-Difluorobenzoic acid (**B**) degrades to 2,6-difluorobenzamide (**D**) and 4-chlorophenylurea (**C**) degrades to 4-chloroaniline (**E**).

urine (Willems et al. 1980). More information on degradation and metabolic pathways of diflubenzuron is given in Metcalf et al. (1975), Schooley and Quistad (1979), Ivie et al. (1980), Willems et al. (1980), Franklin and Knowles (1981), and Jenkins et al. (1986).

The benzoylphenylureas — including diflubenzuron — control target insect populations at extremely low doses by selectively inhibiting their ability to synthesize chitin-bearing parts. Ingested diflubenzuron has no apparent adverse effects until the molting process is under way. Diflubenzuron caused increases in cuticle chitinase and cuticle phenoloxidase activity, producing a softened endocuticle through reduction of its chitin content and a hardened exocuticle as a result of increased phenoloxidase activity (Farlow 1976). Diflubenzuron inhibits serine protease, thus blocking the conversion of chitin synthetase zymogen into an active enzyme (Cunningham 1986; Mazzarelli 1986). Insect larvae treated with diflubenzuron develop cuticles that are unable to withstand the increased turgor occurring during ecdysis and that fail to provide sufficient muscular support during molting. These larvae are unable to cast their exuviae, resulting in death from starvation or rupture of the new, delicate, malformed cuticle (Farlow 1976). In addition to terrestrial insects, diflubenzuron is toxic to a wide variety of aquatic insects and crustaceans (Swift et al. 1988a, 1988b), but it does not seem to affect other organisms that contain chitin, including fungi (Mazzarelli 1986) and marine diatoms (Montgomery et al. 1990).

Chitin is a polymer of *N*-acetylglucosamine (AGA), and it rivals cellulose as the most abundant biopolymer in nature. Measured chitin concentrations in marine waters range between 4 and 21 µg/L, and planktonic crustaceans are the most significant source of chitin in the sea (Montgomery et al. 1990). Insect chitin is synthesized during phosphorylation by uridine dispospho-*N*-acetyl glucosamine (UDPGA) — the immediate precursor of chitin (Crookshank et al. 1978). Diflubenzuron inhibits the incorporation of chitin precursors into chitin, with a resultant accumulation of UDPGA (Crookshank et al. 1978). Chitin is not found in vertebrates, although several important polysaccharides similar to chitin are found, including hyaluronic acid (HA). Hyaluronic acid is found in skin, synovial fluid, connective tissue, vitreous humor, and the covering of the ovum.

Hyaluronic acid is a polysaccharide compound of alternating groups of glucuronic acid and AGA. The immediate precursor for glucuronic acid is uridine diphospho-glucuronic acid and that for AGA is UDPAGA. Because UDPAGA is used in the synthesis of chitin by insects and of HA by vertebrates, and because diflubenzuron interferes with the incorporation of UDPAGA into chitin by insects, diflubenzuron may interfere with the formation of HA in birds (Crookshank et al. 1978) (to be discussed later).

17.2.3 Persistence in Soil and Water

Mobility and leachability of diflubenzuron in soils is low, and residues are usually not detectable after 7 days. In water, half-time persistence (T_b 1/2) is usually less than 8 days and lowest at elevated temperatures, alkaline pH, and high sediment loadings (Fischer and Hall 1992) (Table 17.2). Increased concentrations of diflubenzuron in soils and waters are associated with increased application frequency, flooding of treated supratidal areas, wind drift, and excessive rainfall (Cunningham 1986).

Diflubenzuron is persistent in postharvest soils during winter and spring months, especially if associated with plant litter. Concentrations decline rapidly with the onset of high summer temperatures to <0.3 mg/kg DW soil in summer (Bull and Ivie 1978; Bull 1980). Diflubenzuron particle size and soil flora may be important in the soil degradation process. Diflubenzuron adsorbed to smaller particles of 2 μm diameter had a short T_b 1/2 of 3 to 7 days; diflubenzuron adsorbed to larger particles (10 μm diameter) persisted for 8 to 16 weeks. Diflubenzuron adsorbed to particles of 2 μm diameter had a low rate of degradation in sterile soils (<6% in 4 weeks), but in nonsterile soils 98% degraded in the same period, suggesting that soil bacteria are important in the degradation process (Cunningham 1986). In Canada, data on mobility of a pesticidal chemical in forest soil must be collected before it can be registered for use under the Canadian Pest Control Products Act in order to assess its potential for groundwater contamination (Sundaram and Nott 1989). Diflubenzuron used properly in forest management is unlikely to be leached into groundwater from a site of application (Sundaram and Nott 1989).

Water concentrations of diflubenzuron in treated ponds are significantly higher in surface and middle samples than in bottom samples during the first 5 h after treatment. However, after 24 h, distribution is about the same for all depths (Colwell and Schaefer 1980). Diflubenzuron persists for only a few days in pasture waters at 22 to 45 g/ha applied to control pasture mosquitoes (*Aedes nigromaculatus*, *A. melanimon*); hydrolysis and adsorption onto organic matter limit persistence in water (Schaefer and Dupras 1977). Aerial spraying of 70 g/ha in a forest ecosystem resulted in pondwater concentrations of 5.9 to 13.8 $\mu\text{g}/\text{L}$, which declined to <0.05 $\mu\text{g}/\text{L}$ within 16 to 20 days (Sundaram et al. 1991; Tanner and Moffett 1995). Water temperature and pH significantly affect persistence of diflubenzuron. Degradation is most rapid at elevated temperatures and alkaline pH values. Half-time persistence of diflubenzuron at pH 7.7 and various thermal regimes is 8 days at 38°C, 35 days at 24°C, and 29 days at 10°C. At pH 10, T_b 1/2 values are 2 days at 38°C, 14 days at 24°C, and 32 days at 10°C; degradation is negligible at pH 4 and at low temperatures regardless of pH (Cunningham 1989). In water, as in soil, small-particle (2 to 5 μm diameter) diflubenzuron formulations, such as WP-25%, degrade rapidly, usually in 2 to 8 days (Cunningham 1986). Larger-particle sand-granule formulations, developed for use in mosquito control programs wherein the compound needs to penetrate thick vegetation to reach the water, reduce drift during application and also provide slower release of diflubenzuron into aquatic habitats (Cunningham 1986).

The presence of sediments in diflubenzuron marine microcosms results in rapid removal from seawater and ultimately a reduction in mortality of larval crustaceans (Table 17.2) (Cunningham et al. 1987). But marine sediments that exceed 200 μg diflubenzuron/kg — levels normally encountered at application rates for control of salt marsh mosquitoes — could be detrimental to juvenile and adult crustaceans that consume detritus and organic matter on the surface of the marsh or at the water-sediment interface (Cunningham and Myers 1986; Cunningham et al. 1987).

Table 17.2 Diflubenzuron Persistence in Soil and Water

Sample, Initial Concentration, and Other Variables	Persistence	Reference ^a
SOIL		
0.08 g/ha, aerial spray, single application	Values always <0.05 mg/kg up to 14 days after spraying	1
22.4 g/ha (0.02 pounds/acre) applied 4 times, 1 month between treatments	Residues, in mg/kg, after first treatment were 0.2 at 1 day and 0.016 at 7 days. Residues at time of fourth treatment were nondetectable (ND) at start, 0.01 at 1 h, 0.02 at 1 day, and ND between days 3 and 56	2
44.9 g/ha (0.04 pounds/acre, applied 4 times, 2 weeks between treatments	Maximum residues, in mg/kg, after first treatment were 0.07 at 1 day and 0.05 at 7 days. After fourth treatment, residues were 0.04 at start, 0.09 at 3 days, and ND between days 7 and 56	2
70, 210, or 630 g/ha applied once to sandy loam forest soil or clay loam forest soil, plus water equivalent to 50.8 cm of precipitation	Mobility of diflubenzuron was low and did not increase with dosage. No residues detected below 10 cm or in leachates in either soil type at all dosage levels. At 70 g/ha, all residues were found in the top 2.5 cm; at 630 g/ha, 4–9% moved below 2.5 cm in sandy loam (mobility was lower in clay loam)	3
DISTILLED WATER		
100 µg/L, 37°C	No degradation at pH 4 in 8 weeks; Tb 1/2 was about 7 days at pH 6 and <3 days at pH 10. Major degradation products were 4-chlorophenylurea and 2,6-difluorobenzoic acid; small amounts of 2,6-difluorobenzamide and a quinazolininedione product were also formed	4
PASTURE WATER		
22–45 g/ha (0.02–0.04 pounds/acre), single application	Maximum concentrations, in µg/L, were 8.8 in 1 h, 7.1 in 24 h, 3.9 in 48 h, and 2.6 in 72 h; most treatments produced ND (<1 µg/L) residues in 24 h	5
45 g/ha (0.04 pounds/acre), single application	Concentrations, in µg/L, were 4 at start, 36 at 1 h, 9 at 24 h, and 6 at 14 days	1
45 g/ha, applied 4 times at 2-week intervals	Maximum concentrations, in µg/L, were 7.4 at 1 h after first treatment, 1.3 at 1 h after second application, 2.9 at 1 h after third treatment, and 6.4 at 1 h and 0.9 at 1 day after last treatment	2
80 g/ha, single application	Concentrations, in µg/L, of diflubenzuron declined from 20.3 at 1 h to 2.4 at 4 days; 4-chlorophenylurea increased slightly from 5.6 to 7.2 during this interval; 4-chloroaniline increased from 0.7 at 1 h to 2.6 at 4 days	6
POND WATER		
2.5 µg/L	Concentration after treatment was 1.9 µg/L; after 2 weeks, it was 0.5 µg/L	7
5 µg/L	Concentration immediately after treatment was 4.6 µg/L; after 2 weeks, it was 0.3 µg/L	7
10 µg/L	Initial concentration in medium declined from 9.8 µg/L to 0.2 µg/L after 2 weeks	7
13.8 µg/L	Concentration 1 h after aerial spraying of 70 g/ha; this declined to 6.3 µg/L at 12 h, 3.4 in 2 days, 1.0 in 10 days, 0.2 in 15 days, and was not detectable after 20 days	10
SEAWATER		
10 µg/L, sediments present	Tb 1/2 of 5.3 days; <0.7 µg/L in 19 days; <0.5 µg/L in 22 days	8
10 µg/L, sediments absent	Tb 1/2 of 17.8 days	8

Table 17.2 (continued) Diflubenzuron Persistence in Soil and Water

Sample, Initial Concentration, and Other Variables	Persistence	Reference ^a
100 µg/L	Tb 1/2 of 7.9 days at 38°C, and 35 days at 24°C	9
45 g/ha	Tb 1/2 of 10 days	9

^a 1, Booth and Ferrell 1977; 2, Schaefer and Dupras 1977; 3, Sundaram and Nott 1989; 4, Ivie et al. 1980; 5, Schaefer and Dupras 1976; 6, Schaefer et al. 1980; 7, Apperson et al. 1978; 8, Cunningham et al. 1987; 9, Cunningham and Myers 1986; 10, Sundaram et al. 1991.

17.3 USES

Diflubenzuron effectively inhibits molting in many species of insect pests, especially among the lepidoptera, coleoptera, and diptera. In the United States, diflubenzuron was approved for use by the U.S. Environmental Protection Agency (USEPA) against the gypsy moth in 1976, the cotton boll weevil in 1979, and foliar feeders on soybeans in 1982. By 1989 diflubenzuron was also registered for domestic use against mosquitoes, forest lepidoptera, mushroom flies, and certain leaf-eating insect pests of citrus, woody ornamentals, vegetables, and fruits (Bull 1980; Nimmo et al. 1980; Gartrell 1981; Cunningham 1986; Mazzarelli 1986; Webb and Wildey 1986; Wilson and Costlow 1987; Martinat et al. 1988; Poplyk 1989). In 1990, over 269,000 ha of forest were treated with diflubenzuron to suppress gypsy moth and tent caterpillar (*Malacosoma disstria*) populations (Whitmore et al. 1993).

In Europe and elsewhere, diflubenzuron is used in a variety of ways not permitted in the United States. For example, diflubenzuron and other insect growth regulators are fed as admixtures to rations of chickens, cattle, and swine in order to control fly larvae breeding in their manures, and also as a spray directly on manures prior to disposal (Opdycke et al. 1982b; Opdycke and Menzer 1984; Giga 1987). Diflubenzuron has been administered orally as a bolus to beef cattle for control of face flies (*Musca autumnalis*) and horn flies (*Haematobia irritans*), two serious pests of cattle in North America. Immature insects develop in fresh manure on open pasture. A single bolus released diflubenzuron into feces that killed horn and face fly larvae for 8 weeks and remained partially effective for 16 weeks (Scott et al. 1986).

Three diflubenzuron formulations are now in general use: an oil dispersible concentrate, a wettable powder (WP), and granules (Bull 1980; Cunningham 1986; Poplyk 1989). Granular formulations are produced by applying diflubenzuron to sand granules. Since technical diflubenzuron (99.5% pure) is a crystalline material that is almost insoluble in water (i.e., 0.1 mg/L at 20°C), it is usually dispersed in an organic solvent carrier. Wettable powders (25% active ingredients), however, are dispersed in water for use in many commercial applications; diflubenzuron particle size in WP-25 formulations usually ranges between 2 and 5 microns.

17.4 LETHAL AND SUBLETHAL EFFECTS

17.4.1 General

Diflubenzuron applied to foliage of terrestrial plants tends to remain adsorbed for several weeks with little or no absorption or translocation from plant surfaces; loss is mainly by wind abrasion, rain washing, or shedding of senescent leaves. Among insect species, there is great variability in sensitivity to diflubenzuron. In general, diflubenzuron is toxic to early life stages of insects at concentrations as low as 0.1 mg/kg diet and at topical applications between 0.003 and 0.034 µg/larvae. Among aquatic organisms, early developmental stages of crustaceans and insects are the most sensitive groups tested. Adverse effects on growth, survival, reproduction, and behavior

occur between 0.062 and 2.0 µg/L. Groups highly resistant to diflubenzuron include the algae, gastropods, fishes, and amphibians. Birds are comparatively resistant: acute oral LD₅₀ values exceed 2000 mg diflubenzuron/kg body weight (BW), and dietary levels of 4640 mg/kg ration are tolerated for 8 days. Also, forest birds seem unharmed by recommended diflubenzuron application procedures to control pestiferous insects. No data are available on mammalian wildlife. However, studies with small laboratory animals and domestic livestock suggest a high degree of resistance. No observable adverse effects occur in cows given 0.25 mg/kg BW daily for 4 months, in rabbits given 4 mg/kg BW daily on days 6 to 18 of gestation, in dogs fed diets containing 40 mg/kg for 13 weeks (equivalent to 1.6 mg/kg BW daily), in rats fed diets containing 160 mg/kg for 2 years, and in rabbits and rodents given single oral or dermal doses <2000 mg/kg BW. All of these points are discussed later.

17.4.2 Terrestrial Plants

There is little to no absorption and translocation of diflubenzuron residues from plant surfaces (Gartrell 1981). Due to its stability and low volatility, diflubenzuron residues adhering to plant surfaces are removed primarily through physical effects such as wind abrasion, rain washing, or the loss of dead leaves (Bull 1980). A greenhouse study with corn (*Zea mays*), soybeans (*Glycine max*), cabbage (*Brassica oleracea capitata*), and apples (*Malus* sp.) showed no significant degradation of diflubenzuron residues in leaves for up to 16 weeks after treatment (Gartrell 1981). In a study with radiolabeled diflubenzuron, a single dose applied to a cotton (*Gossypium hirsutum*) leaf showed <5% photodegradation in 4 weeks, <7% absorption in 7 weeks, <50% loss to weathering or volatilization in 4 weeks in samples not exposed to rain, and 77% loss in 3 weeks after a heavy rainfall (Bull and Ivie 1978; Bull 1980). Edible portions of rotational crops treated repeatedly with diflubenzuron at recommended application levels had low, but detectable, residues. Maximum concentrations, in mg/kg DW, were always <0.01 in wheat (*Triticum* spp.), <0.02 in cotton, <0.09 in collards (*Brassica* spp.), and <0.16 in radish (*Raphanus* spp.) (Bull and Ivie 1978; Bull 1980).

Diflubenzuron applied aerially to forest leaves in the spring growing season did not persist when the leaves were placed in stream water (Harrahy et al. 1993). Residues on oak leaves decreased 36% in July, and 23% in August within the first 48 h of stream incubation, reaching >90% loss within 3 weeks. However, in December, after 54 days in the stream, there was no significant loss from leaves of red maple, oak, or poplar. The persistence of diflubenzuron to forest leaves under winter conditions is attributed to the increased stability of diflubenzuron at cold temperatures, the greater retention to leaves at low temperatures, and the reduction in microbial degradation. In view of the persistence of diflubenzuron on hardwood leaves at low stream temperatures, nontarget aquatic organisms that consume these leaves may be exposed for extended periods with possible adverse effects (Harrahy et al. 1993).

Foliage of cotton that initially contained 100 mg/kg DW contained about 60 mg/kg after 7 weeks; leaf residues consisted entirely of the parent diflubenzuron (Gartrell 1981). Diflubenzuron applied topically to lima bean (*Phaseolus lunatus*) foliage was not absorbed by the plant, as expected. Injected diflubenzuron, however, was metabolized, and certain metabolites were similar to those isolated from mites (Franklin and Knowles 1981).

Diflubenzuron mixed into compost layers of the cultivated mushroom (*Agaricus bisporus*) at 30 mg/kg compost to control dipteran pests of mushroom resulted in increased yield and size. However, at higher concentrations of 180 mg/kg and 1080 mg/kg, mushroom yield and number were reduced, and this became more severe over time (White 1986). Frequent applications of diflubenzuron to agricultural soils are not detrimental to nitrogen-fixing bacteria (i.e., *Azotobacter vinelandii*), and high concentrations could stimulate nitrogenase activity in soils. This conclusion is based on a study by Martinez-Toledo et al. (1988) using nonsterile agricultural soils and sterilized soils inoculated with *A. vinelandii*. At diflubenzuron loadings between 100 and 500 mg/kg, all concentrations tested had a stimulatory effect on nitrogen fixation in both soils.

17.4.3 Terrestrial Invertebrates

Diflubenzuron is most toxic to early life stages of some insects at 0.1 mg/kg diet, 0.034 µg/larvae (about 3.1 mg/kg BW), or in combination with various chemicals (Table 17.3). Some beneficial insects, such as the honey bee (*Apis mellifera*), are adversely affected at dietary concentrations of 1 mg/kg for 12 weeks, 10 mg/kg for 10 weeks, or 59 mg/kg for 10 days (Table 17.3). At 28 to 56 g/ha (0.025 to 0.05 pounds/acre), diflubenzuron effectively controls mosquitoes for 8 to 15 days (Schaefer and Dupras 1977; Booth and Ferrell 1977), especially organophosphorus insecticide-resistant strains of salt marsh mosquitoes in California (Lee and Scott 1989). Diflubenzuron was also effective in controlling strains of house fly (*Musca domestica*) that were resistant to organochlorine, organophosphorus, carbamate, and pyrethroid insecticides on a United Kingdom pig farm; 416 mg/m² to slurry pots of pig weaning rooms gave effective control 2 to 4 weeks after application (Webb and Wildey 1986).

Chemical control of larvae of gypsy moth and other forest-insect defoliators may cause indiscriminate reduction of nontarget arthropods, which, in turn, may affect food resources of forest birds and small mammals. This problem is of special concern in West Virginia, where two species of endangered bats (Indiana bat, *Myotis sodalis*; eastern big-eared bat, *Plecotus phyllotis*) occur in areas threatened by gypsy moth defoliation (Martinat et al. 1988). Diflubenzuron applications, usually at 70 g/ha on two consecutive days, controlled gypsy moth larvae and also significantly reduced populations of canopy macrolepidoptera and nonlepidopteran mandibulate herbivores. Sucking herbivorous insects, microlepidoptera, and predaceous arthropods, however, were relatively unaffected, which suggests that although diflubenzuron can potentially affect food supply of forest birds and small mammals, these effects are probably minimal (Martinat et al. 1988).

Researchers generally agree that diflubenzuron causes incomplete ecdysis by interfering with chitin synthesis. However, diflubenzuron at lethal concentrations causes an effect in chironomid larvae (*Chironomus decorus*, *Tanypus grodhausi*) other than inhibition of chitin synthetase, as judged by histopathology of the alimentary canal, especially the ventriculus. Dysfunction of the ventriculus, an organ that normally lacks chitin, results in a general breakdown of the digestive apparatus of exposed chironomid larvae (Pelsue 1985). Exposure of nematodes and of adults of several insect species, including boll weevil, housefly, and stable fly (*Stomoxys calcitrans*), to diflubenzuron results in deposition of eggs that appear normal but fail to hatch. This effect seems to be due to an ovicidal action and not to sterility of the treated adults, since the larvae appear to undergo normal development within the egg. Secretion of unmetabolized diflubenzuron into the eggs apparently accounts for observed ovicidal effects (Ivie and Wright 1978; Veech 1978; Ivie et al. 1980). Treated female boll weevils began to lay viable eggs 12 days after treatment and became as productive as controls in 24 days; additional treatment is required to maintain a significant suppression of egg hatch (Bull 1980).

Diflubenzuron is the most investigated benzoylphenylurea and has shown excellent potency for controlling mosquitoes and certain lepidopterous and coleopterous pests. Some insect species, however, cannot be controlled efficiently by diflubenzuron. For example, the cotton leafworm (*Spodoptera littoralis*) is comparatively resistant because of reduced penetration through the exoskeleton, rapid elimination of unchanged diflubenzuron, and rapid metabolism, which occurs mainly through hydrolysis (El Saidy et al. 1989). To combat *Spodoptera* and other resistant pests, new benzoylphenylurea compounds have been developed, including chlorfluazuron, teflubenzuron, and hexafluron (El Saidy et al. 1989).

Beneficial insects associated with fruit orchards show different responses to diflubenzuron treatment (Broadbent and Pree 1984). Lacewings (*Chrysopa oculata*) in contact with leaves containing 300 mg/kg DW had reduced survival and inhibited molting of first instar larvae, but the assassin bug (*Acholla multispinosa*) was not affected by contact with treated leaves. Lacewings and other beneficial predator insects fed diflubenzuron-treated, two-spotted spider mites (*Tetranychus urticae*) for 3 days showed no adverse effects after 14 days (Broadbent and Pree 1984).

Spraying of diflubenzuron at 28 g/ha to control gypsy moth did not affect *Cotesia melanoscela*, a hymenopterid predator of the gypsy moth. However, another natural enemy, a virus, was adversely affected (Webb et al. 1989). Certain arthropod predators were unaffected by diflubenzuron at 70 mg/ha applied four times in 3 weeks to control the boll weevil; these include the convergent lady bug beetle (*Hippodamia convergens*), the big-eyed bug (*Geocoris punctipes*), and various species of *Coleomegilla*, *Orius*, *Nabis*, and *Chrysopa* (Deakle and Bradley 1982).

Diflubenzuron can be either hydrolyzed at the urea bridge or oxidized by ring hydroxylation followed by conjugation. Hydrolytic cleavage seems to be a major route for diflubenzuron metabolism in many insect species (El Saidy et al. 1989). Two-spotted spider mites showed <10% absorption in 96 h of topically applied diflubenzuron. Of the amount absorbed, about 27% was metabolized in 96 h to 4-chlorophenylurea, 2,6-difluorobenzoic acid, 4'-chloroformanilide, 2,6-difluorobenzamide, and other metabolites (Franklin and Knowles 1981). Effects of diflubenzuron were synergized by profenofos (El Saidy et al. 1989) in cotton leafworm fourth instar larvae, and they were antagonized by 20-hydroxyecdysone (Soltani et al. 1987) in beetle (*Tenebrio molitor*) pupae. More information is needed on interaction effects of diflubenzuron with other chemicals.

Table 17.3 Diflubenzuron Effects on Selected Terrestrial Invertebrates

Organism, Dose, and Other Variables	Effect	Reference ^a
NEMATODE, <i>Acrobeloides</i> sp.		
Fed diet containing 100 mg/kg for 10 days	Population reduction of 97%	1
BOLL WEEVIL, <i>Anthonomus grandis</i>		
1 µg/female weevil, applied topically	After 8 days, about 62% was not absorbed, 3% was absorbed, and 35% was metabolized and excreted	2
113.4 g/ha, applied 5 times during winter	Reduced heavy infestations by >70% in upper Gulf Coast area of Texas	3
HONEYBEE, <i>Apis mellifera</i>		
Fed sucrose syrup/sugar cake diets containing 0.01, 0.1, 1, or 10 mg/kg for 12 weeks	Adult colony survival reduced at 10 mg/kg; inhibited reproduction at 1 and 10 mg/kg; no measurable effect on survival or reproduction at 0.01 or 0.1 mg/kg	4
Fed diet containing 10 mg/kg for 10 weeks	No reduction in consumption of pollen or in quantity of brood reared, but >50% reduction in amount of sucrose syrup stored	5
Fed sucrose syrup containing 59 mg/kg for 10 days	Inhibited reproduction	6
Fed sucrose syrup containing 60 mg/L and drinking water containing 100 mg/L for 40 days	Treated bees consumed significantly less water and pollen and produced significantly less comb, brood, and new workers	7
GERMAN COCKROACH, <i>Blattella germanica</i>		
Nymphs fed diets containing 4, 20, 100, or 500 mg/kg for 4 weeks	None dead at 4 mg/kg, 15% at 20 mg/kg, 88% at 100 mg/kg, and all dead at 500 mg/kg	8
APHID LION, <i>Chrysoperla carnea</i>		
0.5 g/L spray	Reduced incubation period, reduced hatch, and reduced survival	9
2.0 g/L spray	No hatch	9
TERMITES, <i>Coptotermes heimi</i>		
Nymphs fed diets containing 100, 500, or 1000 mg/kg	All dead in 24 days at 200 mg/kg, 20 days at 500 mg/kg, or 16 days at 1000 mg/kg. Some nymphs developed blister-like swellings on the abdomen and failed to molt into the next instar	10

Table 17.3 (continued) Diflubenzuron Effects on Selected Terrestrial Invertebrates

Organism, Dose, and Other Variables	Effect	Reference ^a
MOSQUITO, <i>Culex pipiens quinquefasciatus</i>		
Adults fed 500 or 1000 mg/kg diet for 2 days	At both doses, 40% of eggs failed to hatch or hatched abnormally; at the high dose, ovarian histopathology recorded	11
CAT FLEA, <i>Ctenocephalides felis</i>		
Larvae, held in rearing medium for 5–6 weeks		
90 µg/kg	LC50, 1.5-day-old larvae	12
2220 µg/kg	LC50, 2.5-day-old larvae	12
>100 mg/kg	LC50, 3.5-day-old larvae	12
TERMITE, <i>Heterotermes indicola</i>		
Nymphs fed diets containing 100, 500, or 1000 mg/kg feed	All dead in 14–16 days at 100–1000 mg/kg diet	10
GYPSY MOTH, <i>Lymantria dispar</i>		
100 µg/kg diet	100% lethal to larvae	13
CABBAGE MOTH, <i>Mamestra brassicae</i>		
2.2 mg/L spray	LC90, third instar larvae	14
NEMATODES, various species		
Fed diet containing 1 mg/kg for 10 days	No effect on reproduction	1
Fed diet containing 10 mg/kg for 10 days	53% population reduction in <i>Panagrellus redvirus</i> , and 95% reduction in <i>Pelodera</i> sp.	1
AMERICAN COCKROACH, <i>Periplaneta americana</i>		
Nymphs fed diets containing 100 or 800 mg/kg for 4 weeks	17% dead at low dose and 52% dead at high dose	8
LARGE WHITE BUTTERFLY, <i>Pieris brassicae</i>		
0.39 mg/L spray	LC50, third instar larvae	14
COTTON LEAFWORM, <i>Spodoptera littoralis</i>		
Fourth instar larvae, topical application 3, 10, 30, or 100 ng/larva	Incorporation of N-acetyl glucosamine into chitin was inhibited by 23% at 3 ng/larva, 75% at 10 ng, 90% at 30 mg, and 98% at 100 ng	14
34 ng/larva, equivalent to 3.1 mg/kg BW	LD50, applied in combination with profenofos	15
468 ng/larva, equivalent to 42.5 mg/kg BW	LD50	15
4.3 mg/L, spray	LC90, third instar larvae	14
TERMITES		
Nymphs, 3 species, given 100–1000 mg/kg diet	All dead in 14–24 days	10
Adults, 2 species, given 1000 mg/kg diet	Fecundity reduced and eggs failed to develop	10

17.4.4 Aquatic Organisms: Laboratory Studies

Studies with diflubenzuron and representative aquatic organisms under controlled conditions (Table 17.4) show several trends:

1. Crustaceans are the most sensitive group of nontarget organisms tested. Adverse effects on growth, survival, reproduction, and behavior of copepods, shrimp, daphnids, amphipods, and crabs occur between 0.062 and 2.0 µg/L medium, and early developmental stages were the most vulnerable.
2. Next in sensitivity are aquatic insects, including mayflies, chironomids, caddisflies, and midges. Diflubenzuron concentrations between 0.1 and 1.9 µg/L medium produce low emergence and survival.
3. Other groups tested are comparatively resistant (i.e., adverse effects occur at >45 µg/L). In fish, for example, death occurred at >33,000 µg/L.
4. Elevated accumulations occur in aquatic plants during exposure to 100 µg/L and in fish during exposure between 1 and 13 µg/L. All species in these groups, however, seemed unaffected by elevated body burdens, as judged by normal growth and metabolism.

The major degradation products of diflubenzuron in water are 4-chlorophenylurea and 2,6-difluorobenzoic acid (Metcalf et al. 1975; Ivie et al. 1980). These compounds are less toxic to aquatic organisms than the parent chemical (Julin and Sanders 1978; Schaefer et al. 1979, 1980; Gattavecchia et al. 1981). A minor metabolite, 4-chloroaniline, which is classified as a mutagen by The National Cancer Institute, and the Cancer Assessment group of the U.S. Environmental Protection Agency (Schaefer et al. 1980), is significantly more toxic to fish and *Euglena gracilis* than is diflubenzuron. For example, LC50 (96 h) values for 4-chloroaniline and four species of freshwater teleosts are 16 to 56 times lower than comparable data for diflubenzuron (Julin and Sanders 1978), but 4-chloroaniline is 76 times less toxic than diflubenzuron to *Chironomus* midge larvae in 48 h (Julin and Sanders 1978). There is a dose-dependent effect of 4-chloroaniline on *Euglena* growth inhibition and glycine metabolism in the range of 1 to 200 mg/L during exposure for 30 h (Gattavecchia et al. 1981). The most sensitive organism to 4-chloroaniline was bluegill (*Lepomis macrochirus*) with an LC50 (96 h) value of 2.3 mg/L (Julin and Sanders 1978). It is highly unlikely, however, that this concentration will be encountered under recommended diflubenzuron application practices.

Diflubenzuron inhibits several enzyme systems in crab and insect larvae, resulting in disrupted glucose metabolism, reduced *N*-acetylglucosamine incorporation into cuticle, and ultrastructural deformities of chitinous components of the cuticle (Christiansen and Costlow 1982; Christiansen et al. 1984; Christiansen 1986). Specifically, diflubenzuron inhibits chitin synthetase, a magnesium-requiring enzyme that catalyzes the transfer of *N*-acetyl-*D*-glucosamine to chitin; the final result is relatively large accumulations of *N*-acetylglucosamines (Horst 1981; Machado et al. 1990).

Diflubenzuron acts specifically on insects and crustaceans as a larvicide by interfering with chitin deposition into cuticles during juvenile development through ecdysis (Horst 1981; Antia et al. 1985; Cunningham 1986; Machado et al. 1990). The biosynthesis of chitin in arthropods is under hormonal control. Arthropods increase in size by resorbing a portion of the shell and initiating the secretion of a new exoskeleton under the old cuticle. At this time, chitin synthesis is maximal. After completion of about half the new shell, molting occurs, the old shell is discarded, and the new shell is synthesized. Diflubenzuron exposure produces disturbances in the cuticular structure, weakening the cuticle so that it fails mechanically during ecdysis of insects and crustaceans. In general, treated larvae appear healthy during the entire intermolt period until molting commences, at which time many larvae are unable to cast their molts completely and die within a few hours. Several genera of diatoms, including *Thalassiosira* and *Skeletonema*, produce up to 33% of their biomass as chitin. These diatoms synthesize chitin strands that extend outside their frustules to increase buoyancy (Montgomery et al. 1990). Chitin-producing diatoms, as well as nonchitanaceous

diatoms, are seemingly unaffected at elevated concentrations of 1 mg/L for periods up to 14 days (Antia et al. 1985). Some species of algae, especially *Plectonema boryanum*, are reported to efficiently degrade diflubenzuron (Schooley and Quistad 1979), but this requires verification.

Studies with laboratory stream communities dosed for 5 months confirm that insects and crustaceans are the most severely affected groups. Adverse effects occur in the range of 1.0 to 1.1 µg diflubenzuron/L. Fish and molluscs, however, show no adverse effects at 45 µg/L (Hansen and Garton 1982). Freshwater clams (*Anodonta cygnea*) exposed to high concentrations of diflubenzuron for lengthy periods may experience blocked polycondensation reactions to chitin chains in the outer mantle epithelium secretory cells, producing unstabilized chitin and increasing shell fragility. On this basis, the comparatively resistant burrowing bivalve molluscs may be at risk if exposed over several calcification periods (Machado et al. 1990). Fish accumulated diflubenzuron from water up to 160 times water levels, but tissue concentrations during exposure declined steadily over time (Schaefer et al. 1980).

Exposure of *Aedes albopictus*, a mosquito vector of dengue and encephalitis in Taiwan, for 24 h to 0.00025 to 25 µg/L diflubenzuron resulted in dose-dependent aberrations in larvae, pupae, and adults (Ho et al. 1987) (Table 17.4). In general, most treated second and third instar *Aedes* larvae died during molting, while most fourth instar larvae developed abnormally (Ho et al. 1987). Unfortunately, levels of diflubenzuron used to control saltwater mosquitoes and other insects are also toxic to zoeal stages of crustaceans (Costlow 1979) and adversely affect growth and reproduction of adults (Mazzarelli 1986). Treated larvae of estuarine crustaceans are characterized by the following (Table 17.4) (Cunningham 1986):

- Histological alterations in the cuticular layers of the exoskeleton at concentrations as low as 1 µg/L
- Higher mortality associated with molting and gross morphological deformities at concentrations as low as 0.5 µg/L
- Behavioral modifications at concentrations as low as 0.1 µg/L

Behavioral effects in fiddler crabs (*Uca pugilator*) were the most sensitive indicator of diflubenzuron stress, and these effects potentially may influence the ability of juvenile crabs to avoid predation, construct burrows, or feed adequately in nature (Cunningham and Myers 1987). Behavioral effects on cladocerans that can result in latent mortality include reduced filter feeding rates, reduced body movements, and inability to exhibit positive phototaxis, a characteristic of untreated individuals (Cunningham 1986) (Table 17.4). Shrimp larvae exposed to >2.5 µg/L will not undergo daily vertical migration, and those exposed to 1 µg/L undergo only limited migration, which could affect horizontal transport and dispersal of populations and reduce recruitment to benthopelagic adult populations (Wilson et al. 1987). In addition to its inhibitory effect on cuticle synthesis, diflubenzuron affects hormone balance by delaying or arresting the molt cycle, and it inhibits limb regeneration by inhibiting mitosis and differentiation (Touart and Rao 1987). Regenerated limbs of diflubenzuron-stressed crabs that survived ecdysis had lesions in the form of black areas in which the cuticle was improperly developed (Weis et al. 1987). Also, diflubenzuron caused a reduction in metabolism of beta-ecdysone in larval insects, leading to an excess of this molting hormone in the tissues. Treatment of decapod crustaceans with ecdysones frequently causes high mortality and molt acceleration (Gulka et al. 1982).

Toxicity and persistence of diflubenzuron in aquatic environments depend on formulation, frequency of application, quantity of organic matter, sediment type, and water pH and temperature. Biological variables are more important than physical variables in assessing diflubenzuron toxicity, especially the age of the test organism and frequency and synchrony of molting during the exposure period (Cunningham 1986). Crustaceans and other organisms that molt do not demonstrate a typical survival dose-response curve against diflubenzuron because death occurs only when molting is blocked (Nebeker 1983; Cunningham 1986; Cunningham and Myers 1987; Wilson and Costlow 1987). In general, the most sensitive species had comparatively short larval or nymphal periods,

and the organism molted frequently (Rodrigues and Kaushik 1986). Susceptible species include mayflies (*Leptophlebia* sp., *Baetis pygmaeus*), while more-resistant species include a stonefly (*Paragnetina media*) and caddisfly (*Hydropsyche bettani*). Amphipods were especially sensitive at 25°C, but not at 10°C, 15°C, or 20°C (Rodrigues and Kaushik 1986).

Mortality patterns of megalops larvae of blue crab (*Callinectes sapidus*) were elevated at higher temperatures but were seemingly unaffected by water salinity (Costlow 1979). In studies on larvae of black fly (*Simulium vittatum*), diflubenzuron was more effective (1) against earlier larval instar stages than later ones, (2) against rapidly growing larvae than starved, slow-growing larvae, and (3) at 25°C than at 20°C (Rodrigues and Kaushik 1986). Among diflubenzuron-stressed barnacles (*Balanus eburneus*), mortality was higher in fed groups than in starved groups, perhaps due to an increased uptake from contaminated food or to an increased molting rate due to feeding (Gulka et al. 1980). Increased fragility of cast exuviae from diflubenzuron-treated barnacles suggests mechanical weakening of the cuticle due to a decrease in chitin content (Gulka et al. 1982).

Table 17.4 Diflubenzuron Effects on Selected Aquatic Organisms: Laboratory Studies

Taxonomic Group, Organism, and Concentration in Medium (g/L [ppb])	Effect	Reference ^a
ALGAE AND MACROPHYTES		
Diatom, <i>Cyclotella cryptica</i> 5000	No effect on photosynthesis during 14-day exposure	1
Blue-green alga, <i>Plectonema boryanum</i> 100	Residues, in µg/kg dry weight, during exposure for 4 days were 144,700 at 1 h, 85,700 at 1 day, 56,900 at 2 days, 11,700 at 3 days, and 8300 at 4 days; <i>Plectonema</i> growth rate was unaffected	2
Alga, <i>Selenastrum capricornutum</i> 45	No effect on growth during exposure for 120 h	3
Diatoms, 3 species (<i>Skeletonema costatum</i> , <i>Thalassiosira nordenskioldii</i> , <i>T. weissflogii</i>) 1000	No effect on photosynthesis during exposure for 11–14 days	1
5000	Photosynthesis inhibited 70–80% in 11–14-day exposure	1
COELENTERATA		
Hydra, <i>Hydra oligactis</i> 0.1–0.12 (estimated)	After 24-h exposure, asexual budding rate significantly increased over controls during 20-day posttreatment period; some histopathology. Second-generation hydras not significantly different from controls	4
PLATYHELMINTHES		
Planarian, <i>Dugesia dorotocephala</i> 5	No effect on survival, behavior, or asexual reproductive capacity after 24-h exposure	23
AQUATIC INSECTS		
Mosquito, <i>Aedes aegypti</i> , 4th instar larvae 20 (equivalent to 0.056 kg/ha)	Fatal to 100% within 24 h, about 50% after 4 days, and <20% after 8 days	5
Mosquito, <i>Aedes albopictus</i> 0.00025	LC30 (24 h), 2nd instar larvae	6
0.0028	Adult emergence inhibited when 2nd instar larvae exposed for 24 h	6
0.025	LC67 (24 h), 2nd instar larvae	6

Table 17.4 (continued) Diflubenzuron Effects on Selected Aquatic Organisms: Laboratory Studies

Taxonomic Group, Organism, and Concentration in Medium (g/L [ppb])	Effect	Reference ^a
0.125	Histopathology of cuticle and anal gills in 4th instar larvae after 24-h exposure of 3rd instar larvae	6
0.21	Adult emergence inhibited when 3rd instar larvae exposed for 24 h	6
0.25	LC67 (24 h), 3rd instar larvae	6
12.5	No histopathology of 4th instar larvae after 24-h exposure	6
25	LC16 (24 h), 4th instar larvae	6
39.6	Adult emergence inhibited when 4th instar larvae exposed for 24 h	6
Mosquito, <i>Aedes nigromaculatus</i>		
0.5	LC50 (48 h), larvae	7
Aquatic beetles		
<i>Hydrophilus triangularis</i>		
100	LC50 (48 h), larvae	7
<i>Laccophilus</i> spp.		
250	No deaths of adults in 216 h	7
<i>Thermonectus basillaris</i>		
250	No deaths of adults in 168 h	7
<i>Tropisternus lateralis</i>		
250	No deaths of adults in 48 h	7
Mayfly, <i>Callibaetis</i> sp.		
10	LC90 (168 h), nymphs	7
Chironomid, <i>Chironomus decorus</i> , 4th instar		
1.9	LC50	8
6.0	LC90	8
Midge, <i>Chironomus plumosus</i>		
560	50% of larvae immobilized in 48 h	9, 10
Caddis fly, <i>Clistoronia magnifica</i>		
0.1	Adult emergence inhibited during 4-week exposure	11
Midge, <i>Cricotopus</i> spp.		
1.6	No adult emergence in 96-h exposure	11
4.9	Molting and survival adversely affected during exposure for 96 h	11
Mosquito, <i>Culex pipiens</i> , exposed as 4th instar larvae for 24 h		
8	50% reduction in adult emergence	12
100	74% reduction in adult emergence	12
1000	No adult emergence	12
Mosquito, <i>Culex pipens quinquefasciatus</i>		
1.0	Fourth instar larval dip had no effect on adult sterility	13
Chironomid, <i>Glyptotendipes paripes</i> , 4th instar		
1.8	LC50	8
4.1	LC90	8
Midge, <i>Goeldichironomus holoprasinus</i>		
10	LC90 (168 h), larvae	7
Dragonfly, <i>Orthemis</i> spp., <i>Pantala</i> sp.		
50	LC50 (168 h)	7
Blackfly, <i>Simulium vittatum</i> , larvae		
80 for 30 min at various water temperatures		
10°C	50% dead in 21 days	14
20°C	53% dead in 13 days	14
25°C	92% dead in 3 days	14
500 for 15 min	98% dead in 18 days at 10.5°C	14
1000 for 30 min	All dead in 10 days at 15°C	14

Table 17.4 (continued) Diflubenzuron Effects on Selected Aquatic Organisms: Laboratory Studies

Taxonomic Group, Organism, and Concentration in Medium (g/L [ppb])	Effect	Reference ^a
Stonefly, <i>Skwala</i> sp. 57,500	LC50 (96 h)	15
Midge, <i>Tanytarsus dissimilis</i> 1.0 4.9	LC50, period between 2nd and 3rd instar larvae Molting and survival adversely affected during 5-day exposure	3 11
ARACHNOIDS		
Horseshoe crab, <i>Limulus polyphemus</i> 5 50	Larvae exposed for 24 days showed slight delay in molting at 14 days; survival as in controls Larvae exposed for 24 days showed molt rate as in controls, but high mortality immediately after ecdysis; reduced growth of survivors	6 16
MOLLUSCS		
Clam, <i>Anodonta cygnea</i> 200,000	After exposure for 3 months, all clams survived and appeared healthy. But normal calcification process disrupted on lamellar layer of the shell, producing fragile shell	17
Snail, <i>Juga plicifera</i> 36–45	No effect on survival, growth, or reproduction during 3-week exposure	3, 11
Snail, <i>Physa</i> spp. 45	No measurable effect on growth, survival, or reproduction during 3-week exposure	3, 11
CRUSTACEANS		
Copepod, <i>Acartia tonsa</i> Adults exposed following terminal molt 1 10 100 1000	Hatch of viable nauplii reduced by 50% after 12-h exposure; no hatch after 36-h exposure. Effect not reversible for at least 30 h after exposure Hatch of nauplii reduced by >95% after exposure for 24 h and 100% after 36 h. Effect not reversible for at least 26 h after exposure No effect on egg production during 14-day exposure No adverse effect on survival during exposure for 5 days	18 18 18 18
Brine shrimp, <i>Artemia salina</i> Adults exposed to 1, 2, 5, or 10	During exposure for 80 days, there was a significant reduction in reproductive lifespan at 2, 5, and 10 µg/L. Nauplii produced viviparously by mated pairs were comparable to controls — except for the 10-µg/L group, which produced fewer nauplii. Cysts produced oviparously by treated pairs, however, had lower mean hatchability	19
Nauplii exposed to 1, 10, or 100	All dead within 30 days in the 100 µg/L group; survival same as controls in 12 days for the 1 and 10 µg/L groups	19
Barnacle, <i>Balanus eburneus</i> 50 50–100 100 750 or 1000	Some deaths when exposure exceeds 10 days Significant acceleration of intermolt cycle at low dose, and among survivors at high dose No deaths of adults in 28 days High mortality during 10-day exposure; prolonged premolt; histopathology of cuticle-secreting epidermal cells	20 21 21 20

Table 17.4 (continued) Diflubenzuron Effects on Selected Aquatic Organisms: Laboratory Studies

Taxonomic Group, Organism, and Concentration in Medium (g/L [ppb])	Effect	Reference ^a
1000 for 48 h plus clean seawater for 26 days	No deaths of adults	21
1000 for 72 h plus clean seawater for 25 days	High mortality of adults, especially on days 7–14 postexposure	21
Copepods, 2 species		
100	Negligible mortality in 144 h	7
Blue crab, <i>Callinectes sapidus</i>		
1	High survival of megalops	22
3	Low survival of megalops	22
Ostracod, <i>Cypicerus</i> sp., <i>Cypridopsis</i> sp.		
500	Negligible mortality in 72 h	7
Daphnid, <i>Daphnia magna</i>		
0.062	Survival and reproduction adversely affected in full life cycle (21-day exposure)	3
2	All dead within 6 days	11
4.4–15	50% immobilized or dead in 48 h	3,9,10,15
Daphnids, 2 species		
1.5	LC50 (48 h)	7
Clam shrimp, <i>Eulimnadia</i> spp.		
0.15	LC50 (48 h)	7
Copepod, <i>Eurytemora affinis</i>		
0.75–1.00	MATC ^b	49
2.2	LC50 (48 h) for nauplii	49
Scud (amphipod), <i>Gammarus pseudolimnaeus</i>		
25–45	LC50 (96 h)	9, 10, 15
1000	After exposure for 30 min, 22% dead in 55 days at 15°C	14
1000	After 30-min exposure, 91% dead in 9 days at 25°C	14
Amphipod, <i>Hyalella azteca</i>		
1.8	LC50 (96 h)	3
2	LC60 (96 h)	11
1000	After 30-min exposure, 3–7% dead in 19–21 days at 15°C	14
1000	After 30-min exposure, 62–99% dead in 7–12 days at 25°C	14
Stone crab, <i>Menippe mercenaria</i>		
0.5	LC50 (48 h), larvae	22, 24
Copepod, <i>Mesocyclops thermocyclopoides</i>		
1–15	Impaired fertility of ovigerous females	25
2–1000	Prolongation of copepodite stage for 3–4 days, followed by death without molting, in most cases. At 125 µg/L and higher, partial molting occurred but all died	25
500	No larval deaths in 48 h	25
1000	LC50 (48 h) for copepodites. No effect on mating behavior of adults but abnormal ovisac development and decreased fecundity in some females	25
Mysid shrimp, <i>Mysidopsis bahia</i>		
0.075	Reduction in number of young per female after exposure for 21 days	26
0.075	Reduced survival and reproductive success after exposure for 28 days	24
1.2	LC50 (21 days)	26

Table 17.4 (continued) Diflubenzuron Effects on Selected Aquatic Organisms: Laboratory Studies

Taxonomic Group, Organism, and Concentration in Medium (g/L [ppb])	Effect	Reference ^a
1.9	Exposure for 24 h resulted in 65% mortality 3 days after treatment; progeny produced before death had a significantly lower reproduction rate than controls, as did those in the next generation at nanogram/L (ppt) concentrations	27
2.0–2.1	LC50 (96 h)	24, 26–28
Grass shrimp, <i>Palaemonetes pugio</i>		
0.1–0.5	No effect on duration of molt cycle, but dose-related inhibition of regenerative limb growth noted (EC50 = 0.11 µg/L for left 5th periopod)	29
0.3–0.5	MATC ^b	30
0.3–0.5	Loss of positive phototaxis in embryos exposed for 96 h	31
0.3–1.0	Dose-dependent increase in swimming speed in light-adapted larvae	30
0.65	LC50 (7–14 days) intermolt-molt stage; deaths noted during or immediately after molting	29
<1.0	Almost all larvae that survived to day 15 eventually metamorphosed successfully to postlarvae	32
1.0 (initial), medium aged for 71 days, with or without sediments	No deaths of larvae in 22 days when sediments present; all larvae died within 22 days when sediments absent	34
1.0	Limited vertical migration of larvae	30
1.1	LC50 (96 h), early premolt stage	29
1.4	LC50 (96 h) larvae, 95% confidence interval (CI) 1.27–1.54, for wettable powder (WP-25) in water	32
1.6	LC50 (96 h), postlarvae	33
1.8	LC50 (96 h), larvae, 95% CI for technical grade in acetone is 1.64–2.08	32
2.5	All dead by day 15, regardless of formulation tested	32
2.5–5	Morphological abnormalities, both positive and negative phototaxis suppressed	29
3.4	LC50 (24-h exposure, held until molting complete in 24–48 h)	29
1.0 (initial)	Fatal to larvae exposed to medium aged for 71 days without sediments; no deaths of larvae after exposure for 22 days to medium aged for 71 days with sediments (about 0.5 µg/L)	34
202	LC50 (96 h), adult males and nonovigerous females	33
2000	Negligible mortality of late premolt stage during exposure for 96 h	29
6985	LC50 (96 h), adult ovigerous females	33
Crab, <i>Rithropanopeus harrisi</i>		
0.05	No effect on positive phototaxis response of stage IV larvae	35
0.1	Reduced positive phototaxis of stage IV larvae	35
0.3–0.5	Increased swimming speed of stage I, II, and III larvae	35
0.5	No adverse effects on larval survival during exposure for 20 days	36
1.0	Decreased larval survival during 20-day exposure	36
10	All larvae died during 32-day exposure in containers without sediments; containers with sediments were no longer toxic after 19 days	34
Crab, <i>Sesarma reticulatum</i>		
1	No adverse effects on larval survival during 40-day exposure	36
3	Decreased larval survival during 40-day exposure	36
10	All larvae died during 40-day exposure	36

Table 17.4 (continued) Diflubenzuron Effects on Selected Aquatic Organisms: Laboratory Studies

Taxonomic Group, Organism, and Concentration in Medium (g/L [ppb])	Effect	Reference ^a
Copepod, <i>Tigriopus californicus</i> 0.1–100	During 72-day exposure, no adverse effects were noted on adult survival and juvenile development at 0.1 µg/L. Reproduction was inhibited at 1 and 5 µg/L. Copepods exposed to 10 or 100 µg/L did not reproduce, were moribund, and had decreased survival.	1
Tadpole shrimp, <i>Triops longicaudatus</i> 0.75	LC40 (24 h)	7
Fiddler crab, <i>Uca pugilator</i> Juveniles exposed for 24 h once a week for 10 weeks, then held in clean seawater for an additional 14 weeks 0.2	No adverse effects on survival or ability to escape from test containers	37
2	No effect on survival, but reduced ability to escape from container	37
20	All died in 23 weeks; reduced mobility prior to death	37
200	All dead in 8 weeks; most deaths occurred in first 4 weeks	37
Adults exposed to 0.5, 5, or 50 after multiple autotomy of one chela and 5 walking legs	Continuous exposure for 18 days produced a dose-dependent retardation of regeneration and deaths during molt at 5 and 50 µg/L. The presence of sediment in test containers lessened effects, but did not eliminate them	38
Adults exposed for 1–3 weeks 0.5–50	Some reduction in number of burrows dug at 15 and 60 min after exposure	39
Unknown	Burrowing activity normal on sediments containing 1 mg/kg	39
FISH		
Mummichog, <i>Fundulus heteroclitus</i> 29,800 33,000–255,000	No deaths in 96 h LC50 (96 h)	40 5, 40
Mosquitofish, <i>Gambusia affinis</i> Unknown	Fish exposed to radiolabeled diflubenzuron for 33 days contained about 6% of the parent diflubenzuron vs. 54% for alga (<i>Oedogonium cardiacum</i>), 82% for snail (<i>Physa sp.</i>), and 94% for larvae of mosquito (<i>Culex pipiens quinquefasciatus</i>)	42
200 for 8 days followed by 300 until day 14 1000	Fish were 2.5 times more hyperactive than controls within 2 days, 4 times more during days 4–8, and no different from controls at day 14 No deaths in 10 days	43 7
Brown bullhead, <i>Ictalurus nebulosus</i> 13.2 in pond surface layer 1 h after treatment, <0.2 after 14 days	Maximum concentrations, in µg/kg whole-body fresh weight (FW), were 387 at day 1, 190 at day 2, 42 at day 4, and ND at day 7	44
Channel catfish, <i>Ictalurus punctatus</i> Unknown	Runoff from soil containing 0.55 mg diflubenzuron/kg at start produced maximum residues during 28 days, in µg/kg FW, of 4 in muscle and 10 in viscera	2
>100,000 370,000	LC50 (96 h) LC50 (96 h)	10, 15 9
Bluegill, <i>Lepomis macrochirus</i> 1–10 2.5	Bioconcentration factor of 13–20 after 24-h exposure Growth reduction of 56–86% for young of year held in large enclosures for 3 months — attributed to reduction in food items	45 51

Table 17.4 (continued) Diflubenzuron Effects on Selected Aquatic Organisms: Laboratory Studies

Taxonomic Group, Organism, and Concentration in Medium (g/L [ppb])	Effect	Reference ^a
10	After exposure for 24 h, residues 24 and 48 h later were 848 and 8 µg/kg FW whole fish (less tail and viscera)	45
30	Growth reduction of 88–97% after exposure for 3 months	51
200 (initial); diflubenzuron concentrations ranged from 1.3–5.1 between 3 h and 19 days; for 4-chlorophenyl-urea, they were 0.6–3.1; and for 4-chloroaniline they were <0.1–0.4	Maximum concentrations in µg/kg whole-fish FW, for diflubenzuron were 119 at 3 h, 812 at 1 day, 55 at 5 days, 196 at 12 days, and 86 at 19 days. For the metabolite 4-chlorophenylurea, these values were 1.6 at 3 h, 8 at 1 day, 40 at 50 days, and 33 at 19 days; and for 4-chloroaniline, 0.8 at 3 h, 2.1 at 1 day, and 1.1–1.3 for days 5–19	46
135,000–660,000	LC50 (96 h)	5, 9
Cutthroat trout, <i>Oncorhynchus clarki</i>		
57,000–75,000	LC50 (96 h)	10, 15
Coho salmon, <i>Oncorhynchus kisutch</i>		
150,000	No deaths in 96 h	47
1,000,000	No deaths in 96 h after 15-min exposure	47
Rainbow trout, <i>Oncorhynchus mykiss</i>		
29–300	No adverse effects on eyed eggs or fingerlings in 30-day flowthrough exposure	10
625–10,000	Dose-dependent decrease in serum glutamate oxalacetate transaminase (GOT) activity in 96 h, but values overlapped normal GOT range from this hatchery	50
150,000	No deaths in 96 h	47
240,000 (95% CI 201,000–286,000)	LC50 (96 h)	9, 10
1,000,000	No deaths in 96 h after 15-min exposure	47
Yellow perch, <i>Perca flavescens</i>		
>50,000	LC50 (96 h)	15
Fathead minnow, <i>Pimephales promelas</i>		
36–45	Embryo-larval exposure for 30 days had no effect on survival, egg hatch, or growth	3, 11
>100,000	LC50 (96 h)	10, 15
430,000	LC50 (96 h)	9
White crappie, <i>Pomoxis annularis</i>		
5 (nominal), 3.3 (measured), 0.4 after 5 weeks	Whole-body residues, in µg/kg FW, were 133 at 1 day, 355 at 4 days, 197 at 14 days, and 62 at 21 days	48
10	Fish exposed for 24 h in uncontaminated media contained 822 µg/kg FW whole fish less tail and viscera. Exposure for 48 or 72 h plus 24 h in uncontaminated media produced residues of 533 and 630 µg/kg FW	45
Atlantic salmon, <i>Salmo salar</i>		
10	Avoided medium when given choice in 10-min trials	41
>50,000	LC50 (96 h)	15
Brook trout, <i>Salvelinus fontinalis</i>		
>50,000	LC50 (96 h)	15

^b Maximum acceptable toxicant concentration. Lower value in each pair indicates highest concentration tested producing no measurable effect on growth, survival, reproduction, or metabolism during chronic exposure; higher value indicates lowest concentration tested producing a measurable effect.

17.4.5 Aquatic Organisms: Field Studies

Field use of diflubenzuron in aquatic habitats for control of pestiferous insects also affects other species (Table 17.5). Diflubenzuron applications in marshes, ponds, streams, lakes, and rice fields routinely cause population reductions — sometimes irreversible — in many species of nontarget organisms, especially crustaceans and aquatic insects. Taxonomic groups that seem comparatively tolerant to diflubenzuron include algae, turbellarians, rotifers, aquatic beetles, molluscs, annelid worms, ostracods, and fish (Table 17.5). Following multiple applications to lake and pond ecosystems, diflubenzuron was not measurable in water, sediment, and aquatic vegetation after several days (Booth and Ferrell 1977). Algae (*Plectonema boryanum*) reportedly degrade 80% of absorbed diflubenzuron in 1 h, primarily to 4-chlorophenylurea and 4-chloroaniline (Booth and Ferrell 1977).

Most authorities agree on four points:

1. Rates as low as 28 to 56 g diflubenzuron/surface ha (0.025 to 0.05 pounds/surface acre), or 2.5 to 16 µg/L, are highly effective against pestiferous dipterans, including many species of chaoborids, chironomids, and culicids (Mulla et al. 1975; Julin and Sanders 1978; Ali and Lord 1980a, 1980b; Cunningham 1986; Ali et al. 1988).
2. These same dosages suppress nontarget populations of cladocerans, copepods, mayfly nymphs, corixids, and springtails (Miura and Takahashi 1975; Mulla et al. 1975; Booth and Ferrell 1977; Julin and Sanders 1978; Ali and Lord 1980a; Cunningham 1986; Ali et al. 1988).
3. Moderately resistant to diflubenzuron are larvae of diving beetles, dragonfly adults and naiads, ostracods (*Cybericercus*, *Cyprinotus*), backswimmers, and water boatmen; highly resistant species include mosquitofish (*Gambusia affinis*), frogs and toads, snails, and algae (Miura and Takahashi 1974; Mulla et al. 1975; Nimmo et al. 1980).
4. All populations of survivors begin to recover within days or weeks, and recovery is usually complete within 80 days after the last treatment (Mulla et al. 1975; Booth and Ferrell 1977; Ali and Lord 1980a; Nimmo et al. 1980; Cunningham 1986).

Unlike laboratory studies, diflubenzuron does not bioaccumulate markedly in fish or biomagnify through food chains, although altered feeding habits may occur. Under field conditions, marsh or pond sediments usually contain <50 µg/kg FW. This concentration presents negligible risk to channel catfish (*Ictalurus punctatus*) over a 28-day period, suggesting little hazard to catfish during multiple mosquito control applications of diflubenzuron (Booth and Ferrell 1977). Bioaccumulation of diflubenzuron from marsh applications is minimal, as judged by results of uptake studies using marsh sediments containing 550 µg/kg. Maximum residues in fish tissues after 3 days were 4 µg/kg FW in muscle and 10 µg/kg DW in viscera (Schooley and Quistad 1979). Diflubenzuron residues are moderately persistent in algae, snails, salt marsh caterpillars (*Estigmene* spp.), and mosquito larvae, but are not biomagnified in food chains ending in fish (Schooley and Quistad 1979). Maximum diflubenzuron concentrations range from 50 to 720 µg/kg FW in whole body of three species of freshwater teleosts exposed to water treated up to 8 times with 135 g/ha (Gartrell 1981). Feeding habits of freshwater fishes change in ponds showing marked reductions (94 to 99%) in copepod and cladoceran populations after diflubenzuron treatment (Colwell and Schaefer 1980), perhaps due to availability of various food items. In one study, black crappie (*Pomoxis nigromaculatus*) and brown bullhead (*Ictalurus nebulosus*) altered their diets for 1 month after treatment,

eating about 3 times more insects and ostracods, and almost no cladocerans and copepods (usually, major items), than before treatment (Colwell and Schaefer 1980).

Although diflubenzuron is not sprayed directly on fresh waters in gypsy moth control, aerial spraying of large forest tracts may result in exposure of streams by way of leaf litter (Swift et al. 1988a). Residual diflubenzuron was present for at least 4 months on leaves submerged in flowing water, and it was toxic to various invertebrates. For example, treated leaves of the tulip poplar (*Liriodendron tulipifera*) that contain 10 mg diflubenzuron/m² after 4 months of submersion produce adverse effects on survival and growth when fed to craneflies (*Tipula abdominalis*, *Platycentropus radiatus*) (Swift et al. 1988b). The effects of diflubenzuron on leaf-litter processing rates in streams is unresolved and merits additional research (Swift et al. 1988a, 1988b).

Table 17.5 Diflubenzuron Effects on Selected Aquatic Organisms: Field Studies

Ecosystem, Dose, and Other Variables	Effect	Reference ^a
COASTAL MARSH, LOUISIANA		
6 applications, each of 28 g/ha, over 18-month period	Severe reduction in populations of amphipods, dragonfly naiads, corixid nymphs, and some adult beetles. Increased populations of snails, aquatic insect adults, and 2 species of fish. No change in 27 taxa. Results confounded by severe drought in experimental and control areas	1, 2
FARM POND		
2.5, 5, or 10 µg/L; single application	Inhibited adult emergence by 95–100% of a gnat (<i>Chaoborus astictopus</i>), 2–7 days after treatment. Crustacean zooplankton suppressed at all treatment levels, especially cladocerans and copepods. Rotifers and algae were not affected. Bluegills that fed predominantly on cladocerans and copepods switched to chironomid midges and terrestrial insects after treatment, with no adverse effects	3
LABORATORY STREAM COMMUNITIES		
0.1, 1, 10, or 50 µg/L for 5 months	Aquatic insect populations were the most sensitive group, especially mayflies, stoneflies, and dipterans. These, and other invertebrates, showed rapid and permanent reductions in biomass and diversity at 1.0 µg/L and higher. Diversity showed an apparent dose-response relation, with no effect at 0.1 µg/L, intermediate reductions at 1 µg/L, and maximal reductions at 10 and 50 µg/L	4
LAKE		
110 g/ha (3.7 µg/L), or 220 g/ha (7.4 µg/L); single application	At low dose, amphipods (<i>Hyalella azteca</i>) had 97% population reduction that remained depressed; temporary reduction in cladoceran and copepod populations. At high dose, marked population reductions in cladocerans, copepods, and ostracods (<i>Cyrinofus</i> sp.). Oligochaete worms were tolerant to both doses	5
110–280 g/ha	Effectively suppressed adult emergence of nuisance midges (<i>Tanytarsus</i> , <i>Procladius</i>) for up to 2 weeks; ineffective against a more pestiferous midge species (<i>Chironomus decorus</i>)	6
156 g/ha to lake surface, equivalent to 12 µg/L on April 26 and again on August 24	After first treatment, reduction within 1 week of 3 species of cladocerans (<i>Daphnia laevis</i> , <i>Ceriodaphnia</i> sp., <i>Bosmina longirostrus</i> sp.), and 2 species of copepods (<i>Cyclops</i> sp., <i>Diaptomus</i> sp.). No recovery of <i>Daphnia</i> and <i>Ceriodaphnia</i> for 6 months, but <i>Bosmina</i> reappeared 11 weeks later. <i>Diaptomus</i> was depleted for 4 months, but <i>Cyclops</i> recovered in 6–7 weeks. The amphipod <i>Hyalella azteca</i> was eliminated within 4 weeks, and no recolonization was evident after 6 months. No adverse effects on oligochaetes, snails (<i>Physa</i> sp.), or ostracods (<i>Cypridopsis</i> sp.). After second treatment, temporary reduction in <i>Cyclops</i> and <i>Bosmina</i> , and no significant effects on ostracods, snails, or worms	7

Table 17.5 (continued) Diflubenzuron Effects on Selected Aquatic Organisms: Field Studies

Ecosystem, Dose, and Other Variables	Effect	Reference ^a
PASTURE POND		
280 g/ha, single application	Controlled pasture mosquitoes, <i>Aedes nigromaculatus</i> and <i>Aedes melanimon</i> , and caused temporary reductions of cladoceran and mayfly nymph populations. Many cladocerans and mayflies died during the posttreatment ecdysis, characteristically with signs of incomplete cleavage of the middorsal ecdysial suture. More-tolerant groups included corixid and notonectid nymphs, and adult aquatic beetles. No effects on the most tolerant groups: turbellarians (<i>Mesotoma</i> , <i>Bothromestoma</i>), rotifers (<i>Asplanchna</i>), ostracods, algae, and spiders (<i>Pardosa</i> spp., <i>Lycosa</i> spp.)	8
POND		
13.2 µg/L in pond surface layer 1 h after treatment; <0.2 µg/L after 14 days	Residues, in µg/kg whole-body FW, in black crappie (<i>Pomoxis nigromaculatus</i>) were 426 at day 1, 194 at day 2, 56 at day 4, and not detectable at day 7	9
13.8 µg/L 1 h after forest was sprayed with 70 g/ha; this declined to not detectable in 20 days	Zooplankton populations were reduced 3 days after treatment and remained suppressed for 2–3 months; low survival of caged amphipods and immature corixids 1–6 days after treatment; littoral insects were reduced in abundance 21–34 days after treatment, but recovered; manna grass (<i>Glyceria borealis</i>) concentrations declined from 0.3 mg/kg FW 1 h post spray to not detectable in 10 days; sediment residues were 0.1 mg/kg FW after 12 h and not detectable in 10 days	14
16 µg/L (estimated from application of 56 g/ha)	Caused declines in 3rd and 4th instar larvae of <i>Culex tarsalis</i> mosquito 2–8 days after treatment, but not at 11 days	10
80 µg/L (estimated from application of 280 g/ha)	Adult <i>C. tarsalis</i> emergence from treated larvae almost completely inhibited for at least 11 days posttreatment	10
RICE FIELD, FLOODED		
1.1–28 g/ha	100% control of massive rice field populations of 4th instar larvae of the mosquito <i>Psorophora columbiiae</i> 3–5 days after treatment. Significant reductions in certain nontarget aquatic insect populations	11
About 1000 µg/L (as judged by 280 g/ha in rice field water 10 cm deep)	Significant reductions in immature populations of the rice water weevil (<i>Lissorhopterus oryzophilus</i>) 4–5 days after rice emergence in a continuously flooded field	12
About 1500 µg/L (420 g/ha)	<i>Lissorhopterus</i> population reduced 75% when applied 7 days after rice emergence	12
RIVER		
1250 µg/L added for 1 h to control simuliid flies	After initial depression, target dipteran insects, including simuliids, increased 4–40 times over pretreatment levels after 3–4 weeks, suggesting that one-time applications are useless. No adverse effects on adults and fry 3–4 weeks after exposure of dace (<i>Phoxinus lagowski</i>) and minnow (<i>Leuciscus hakonensis</i>)	13

^a 1, Farlow 1976; 2, Farlow et al. 1978; 3, Apperson et al. 1978; 4, Hansen and Garton 1982; 5, Ali and Mulla 1978a; 6, Johnson and Mulla 1981; 7, Ali and Mulla 1978; 8, Miura and Takahashi 1975; 9, Colwell and Schaefer 1980; 10, Mulla et al. 1975; 11, Steelman et al. 1975; 12, Smith et al. 1988; 13, Satake and Yasuno 1987; 14, Sundaram et al. 1991.

17.4.6 Birds

Birds are comparatively resistant to diflubenzuron, as judged by the ability of the mallard (*Anas platyrhynchos*) to tolerate single oral doses up to 2000 mg/kg BW or dietary loadings up to 4640 mg/kg ration for 8 days (Table 17.6). Poisoning of insectivorous birds by diflubenzuron, after

spraying in orchards as recommended, is highly improbable (Muzzarelli 1986). This conclusion is based on the maximum possible daily intake of insects by wild nestlings (15 mg/kg BW in Great tit, *Parus major*; 10 mg/kg BW in tree sparrow, *Passer montanus*), on a maximum whole-body loading of 0.5 mg diflubenzuron/kg FW in insect prey, and on observations of normal growth and subsequent breeding of nestlings in orchards sprayed with diflubenzuron (Muzzarelli 1986).

Despite the apparent absence of direct effects in forest birds, the widespread use of diflubenzuron in the suppression of forest insect defoliators may lead to potentially harmful effects by reducing populations of immature lepidoptera and other mandibulate herbivorous insects upon which they feed. All field evidence collected to date, however, is either inconclusive or negative. In one study, 70.75 g diflubenzuron/ha was applied to an oak forest (*Quercus rubra*, *Q. velutina*, *Q. prinus*) in West Virginia to control first and second instars of gypsy moths (Martinat et al. 1987) (Table 17.6). The maximum diflubenzuron residue recorded in a wide variety of canopy forager birds (great crested flycatcher, *Myiarchus crinitus*; eastern wood peewee, *Contopus virens*; black-capped chickadee, *Parus atricapillus*; tufted titmouse, *Parus bicolor*; blue-gray gnatcatcher, *Polioptila caerulea*; red-eye vireo, *Vireo olivaceus*; warblers, *Dendroica* spp.; scarlet tanager, *Piranga olivacea*) was 0.21 mg/kg whole-body FW. A similar value, 0.20 mg/kg whole-body FW, was recorded in ground or low foragers, including wood thrush (*Hylocichla mustelina*), ovenbird (*Seiurus aurocapillus*), rufous-sided towhee (*Pipilo erythrorthalmus*), chipping sparrow (*Spizella passerina*), song sparrow (*Melospiza melodia*), and indigo bunting (*Passerina cyanea*) (Martinat et al. 1987). Neotropical migrants breeding in a diflubenzuron-treated forest had significantly lower fat reserves on a dry weight basis than did conspecifics from reference sites, possibly due to a reduction in food availability and quality (Whitmore et al. 1993). In another study, up to 280 mg diflubenzuron/ha applied to control the Douglas-fir tussock moth (*Orygia pseudotsugata*), an important defoliator of true firs (*Abies* spp.) and Douglas-fir (*Pseudotsuga menziesii*) in western North America, had no adverse effects on forest birds, as judged by population censuses, nesting studies, and bird behavior (Richmond et al. 1979) (Table 17.6).

Domestic chickens (*Gallus* sp.) metabolize diflubenzuron to a greater extent than insects, but less than rodents and ruminants. The main pathway of diflubenzuron degradation in chickens is through cleavage of the urea bridge, whereas rats and cows tend to hydroxylate and conjugate the parent molecule (Opdycke and Menzer 1984). Metabolism studies in chickens showed that major residues in tissues and eggs were unchanged diflubenzuron and 4-chlorophenylurea; also present were 2,6-difluorobenzoic acid and 4-chloroaniline (Gartrell 1981). Metabolites in chicken excreta included 4-chlorophenylurea, 4-chloroaniline, 2,6-difluorobenzamide, 2,6-difluorobenzoic acid, and several unidentified compounds (Opdycke and Menzer 1984). At high dietary loadings of 50 to 500 mg/kg ration, diflubenzuron accumulates in fat, egg, and muscle tissues of chickens; however, excretion is rapid and residues are usually negligible after 5 weeks on a clean diet (Table 17.6). Diflubenzuron fed at levels up to 250 mg/kg ration to male broiler chickens for 98 days had no effect on hyaluronic acid (HA) concentration in the combs and wattles (Crookshank et al. 1978). Both chitin and HA are polysaccharides and have a common biochemical precursor, uridine diphospho N-acetyl-glucosamine (UDPGA) (Crookshank et al. 1978), which is used in the synthesis of chitin by insects and in the production of HA by vertebrates. Since diflubenzuron interferes with the incorporation of UDPGA into chitin by insects but not with HA production, it would seem that diflubenzuron is relatively harmless to birds. However, more research is needed for verification.

Intraspecies differences in diflubenzuron metabolism are reported for domestic chickens. The White Leghorn breed, for example, produced eggs with significantly higher residues than other breeds tested after 3 weeks on a diet containing 50 mg diflubenzuron/kg, and it had elevated concentrations in fat tissues after 15 weeks on a 10-mg/kg diet (Opdycke et al. 1982b; Opdycke and Menzer 1984). In chickens, diflubenzuron is usually eliminated more rapidly in feces than in eggs, but in the White Leghorn breed, the major route of elimination is via egg production. The White Leghorn breed also differed significantly from the Rhode Island Red/Barred Plymouth Rock

(RIR/BPR) breed in ability to metabolize diflubenzuron administered orally or intravenously (Table 17.6). White Leghorn chickens accumulated diflubenzuron to a greater extent than RIR/BPR chickens, and they retained residues for longer periods. Also, White Leghorn chickens produced a higher percentage and greater number of diflubenzuron metabolites in their excreta than other breeds tested (Opdycke et al. 1982b). Differences in ability to metabolize diflubenzuron between different strains of domestic chickens may be due to differences in lipid metabolism associated with egg production (Opdycke and Menzer 1984). No comparable database exists for avian wildlife, and one should be developed through research.

Table 17.6 Diflubenzuron Effects on Selected Birds

Species, Route of Administration, Dose, and Other Variables	Effect	Reference ^a
RED-WINGED BLACKBIRD, <i>Agelaius phoeniceus</i>		
Oral, single dose, 3700 mg/kg body weight (BW)	Insufficient to kill 50%	12
MALLARD, <i>Anas platyrhynchos</i>		
Oral, single dose, 2000 mg/kg BW	Insufficient to kill 50%; anorexia observed on day after treatment	1
Dietary, 4640 mg/kg ration	Insufficient to kill 50% in 8 days	2
FOREST BIRDS		
From oak (<i>Quercus</i> spp.) forest sprayed aerially with 70.75 g diflubenzuron/ha to control gypsy moth instars; samples collected 3 days prior to spraying, and up to 21 days after spraying	Maximum concentrations, in mg/kg fresh weight (FW) whole body, were 0.21 in canopy birds 3 days postspray (0.09 at day 21); 0.20 in understory birds 1 day postspray, and nondetectable (ND) at day 21; 0.45 in foliage 1 day postspray (0.18 at day 21); 0.49 in foliage arthropods at day 3, and 0.1 at day 21; ND in litter at all times; 0.11 in litter arthropods at day 10 and 0.03 at day 21. Controls, in all cases, contained <0.03, except litter arthropods, which contained 0.06 mg/kg	3
From fir (<i>Abies</i> sp., <i>Pseudotsuga menziesii</i>) forest sprayed aerially with 140 or 280 mg/ha to control Douglas-fir tussock moth; effects evaluated in year of spraying and 1 year later	No significant changes in species diversity, brain cholinesterase activity, survival, morbidity, or behavior at either dose. Significant increases in total breeding pairs noted 1 year later in Townsend's warbler (<i>Dendroica townsendi</i>), MacGillivray's warbler (<i>Oporornis tolmiei</i>), and mountain chickadee (<i>Parus gambeli</i>). Some reductions in populations of golden-crowned kinglet (<i>Regulus satrapa</i>), lazuli bunting (<i>Passerina amoena</i>), and warbling vireo (<i>Vireo gilvus</i>), but all differences were attributed to biological variability rather than to insecticide effects	4
DOMESTIC CHICKEN, <i>Gallus</i> spp.		
Intravenous injection		
1 mg/kg BW, White Leghorn breed, single dose	Half-time (T _b 1/2) persistence in blood of 14.7 h, 12% of dose excreted in 24 h	5
1 mg/kg BW, Rhode Island Red/Barred Plymouth Rock breed (RIR/BPR), single dose	T _b 1/2 of 8.4 h in blood; 29% of dose excreted in 24 h	5
Oral route		
5 mg/kg BW, White Leghorn breed, single dose	Maximum residues after dosing, in mg/kg FW, were 0.25 in egg, 0.4 in eggshell, 0.19 in kidney, and 0.16 in ovary. Excretion of 50% in 8–12 h	5, 6
5 mg/kg BW, RIR/BPR breed, single dose	Maximum residues after dosing were 0.14 mg/kg FW in eggs and ND in eggshell, kidney, and ovary. Excretion of 51% in 30–36 h and 82–91% in 13 days	5, 6

Table 17.6 (continued) Diflubenzuron Effects on Selected Birds

Species, Route of Administration, Dose, and Other Variables	Effect	Reference ^a
White Leghorn and RIR/BPR strains given 5 mg/kg BW daily for 11 days; residues measured in egg during dosing and for 10 days after dosing	Residues, in mg/kg FW egg, for White Leghorn strain were highest at days 9 (3.5) and 11 (2.6). Values were 0.04 at day 20, and ND at day 21. Residues in RIR/BPR were lower: 1.7 at day 9, 1.1 at day 11, 0.02 at day 20, and ND at day 21. Tb 1/2 for egg residues ranged between 34 and 38 h	5
Dietary route		
0.05 mg/kg for 28 days	Fat contained 0.018 mg/kg FW at 28 days and <0.0006 mg/kg 7 days after withdrawal	7
0.5 mg/kg for 28 days	Fat contained 0.033 mg/kg FW at 28 days and less than 0.005 mg/kg 7 days after withdrawal	7
1.6 mg/kg for 3 weeks	Minor effects on larvae of house fly (<i>Musca domestica</i>) in manure; egg residue of 0.05 mg/kg FW	8
3.1 mg/kg for 3 weeks	Killed 85% of fly larvae in manure; egg residue of 0.25 mg/kg FW	8
5 mg/kg for 28 days	Fat contained 1.16 mg/kg FW at 28 days and <0.032 mg/kg 7–14 days after withdrawal	7
6.2 mg/kg for 3 weeks	Complete inhibition of fly larvae in manure; egg residue of 0.55 mg/kg FW	8
12.5, 25, or 50 mg/kg for 3 weeks	All diets completely inhibited fly larval development in manure; white egg residues, in mg/kg FW, were 1.0 for 12.5 mg/kg diet, 2.1 for 25-mg/kg group, and 2.9 for the 50-mg/kg group; residues in brown eggs were half those of white eggs	8
Mature White Leghorn hens fed diets containing 10, 50, 100, or 500 mg diflubenzuron/kg for 8 weeks	No adverse effects of any diet on feed consumption, growth, egg production, egg weight, eggshell thickness, fertility, hatchability, or progeny performance. Maximum concentrations in tissues after 8 weeks, in mg/kg FW, in the 500-mg/kg diet group, were 53 in fat, 10 in egg, 9 in liver, and 0.9 in muscle; for the 100-mg/kg group, these values were 21 in fat, 10 in liver, 3 in egg, and 0.5 in muscle; for the 50-mg/kg group, residues were 1.5 in fat, 1 in egg, 0.8 in liver, and 0.2 in muscle. Five weeks after withdrawal from all diets, diflubenzuron was <0.05 mg/kg FW in all tissues	9
Male broiler and layer breed chickens fed 205 mg/kg ration for 98 days beginning at age 1 day	No significant effect on body weight, food consumption, or weight of testes, liver, comb, and feet	10
Male and female layer-breed chickens were fed diets containing up to 250 mg/kg for 58 weeks, including a 26-week laying cycle. Progeny were reared to age 2 weeks	No significant effect of any dose level on survival, egg production, egg weight, eggshell weight, fertility, hatchability, or hatch weight and body weight of progeny. No gross abnormalities in progeny; growth and feathering as in controls	11

17.4.7 Mammals

No data are available on effects of diflubenzuron on mammalian wildlife. However, results of studies on small laboratory animals and domestic livestock are available (Table 17.7), and these indicate several trends. Adverse effects levels occurred in dogs fed diets containing 160 mg/kg (6.2 mg/kg BW daily) for 13 weeks (abnormal blood chemistry), in mice given 125 mg/kg BW daily for 30 days (hepatocellular changes), in rabbits fed diets containing 640 mg/kg for 3 weeks

(abnormal hemoglobin), and in rats given 5000 mg/kg BW daily for 13 weeks (abnormal hemoglobin). Accumulations of diflubenzuron occurred in several species. Elevated tissue residues — but no other measurable effects — occurred in cows given 0.05 to 0.5 mg/kg ration for 28 days or 1 to 16 mg/kg BW for 4 months, in pigs given a single oral dose of 5 mg/kg BW; and in sheep given a single oral dose of 10 mg/kg BW (Table 17.7). No observable adverse effect levels occurred in cows given 0.25 mg/kg BW daily for 4 months; in rabbits given 4 mg/kg BW daily on days 6 to 18 of gestation, in dogs fed diets containing 40 mg/kg for 13 weeks (equivalent to 1.6 mg/kg BW daily); in rats fed diets containing 160 mg/kg for 2 years; and in rabbits and rodents given single oral or dermal doses <2000 mg/kg BW (Table 17.7).

All available data indicate that diflubenzuron is not a mutagen, teratogen, or carcinogen. Diflubenzuron is not mutagenic, as judged by the results of:

1. The mouse lymphoma forward mutation test at the thymidine kinase locus (detects mutations to a nonfunctional thymidine kinase in a line of culture mouse lymphoma cells).
2. The Ames *Salmonella typhimurium* microsome reverse mutation test (ability to produce point gene mutations of a base pair).
3. The mouse micronucleus test (which detects chromosome breakage or chromosome loss from mitotic abnormalities in bone marrow erythrocytes) (MacGregor et al. 1979).
4. A DNA damage study with yeast, *Saccharomyces cerevisiae* (Gartrell 1981).

No teratogenicity or reproductive effects were associated with elevated doses of diflubenzuron in all species of mammals tested (Gartrell 1981). Diflubenzuron suppresses melanogenesis and uptake of nucleosides in mouse melanoma cells (Jenkins et al. 1986), and it inhibits growth of experimental tumors in mice, either alone or in combination with CoCl₂ (Table 17.7). Mixed function oxidase, induced by 3-methylcholanthrene, enhances the antitumor properties of diflubenzuron, suggesting that aromatic hydroxylation may be required for tumor growth regulation (Jenkins et al. 1986). The most likely diflubenzuron metabolite that affects tumor growth regulation is the form oxidized at the 2 carbon of the phenyl ring; other metabolites tested (i.e., 4-chlorophenylurea, 3-OH-diflubenzuron) are only marginally effective (Jenkins et al. 1986). Diflubenzuron did not produce tumors in fetal cells of hamsters (*Cricetus* spp.) at whole-body doses of 500 mg/kg, and this also suggests a relatively low oncogenic potential (Quarles et al. 1980). Diflubenzuron is not cytotoxic and does not inhibit the synthesis of complex carbohydrates in animal cells, as judged by results of studies with cultured rat glial cells, wherein diflubenzuron was not metabolized to any measurable extent, and more than 98% could be recovered from particulate fractions of whole cells (Bishai and Stoolmiller 1979).

Intestinal absorption of diflubenzuron in laboratory rats, measured as the sum of urinary and biliary excretion, decreases with increasing dose: from 50% at a single oral dose of 4 mg/kg BW to 4% at 900 mg/kg BW. Excretion is almost complete after 75 h; at that time, up to 4% of the administered dose is recovered from skinned carcasses (Willems et al. 1980). About 80% of diflubenzuron metabolites excreted by rats seem to have the basic diflubenzuron structure intact. Three metabolites are largely excreted as conjugates in the bile. One metabolite, 2,6-difluorobenzoic acid, is excreted largely in urine. Its counterpart, 4-chlorophenylurea, was not present in urine or bile in appreciable quantity, nor was 4-chloroaniline detected (Willems et al. 1980). Lifetime feeding studies of 4-chloroaniline, a relatively common diflubenzuron metabolite, showed no compound-related effects in laboratory mice and rats (Gartrell 1981).

Oral treatment of sheep and cattle (*Bos* spp.) with diflubenzuron is followed by absorption of the compound through the gastrointestinal tract, metabolism, and elimination of residues through the urine, feces, and, to a very limited extent, milk. Intact diflubenzuron is eliminated in the feces of orally dosed cattle and sheep (Ivie 1978). Major metabolites of diflubenzuron excreted by cattle and sheep result from hydroxylation on the difluorobenzoyl and chlorophenyl rings, and by cleavage between the carbonyl and amide groups to produce metabolites that are excreted free or as conjugates (Ivie 1978). Cattle dosed repeatedly with diflubenzuron had detectable residues only in liver

and milk. The parent compound, 4-chlorophenylurea, 2,6-difluorobenzoic acid, and 4-chloroaniline compose only 15% of the total residue in liver. The bulk of the residue is not extractable (Gartrell 1981). Dietary levels of 5 mg/kg ration produce low (13 µg/L), but detectable, diflubenzuron concentrations in milk of cattle (Gartrell 1981). The major hydroxylated diflubenzuron metabolite in cow milk (*N*-[[(4-chlorophenyl)amino]carbonyl]-2,6-difluoro-3-hydroxybenzamide) when fed to white rats is rapidly excreted with little biotransformation (Ivie 1978).

Metabolism of diflubenzuron by mammals and birds probably occurs by way of hydroxylation, conjugation, and cleavage of the urea moiety (Opdycke et al. 1982a); however, interspecies differences are considerable. In cows, for example, the major identified metabolic transformation is hydroxylation at the 3-position of the 2,6-difluorobenzoyl ring. In sheep, however, major metabolites arise through cleavage of the amide bond at the benzoyl carbon to produce 2,6-difluorobenzoic acid, which is excreted in the urine either free or conjugated with glycine (Ivie 1978). The major diflubenzuron metabolite in cow urine is 2,6-difluoro-3-hydroxydiflubenzuron, accounting for 45%, and in feces 18%; unchanged diflubenzuron accounts for 43% of the administered dose in cow feces. In sheep urine, 2,6-difluorobenzoic acid and 2,6-difluorohippuric acid account for 57%; in sheep feces, unchanged diflubenzuron is 97% (Ivie 1978). In swine, the great majority of the administered dose is eliminated in feces unchanged; the urine contains mostly metabolites, indicating that most of the absorbed diflubenzuron is metabolized (Opdycke et al. 1982a).

Table 17.7 Diflubenzuron Effects on Selected Mammals

Species, Mode of Administration, Dose, and Other Variables	Effect	Reference ^a
CATTLE, <i>Bos</i> sp.		
Dermal 0.125 mg/cm ² hide, single application, 1% solution to 400 cm ² skin surface	No absorption through skin; rapid disappearance. Maximum residues in hair, in mg/kg fresh weight (FW), were 128 after 1 week, 19 after 2 weeks, and 4 after 4 weeks. For skin, these values were 0.4, 0.1, and <0.1	1
Diet 0.05 mg/kg ration for 28 days	No detectable residues in milk and tissues, except liver (0.01 mg/kg FW); liver residues remained detectable after a 7-day withdrawal period	2
0.5 mg/kg ration for 28 days	No detectable residues in milk and tissues, except liver (0.08 mg/kg FW); liver residues remained detectable after a 7-day withdrawal period	2
5 mg/kg ration for 28 days	Liver residue of 0.54 mg/kg FW remained elevated after a 7-day withdrawal period; residues in milk reached 0.013 mg/L within the first few days of feeding and declined to nondetectable (ND) levels after a 4-day withdrawal period	2
Fed diets equivalent to 0.25 mg/kg body weight (BW) daily for 4 months, single animal	No detectable residues in any tissue. Tb 1/2 of 4–5 days in manure; manure gave >95% control of larvae of the face fly, <i>Musca autumnalis</i>	3
Fed diet equivalent to 1 mg/kg BW daily for 4 months, single animal	No detectable residues in any tissue except omental fat (0.1 mg/kg FW). No houseflies (<i>Musca domestica</i>) or face flies developed in manure	3
Fed diet that increased from 1 mg/kg BW daily to 8 mg/kg BW over a 2-month period, then 16 mg/kg BW daily for 3 months	No detectable diflubenzuron residues in heart, muscle, or kidney; 130 µg/kg FW in liver; about 250 µg/kg FW in subcutaneous fat	3
Holstein bull calves fed diet equivalent to 2.8 mg/kg BW daily for first 7 months, then 1 mg/kg BW daily for 6–12 months	No effect on weight gain, serum testosterone at age 11 months, libido, sperm mobility, semen volume, and sperm concentration. No histopathology of liver, lung, kidney, or spleen. No tissue residues — except for one bull slaughtered at age 5 months: <20 µg/kg FW in muscle, 20 in liver and kidney, 40 in subcutaneous fat, and 80 in renal and omental fat	4

Table 17.7 (continued) Diflubenzuron Effects on Selected Mammals

Species, Mode of Administration, Dose, and Other Variables	Effect	Reference^a
Fed diet equivalent to 8 mg/kg BW daily for 4–5 months, single animal	No detectable residues in milk	3
Fed diet equivalent to 16 mg/kg BW daily for 4–5 months, single animal	Maximum concentrations recorded were 20 µg/L in milk and 250 µg/kg FW in body fat. No obvious adverse effects on feeding behavior	3
Oral 10 mg/kg BW, single-dose to a lactating cow	Extensively metabolized in 4 days; almost all totally excreted in 7 days: about 85% in feces, 15% in urine, 0.2% in milk. At 7 days, liver contained 2.9 mg/kg FW, skin 0.4, and all other tissues <0.4	1
DOG, <i>Canis familiaris</i>		
Fed diets containing 10, 20, 40, or 160 mg/kg (equivalent to 0.42, 0.84, 1.64, or 6.24 mg/kg BW daily) for 13 weeks	Abnormal hemoglobin levels in 160 mg/kg group after 6 weeks; no other abnormal findings or histopathology observed in any group at 13 weeks	2
ANGORA GOAT, <i>Capra</i> sp.		
30 mL of 2% diflubenzuron solution applied dermally 6 weeks after shearing, 25-kg females	Protected against Angora goat-biting lice (<i>Bovicola limbatus</i>) for up to 18 weeks	5
DOMESTIC MOUSE, <i>Mus</i> sp.		
Diet 4, 8, 16, or 50 mg/kg ration for 80 weeks	Increase in tumors in females at the 16 mg/kg level	2
Intraperitoneal injection 3 daily injections of 1.2 mg, equivalent to 144 mg/kg BW, tumor-bearing strain	Tumors conditioned with CoCl ₂ then treated with diflubenzuron showed a 75% reduction in rate of tumor increase	6
5 daily injections of 20 mg (total of 100 mg, equivalent to 4000 mg/kg BW), C57BL/6 strain with B16 melanomas 2150 mg/kg BW	Initial antitumor activity, as judged by 11–20% decrease in tumor volume, and a 2–3 day increase in tumor doubling time. But at midtreatment, tumors regained control rate of volume increase	6
Oral Adult males given 125, 500, or 2000 mg/kg BW daily for 30 days	Insufficient to kill 50%	7
>4640 mg/kg BW	Hepatocellular changes at all dose levels, including histopathology and altered activities of glutathione S-transferase enzymes	8
	Acute oral LD ₅₀	2, 7, 8
RABBIT, <i>Oryctolagus</i> sp.		
Dermal 2000 mg/kg BW	Insufficient to kill 50%	7
Diet Males given 640 mg/kg feed for 18–21 days	Abnormal hemoglobin	2
<i>In vitro</i> studies Up to 5 mg/L	Protein and RNA synthesis rates were significantly stimulated in liver, and inhibited in muscle in a dose-dependent manner. Maximum effect in both tissues occurred at 5 mg/L for protein synthesis and 0.2 mg/L for RNA synthesis	9
Oral Females given 1, 2, or 4 mg/kg BW daily on days 6–18 of gestation	No compound-related maternal toxicity or birth defects	2

Table 17.7 (continued) Diflubenzuron Effects on Selected Mammals

Species, Mode of Administration, Dose, and Other Variables	Effect	Reference ^a
SHEEP, <i>Ovis aries</i>		
Dermal		
Merino sheep exposed to mass-released gravid females of the sheep blowfly (<i>Lucilia cuprina</i>) — a severe ectoparasite in Australia that may kill — in a fly-proof animal house after dermal application of 1000, 1500, or 2500 mg diflubenzuron/L; sheep thoroughly wetted twice during 4 days	1000 mg/L protected against fly strike for at least 110 days; 1500 mg/L protected until end of trial at 170 days; 2500 mg/L provided excellent protection against severe infestation. No resistance to diflubenzuron was acquired by blowflies	10
Oral		
Single dose of 10 mg/kg BW	Residues after 7 days, in mg/kg FW, were about 3 in liver, 0.4 in kidney, and <0.2 in all other tissues	1
Single dose of 500 mg/kg BW	In 4 days, bile accounted for 36% of diflubenzuron metabolites excreted, feces 32%, and urine 24%; in 7 days, feces were the major pathway	1
LABORATORY WHITE RAT, <i>Rattus sp.</i>		
Diet		
Fed 10, 20, 40, or 160 mg/kg ration for three generations	No effect on fetotoxicity or teratogenicity	2
Fed 10, 20, 40, or 160 mg/kg ration for 2 years	No compound-related effects	2
Oral		
Females given 1, 2, or 4 mg/kg BW daily on days 6–15 of gestation	No compound-related maternal toxicity or birth defects	2
4 mg/kg BW, single dose	Intestinal absorption of 50%	11
5 mg/kg BW, single dose	72–93% excreted in 6 days, mostly in feces	11
900 mg/kg BW, single dose	Intestinal absorption of 4%	11
>4640 mg/kg BW	Acute oral LD ₅₀	2, 7
Males given 5000 mg/kg BW daily for 13 weeks	Abnormal hemoglobin on days 1–4, and on day 8	2
SWINE, <i>Sus sp.</i>		
Adult female pig given single oral dose of 5 mg/kg BW and observed for 11 days	By 11 days, 82% of dose was excreted unchanged in feces, and 5% in urine as metabolites (4-chlorophenylurea, 2, 6-difluorobenzoic acid, 4-chloroaniline, and 2,6-difluorobenzamide). Tissue residues, in mg/kg FW, ranged from ND in bone to 0.04–0.09 in stomach wall, brain, pancreas, small intestine, blood, heart, muscle and ovary; from 0.11–0.2 for large intestine, subcutaneous fat, lymph, lung, and kidney; and from 0.23–0.4 in liver, omental fat, and gall bladder	12

17.5 RECOMMENDATIONS

Since diflubenzuron toxicity seems to be similar in both insects and crustaceans, extreme care must be taken when this compound and other chitin synthesis inhibitors are used for insect control in areas where aquatic crustaceans occur. Otherwise, ecological instability may result, with consequences

for feeding, metabolism, growth, reproduction, and survival of numerous nontarget organisms (Christiansen 1986). Specifically, diflubenzuron use in saltmarsh mosquito breeding areas or on agricultural lands less than 5 km from coastal areas is not recommended because of concerns that runoff may reach the adjacent estuaries, which are the primary hatcheries for many economically important species of crustaceans (Costlow 1979; Cunningham 1986; Cunningham and Myers 1986; Fischer and Hall 1992). Also, diflubenzuron concentrations in seawater should not exceed 0.1 µg/L, the minimum concentration known to produce measurable behavioral changes in estuarine crustacean larvae (Cunningham and Myers 1986). Concentrations of 2.5 µg diflubenzuron/L and higher in freshwater are known to reduce arthropod populations by 67 to 71%, resulting in reduced growth of young of year bluegills. Growth inhibition, in turn, may result in greater starvation, increased predation, reduction in over-winter survival, and diminished to poor recruitment (Tanner and Moffett 1995). If diflubenzuron and other insect growth regulators continue to be used near productive aquatic habitats, then food chain transfer studies are recommended (Fischer and Hall 1992). High accumulations of diflubenzuron by aquatic algae — up to 4.5 mg/kg DW in some cases (Booth and Ferrell 1977) — strongly implicate food chain transfer as a potential mechanism of contaminant transfer in aquatic invertebrate food webs. To protect certain fishes, diflubenzuron use to control copepod vectors of human disease — including various species of *Cyclops* — is not recommended in areas where these fishes breed or feed on *Cyclops* (Rao and Paul 1988).

For control of cotton pests, including the boll weevil, a maximum recommended treatment schedule is 421 g diflubenzuron/ha, applied 6 times, usually weekly, during the growing season (Bull 1980). Honeybees (*Apis mellifera*) in heavily sprayed areas, however, may experience adverse effects if their diets exceed 1 mg diflubenzuron/kg FW (Stoner and Wilson 1982). Diflubenzuron inhibits house fly development in poultry manure. A recommended cost-effective fly control program in poultry houses involves the feed-through method (5 mg diflubenzuron/kg FW poultry diet) during hot, wet summers for 3 to 4 months, coupled with good sanitation and good manure management (Giga 1987).

For protection of domestic cattle, feeds should contain <0.05 mg diflubenzuron/kg FW. Cottonseed may be added to cattle diets provided that diflubenzuron concentrations in the seed do not exceed 0.2 mg/kg FW and that cottonseed composes <17% of the total diet bulk (Gartrell 1981). Diflubenzuron causes biochemical upset, as judged by lowered testosterone levels in chickens and rats (USEPA 1979), altered glutathione S-transferase activity in mouse liver (which adversely affects the ability to detoxify foreign substances by way of conjugation; Young et al. 1986), and disrupted hydroxylamine activity in human infants (USEPA 1979). Additional research seems needed on biochemical alterations induced by diflubenzuron. No diflubenzuron criteria are currently recommended for protection of avian and mammalian wildlife. All data available suggest that wildlife species are about as tolerant to diflubenzuron as are domestic poultry and livestock; however, the wildlife database seems inadequate for practicable criteria formulation.

Anti-cancer properties of diflubenzuron require elucidation. The indication that one or more hydroxylated forms of diflubenzuron can regulate growth of mouse tumor cells provides a basis for further studies to identify and isolate the most active analog of this compound, and it suggests that other benzoylphenyl ureas may have similar properties (Jenkins et al. 1986).

Diflubenzuron has a Surveillance Index Classification of Class IV, indicating a sufficiently low hazard potential to human health from toxicological and exposure standpoints to justify only minimal monitoring efforts (Gartrell 1981). Human cancer risk of lifetime dietary exposure to diflubenzuron in a worst-case scenario is considered slight (USEPA 1979). Diflubenzuron has little potential for human dietary exposure because of its limited use on cotton and the low residues measured on cottonseed, meat, milk, poultry, and eggs (Gartrell 1981). For protection of human health, tolerances of <0.05 mg/kg FW have been set for fat, meat, meat by-products, poultry, milk, dairy products, and eggs, and <0.2 mg/kg FW for cottonseed (USEPA 1979). These foods compose about 45% of the average human diet. If all of these foods bore residues at the tolerance level, they would contribute 0.035 mg daily on the basis of 1.5 kg food eaten daily. For a 60-kg adult, the

theoretical maximum residue concentration would be 0.6 µg/kg BW daily. Tolerances would be approached only when maximum quantities of cottonseed fraction (i.e., hulls, meal, soapstock), all bearing tolerance-level residues, are incorporated into livestock diets. At present, however, no acceptable daily intake level in humans has been established (Gartrell 1981).

17.6 SUMMARY

Diflubenzuron (1-(4-chlorophenyl)-3-(2,6-difluorobenzoyl)urea), also known as dimilin, is a potent broad-spectrum insect growth regulator that interferes with chitin synthesis at time of molting and is effective in controlling immature stages of insects. Diflubenzuron was approved for domestic use in 1976 to control gypsy moth (*Lymantria dispar*), and in 1979 against the cotton boll weevil (*Anthonomus grandis*). By 1989 this compound was also registered for domestic use against mosquitoes, forest lepidoptera, mushroom flies, and leaf-eating insect pests of citrus, woody ornamentals, vegetables, and fruit.

Diflubenzuron seldom persists for more than a few days in soil and water. When used properly in forest management, it is unlikely to be leached into groundwater from the application site. Degradation in water and soil is most rapid when small-particle formulations are applied, micro-organisms are abundant, and at elevated pH, temperature, and organic loading. Chemical and biological processes initially yield 2,6-difluorobenzoic acid and 4-chlorophenylurea. Soil degradation processes and plant and animal metabolism involve further conversion of these compounds to 2,6-difluorobenzamide and 4-chloroanaline. Ultimately, the end products are either conjugated into mostly water-soluble products or are biologically methylated.

Diflubenzuron applied to foliage of terrestrial plants tends to remain adsorbed for several weeks with little or no absorption or translocation from plant surfaces; loss occurs mainly from wind abrasion, rain washing, or shedding of senescent leaves. Among terrestrial insects, there is great variability in sensitivity to diflubenzuron. Sensitive pestiferous species of insects die at topical applications of 0.003 to 0.034 µg/larvae or after consuming diets containing 0.1 mg/kg. Some beneficial insects, such as the honey bee (*Apis mellifera*), are adversely affected at 1 mg/kg fresh weight (FW) of diet.

Diflubenzuron application rates between 28 and 56 g/ha (0.025 to 0.05 pounds/acre) or 2.5 to 16 µg/L are highly effective against pestiferous aquatic dipterans, including representative chironomids, chironomids, and culicids. These same dosages temporarily suppress nontarget populations of cladocerans, copepods, mayfly nymphs, corixids, and springtails; population recovery is usually complete within 80 days. In general, crustaceans were the most sensitive nontarget aquatic organisms tested. Adverse effects on crustacean growth, survival, reproduction, and behavior occur between 0.062 and 2 µg/L. Next in sensitivity are mayflies, chironomids, caddisflies, and midges; concentrations between 0.1 and 1.9 µg/L produce low emergence and survival. Moderately resistant to diflubenzuron are larvae of diving beetles, dragonfly adults and naiads, ostracods, spiders, backswimmers, and water boatmen. Relatively tolerant of diflubenzuron (i.e., no observable adverse effects at ≤45 µg/L) are the algae, molluscs, fishes, and amphibians. High accumulations occur on some aquatic plants during exposure to 100 µg/L and in fish during exposure to 1 to 13 µg/L, but all species in these groups seem unaffected by elevated body burdens and grow and metabolize normally.

Birds seem comparatively resistant to diflubenzuron: acute oral LD₅₀ doses exceed 2000 mg/kg body weight (BW); dietary concentrations <4640 mg/kg FW are tolerated for at least 8 days; and forest birds seem unharmed by recommended diflubenzuron application procedures to control pestiferous insects, except for a possible loss in fat reserves. Intraspecies differences in ability to metabolize diflubenzuron are probably large; different strains of domestic chickens show significant differences in ability to accumulate and retain this compound.

No data were found on diflubenzuron effects on mammalian wildlife. However, studies on small laboratory animals and domestic livestock indicate no observable effects in cows (*Bos bovis*) given

0.25 mg/kg BW daily for 4 months; in rabbits (*Oryctolagus cuniculus*) given 4 mg/kg BW daily on days 6 to 18 of gestation; in dogs (*Canis familiaris*) fed diets containing 40 mg/kg for 13 weeks (equivalent to 1.6 mg/kg BW daily); in rats (*Rattus spp.*) fed diets containing 160 mg/kg for 2 years; and in rabbits and rodents given single oral or dermal doses <2000 mg/kg BW. All experimental studies conducted with laboratory animals indicate that diflubenzuron is nonmutagenic, nonteratogenic, and noncarcinogenic. Adverse effects occur in dogs fed diets containing 160 mg/kg (6.2 mg/kg BW daily) for 13 weeks (abnormal blood chemistry); in mice (*Mus spp.*) given 125 mg/kg BW daily for 30 days (hepatocellular changes); in rabbits fed diets of 640 mg/kg for 3 weeks (abnormal hemoglobin), and in rats given 5000 mg/kg BW daily for 13 weeks (abnormal hemoglobin). Elevated tissue residues — but no other measurable effects — occur in cows given 0.05 to 0.5 mg/kg ration for 28 days or 1 to 16 mg/kg BW for 4 months; in pigs (*Sus spp.*) given a single oral dose of 5 mg/kg BW; and in sheep (*Ovis aries*) given a single oral dose of 10 mg/kg BW.

Criteria now recommended for protection of various species include the following: dietary loadings, in mg/kg FW ration, of <0.05 for human health, <0.05 for livestock, <1 for honey bees, and <5 for poultry; seawater concentrations <0.1 µg/L for estuarine crustacean larvae; and, for all aquatic life, restricted or prohibited use of diflubenzuron in saltmarsh mosquito breeding areas and on agricultural lands less than 5 km from coastal areas. No criteria are available or proposed for protection of avian and mammalian wildlife against diflubenzuron, probably because of an incomplete toxicological database.

CHAPTER 18

Dioxins

18.1 INTRODUCTION

Accidental contamination of the environment by polychlorinated dibenzo-*para*-dioxins (PCDDs), especially 2,3,7,8-tetrachlorodibenzo-*para*-dioxin (2,3,7,8-TCDD), is the cause of poor reproduction of herring gulls (*Larus argentatus*) in Lake Ontario (Stolzenburg and Sullivan 1983), and of other fish-eating birds in the Great Lakes and on Canada's west coast (Boddington et al. 1990). Humans exposed to herbicides contaminated with 2,3,7,8-TCDD and higher chlorinated dioxins may experience an increase in overall cancer risk and in risk for specific tumors (Kogevinas et al. 1997). The sale of striped bass (*Morone saxatilis*) and blue crabs (*Callinectes sapidus*) from Newark Bay, New Jersey, was prohibited because levels of 2,3,7,8-TCDD exceeded 50 ng/kg (parts per trillion = ppt), a level of concern established by the U.S. Food and Drug Administration (Prince and Cooper 1995a). PCDDs are associated with the closure of selected rivers in Missouri (Powell 1984) and Arkansas (Johnson et al. 1996) to anglers because of high residues in fish, with the destruction of fish and wildlife in Vietnam during military defoliation operations using phenoxy herbicides (Rappe 1984), and with the death of livestock and wildlife in Missouri (Powell 1984) and Italy (Fanelli et al. 1980b). For example, in 1976, massive kills of small animals (predominantly rabbits and poultry) occurred within the first few weeks after a chemical plant explosion in Seveso, Italy, in which 2,3,7,8-TCDD was released; many humans were hospitalized (Fanelli et al. 1980b). Levels of 2,3,7,8-TCDD in milk from dairy cows and tissues of pigs, chickens, cattle, goats, and sheep from Seveso were sufficiently elevated to pose a risk to human health. Accordingly, all domestic livestock in the most seriously afflicted areas were destroyed. In eastern Missouri during 1971, waste oil contaminated with 2,3,7,8-TCDD was applied to control road dust (Powell 1984). Later, hundreds of horses kept in riding arenas became sick, and 75 died; deaths were also observed among dogs, rodents, chickens, cats, and birds near the treated areas. Soils in Times Beach, Missouri were so heavily contaminated with 2,3,7,8-TCDD that it was permanently evacuated in December 1982. The U.S. Environmental Protection Agency [USEPA] had earlier announced it would buy the dioxin-contaminated city of Times Beach; once purchase is completed, the city will no longer exist officially (Powell 1984). Approximately 22 kg (48.4 pounds) of 2,3,7,8-TCDD were involved in the Times Beach incident (Westing 1978).

PCDDs are present as trace impurities in some commercial herbicides and chlorophenols. They can be formed as a result of photochemical and thermal reactions in fly ash and other incineration products. Their presence in manufactured chemicals and industrial wastes is neither intentional nor desired. The chemical and environmental stability of PCDDs, coupled with their potential to accumulate in fat, has resulted in their detection throughout the global ecosystem. The number of chlorine atoms in PCDDs can vary between one and eight to produce up to 75 positional isomers. Some of these isomers are extremely toxic, while others are believed to be relatively innocuous.

The most toxic and extensively studied PCDD isomer is 2,3,7,8-TCDD. In fact, it is the most toxic synthetic compound ever tested under laboratory conditions. This isomer is produced during the synthesis of 2,4,5-trichlorophenol, which is used in the manufacture of the herbicide 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), other trichlorophenoxy acids, and the germicide hexachlorophene. There is general agreement that 2,3,7,8-TCDD is exceedingly stable, readily incorporated into aquatic and terrestrial ecosystems, extraordinarily persistent, and virtually impossible to destroy. PCDD-contaminated phenoxy herbicides are not the only sources of 2,3,7,8-TCDD; others include polychlorinated biphenyls and pentachlorophenols. The other 74 isomers enter the biosphere from a variety of sources (National Research Council of Canada [NRCC] 1981). The fate and effects of PCDDs — with special reference to 2,3,7,8-TCDD and its role in poisonings of humans, aquatic organisms, wildlife, livestock, poultry, and its contamination of vegetation, soils, and sediments — have been extensively reviewed (Blair 1973; Cattebeni et al. 1978; Ramel 1978; Nicholson and Moore 1979; NRCC 1981; Hay 1982; Kociba and Schwetz 1982a, 1982b; Choudhary et al. 1983; Josephson 1983; Long et al. 1983; Stolzenburg and Sullivan 1983; Tucker et al. 1983; NIOSH 1984; Nriagu and Simmons 1984; Rappe 1984; U.S. Environmental Protection Agency [USEPA] 1984, 1993; Webb 1984; Kamrin and Rodgers 1985; Stalling et al. 1985a, 1985b; Young and Cockerham 1985; Eisler 1986; Cooper 1989; World Health Organization [WHO] 1989; Boddington et al. 1990; Clement et al. 1990; Ahlborg et al. 1992; Damstra et al. 1992; Cook et al. 1993; Fletcher and McKay 1993; Sijm and Opperhuizen 1996; U.S. Public Health Service [USPHS] 1998).

18.2 ENVIRONMENTAL CHEMISTRY

The PCDDs consist of 75 isomers that differ in the number and position of attached chlorine atoms. Each isomer has its own unique identity and toxicological properties. The most toxic of the chlorinated dioxin isomers is 2,3,7,8-TCDD (Figure 18.1). It is one of 22 possible congeners of tetrachlorodibenzo-*p*-dioxin. There is general agreement that PCDDs, including 2,3,7,8-TCDD, are (or were, until recently) found in chlorophenols, especially trichlorophenol and pentachlorophenol (Table 18.1), in certain phenoxy pesticides (2,4,5-T; 2,4-D; Fenoprop; Silvex; Ronnel; Erbon; Agent Orange), in hexachlorophene, and in polychlorinated biphenyls (used in electrical transformers and capacitors, and contaminated with trichlorobenzenes). PCDDs enter the environment naturally through forest fires and volcanoes, and through human activities such as accidental release during chlorophenol production, aerial application of some phenoxy herbicides, and through improper disposal of wastes into terrestrial and aquatic ecosystems from municipal incinerators and pulp and

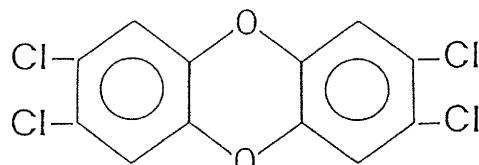

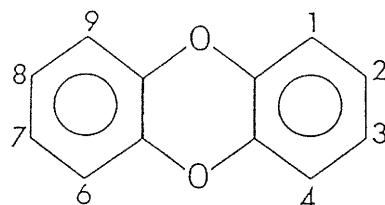

Figure 18.1 Upper: numbering system used for identification of individual PCDD isomers. Lower: the isomer 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (2,3,7,8-TCDD).

Table 18.1 Levels of PCDDs in Commercial Chlorinated Phenols, and Levels of 2,3,7,8-TCDD in 2,4,5-T Acid and Ester Formulations

Formulation	Geographic Locale (year)	Concentration (mg/kg)	
		PCDDs	2,3,7,8-TCDD
2,4,5-T acid	Sweden (1952)	—	1.10
2,4,5-T ester	Sweden (1960)	—	0.40
2,4,5-T ester	Finland (1962)	—	0.95
2,4,5-T ester	Finland (1967)	—	0.22
2,4,5-T acid	U.S. (1964)	—	4.8
2,4,5-T acid	U.S. (1969)	—	6.0
Agent orange	U.S. (—)	—	0.12
Agent orange	U.S. (—)	—	5.1
2,4,6-Trichlorophenol	Sweden (—)	3.0	—
2,4,6-Trichlorophenol	U.S. (—)	0.3	—
2,3,4,6-Tetrachlorophenol	England (—)	12.0	—
Pentachlorophenol	U.S. (—)	1900–2625	—
Pentachlorophenol	Germany (—)	6.8	—

Data from Hardell, L. 1983. Epidemiological studies on soft-tissue sarcoma, malignant lymphoma, nasal and nasopharyngeal cancer, and their relation to phenoxy acid or chlorophenol exposure. Pages 367-374 in G. Choudhary, L.H. Keith, and C. Rappe (eds.). *Chlorinated Dioxins and Dibenzofurans in the Total Environment*. Butterworth, Woburn, MA.

paper mills that use chlorine for the bleaching process (Ramel 1978; NRCC 1981; Ogilvie 1981; Choudhary et al. 1983; Josephson 1983; Stolzenburg and Sullivan 1983; NIOSH 1984; Rappe 1984; Kamrin and Rodgers 1985; USEPA 1988; WHO 1989; Boddington et al. 1990; Schell et al. 1993; Allinson et al. 1994; Blus et al. 1998; Elliott et al. 1998; Lynam et al. 1998). In Japan, major PCDD sources include waste incineration and the herbicide chlornitofen with metabolites of chlornitofen that include 1,3,6,8-TCDD and 1,3,7,9-TCDD (Ishizuka et al. 1998). The PCDD content of technical products varies between manufacturers, between lots and grades, and between various formulations of pesticidal chemicals (NRCC 1981). PCDDs have been identified in effluents from combustion products of municipal and industrial incinerators, including fly ash and flue gas (Czuczwa and Hites 1984). These PCDDs may be associated with small particles that have long residence times in the atmosphere and can become distributed over large areas. For example, in the Great Lakes, atmospheric transport of combustion products is the major source of PCDDs (mostly octa-, hepta-, and hexa-CDDs) in sediments (Czuczwa et al. 1984). Increased retentive capacity of the higher chlorinated PCDDs may account for the pattern of increasing dioxin concentrations in sediments with increasing chlorine substitution observed in the Great Lakes and other aquatic environments (Servos et al. 1992a). High-temperature combustion of bituminous coal in an oxidized and chlorinated atmosphere (produced experimentally) yielded chlorodioxins, mostly octa-, hepta-, and hexa-CDDs, and measurable quantities of tetra-CDDs (Mahle and Whiting 1980). Other potential sources of PCDDs include microbial by-products in activated sludge basins fed with chlorophenol-containing wastes (Lynam et al. 1998), fossil fuel power plants, internal combustion engines, home fireplaces, and cigarette smoke (Kociba and Schwetz 1982a, 1982b).

In general, PCDDs exhibit a relative inertness to acids, bases, oxidation, reduction, and heat. With increasing halogen content, they become more environmentally and chemically stable (NRCC 1981; WHO 1989). PCDDs are usually destroyed at temperatures greater than 1000°C. They are resistant to biological breakdown, concentrated in fat, not readily excreted, extremely toxic to some animals, and the cumulative effects of small doses to both animals and humans are a source of increasing concern (Stolzenburg and Sullivan 1983). Most PCDDs are relatively insoluble in water, sparingly soluble in organic solvents, and will decompose on exposure to UV light, including sunlight (NIOSH 1984), or to hydroxyl compounds (Josephson 1983). The isomer 2,3,7,8-TCDD is a colorless crystalline solid at room temperature and decomposes when heated to more than 700°C (Table 18.2).

Table 18.2 Chemical and Physical Properties of 2,3,7,8-TCDD, Also Known as CAS Registry No. 1746-01-6

Criterion	Property
Empirical formula	C ₁₂ H ₄ Cl ₄ O ₂
Percent by weight	
Carbon	44.70
Oxygen	9.95
Hydrogen	1.25
Chlorine	44.1
Molecular weight	322
Vapor pressure, mmHg at 25°C	1.7 × 10 ⁻⁶
Melting point	305°C
Decomposition temperature	>700°C
Solubilities, g/L	
o-Dichlorobenzene	1.4
Chlorobenzene	0.72
Benzene	0.57
Chloroform	0.37
n-Octanol	0.05
Methanol	0.01
Acetone	0.11
Water	2.0 × 10 ⁻⁷

Data from NIOSH. 1984. Current Intelligence Bulletin 40: 2,3,7,8-Tetrachlorodibenzo-p-dioxin (TCDD, "dioxin"). U.S. Dep. Health Human Serv., NIOSH Publ. 84-104. 20 pp.

Data on the bioavailability of PCDDs are limited. It is known that PCDDs incorporated into wood as a result of chlorophenol (preservative) treatment are bioavailable. Swine and poultry using chlorophenol-treated wooden pens or litter have been found to be contaminated with PCDDs (NRCC 1981). Toxicities of individual PCDD isomers can vary by a factor of 1000 to 10,000 for isomers as closely related as 2,3,7,8-TCDD and 1,2,3,8-TCDD, or 1,2,3,7,8-penta-CDD and 1,2,4,7,8-penta-CDD (Rappe 1984). Isomers with the highest biological activity and acute toxicity have four to six chlorine atoms, and all lateral (i.e., 2,3,7, and 8) positions substituted with chlorine. On this basis, the most toxic PCDD isomers are 2,3,7,8-TCDD, 1,2,3,7,8-penta-CDD, 1,2,3,6,7,8-hexa-CDD, 1,2,3,7,8,9-hexa-CDD, and 1,2,3,4,7,8-hexa-CDD (Rappe 1984). Ishizuka et al. (1998) have assigned toxic equivalencies for various PCDDs, with 2,3,7,8-TCDD given a value of 1 (highest biological activity), followed by a value of 0.5 for 1,2,3,7,8-penta-CDD; a value of 0.1 for three PCDD isomers (1,2,3,4,7,8-hexa-CDD, 1,2,3,4,7,8-hexa-CDD, 1,2,3,7,8,9-hexa-CDD), a value of 0.01 for 1,2,3,4,6,7,8-hepta-CDD; and a value of 0.001 for 1,2,3,4,6,7,8,9-octa-CDD.

Although PCDDs are highly persistent, volatilization and photolysis are major removal processes (NRCC 1981). In soils, 2,3,7,8-TCDD undergoes photolysis rapidly on the surface in a few hours, but more deeply buried 2,3,7,8-TCDD could have a chemical half-time greater than 10 years (NRCC 1981). When more than one degradation pathway was possible, microbial dechlorination of dioxins occurred at the most positively charged atom in the ring, which was usually a lateral carbon atom (Lynam et al. 1998). Microbial degradation of 2,3,7,8-TCDD in soils is slow, with biological half-times estimated at 1.0 to 1.5 years (Ramel 1978). However 2,3,7,8-TCDD was detected in northwestern Florida from samples of soils, rodents, birds, lizards, fishes, and insects 12 years after application. This half-time in soil was estimated at 2.9 years (Westing 1978). Uptake of 2,3,7,8-TCDD from soils by vegetation is considered negligible (Blair 1973; Ramel 1978).

The half-time persistence of 1,3,6,8-TCDD and OCDD in freshwater is short, of the order of 2.6 to 4 days; the rapid partitioning to dissolved and particulate organic matter in the water column and sediments limited their bioavailability (Servos et al. 1992a). Techniques are now available to

measure 2,3,7,8-TCDD at the part-per-quadrillion (0.1 parts per trillion) level in foods with high fat content (La Fleur et al. 1990) and human blood (Boddington et al. 1990), and in fish tissues to 1 ppt (Marquis et al. 1994). Analyses at such low levels are complicated by interference from a multitude of other compounds, as well as by the large number of PCDD isomers and their differences in chemical properties (Rappe 1984). Although 2,3,7,8-TCDD is the most extensively studied PCDD isomer, data on its fate and persistence are generally poor, interpretations are frequently absent, and extrapolations from case to case usually impossible. The general result is a qualitative concept of this compound's behavior in environmental situations (NRCC 1981). This issue is further confounded by the presence in biological and abiotic samples of chemicals of similar structure and toxicological properties to that of 2,3,7,8-TCDD. These isosteric compounds include: 2,3,6,7-tetrachlorobiphenylene; 2,3,7,8-chlorine substituted dibenzofurans; and 3,3',4,4'-tetra-, 3,3',4,4',5-penta-, and 3,3',4,4',5,5'-hexachlorobiphenyl (Stalling et al. 1985a, 1985b). For example, analytical results of fish, birds, and sediments indicated that every sample that was positive for 2,3,7,8-TCDD also contained 2,3,7,8-chlorine-substituted dibenzofurans (Stalling et al. 1985a, 1985b).

In mammals, biochemical and pathological responses of 2,3,7,8-TCDD are mediated through binding to a cytoplasmic protein, the Ah receptor. Many of the toxic responses to 2,3,7,8-TCDD are associated with alterations of cell proliferation in affected tissues. Common examples of 2,3,7,8-TCDD-mediated differentiation and proliferation in both fishes and mammals include dermal hyperkeratinization (fin necrosis in fish), teratogenicity, lymphoid involution, immunotoxicity, and carcinogenesis (Newsted and Giesy 1992). Lipid peroxidation in liver, kidney, thymus, and testes is induced in rats by 2,3,7,8-TCDD in a dose- and time-dependent manner. The enhanced lipid peroxidation by microsomes from 2,3,7,8-TCDD-treated rats may be associated with an increase in hydrogen peroxide production in conjunction with a decrease in glutathione peroxidase activity and an increase in free iron (Al-Bayati et al. 1987).

18.3 CONCENTRATIONS IN FIELD COLLECTIONS

PCDDs are ubiquitous in the environment and have been measured in air, water, soil, sediments, and foods. In Canada, all animals have been and continue to be exposed to these substances (Boddington et al. 1990). Plasma dioxin levels of Canadian villagers are about 8 times higher than levels in urban residents, and this is attributed to consumption of contaminated wildlife (Ryan et al. 1997). Many PCDDs, in addition to 2,3,7,8-TCDD, are present in biological and abiotic samples (NRCC 1981; O'Keefe et al. 1983; Petty et al. 1983; Stalling et al. 1983; Czuczwa et al. 1984; Lamparski et al. 1984; Kamrin and Rodgers 1985; Stalling et al. 1985a; Ryan et al. 1997). In general, wherever high levels of dioxins have been detected in the environment, a local application of 2,3,7,8-TCDD-contaminated herbicide, hazardous waste site, or industrial discharge has usually been implicated as the source (Stolzenburg and Sullivan 1983; Eisler 1986; USEPA 1987, 1988; WHO 1989). Aside from direct deposition, observed increases in 2,3,7,8-TCDD concentrations may result from microbial dechlorination as modified by the action of humic constituents such as resorcinol, 3,4-dihydroxybenzoic acid, and catechol (Barkovskii and Adriaens 1998).

At Eglin Air Force Base (EAFB), located in northwestern Florida, contamination of a 208-hectare section with 2.8 kg of 2,3,7,8-TCDD (equivalent to 13 mg/ha) occurred between 1962 and 1970 as a result of repeated, massive herbicide applications (Young and Cockerham 1985). The 2,3,7,8-TCDD isomer was present as an impurity in 76,740 kg of 2,4-D and 73,010 kg of 2,4,5-T applied to this section of EAFB during the 9-year span. Ecological surveys conducted between 1970 and 1975 showed an apparently healthy and diverse wildlife fauna, although soil levels of 520 ppt (ng/kg) of 2,3,7,8-TCDD were frequently encountered, and 2,3,7,8-TCDD residues were elevated in some species examined. The highest residues recorded in various trophic levels were 283 ppt in whole beetle grubs; up to 1360 ppt in whole southern toads (*Bufo terrestris*); 360 ppt in viscera and 430 ppt in carcass of a lizard, the six-lined racerunner (*Cnemidophorus sexlineatus*);

18 ppt in gonad and 85 ppt in gut contents of the spotted sunfish (*Lepomis punctatus*); 100 to 1200 ppt in stomach contents of the southern meadowlark (*Sturnella magna argutula*); and 300 to 2900 ppt in liver and 130 to 200 ppt in the pelt of a beachmouse (*Peromyscus polionotus*) (Young and Cockerham 1985). The significance of these elevated residues is discussed later.

In some cases, 2,3,7,8-TCDD has constituted up to 95% of the total body PCDD burden, as was true in lake trout, *Salvelinus namaycush* (O'Keefe et al. 1983), and rainbow trout, *Oncorhynchus mykiss* (Petty et al. 1983) from Lake Ontario. Concentrations of 2,3,7,8-TCDD in whole carp (*Cyprinus carpio*), varied from 24% of total body PCDDs in Saginaw Bay, Michigan (Stalling et al. 1983), to 45 to 56% in the Niagara River (NRCC 1981). In herring gulls from Saginaw Bay, 2,3,7,8-TCDD comprised 40 to 60% of the whole-body PCDD content (NRCC 1981; Petty et al. 1983), and 72 to 78% in gulls from Lakes Huron and Ontario (Stalling et al. 1983, 1985a). In 1983, Forster's tern (*Sterna forsteri*) from Green Bay, Wisconsin, contained 114 ppt of PCDDs in egg, of which 41% was 2,3,7,8-TCDD. Double-crested cormorants (*Phalacrocorax auritus*) from the same area contained 25 to 214 ppt of PCDDs in whole body, of which only 10 to 31% was 2,3,7,8-TCDD (Stalling et al. 1985a). The causes of the observed variations are not known but may be associated with localized inputs from municipal sewage treatment plants (Lamparski et al. 1984) and with atmospheric transport of incinerated domestic and industrial chemical wastes (Czuczwa et al. 1984). For example, the PCDD composition of sewage sludge from Milwaukee, Wisconsin, was relatively constant, as judged by analysis of samples from 1933, 1981, and 1982 (Lamparski et al. 1984). Total PCDD content in sewage sludge samples ranged between 60,950 and 70,191 ppt, of which the great majority was in the form of octa-CDDs (82 to 86%), hepta-CDDs (11.0 to 15.4%), and hexa-CDDs (1.3 to 2.1%). However, the tetra-CDDs increased from 34 ppt in 1933, to 138 in 1981, and to 222 in 1982. Corresponding values for the 2,3,7,8-TCDD isomer in 1933, 1981 and 1982 were 2.2, 11.0, and 16.0 ppt, respectively. Other TCDD isomers also showed increases from 6 ppt in 1933 to 22 ppt in 1982 (1,3,7,8-TCDD), and during that same period from 2.2 ppt to 140 ppt (1,2,3,7-, and 1,2,3,8-TCDD). It seems that chlorinated dibenzodioxins have been present in dried sludge from this plant for at least 50 years. Their presence in this material suggests that they may have been formed by the condensation of chlorophenols resulting from the chlorination of naturally occurring phenolic compounds (Lamparski et al. 1984). PCDDs were also found in sediments from Siskiwit Lake on Isle Royale in Lake Superior, a location that can receive only atmospheric inputs. The source of these compounds is the atmospheric transport of dioxins formed by combustion of domestic and chemical wastes. For example, particulates from a chemical waste incinerator in Midland, Michigan, had 260,000,000 ppt octa-CDDs and 170,000,000 ppt hepta-CDDs; lower, but still elevated levels of 440,000 ppt octa-CDDs and 310,000 ppt hepta-CDDs were measured in municipal trash incinerator particulates (Czuczwa et al. 1984).

Mussels and fish can accumulate 2,3,7,8-TCDD and other PCDDs from the medium and may be used as sentinel organisms. Mussels (*Elliptio complanata*) from an uncontaminated site exposed for 21 days in the contaminated Rainy River, Ontario, were sensitive monitors of PCDD sources, such as kraft pulp and paper mills (Hayton et al. 1990). Fish in Maine rivers contaminated by the effluent of bleached kraft paper mills accumulated 2,3,7,8-TCDD from the medium by factors as high as 24,600 in muscle of smallmouth bass (*Micropterus dolomieu*); 28,300 in muscle of brown trout (*Salmo trutta*); 7500 in white perch (*Morone americana*) fillets; and 106,000 in whole white suckers (*Catostomus commersoni*) (Frakes et al. 1993). High levels of PCDDs were found in edible tissues of mountain whitefish (*Prosopium williamsoni*) exposed to effluent from bleached kraft pulp mills in Canada; uptake was attributed to the food prey selection of filter-feeding invertebrates that ingest suspended sediments (Law and Gudaitis 1994; Owens et al. 1994). The primary route of exposure of 2,3,7,8-TCDD for pelagic fish is the diet, which accounts for 75% or more of the total uptake in lake trout (Tietge et al. 1998). Food chain biomagnification of PCDDs is reported for fish to birds (de Wit et al. 1992), fish to turtle (Ryan et al. 1986), and in Great Lakes food chains of phytoplankton to zooplankton to forage fish to lake trout (Whittle et al. 1992). But food chain biomagnification has not been observed in a complex Baltic Sea food chain using sophisticated

stable nitrogen isotope techniques (Broman et al. 1992), and in fish to seal, and fish to bird (guillemot, *Uria aalge*) food chains (de Wit et al. 1992). To confound matters, PCDD patterns in different fish species collected at the same site are highly variable, indicating species differences in accumulation (de Wit et al. 1992). PCDD sources from pulpmill effluents, combustion, and magnesium production can now be recognized in aquatic fauna by analysis of profiles of 2,3,7,8-substituted chlorinated dibenzodioxins using statistical principal component analysis techniques (Zitko 1992).

Eggs of the lake trout (*Salvelinus namaycush*) from Lake Ontario had higher 2,3,7,8-TCDD toxic equivalents (10.7 ppt) than eggs from Lake Superior or a hatchery (0.3 ppt), but these were below the levels considered fatal to lake trout eggs (LD₅₀ of 42 to 72 ppt) or harmful (NOAEL of 30 to 45 ppt) (Guiney et al. 1996). Concentrations of 2,3,7,8-TCDD in whole fish collected nationwide in the United States in 1983 from 395 sites usually contained 0.5 to 2.0 ppt FW, with a maximum of 85 ppt; concentrations were highest in predatory fish collected near pulp and paper manufacture discharge sites and lowest in estuarine areas (Kuehl et al. 1989) (Table 18.3). In the Great Lakes area, fish from the Tittabawasee and Saginaw Rivers, two tributaries of Lake Huron's Saginaw Bay, contained up to 695 ppt of 2,3,7,8-TCDD (Stolzenburg and Sullivan 1983). High 2,3,7,8-TCDD levels (87 to 162 ppt) were also recorded in fish from the Niagara River, New York, and from parts of Lake Ontario; lower concentrations (2 to 28 ppt) were noted in fish from Lakes Erie, Huron, Michigan, and Superior (Stolzenburg and Sullivan 1983). Muscle from larger specimens of commercial fish collected from Lake Ontario in 1980 had higher levels of 2,3,7,8-TCDD than smaller fish (Ryan et al. 1984), suggesting that accumulation increases with age. The larger fish also contained high concentrations (1.2 to 4.9 mg/kg, fresh weight) of polychlorinated biphenyls (Ryan et al. 1984), demonstrating a need to elucidate TCDD interaction kinetics with other contaminants. Bottom-feeding fish, such as carp and catfish, from rivers in Michigan during 1978 contained higher 2,3,7,8-TCDD residues than surface feeders (Marless et al. 1982), indicating an association with contaminated sediments. Marine amphipods (*Ampelisca abdita*) held on sediments containing as much as 25 µg 2,3,7,8-TCDD/kg DW for 10 days had normal survival and growth (Barber et al. 1998), although the authors did not measure 2,3,7,8-TCDD residues in amphipods. Sediments from the Spring River, Missouri, contained 12 ppt of 2,3,7,8-TCDD immediately downstream of a now defunct hexachlorophene facility (Kleopfer and Zirscky 1983). Concentrations in fish were measurable 111 km downstream from this disposal site (Table 18.3). Fish from the Spring River (and also the Meremac River, Missouri) contained inordinately high levels of 18 to 78 ppt 2,3,7,8-TCDD, prompting the U.S. Food and Drug Administration to issue a health advisory in 1982 against fish consumption from these areas (Powell 1984). In Massachusetts, six ponds were surveyed for 2,3,7,8-TCDD in 1983 after prior treatment with phenoxy herbicides between 1958 and 1978 (Anonymous 1984). Only one fish, a brown bullhead (*Ictalurus nebulosus*), age 3+ years, contained measurable (25 ppt) dioxin levels. Residues were not detectable in other species of fish sampled, including several species of ictalurid catfish, yellow perch (*Perca flavescens*), and chain pickerel (*Esox niger*). Negative results (less than 10 ppt 2,3,7,8-TCDD) were also documented in freshwater fish from Arkansas and Texas following spraying of the herbicide 2,4,5-T (Shadoff et al. 1977).

In general, high PCDD concentrations in avian tissues were correlated with poor growth, survival, and reproduction. Nest success, hatching success, and duckling production of wood ducks (*Aix sponsa*) were suppressed at nesting sites within 58 km of a PCDD point source (a former chemical plant that manufactured the herbicide 2,4,5-T). Egg toxicity equivalent factors were inversely correlated with productivity in nests, and teratogenic effects occurred in ducklings at the most contaminated sites (White and Seginak 1994). High PCDD levels in yolk-sacs of cormorant (*Phalacrocorax carbo*) hatchlings may have been responsible for the observed low breeding success of Dutch colonies in 1989 (Van den Berg et al. 1994). The endangered Forster's tern (*Sterna forsteri*) population on Green Bay, Wisconsin, showed signs of embryotoxicity, congenital deformities, and poor hatching success Kubiak et al. 1989). Eggs from this population contained 215 (90 to 245)

ppt FW of 2,3,7,8-TCDD equivalents vs. 23 (14 to 34) ppt from a reference population (Baumann and Whittle 1988; Tillitt et al. 1993). Great blue herons (*Ardea herodias*) located near a pulp mill in British Columbia failed to fledge young in 1987, with a concurrent sharp increase in PCDD levels in their eggs. In 1988, levels in heron eggs were — in ppt FW — 211 for 2,3,7,8-TCDD, 263 for 1,2,3,7,8-penta CDD, and 430 for 1,2,3,6,7,8-hexa-CDD. These values were significantly higher than eggs from other sites, although other factors may have contributed to the decline of the heron population (Boddington et al. 1990; Hart et al. 1991). Eggs of the osprey (*Pandion haliaetus*), however, collected near a bleached kraft mill facility in Wisconsin between 1992 and 1996 hatched and fledged normally despite 2,3,7,8-TCDD concentrations as high as 162 ppt on a fresh weight basis (Woodford et al. 1998).

Proposed indicators of 2,3,7,8-TCDD contamination in bird eggs include changes in yolk retinoid concentrations and EROD enzyme activity levels. Changes in yolk retinoids, as measured by Vitamin A concentrations, of herring gulls (*Larus argentatus*) from the Great Lakes during 1986/87 were associated with increasing concentrations of 2,3,7,8-TCDD, and this may be an early indicator of survival and teratogenesis in birds from the Great Lakes (Spear et al. 1990). Eggs of the great blue heron (*Ardea herodias*) from British Columbia in 1990 to 1992 had decreased concentrations of 2,3,7,8-TCDD when compared to 1988. Decreases in 2,3,7,8-TCDD content in eggs was associated with decreased EROD activity in eggs and resultant chicks, decreased incidence of chick edema, and increased growth rate of chicks (Sanderson et al. 1994a). The use of avian hepatic microsomal EROD activity is a useful index of cytochrome P4501A1 induction by polychlorinated aromatic hydrocarbons, including PCDDs. A significant regression of hepatic microsomal EROD activity on TCDD-toxic equivalent was measured in chicks of the double-crested cormorant (*Phalacrocorax auritus*) (Sanderson et al. 1994b).

Fish-eating birds usually have the highest concentrations of PCDDs of all birds measured (Baumann and Whittle 1988; Ankley et al. 1993; Jones et al. 1993). Diet is the major route of PCDD accumulation in livers of fish-eating birds. Fish-eating birds and their food from the Netherlands are contaminated with 2,3,7,8-substituted PCDDs and polychlorinated dibenzofurans (PCDFs); pentachlorophenol and polychlorinated biphenyls are the two major contaminating sources of PCDDs and PCDFs (Van den Berg et al. 1987). A linear relation exists between the retained PCDDs and PCDFs in the livers of cormorants (*Phalacrocorax carbo*), probably caused by continuous exposure to a relatively stable mixture of these compounds in their fish diet. Biomagnification of 2,3,7,8-TCDD and 1,2,3,6,7,8-hexa CDD probably occurs from the European eel (*Anguilla anguilla*) to the cormorant (Van den Berg et al. 1987). In birds, the levels of 2,3,7,8-TCDD have been decreasing, according to analysis of herring gull eggs from Lake Ontario. During the decade 1970 to 1980, there was a reduction of about 50% in 2,3,7,8-TCDD levels every 2 years (Ogilvie 1981; NRCC 1981; Nriagu and Simmons 1984). The reasons for the decline are unknown, and the relevance to higher-chlorinated PCDDs has not yet been determined. Until these questions are resolved and more substantive data are acquired on dioxin residues in birds, the current predictive trends on decline rates should be interpreted with caution.

Some information on 2,3,7,8-TCDD levels in wildlife and domestic livestock are from the vicinity of Seveso, Italy (Table 18.3). There, on July 10, 1976, a thick cloud of chemicals — including at least 34 kg 2,3,7,8-TCDD, and perhaps as much as 250 kg — was released into the atmosphere when a runaway reaction accidentally occurred in a trichlorophenol-producing facility (di Domenico et al. 1990). Its wind-driven settling contaminated large inhabited areas. It contaminated the food (hay, grass, cut-up corn) of dairy cows (Fanelli et al. 1980a). Grossly elevated levels (7900 ppt) were measured in milk from these herds at concentrations considered hazardous to human health (i.e., more than 7000 ppt) (Fanelli et al. 1980a). Wildlife from the most heavily contaminated area appeared to accumulate 2,3,7,8-TCDD. Field mice (*Microtus arvalis*), for example, contained very high whole-body concentrations of 2,3,7,8-TCDD (up to 49,000 ppt) almost 2 years after the critical contamination. The mechanisms for this phenomenon included ingestion of contaminated soil and licking of their dioxin-contaminated pelt (Fanelli et al. 1980c). In 1996,

humans from the most heavily contaminated area of Seveso (based on soil 2,3,7,8-TCDD concentrations) had 53 ppt of 2,3,7,8-TCDD in plasma on a fresh weight basis compared to 4.9 ppt in a reference population; women had significantly higher plasma 2,3,7,8-TCDD concentrations than men, especially women closest to the accident site and who consumed meat regularly (Landi et al. 1997). In another study, no 2,3,7,8-TCDD was detected in livers of mountain beavers (*Aplodontia rufa*) that fed for 45 to 60 days in Oregon forests that had been sprayed with 2.2 kg of 2,4,5-T/ha (Newton and Snyder 1978). Although it was presumed that the herbicide was heavily contaminated with dioxins, no chemical analysis of the 2,4,5-T was performed.

In Germany, humans ingest an average of 85 pg daily of 2,3,7,8-TCDD equivalents per person or 1.2 pg/kg BW daily, mostly from fish and fish products (32%), beef (20%), and cow's milk (16%) (Furst et al. 1990). In the United States, there is a potential for 2,3,7,8-TCDD to migrate from paperboard-based food packaging on contact with food. The migration rate of 2,3,7,8-TCDD from bleached paperboard cartons into whole milk was linear with the square root of exposure time. After 12 days of storage, 6.7% of the 2,3,7,8-TCDD in the paperboard carton migrated into the milk (La Fleur 1990). The amount of 2,3,7,8-TCDD formed in the U.S. bleached kraft industry in 1988 was estimated at 0.64 kg annually (Whittemore et al. 1990). In Vietnam, 2,3,7,8-TCDD concentrations in food and wildlife in 1985 to 1987 were higher in South Vietnam than in North Vietnam, with elevated values attributed to the increased industrialization of South Vietnam (Olie et al. 1989).

18.4 LETHAL AND SUBLETHAL EFFECTS

18.4.1 General

Information is lacking or scarce on the biological properties of PCDD isomers, except 2,3,7,8-TCDD. The latter has been associated with lethal, carcinogenic, teratogenic, reproductive, mutagenic, histopathologic, and immunotoxic effects. There are substantial inter- and intraspecies differences in sensitivity and toxic responses to 2,3,7,8-TCDD. Typically, animals poisoned by 2,3,7,8-TCDD exhibit weight loss, atrophy of the thymus gland, and eventually death. The toxicological mechanisms are imperfectly understood.

18.4.2 Terrestrial Plants and Invertebrates

Higher plants, such as corn (*Zea mays*) and beans (*Phaseolus vulgaris*), grown on soil contaminated with 2,3,7,8-TCDD (12 to 2750 ng 2,3,7,8-TCDD/kg FW) accumulated the toxin in the aerial parts progressively over time with increasing soil burdens of 2,3,7,8-TCDD. In hydroponic tests, TCDD uptake occurred only in light (Sacchi et al. 1986). Aerial parts of beans grown in soil containing 12 ng 2,3,7,8-TCDD/kg had 0.09 ng 2,3,7,8-TCDD/kg FW after 7 days; beans grown in soils with 2750 ng 2,3,7,8-TCDD/kg had 7.2 ng/kg FW after 7 days. After 57 days, beans contained a maximum of 5 ng/kg FW. Aerial parts of corn had 0.74 to 10 ng 2,3,7,8-TCDD/kg FW after 17 days; after 57 days, this range was 1.2 to 3.2 ng/kg FW (Sacchi et al. 1986).

Reinecke and Nash (1984) reported that two species of earthworms (*Allolobophora caliginosa* and *Lumbricus rubellus*) showed no adverse effects when held for 85 days in soils containing grossly elevated levels of 5 mg/kg of 2,3,7,8-TCDD, but both species died at 10 mg/kg. In soils containing lower concentrations of 50 µg/kg of 2,3,7,8-TCDD, earthworms accumulated 5 times the soil levels in 7 days. There was no avoidance of soils contaminated with 2,3,7,8-TCDD, suggesting indifference. No surface penetration of dioxins into the body of earthworms was noted, and there was no biological breakdown of 2,3,7,8-TCDD during digestion as judged by the absence of mono-, di-, and tri-CDDs in excrement. Worm-worked soils had 2,3,7,8-TCDD retention times of 80 to 400 days, suggesting that earthworms may significantly alter half-time patterns of 2,3,7,8-TCDD in soils (Reinecke and Nash 1984).

Mutagenic responses were produced in *Escherichia coli* and certain strains of *Salmonella typhimurium* bacteria by 2,3,7,8-TCDD, but not by octa-CDD (Vos 1978). Further, chromosomal aberrations were induced in at least one species of higher plant and mammal (Ramel 1978). It must be concluded at this time that 2,3,7,8-TCDD is mutagenic or has mutagenic potential.

18.4.3 Aquatic Organisms

Limited data are available on lethal and sublethal effects of any PCDD isomer to aquatic organisms, except for 2,3,7,8-TCDD and freshwater biota (Table 18.4); 2,3,7,8-TCDD and liver microsomal enzyme activities in two marine species: winter flounder, *Pleuronectes americanus*, and the little skate, *Raja erinacea* (Pohl et al. 1976); and 1,3,6,8-TCDD uptake and elimination by fathead minnows (*Pimephales promelas*) and rainbow trout (Corbet et al. 1983). Lymphomyeloid and epithelial tissues are the primary target organs for TCDD-induced pathologic lesions in rainbow trout (Spitsbergen et al. 1988a). Cardiovascular systems seem to be the initial tissue affected in both the TCDD toxicity syndrome and in blue-sac disease of developing lake trout. Lesions in other organs, including brain, retina, and liver, develop as a result of circulatory derangements, anemia, and hypoxia (Spitsbergen et al. 1991). The mode of action of 2,3,7,8-TCDD in rainbow trout and mammals on the epidermal growth factor is mediated, in part, through protein kinase C activity (Newsted and Giesy 1993).

Tissue residues of 55 ng 2,3,7,8-TCDD/kg FW in sac fry of the lake trout (*Salvelinus namaycush*) were lethal (Walker et al. 1991), and water concentrations of 0.038 ng 2,3,7,8-TCDD/L caused a reduction in feeding activity and general activity levels of rainbow trout (Mehrle et al. 1988; Newsted and Giesy 1992). Less-sensitive species of teleosts exhibited reduced growth and fin necrosis at concentrations as low as 0.1 ppt of 2,3,7,8-TCDD after exposure for 24 to 96 h. Concentrations of 1.0 ppt and higher were eventually fatal, and exposure to lower concentrations of 0.01 ppt for 24 h had no measurable effect (Table 18.4). A typical 2,3,7,8-TCDD poisoning sequence in guppies (*Poecilia reticulatus*) and coho salmon (*Oncorhynchus kisutch*) during a postexposure observation period included: declining interest in feeding (5 to 8 days postexposure); skin discoloration and fin necrosis (30 days), with caudal fin most severely affected; reduced resistance to fungal infestations; reduced swimming; and, finally, death several weeks to months after exposure (Miller et al. 1973). In general, older and larger fish die last, and smaller or younger specimens succumb first (Norris and Miller 1974).

In brook trout (*Salvelinus fontinalis*), feces was the most important egestion route, and spawning was not an important source of chemical elimination of 2,3,7,8-TCDD (Nichols et al. 1998). However, Tietge et al. (1998) disagree and, using radioisotope techniques, show 39% maternal transfer of 2,3,7,8-TCDD to eggs in brook trout, and suggest the need for additional research in this area.

Histopathologic and teratogenic effects were noted in fry of rainbow trout (*Oncorhynchus mykiss*) exposed to 10 ppt 2,3,7,8-TCDD for 96 h as eggs, or as yolk-sac fry (Helder 1981). Some fry showed extensive degeneration and necrosis of the liver, and subsequently developed edema prior to death. The remaining fry showed a high incidence of teratogenic changes, including opercular defects, and foreshortened maxillas. Invertebrates, plants, and amphibians were comparatively resistant to 2,3,7,8-TCDD. For example, there were no adverse effects on growth, reproduction, or food consumption of algae, daphnids, and snails during immersion for 32 days in solutions containing 2.4 to 4.2 ppt 2,3,7,8-TCDD (Yockim et al. 1978). Populations of the mummichog (*Fundulus heteroclitus*) from New Jersey coastal waters contaminated with 2,3,7,8-TCDD are unusually resistant to dioxins when compared to reference populations (Prince and Cooper 1995a). Mummichogs from a TCDD-contaminated site were resistant to the toxicity of 2,3,7,8-TCDD and the ability of 2,3,7,8-TCDD to induce P4501A activity, which may imply an alteration in the Ah receptor complex of TCDD-contaminated mummichogs (Prince and Cooper 1995b).

Bioconcentration factors of dioxins in fishes are relatively low compared to other chlorinated aromatic compounds because of the low metabolic conversion of dioxins, their low available concentrations in test systems, and their highly variable uptake rates (de Voogt et al. 1990). In general, bioconcentration factors for persistent superlipophilic chemicals, such as OCDD, derived for freshwater fishes from supersaturated solutions may seriously underestimate the true BCF (Geyer

et al. 1992). BCF values for OCDD in various fish species are about 4.3×10^6 on a fresh weight basis and 8.5×10^7 on a lipid weight basis. However, these values are several orders of magnitude higher than those reported for guppies, rainbow trout, and fathead minnows because the lower values were derived from OCDD concentrations that exceeded the water solubility of OCDD (Geyer et al. 1992). Although uptake from food predominates over direct uptake of dioxins from water (de Voogt et al. 1990), the accumulation of 2,3,7,8-TCDD from the aquatic environment occurred in all species examined (Table 18.4). The isomer 1,3,6,8-TCDD was also accumulated from the environment by freshwater teleosts, but accumulations were much lower than predicted when compared to 2,3,7,8-TCDD, and elimination was 10 to 15 times more rapid than 2,3,7,8-TCDD (Corbet et al. 1983). Of seven chlorinated dibenzodioxins tested, 2,3,7,8-TCDD was concentrated by rainbow trout and fathead minnows to the greatest extent (de Voogt et al. 1990). In outdoor pond studies, a major portion of the added 2,3,7,8-TCDD concentrated in aquatic plants and at the sediment–water interface (Tsushimoto et al. 1982); however, most (85 to 99%) of the 2,3,7,8-TCDD originally added to the ecosystem remained in the sediments at the end of the study (Isensee and Jones 1975), with significant reduction in bioavailability of PCDDs to fishes (Loonen et al. 1994a). Among teleosts, body burdens of 2,3,7,8-TCDD increased with increasing concentration in the water column and with increasing duration of exposure. On removal to uncontaminated water, less than 50% was lost in 109 days (Miller et al. 1979). Accumulation of PCDDs in biota shifted from direct equilibrium partitioning during the first few days when concentrations in the water column were relatively high, to a detrital food chain transfer as the freely available PCDDs in the water column declined (Servos et al. 1992b).

Table 18.4 Effects of 2,3,7,8-TCDD and Other PCDDs on Representative Species of Freshwater Organisms

Taxonomic Group, Organism, Dose, and Other Variables	Effects	Reference ^a
ALGAE AND MACROPHYTES		
Alga, <i>Odegonium cardiacum</i> ; 2.4–4.2 parts per trillion (ng/L) 2,3,7,8-TCDD for 32 days	Bioconcentration factor (BCF) of 6 at day 1, 654–2083 at days 3–32, 500 at day 7 postexposure (pe), and 230 at day 14 pe. Residues of 7000 ng/kg fresh weight (FW) in 5 days, and 2500 ng/kg FW in 30 days	1, 11
Pondweeds, <i>Elodea</i> sp. and <i>Ceratophyllum</i> sp.; 53.7 ng/L 2,3,7,8-TCDD for 30 days	Residues of 7000 ng/kg in 5 days and 2500 in 30 days	2
Duckweed, <i>Lemna minor</i> ; 710 ng/L 2,3,7,8-TCDD for 30 days	No adverse effects	11
MOLLUSCS		
Snail, <i>Helisoma</i> sp.; 2.4–4.2 ng/L 2,3,7,8-TCDD for 32 days	Maximum BCF of 3731	1
Snail, <i>Physa</i> sp.; 200 ng/L 2,3,7,8-TCDD for 36 days	Reduced reproduction at day 12 pe	3
ANNELIDS		
Worm, <i>Paranais</i> sp.; 200 ng/L 2,3,7,8-TCDD for 55 days	Reduced reproduction	3
ARTHROPODS		
Mosquito, <i>Aedes aegypti</i> ; larvae exposed to 200 ng/L 2,3,7,8-TCDD for 17 days	No effect at day 30 pe	3
Daphnid, <i>Daphnia magna</i> 2.4–4.2 ng/L 2,3,7,8-TCDD for 32 days 1030 ng/L 2,3,7,8 TCDD for 48 h, then observed for 7 days	Maximum BCF of 7125 No adverse effects	3 12

Table 18.4 (continued) Effects of 2,3,7,8-TCDD and Other PCDDs on Representative Species of Freshwater Organisms

Taxonomic Group, Organism, Dose, and Other Variables	Effects	Reference ^a
FISHES		
Zebrafish, <i>Brachydanio rerio</i> ; females fed diets equivalent to a single exposure of 1, 5, 10, or 20 ng 2,3,7,8-TCDD per fish. A value of 5 ng 2,3,7,8-TCDD/fish = 1.7–2.0 µg 2,3,7,8-TCDD/kg BW	No significant toxic effects at 1 ng/fish. Doses of 5 ng/fish and higher led to dose-related reduction of egg numbers and to lethal developmental abnormalities in their offspring; ovaries of parents were abnormal histologically	13
Common carp, <i>Cyprinus carpio</i> ; juveniles given single intraperitoneal (ip) injection of 10, 30, 50, 270, 570, or 2930 ng 2,3,7,8-TCDD/kg BW and observed for 6 weeks	Dose-dependent induction of EROD activity at 30 ng/kg BW and higher; lymphocyte depletion at 270 ng/kg and higher. The 270- and 570-ng/kg groups had reduced food intake, severe cutaneous hemorrhages, and swollen eyes. The 570- and 2930-ng/kg groups had liver histopathology. The high-dose group had 60% dead; survivors had reduced growth	14
Northern pike, <i>Esox lucius</i> ; eggs and fry exposed to 0.1 or 10.0 ng/L 2,3,7,8-TCDD for 96 h	Low-dose group had reduced growth that persisted for 21 days; in high-dose group, most died within 23 days	5, 11
Freshwater fishes		
2,3,7,8-TCDD concentrations in eggs of seven species after exposure as fertilized eggs to nominal concentrations of 9–285 ng 2,3,7,8-TCDD/L for up to 540 h. Lowest observed effect concentration (LOEC) in ng/kg FW associated with adverse effects on survival or growth 32 days post exposure vs. no observed effect concentration (NOEC) in ng/kg FW		
Lake herring, <i>Coregonus artedi</i> ; 270 vs. 175	LOEC (after 100 days) vs. NOEC	37
Fathead minnow, <i>Pimephales promelas</i> ; 435 vs. 235	LOEC vs. NOEC	37
Channel catfish, <i>Ictalurus punctatus</i> ; 855 vs. 385	LOEC vs. NOEC	37
Medaka, <i>Oryzias latipes</i> ; 949 vs. 455	LOEC vs. NOEC	37
White sucker, <i>Catostomus commersoni</i> ; 1220 vs. 848	LOEC vs. NOEC	37
Northern pike, <i>Esox lucius</i> ; 1800 vs. 1190	LOEC vs. NOEC	37
Zebrafish, <i>Brachydanio rerio</i> ; 2000 vs. 424	LOEC vs. NOEC	37
Single intraperitoneal injection of 2,3,7,8-TCDD 3–5 µg/kg BW	Estimated LD ₅₀ (80 days postexposure) for sensitive species; fin necrosis in all species	15
10–16 µg/kg BW	Estimated LD ₅₀ (80 days postexposure) for resistant species; fin necrosis in all species	15
60 µg/kg BW radiolabeled 2,3,7,8-TCDD; 6 species	At least 3 TCDD metabolites in addition to the parent compound were found in gall bladder bile of all 6 species and at least 2 metabolites were glucuronide conjugates	15
Mosquitofish, <i>Gambusia affinis</i> ; 2.4–4.2 ng/L 2,3,7,8-TCDD for 15 days	BCF of 676 at day 1 and 1482 at day 7. All dead at day 15, with death preceded by nasal bleeding and listless swimming	1
Channel catfish, <i>Ictalurus punctatus</i> ; 2.4–4.2 ng/L 2,3,7,8-TCDD for 20 days	Fin necrosis, erratic swimming, hemorrhaging from anus and lower jaw, BCF of 2181; all dead between days 15 and 20	1

Table 18.4 (continued) Effects of 2,3,7,8-TCDD and Other PCDDs on Representative Species of Freshwater Organisms

Taxonomic Group, Organism, Dose, and Other Variables	Effects	Reference ^a
Rainbow trout, <i>Oncorhynchus mykiss</i>		
Radiolabeled 1,3,6,8-TCDD; 4–211 ng/L for 5 days; depuration for 24–48 days	Whole fish BCF at equilibrium of 2100; highest concentration in bile; half-time persistence of 6–9 days	20, 25
Radiolabeled OCDD; 9–415 ng/L for 5 days; depuration for 24–48 days	Whole fish BCF at equilibrium was 85; highest concentration in bile; Tb 1/2 of 5–13 days	20, 25
Whole fish bioconcentration factors at equilibrium		
2,3,7,8-TCDD	7762–9270	25
1,2,3,4,7-penta-CDD	810	25
1,2,3,4,7,8-hexa-CDD	2278	25
1,2,3,4,6,7,8-hepta-CDD	1413	25
Single intraperitoneal injection		
0.006, 0.03, 0.06, 0.3, 0.6, or 3.06 µg 2,3,7,8-TCDD/kg BW; juveniles; killed 3, 6, or 12 weeks after injection	The high-dose group had 20% dead at week 12, with lethargy and growth inhibition evident in survivors at week 6. A dose-related increase in EROD activity and total cytochrome P450 content was observed after 3 weeks at dose levels of 0.3 µg/kg BW and higher; the ED50 for EROD activity was 0.8 µg/kg. Six weeks after single injections of 0.3 µg/kg BW and higher, trout had hemorrhages in fins and the skin and significant enzyme induction in spleen and liver	26
0.1 µg 2,3,7,8-TCDD/kg BW; juveniles	Increase in hepatic EROD and AHH activity	28
0.1, 1, 5, 10, 25, or 125 µg 2,3,7,8-TCDD/kg BW; fingerlings and yearlings	Doses of 25 and 125 µg/kg BW resulted in 85% dead 2–4 weeks after injection. Gross and microscopic lesions found in the 10-µg/kg and higher groups. The 5-µg/kg group had reduced growth and 20% dead after 11 weeks. The 1-µg/kg group had leukopenia and thrombocytopenia	27
0.91 µg 2,3,7,8-TCDD/kg BW; juveniles	50% increase in hepatic ethoxresorufin O-deethylase (EROD) activity	28
10.0 µg 2,3,7,8-TCDD/kg BW; fingerlings and yearlings	LD50, single ip injection	27
10.0 µg 2,3,7,8-TCDD/kg BW; juveniles	Maximum reduction in epidermal growth factor receptor in liver plasma membranes 10–40 days after injection	29
Fingerlings given single ip injection of 60 µg 2,3,7,8-TCDD/kg BW	One week after injection, the bile contained at least 3 TCDD metabolites plus the parent compound; at least one of the metabolites was a glucuronide conjugate	31
Oral dose		
4 µg 2,3,7,8-TCDD/kg BW twice with 4-day interval, for a total dose of 8 µg/kg BW	EROD activity increased by 1450% at day 9	33
Single oral dose of 30 µg 2,3,7,8-TCDD/kg BW to seawater-adapted juveniles	Highest TCDD accumulations in visceral and extravisceral fat deposits. But Atlantic cod, <i>Gadus morhua</i> , treated similarly, accumulated TCDDs in liver and brain and to a significantly greater extent than did seawater-adapted rainbows	32
Isolated liver membranes; 0.17 or 0.79 µg 2,3,7,8-TCDD/kg FW	Low dose caused 50% reduction in epidermal growth factor receptor; high dose caused 50% increase in EROD activity	29

Table 18.4 (continued) Effects of 2,3,7,8-TCDD and Other PCDDs on Representative Species of Freshwater Organisms

Taxonomic Group, Organism, Dose, and Other Variables	Effects	Reference ^a
Juveniles (0.4 g BW) exposed for 28 days to 0.038, 0.079, 0.176, 0.382, or 0.789 ng 2,3,7,8-TCDD/L (parts per trillion) followed by 28 days in clean water	Significant adverse effects on survival, growth, and behavior during exposure and depuration at all concentrations tested. The lowest concentration group tested (0.038 ng/L) — which was the least affected — had 45% dead after day 28 of depuration and a whole-body BCF of 39,000 after exposure and about 26,000 after depuration. Controls had 93% survival	30
Eggs held in 0.1 ng/L 2,3,7,8-TCDD for 96 h Yolk-sac fry exposed to 1.0 ng 2,3,7,8-TCDD/L for 96 h	Growth retardation of fry at day 72 pe Growth retarded for 23 weeks	6 11
Juveniles held in 10.0 ng/L 2,3,7,8-TCDD for 96 h	Growth retardation, edema; 26% dead at day 72 pe	6
Immatures held in 107.0 ng/L 2,3,7,8-TCDD for 2 h Immatures held in 107.0 ng/L 2,3,7,8-TCDD for 6 h	Whole-body residues of 1010 ng/kg FW Some deaths beginning at day 78 pe. At day 136 pe, survivors had reduced growth and enlarged livers; tissue residues, in ng/kg FW, were 650 in whole trout, 260 in muscle, 3710 in liver, and 3800 in fat	7 7
Fingerlings fed a diet containing 494 ng radiolabeled 2,3,7,8-TCDD/kg ration for 13 weeks followed by a clean diet for 13 weeks	No overt signs of toxicity. After 13 weeks, more than 90% of the 2,3,7,8-TCDD recovered was in fatty tissues; 98% of the 2,3,7,8-TCDD had not been metabolized. Time for 50% depuration from whole body was 15 weeks and for individual organs 8–19 weeks	31
Coho salmon, <i>Oncorhynchus kisutch</i> ; juveniles 0.56 ng/L 2,3,7,8-TCDD for 48 h 2.05 ng/L 2,3,7,8-TCDD for 96 h	12% dead in 60 days Whole-body residues of 125 ng/kg at day 114 pe	3 9
5.6 ng/L 2,3,7,8-TCDD for 96 h 56.0 ng/L 2,3,7,8-TCDD for 24 h 10.53 ng/L 2,3,7,8-TCDD for 96 h	55% dead in 60 days All dead in 40 days Whole-body residues of 2117 ng/kg at day 114 pe; reduced growth and survival	3, 11 3 9
Medaka, <i>Oryzias latipes</i> Exposed to radiolabeled 2,3,7,8-TCDD for as long as 12 days and then transferred to uncontaminated media for up to 175 days	The predicted steady-state BCF for 2,3,7,8-TCDD in medakas is 510,000. But observed whole-body BCF after 12 days was only 24,000 times the water concentration; this decreased by 47% after 175 days in uncontaminated media	16
Fed diets containing 0.04, 0.4, 1, 4, 10, 40, 100, or 400 mg 1,3,6,8-TCDD/kg ration for 28 days and observed for an additional 60 days. Snails (<i>Indoplanorbis exustus</i>) were given medaka detritus in their diets	No harmful effects in fish, even at highest dose fed of 400 mg 1,3,6,8-TCDD/kg ration. Absorption ranged between 0.05 and 0.1% and almost all was excreted within 8 weeks. Snails, however, were more efficient at absorbing 1,3,6,8-TCDD and their populations were reduced dramatically, even at the lowest dioxin dose fed. Medaka whole-body concentrations, in µg 1,3,6,8-TCDD/kg FW, at day 28 were 13 in the 40 mg/kg group, 65 in the 100 mg/kg group, and 354 in the 400 mg/kg group; by day 84, it was less than 2 µg/kg FW (<17 µg/kg lipid weight) in all groups. Snails at	17

Table 18.4 (continued) Effects of 2,3,7,8-TCDD and Other PCDDs on Representative Species of Freshwater Organisms

Taxonomic Group, Organism, Dose, and Other Variables	Effects	Reference ^a
Yellow perch, <i>Perca flavescens</i> Fed diet containing 424 ng 2,3,7,8-TCDD/kg ration for 13 weeks, then fed clean diet for another 13 weeks	day 28 had 4 µg/kg BW fresh weight (80 µg/kg BW lipid weight) from detritus in the 0.04-mg/kg group and 6534 µg/kg FW (130,680 µg/kg lipid weight) at 400 mg/kg ration	18
Single intraperitoneal injection of 1, 5, 25, or 125 µg 2,3,7,8-TCDD/kg BW	No overt signs of toxicity. After 13 weeks, 78% of the total 2,3,7,8-TCDD was in carcass and visceral fat, and the rest in liver (9%), gill (5%), skin (3%), muscle (2%), and GI tract, pyloric caeca, kidney, spleen, and heart. At least 96% of the 2,3,7,8-TCDD was not metabolized; however, gall bladder bile had 4 TCDD metabolites. The half-time persistence for 2,3,7,8-TCDD in whole body was 18 weeks, and for individual organs 6–19 weeks	19
3 (2–4) µg 2,3,7,8-TCDD/kg BW, single intraperitoneal injection	Hepatocyte lipidosis in all groups. Dose-related splenic lymphoid depletion in perch given 5 µg/kg BW and higher. The 5-µg/kg group had progressive loss of body weight and 80% mortality by day 80 postinjection. The 25- and 125-µg/kg groups had 95% dead within 28 days postinjection. Groups given 5 µg/kg and higher had fin necrosis, ascites, and petechial cutaneous hemorrhage	19
Fathead minnow, <i>Pimephales promelas</i> Half-time persistence of various PCDDs 1,2,3,7-TCDD 1,3,6,8-TCDD 2,3,7,8-TCDD 1,2,3,4,7,8-hexa-CDD 1,2,3,4,6,7,8-hepta-CDD OCDD 9–415 ng/L OCDD for 5 days and depuration for 48 days	LD50 (80 days postinjection) 2.7 days 6.9 days 14.5–58 days 3.1 days 17.3 days 13.9 days BCF for whole minnows was 2200 with highest concentrations in bile; half-time persistence of 5–13 days	19 12 12 12 12 12 20
4–211 ng/L 1,3,6,8-TCDD for 5 days and depuration for up to 48 days	Whole fish BCF of 5702 with highest concentrations in bile; half-time persistence of 6–9 days	20
0.9 ng/L 2,3,7,8-TCDD for 28 days, then uncontaminated media for 28 days	Whole-body BCF was 5840 and whole-body residue of 15–25 µg/kg DW on day 28; steady state not achieved	12
1.7 ng/L 2,3,7,8-TCDD 53.7 ng/L 2,3,7,8-TCDD for 40 days	LC50 (28 days) Survivors had whole-body residues of 8500 ng/kg in 10 days, 2500 ng/kg in 40 days	12 2
Guppy, <i>Poecilia reticulatus</i> ; adults Exposed to a complex mixture of radiolabeled PCDDs and dibenzofurans for 21 days 0.01 ng/L 2,3,7,8-TCDD for 24 h 1.0 ng/L 2,3,7,8-TCDD for 24 h	Highest uptake was by 2,3,7,8-substituted isomers; whole-body BCF values were log 5.24 for 2,3,7,8-TCDD and log 5.27 for 1,2,3,7,8-penta-CDD No effect at day 32 pe LC50 at day 42 pe	21 9 9

Table 18.4 (continued) Effects of 2,3,7,8-TCDD and Other PCDDs on Representative Species of Freshwater Organisms

Taxonomic Group, Organism, Dose, and Other Variables	Effects	Reference ^a
1.1 ng/L 2,3,7,8-TCDD for 24 h	Fin disease after 42 days	9
10.0 ng/L 2,3,7,8-TCDD for 24 h	10% dead within 41 days pe	11
100.0 ng/L 2,3,7,8-TCDD for 24 h	Fin necrosis in 10 days; all dead at day 32 pe	10
Brook trout, <i>Salvelinus fontinalis</i>		
Adults fed various dietary concentrations of 2,3,7,8-TCDD for extended period to produce eggs that contain 0, 41, 84, 156, 285, or 517 ng 2,3,7,8-TCDD/kg FW	No effect on adult fertility and growth or on juvenile sex ratios. All exposed groups had edema in free embryos at hatch. Egg concentrations of 41 and 117 ng/kg caused 13.8% and 50% exophthalmia in juveniles, respectively; 138 ng/kg egg caused 50% kill at swimup	36
Newly fertilized eggs exposed to various concentrations of 2,3,7,8-TCDD for 48 h to produce 101–470 ng 2,3,7,8-TCDD/kg FW egg, then transferred to clean water until hatch	Dose-related increases in sac-fry mortality associated with yolk-sac edema hemorrhages and arrested development; signs resembled blue-sac disease	22
135 ng 2,3,7,8-TCDD/kg FW egg	NOEL for sac-fry mortality	22
185 ng 2,3,7,8-TCDD/kg FW egg	LOEL for increased mortality	22
200 (179–215) ng 2,3,7,8-TCDD/kg FW egg	LD50, sac fry	22
324 (283–488) ng 2,3,7,8-TCDD/kg FW egg	LD100, sac fry	22
Adults, age 18 months, fed diets containing stable and radiolabeled 2,3,7,8-TCDD for various periods to produce whole-body concentrations as high as 1200 ng/kg BW	At 600 ng/kg BW, no adverse effects on survival, growth, or reproduction. At 1200 ng/kg BW, spawning was delayed 13 days. Dietary assimilation of 2,3,7,8-TCDD is high at 89% and is independent of time and whole-body TCDD burdens. Regardless of dose, ovarian tissues of adult females had 74% of the whole-body 2,3,7,8-TCDD concentration on a lipid weight basis and 61% on a nonlipid basis. Spawning eggs had 39% of the whole-body 2,3,7,8-TCDD concentration on a nonlipid basis	34
Lake trout, <i>Salvelinus namaycush</i>		
Fertilized eggs were exposed for 48 h to graded concentrations (0, 0.1, 1, 10, or 100 ng 2,3,7,8-TCDD/L) to achieve egg concentrations of 0, <15, 40, or 400 ng 2,3,7,8-TCDD/kg FW egg. Eggs were then transferred to flowing uncontaminated media through hatch	Development normal in all groups until 1 week prior to hatch. At this time, embryos and sac fry in the 400-nug/kg group had a variety of hemorrhages and experienced low survival at hatch; survivors developed severe subcutaneous edema and all died prior to swimup. Blue sac disease occurred at 2% frequency in the 40 ng/kg group versus 1% in the <15 and control groups	23
Fertilized eggs were exposed for 48 h to 10, 20, 40, 62, or 100 ng 2,3,7,8-TCDD/L to produce 2,3,7,8-TCDD concentrations in eggs of 34, 55, 121, 226, or 302 ng/kg FW, then transferred to uncontaminated media through hatching	TCDDs were not eliminated by eggs or sac fry, but were rapidly eliminated (Tb 1/2 of 35–37 days) from fry. Hatchability was reduced at 226 and 302 ng/kg egg, with greatest mortality at the sac-fry stage. In all TCDD groups, sac fry that died developed subcutaneous yolk-sac edema. There were no deaths at egg concentrations of 34 ng/kg and some deaths at 55 ng/kg	24
Egg concentrations of 50 ng 2,3,7,8-TCDD/kg FW and higher, regardless of route of transfer (injection, ambient medium, internal transfer)	Fry exposed as eggs show pericardial and yolk-sac edema, subcutaneous hemorrhaging, craniofacial alterations, arrested development, and frequently death	35

Table 18.4 (continued) Effects of 2,3,7,8-TCDD and Other PCDDs on Representative Species of Freshwater Organisms

Taxonomic Group, Organism, Dose, and Other Variables	Effects	Reference ^a
Egg concentrations of 65 ng 2,3,7,8-TCDD/kg FW Adult whole-body concentrations of 78 ng 2,3,7,8-TCDD/kg FW	Associated with 50% mortality by swimup Reproduction inhibited	34 34
AMPHIBIANS

18.4.4 Birds

LD50 values computed 37 days after a single oral dose of 2,3,7,8-TCDD varied from 15 µg/kg body weight in northern bobwhite (*Colinus virginianus*), with 95% confidence limits of 9.2 and 24.5 µg/kg, to more than 810 µg/kg body weight for the ringed turtle-dove (*Streptopelia risoria*). Mallards (*Anas platyrhynchos*) were intermediate in sensitivity, with an acute oral LD50 value of more than 108 µg/kg body weight (Hudson et al. 1984). For all three species, death occurred 13 to 37 days after treatment. Remission in survivors had apparently occurred by day 30 posttreatment. Gross necropsy of ringed turtle-doves that survived treatment showed enlarged livers, about twice normal size. Bobwhites showed severe emaciation, high accumulations of uric acid salts in connective tissues, and fluid accumulations in the pericardial and abdominal cavities (Hudson et al. 1984). Some birds regurgitated within a few minutes after treatment. Signs of intoxication that began 7 days after treatment included excessive drinking, loss of appetite, hypoactivity, emaciation, weakness, debility, muscular incoordination, increased reaction to stimuli, fluffed feathers, huddled position, unkempt appearance, falling, tremors, spasms, convulsions, and immobility (Hudson et al. 1984).

In ovo exposure to dioxins is associated with development of grossly asymmetric avian brains, especially the forebrain and tectum. Brain asymmetry was observed in herons, cormorants, eagles, and chickens exposed to 2,3,7,8-TCDD under controlled conditions. Asymmetry appears with increasing frequency and severity in embryos and hatchlings exposed to increasing doses of 2,3,7,8-TCDD, beginning early in development (Henshel 1998). Injection of 1.3 to 11.7 µg 2,3,7,8-TCDD/kg FW egg into yolks of the double-crested cormorant (*Phalacrocorax auritus*) prior to incubation produced an LD50 at hatch of 4.0 µg/kg; hepatic EROD activities were elevated in all treatment groups when compared to controls, but development was normal (Powell et al. 1998).

Studies with 2,3,7,8-TCDD and various life stages of the ring-necked pheasant (*Phasianus colchicus*) by Nosek and co-workers (Nosek et al. 1992a, 1992b, 1993) showed several trends:

1. Hens given a single intraperitoneal (ip) injection of 25 µg/kg BW and higher had reduced growth and survival during an 11-week observation period.
2. Hens given weekly ip injections of 1.0 µg/kg BW for 10 weeks had reduced egg production and hatchability, and a wasting disease that proved fatal to 100% by 13 weeks after the last injection.
3. Hens given weekly ip injections for 10 weeks prior to egg laying of 0.1 µg/kg BW had no adverse effects on growth, reproduction, or survival; translocation of 2,3,7,8-TCDD to egg yolks indicates that egg laying is an important route of elimination.
4. The half-time persistence of 2,3,7,8-TCDD in hatchlings exposed as embryos is about 13 days; for adult hens not producing eggs, the half-time persistence of radiolabeled 2,3,7,8-TCDD is 378 days.
5. The most sensitive effect of *in ovo* exposures was induction of hepatic ethoxyresorufin O-deethylase (EROD) activity in 1-day-old chicks, with an ED50 dose of 0.312 µg/kg FW egg.
6. LD50 values for embryos were 1.35 µg/kg egg when injected into the egg albumin and 2.18 µg/kg when injected into the egg yolk.
7. No adverse effects on 1-day-old hatchlings and 28-day-old chicks on growth, survival, development, and metabolism were observed at egg 2,3,7,8-TCDD doses up to and including 1.0 µg/kg.
8. Embryo mortality is the most sensitive sign of 2,3,7,8-TCDD toxicity in the ring-necked pheasant; pheasant embryos were more sensitive to 2,3,7,8-TCDD than were embryos of the eastern bluebird (*Sialia sialis*), but less sensitive than embryos of the domestic chicken (*Gallus* sp.).

Domestic chickens were relatively sensitive to PCDDs, especially 2,3,7,8-TCDD, with an estimated 2,3,7,8-TCDD oral LD50 range of 25 to 50 µg/kg body weight (Kociba and Schwetz 1982a, 1982b). EROD induction by 2,3,7,8-TCDD in avian hepatocytes of five species followed a concentration-response relation in livers of hatchlings. Chickens were the most sensitive species tested, followed by the double-crested cormorant, ring-billed gull (*Larus delawarensis*), herring gull, and Forster's tern (Sanderson et al. 1998). Chickens fed 1 or 10 µg 2,3,7,8-TCDD, 1,2,3,7,8,9-hexa-CDD, or hepta-CDDs per kilogram body weight daily for 21 days showed signs of chick edema disease, that is, pericardial, subcutaneous, and peritoneal edema; liver enlargement and necrosis with fatty degeneration; and frequently died (NRCC 1981; Gilbertson 1983). Autopsies of poultry killed by 2,3,7,8-TCDD in Seveso, Italy, in 1976 showed signs characteristic of chick edema disease (Fanelli et al. 1980b). Pathological signs of chick edema disease were also seen in herring gull chicks on the lower Great Lakes in the early 1970s (Gilbertson 1983). Concentrations of 2,3,7,8-TCDD in eggs of the herring gull declined from about 1000 ppt in 1971 to less than 80 ppt in 1981. This was accompanied by a decrease in the frequency of chick edema disease (Gilbertson 1983). Decreases in levels of other contaminants — notably mirex — were probably more important to the survival of gulls in these colonies than 2,3,7,8-TCDD (Eisler 1985). However, little data exist on the interaction of PCDDs, including 2,3,7,8-TCDD, with other contaminants appearing concomitantly in bird tissues or their diets. Although there presently is no evidence of biomagnification of PCDDs in birds (Gilbertson 1983), it is speculated that piscivorous birds have a greater potential to accumulate PCDDs than the fish that they eat (NRCC 1981).

18.4.5 Mammals

Many industrial accidents involving malfunctioning reaction vessels used to manufacture chlorinated phenols or phenoxy herbicides have exposed more than 1300 workers to short-term, high-level doses of the dioxins that occur as contaminants of these substances (Boddington et al. 1990). Exposures have frequently been associated with acne-like skin lesions, dermatitis, altered liver enzyme concentrations, pulmonary deficiency, numbness, nausea, headache, hearing loss, sleep disturbance, tiredness, sexual dysfunction, depression, and appetite loss. Populations exposed to dioxin-contaminated materials through nonoccupational sources — including dioxin-contaminated soils in Missouri, a trichlorophenol reactor explosion in Italy, a dioxin-containing herbicide in Vietnam, and assorted laboratory accidents — have all experienced similar effects (WHO 1989; Boddington et al. 1990).

The International Agency for Research on Cancer (IARC) concludes that there is inadequate human data but sufficient animal data for 2,3,7,8-TCDD to be a possible human carcinogen (Boddington et al. 1990). In rats, carcinomas in liver, pharynx, skin, lung, and thyroid were documented at daily dosages of 0.01 to 0.1 µg 2,3,7,8-TCDD/kg body weight; comparable values for mice were 0.03 to 0.07 µg/kg body weight (Kociba and Schwetz 1982a, 1982b; Rappe 1984; WHO 1989; Andersen et al. 1993). No response occurred at continuous daily dose levels of 0.001 to 0.0014 µg/kg body weight in rats and 0.001 to 0.03 in mice. Carcinogenic or cocarcinogenic effects were also induced in rodents by 1,2,3,6,7,8-hexa-CDD and 1,2,3,7,8,9-hexa-CDD, but only at high dose levels (Rappe 1984). In rodents, 2,3,7,8-TCDD was a potent tumor promoter and inducer of the cytochrome P-450 1A family, especially in liver, lungs, and kidneys (Beebe et al. 1992; Andersen et al. 1993). In Seveso, Italy, a follow-up study of the human population between 1976 and 1986 showed an increased cancer incidence of soft tissue sarcoma, and hepatobiliary and hematologic neoplasms (Pesatori et al. 1992). Workers exposed to 2,3,7,8-TCDD or higher chlorinated dioxins had an increased risk for all neoplasms, especially soft tissue sarcomas, compared with workers from the same cohort exposed to phenoxy herbicides and chlorophenols but with minimal or no exposure to 2,3,7,8-TCDD and higher chlorinated dioxins (Kogevinas et al. 1997). In 1997, the IARC reclassified 2,3,7,8-TCDD as a Group 1 human carcinogen (USPHS 1998).

The greater toxic potential of certain PCDD isomers involves two properties: halogen atoms occupying at least three of the four lateral ring positions (2,3,7,8 positions) and at least one of the adjacent ring positions being nonhalogenated (Kociba and Schwetz 1982a, 1982b). Comparative toxicity data for selected PCDD isomers to the guinea pig (*Cavia* sp.) and the mouse (*Mus* sp.) confirmed this generalization and demonstrated significant interspecies differences in sensitivity (Table 18.5). Other PCDD isomers tested (2,8-di CDD, octa-CDD) were relatively nontoxic to mice and guinea pigs (NRCC 1981). In marmoset monkeys (*Callithrix jacchus*) given a subcutaneous injection of a mixture of PCDDs and PCDFs, only the 2,3,7,8-substituted congeners were detected at high concentrations in liver and fat, equivalent to 25% of the administered dose for 2,3,7,8-TCDD to 74% for 2,3,4,6,7,8-hexa-CDD (N. Neubert et al. 1990). The half-time persistence of 2,3,7,8-TCDD was about 8 weeks in hepatic tissues and 11 weeks in adipose tissue. Half-time persistence increased with increasing chlorination and, in the case of OCDD, there was no loss of accumulated OCDD after 28 weeks (N. Neubert et al. 1990; 1992).

Table 18.5 Acute Toxicities of Selected PCDD Isomers to the Guinea Pig and the Mouse

PCDD Isomer	Oral LD50 (g/kg body weight)	
	Guinea Pig	Mouse
2,8-di-CDD	>300,000	—
2,3,7-tri-CDD	29,444	>3000
2,3,7,8-TCDD	2	284
1,2,3,7,8-penta-CDD	3	338
1,2,4,7,8-penta-CDD	1125	>5000
1,2,3,4,7,8-hexa-CDD	73	825
1,2,3,6,7,8-hexa-CDD	70–100	1250
1,2,3,7,8,9-hexa-CDD	60–100	>1440
1,2,3,4,6,7,8-hepta-CDD	>600	—

Data from Kociba, R.J. and B.A. Schwetz. 1982b. A review of the toxicity of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) with a comparison to the toxicity of other chlorinated dioxin isomers. *Assoc. Food Drug Off. Quart. Bull.* 46:168-188.

Acute toxicity studies with 2,3,7,8-TCDD have shown marked differences — up to 8400 times — between the single oral LD50 dose for the guinea pig and the hamster (*Cricetus* sp.) (Table 18.6). The acute oral LD50 value of 0.6 µg/kg body weight for guinea pigs suggests that 2,3,7,8-TCDD

may be the most toxic compound ever tested on small laboratory animals. The unusual resistance of hamsters may be associated with its enhanced rate of metabolism and excretion of 2,3,7,8-TCDD relative to other PCDD isomers examined (Olson et al. 1980b; NRCC 1981; WHO 1989). Poisoning in mammals by 2,3,7,8-TCDD is typically characterized by loss of body weight, shrinkage of the thymus, and delayed lethality; large interspecies differences exist in lethal dosages and toxic effects (Vos 1978; Neal et al. 1979; Kociba and Schwetz 1982a, 1982b; Josephson 1983; Matsumura 1983; Kimbrough 1984; Seefeld et al. 1984; WHO 1989; Boddington et al. 1990). For example, 2,3,7,8-TCDD produces prominent chloracne-type skin lesions in man and monkeys, edema formation in birds, and severe liver damage in rats, mice, and rabbits.

Studies with mink (*Mustela vison*) indicate that route of administration, age, and sex of the animal influence 2,3,7,8-TCDD toxicity. Adult male minks given a single oral dose showed a dose-dependent decrease in food consumption and body weight, and a calculated LD₅₀ after 28 days of 4.2 µg/kg BW (Hochstein et al. 1988). Livers, spleens, and kidneys were discolored after a single oral dose of 2,3,7,8-TCDD and, at high sublethal doses, the brain, kidneys, heart, thyroid, and adrenals were enlarged (Hochstein et al. 1988). Newborn mink kits given 0.1 or 1.0 µg/kg BW daily by intraperitoneal injection for 12 consecutive days had mortality in excess of 50% in the high-dose group and growth rate reduction at 0.1 µg/kg BW daily (Aulerich et al. 1988). Adult minks fed diets containing 1.0 to 80.8 ng 2,3,7,8-TCDD equivalents/kg ration for 85 days (equivalent to total ingestion of 23 to 1019 ng 2,3,7,8-TCDD) prior to and throughout the reproductive period had impaired reproduction with reduced body weights and survival in a dose-dependent manner (Heaton et al. 1995). Females in the highest dose group whelped the fewest number of kits, all of which were stillborn or died with 24 h. For adult females, a value of 3.6 ng 2,3,7,8-TCDD equivalents/kg BW daily was determined for the lowest observable adverse effect level (Heaton et al. 1995). Adult females fed diets containing 0.001, 0.01, 0.1, 1, 10, or 100 µg 2,3,7,8-TCDD/kg ration for up to 125 days showed a dose-dependent decrease in food consumption and body weight (Hochstein et al. 1998). At day 125, 63% of the 1-µg/kg group, and 100% of the 10- and 100-µg/kg groups had died. Calculated LD₅₀ values were 4.8 µg 2,3,7,8-TCDD/kg diet at day 28 and 0.85 µg/kg diet at day 125, equivalent to 0.264 µg 2,3,7,8-TCDD/kg BW daily for the 28-day exposure and 0.047 µg/kg BW daily for the 125-day exposure (Hochstein et al. 1998).

Table 18.6 Acute Oral Toxicities of 2,3,7,8-TCDD to Mammals

Organism	LD ₅₀ (g/kg body weight [ppb])	Reference ^a
Guinea pig, <i>Cavia</i> sp.	0.6–2.0	1, 2, 5
In corn oil	2.5	3
In aqueous methyl cellulose	19.0	3
Mink, <i>Mustela vison</i> ^b	4.2	7, 8
Rat, <i>Rattus</i> sp.	22–45	2, 5
Rhesus monkey, <i>Macaca mulatta</i>	<70	4, 6
Dog, <i>Canis familiaris</i>	100–200	2, 5
Mouse, <i>Mus</i> sp.	114–284	2, 5
Rabbit, <i>Oryctolagus</i> sp.	115	4, 6
Hamster, <i>Cricetus</i> sp.	1157–5051	2, 5

^a 1, Harless et al. 1982; 2, Kociba and Schwetz 1982a; 3, Silkworth et al. 1982; 4, Olson et al. 1980a; 5, Kociba and Schwetz 1982b; 6, Olson et al. 1980b; 7, Hochstein et al. 1988; 8, Boddington et al. 1990.

^b Calculated LD₅₀ values for adult females fed 2,3,7,8-TCDD diets were 0.264 µg 2,3,7,8-TCDD/kg BW daily for a 28-day exposure period and 0.047 µg/kg BW daily for a 125-day exposure period (Hochstein et al. 1998).

Intraspecies differences in sensitivity to 2,3,7,8-TCDD — up to 14-fold — are reported among three strains of mice; no reasons were given to account for these differences. Oral LD₅₀ (30-day) values varied from 182 µg 2,3,7,8-TCDD per kg body weight in strain C57, the most sensitive

strain tested, to 296 for strain BD6, to 2570 for strain DBA (Chapman and Schiller 1985). All three strains of mice evidenced a 25 to 34% weight loss prior to death; however, there was no measurable decline in food consumption.

Atrophy of the thymus is a consistent finding in mammals poisoned by 2,3,7,8-TCDD, and suppression of thymus-dependent cellular immunity, particularly in young animals, may contribute to their death. Although the mechanisms of 2,3,7,8-TCDD toxicity are unclear, research areas include the role of thyroid hormones (Rozman et al. 1984); interference with plasma membrane functions (Matsumura 1983); alterations in ligand receptors (Vickers et al. 1985); the causes of hypophagia (reduced desire for food) and subsequent attempts to alter or reverse the pattern of weight loss (Courtney et al. 1978; Seefeld et al. 1984; Seefeld and Peterson 1984); and excretion kinetics of biotransformed metabolites (Koshakji et al. 1984).

Teratogenic and fetotoxic effects of 2,3,7,8-TCDD are well documented in several species of animals (Marless et al. 1982; Kociba and Schwetz 1982a, 1982b; Kimbrough 1984; Weber et al. 1985). Cleft palate in young mice was associated with daily dosages of 1.0 µg 2,3,7,8-TCDD per kg body weight in pregnant females (no-effect level at 0.1 µg/kg), and intestinal hemorrhage was found in sensitive strains of rats given daily dosages of 0.125 µg/kg body weight (no-effect level at 0.03 µg/kg) (Kociba and Schwetz 1982a, 1982b). Developing mammalian fetuses are especially sensitive to 2,3,7,8-TCDD, and maternal exposure results in increased frequencies of stillbirths. Among live births, exposure to 2,3,7,8-TCDD produces teratogenic effects such as cystic kidney, cleft palate, and spinal column deformities (Ramel 1978). Effects of 2,3,7,8-TCDD on reproduction are reported for rats (McNulty 1977; Murray et al. 1979; Kociba and Schwetz 1982a, 1982b; WHO 1989; Boddington et al. 1990) and monkeys (Ramel 1978; Barsotti et al. 1979; NRCC 1981; Kociba and Schwetz 1982a, 1982b; WHO 1989; R. Neubert et al. 1990). In a three-generation study with rats, daily dose levels of 0.01 µg 2,3,7,8-TCDD/kg body weight (equivalent to 120 to 290 ppt or ng/kg in the diet) produced decreased litter size at birth, increased the number of stillborns, and reduced the survival and growth of young in both the F1 and F2 generations. In rats, no adverse effect occurred at daily dosages of 0.001 µg/kg BW — equivalent to 12 to 30 ng/kg 2,3,7,8-TCDD in the diet — on growth, survival, reproduction, metabolism, or cancer incidence during exposure for three generations. Abortion and weight loss were reported in rhesus monkeys (*Macaca mulatta*) at dietary levels as low as 50 ppt 2,3,7,8-TCDD (about 0.0017 µg/kg body weight daily) after 7 to 29 months. However, comparatively high dosages (200 ppt in diets equivalent to 0.0095 µg/kg body weight daily) could be tolerated by monkeys for short periods (three times weekly for 3 weeks) with no adverse effects on reproduction. Higher dose levels for extended periods (i.e., 500 ppt in diets equivalent to about 0.011 µg/kg body weight daily for 9 months) caused death (63%) or, among survivors, abortion, chloracne, nail loss, scaly and dry skin, and progressive weakness. Most treated monkeys remained fairly alert to external stimuli until just prior to death. On removal from the 500-ppt 2,3,7,8-TCDD diet and transfer to an uncontaminated diet, a severely affected monkey became pregnant and gave birth to a well-developed infant after an uneventful gestation. This suggests that some 2,3,7,8-TCDD damage effects are not permanent.

Androgenic deficiency in male rats given a single oral dose of 15 µg 2,3,7,8-TCDD/kg BW was evident as early as 2 days posttreatment, with persistence up to 12 days. These deficiencies may account for male reproductive pathology and dysfunction in rats treated with overtly toxic doses of TCDD. Findings included depression in plasma testosterone concentrations, as well as decreased weight of seminal vesicles (by 68%), ventral prostate gland (by 48%), testes, and epididymis (Moore et al. 1985).

Accumulation of 2,3,7,8-TCDD is reported in the liver of rats during lifetime exposure to diets containing 0.022 µg 2,3,7,8-TCDD/kg (Newton and Snyder 1978), or when administered orally at 0.01 µg/kg body weight once a week for 45 weeks (Cantoni et al. 1981). Liver residues of rats fed 2,3,7,8-TCDD were 0.54 µg/kg, or about 25 times dietary levels; livers of rats dosed orally contained 1.05 µg/kg, or about 2.3 times the total dose received on a unit weight basis. Unlike toxicity, elimination rates of accumulated 2,3,7,8-TCDD were within a relatively narrow range. The estimated retention times of 2,3,7,8-TCDD in small laboratory mammals (rats, mice, guinea pigs, and

hamsters) extended from 10.8 to 30.2 days for 50% elimination and seemed to be little influenced by species, concentration administered, duration of dose, or route of administration (Blair 1973; Olson et al. 1980b; NRCC 1981; Koshakji et al. 1984). Half-time persistence in primates is usually lengthy: about 1 year in most species of monkeys and 5.8 years in humans (Boddington et al. 1990), although the half-time persistence of 2,3,7,8-TCDD in marmoset monkeys (*Callithrix jacchus*) is only 6 to 8 weeks (N. Neubert et al. 1992).

Histopathological effects have been reported in rabbits and horses poisoned by 2,3,7,8-TCDD. Rabbits surviving exposure to an industrial accident in Seveso, Italy, in which 2,3,7,8-TCDD was released, had edema, hemorrhagic tracheitis, pleural hemorrhage, and dystrophic lesions of hepatic tissue (Fanelli et al. 1980b). Horses from Missouri that died after waste oil contaminated with 2,3,7,8-TCDD was applied as a dust control agent in riding arenas had liver lesions, skin hyperkeratosis, gastric ulcers, and lung and kidney lesions (Kimbrough 1984). Since 2,3,7,8-TCDD is an extremely potent porphyrogenic agent, it is probable that these animals also exhibited porphyria, a condition characterized by fragility of the skin, photosensitivity, and accumulation of porphyrins in the liver (Cantoni et al. 1981).

Thermoregulatory function and Vitamin A metabolism in rodents are altered by 2,3,7,8-TCDD. Perinatal exposure to 2,3,7,8-TCDD alters thermoregulatory function in adult rats and hamsters, as judged by a reduced body temperature during sleep; however, normal behavioral regulation suggests that hypothalamic thermoregulatory centers are not permanently altered (Gordon and Miller 1998). For example, pregnant rats exposed on gestational day 15 to 1 µg 2,3,7,8-TCDD/kg BW by gavage produced male offspring with reduced body temperature during nocturnal phases; TCDD-treated rats given endotoxins had higher fevers than controls (Gordon and Miller 1998). Rats given a single oral dose of 10 µg 2,3,7,8-TCDD/kg BW had altered Vitamin A turnover and inhibited hepatic accumulation of dietary Vitamin A, and this is attributed to a combination of inhibited retinol esterification in hepatic cells, increased release of endogenous Vitamin A, and increased hepatic catabolism of retinoids (Hansberg et al. 1998).

Interaction effects of PCDDs with other polychlorinated compounds or mixtures are not extensively documented. For example, certain polychlorinated hexachlorobiphenyls (PCBs) have a low toxic potency to induce cleft palate deformities in mice (Birnbaum et al. 1985). However, mixtures of 2,3,7,8-TCDD and 2,3,4,5,3',4'-hexachlorobiphenyl resulted in a tenfold increase in incidence of cleft palate in mice. Thus, the toxicity of compounds such as 2,3,7,8-TCDD may be enhanced by compounds of relatively low acute toxicity, such as selected PCBs. Birnbaum et al. (1985) concluded that the widespread environmental occurrence of such combinations suggests a need for further evaluation of the mechanism of this interaction.

18.5 RECOMMENDATIONS

No criteria or standards have been promulgated for any of the 75 PCDD isomers by any regulatory agency for the protection of sensitive species of wildlife and aquatic organisms — except 2,3,7,8-TCDD (Table 18.7). Data are scarce or missing on the distribution and upper limits of background levels of PCDDs in natural resources (except 2,3,7,8-TCDD), on the identification of fish and wildlife resources potentially at risk, on the relative importance of PCDD sources, and on the comparative toxicities of various PCDDs to fish and wildlife, especially reproductive and immunosuppressive toxicities (NRCC 1981; Eisler 1986; WHO 1989; USEPA 1993). Multigeneration reproductive studies are recommended for the most widespread PCDDs, including 1,2,3,7,8-penta-CDD and -OCDD (WHO 1989). Improved analytical accuracy and standardized protocols are needed in PCDD sampling techniques to account for the organic content of sediments, dissolved organic content of water, and lipid content of samples (WHO 1989; Fletcher and McKay 1993). The stability and mobility of organic-associated PCDDs and their partitioning between substrates need clarification (Fletcher and McKay 1993).

Lethality of 2,3,7,8-TCDD to freshwater teleosts is documented at concentrations as low as 0.038 ng/L in water and 55 ng/kg FW in sac fry ([Table 18.7](#)). It is noteworthy that water column concentrations of 2,3,7,8-TCDD immediately downstream of 89% of 104 chlorine-bleaching pulp and paper mills exceeded 0.038 ng/L (USEPA 1990). More research is needed on dietary routes of PCDD exposure to aquatic organisms. A simple apparatus for loading 2,3,7,8-TCDD and other chemicals onto commercially available, pelletized fish food is now available (Fernandez et al. 1998). Recommended safe levels for aquatic life protection are 0.01 ng/L in water and 34 ng/kg FW tissue, and these confer a degree of protection — based on lethal action — of 1.6 to 3.8 times ([Table 18.7](#)). Values for 2,3,7,8-TCDD protection of freshwater aquatic life are in sharp contrast to those recommended for birds and mammals, which were usually derived from the highest concentration tested that produced no observed adverse effect, and on uncertainty factors of 100 or more ([Table 18.7](#)). Proposed 2,3,7,8-TCDD criteria for birds include <12 ng/kg FW ration, whole-body concentrations of <1 ng/kg BW in domestic chickens and <6 ng/kg BW in woodcocks, and <20 ng/kg FW in wood duck eggs ([Table 18.7](#)). Concentrations of 2,3,7,8-TCDD as high as 50 ng/kg in soil were not likely to produce adverse effects in woodcocks, nor does this soil concentration present a significant risk to humans who may consume game birds inhabiting these sites (Keenen et al. 1990). Proposed criteria for non-human mammals include <0.01 ng/kg BW daily from all sources and 10 to 30 ng/kg ration ([Table 18.7](#)). To protect human health, edible fish tissues should contain <25 ng/kg FW in most states and <10 ng/kg FW in New York; dairy cattle need to be grazed on soils containing <6 ng/kg FW; drinking water should contain <0.015 ng/L and ambient air <0.03 ng/m³. Food items containing more than 50 ng/kg FW are considered unsafe for human consumption, but fish fillets containing between 25 and 50 ng/kg of 2,3,7,8-TCDD may be eaten once weekly by occasional consumers of fish, and twice monthly for those who eat contaminated fish year-round ([Table 18.7](#)). It is not known at this time whether residues of 10 to 50 ng/kg (or higher) of 2,3,7,8-TCDD in fish flesh represent an unacceptable risk to the growth, survival, reproduction, metabolism, or behavior of the teleost, or to its predators; clearly, this is a high-priority research topic. Also, mechanisms of PCDD toxicity need to be established in mammals, birds, and poikilotherms to support extrapolation to humans and other species (WHO 1989; USEPA 1993).

More research is needed on factors that alter bioconcentration, toxicokinetics, and metabolism of PCDDs (Cooper 1989). For example, field bioconcentration factors (BCF) for 2,3,7,8-TCDD in fish from contaminated rivers in Maine ranged from 3000 to 106,000, and most exceeded the value of 5000 recommended by the U.S. Environmental Protection Agency. BCF values between 15,000 and 25,000 are now considered a reasonable estimate of the BCF for use in regulatory purposes in the state of Maine (Frakes et al. 1993). Mixtures of 2,3,7,8-TCDD and PCB 77 were slighter greater than additive in toxicity to rainbow trout (Newsted et al. 1995), indicating a need for more research on chemical interactions. Daily intakes of PCDDs vary substantially between and within species, and this needs to be incorporated into future models of risk assessment (Law and Gudaitis 1994). In humans, for example, daily intake of 2,3,7,8-TCDD — on a ng/kg BW basis — is 78 times higher in neonates than adults, and 2.3 times higher in children and 5.2 times higher in infants than adults (Boddington et al. 1990).

In the past, the major source of 2,3,7,8-TCDD in the environment was as a contaminant in phenoxy herbicides (such as 2,4,5-T; Silvex; 2,4-D; and Agent Orange), in hexachlorophene, and in other chlorophenol-type compounds. Concentrations of 2,3,7,8-TCDD in some of these products exceeded 60,000 µg/kg. This situation has been largely corrected by new manufacturing processes and by increasingly stringent federal regulations (NRCC 1981; Choudhary et al. 1983; Stolzenburg and Sullivan 1983; NIOSH 1984; Rappe 1984). For example, the 2,3,7,8-TCDD level in 2,4,5-T has decreased from 60,000 µg/kg in 1957 to 2000 µg/kg in 1965 as a result of new manufacturing processes, and it was limited to 500 µg/kg in 1970 by the Canadian federal government. In 1970, the U.S. Department of Defense halted the spraying of Agent Orange. In 1972, the U.S. Food and Drug Administration banned the use of hexachlorophene in nonprescription soaps and deodorants.

In 1978, 7 of 14 major producers of 2,4,5-T no longer manufactured this product, and the remainder claimed that their products contained less than 100 µg/kg of 2,3,7,8-TCDD. In 1979, production of 2,4,5-T and Silvex ceased in the United States, although stockpiles of both are still being distributed and permitted for use on rice fields, sugarcane fields, orchards, fence rows, vacant lots, and lumber yards. In 1982, the USEPA required some industries to certify that chlorophenol-type compounds would no longer be used as slime control agents. On October 18, 1983, the USEPA published its intent to cancel the registration of pesticide products containing 2,4,5-T and Silvex, and to prohibit the transfer, distribution, sale, or importation of any unregistered product containing 2,4,5-T, Silvex, or their derivatives (NIOSH 1984). Continued monitoring is recommended of food, air, and sediments, including time trends and determinations of isomer patterns (WHO 1989).

Burning or heating of commercial and purified chlorophenates, and pyrolysis of polychlorinated biphenyls contaminated with trichlorobenzenes can result in the production of 2,3,7,8-TCDD and other PCDDs (NIOSH 1984). These sources, together with discharges from various municipal and industrial incinerators of chlorinated compounds, probably constitute the largest source of PCDDs in the environment today. In 1983, the U.S. Environmental Protection Agency proposed to monitor 2,3,7,8-TCDD in the environment (Stolzenburg and Sullivan 1983; WHO 1989). Specific goals of the monitoring program included:

- Determination of 2,3,7,8-TCDD concentrations in soils and biota, with emphasis on geographic areas where PCDDs may have been manufactured, used, or stored — and where concentrations may be in excess of 1000 ng/kg
- Monitoring of industrial and municipal incinerators for 2,3,7,8-TCDD emissions
- Establishment of background levels for PCDDs in areas where these compounds are not expected to occur in high levels.

Information is also needed on the toxicological interactions of groups of polychlorinated chemicals (such as certain biphenyls, biphenylenes, and dibenzofurans) known to be isosteric with 2,3,7,8-TCDD and that frequently coexist with 2,3,7,8-TCDD in environmental samples. Acquisition of these data should provide the basis of a risk assessment analysis for dioxin and fishery and wildlife resources.

Table 18.7 Proposed 2,3,7,8-TCDD Criteria for the Protection of Natural Resources and Human Health

Resource, Criterion, and Other Variables	Effective 2,3,7,8-TCDD Concentration	Reference ^a
AQUATIC ORGANISMS, FRESHWATER		
Water		
Acceptable	<0.01 ng/L (ppt) ^b	1
Safe	0.01 ng/L ^c	2
No observed adverse effects on rainbow trout, <i>Oncorhynchus mykiss</i> , juveniles	<0.038 ng/L	3
Safe	<0.038 ng/L	7
Unacceptable		
Adverse effects on growth, survival and swimming of rainbow trout juveniles	0.038 ng/L	3
Adverse effects expected in sensitive species	0.1–1.0 ng/L and higher	1, 4, 24
Death observed in sensitive species several weeks after exposure for 6 days	10.0 ng/L	2
Death expected in sensitive species shortly after exposure	>1000 ng/L	2
Tissue residues		
Lake trout, <i>Salvelinus namaycush</i>		
Egg and sac fry		
No effect on survival	34 ng/kg fresh weight (FW)	6
Some deaths	55 ng/kg FW	6
50% dead by swimup	65 ng/kg FW	6, 23, 25

Table 18.7 (continued) Proposed 2,3,7,8-TCDD Criteria for the Protection of Natural Resources and Human Health

Resource, Criterion, and Other Variables	Effective 2,3,7,8-TCDD Concentration	Reference ^a
Whole body		
Reproduction inhibited	78 ng/kg FW	25
Rainbow trout; adverse effects expected; egg	More than 0.4 µg/kg FW	23
BIRDS		
Diet		
Safe	10–12 ng/kg FW ration	8, 9
Adverse effects		
Domestic chicken, <i>Gallus</i> sp.	Equivalent to about 1.0 ng/kg body weight (BW) daily	10, 11
Woodcock, <i>Philohela minor</i> ; adults; Maine	Daily intake of >6 ng/kg BW, and half-time persistence of 7.2 days	12
Soils, Maine		
No adverse effects expected in woodcocks after consuming earthworms and insects from 2,3,7,8-TCDD-contaminated soils	<50 ng/kg FW soil	12
Adverse effects observed in woodcocks	>27–250 ng/kg FW soil	12
Tissue residues		
Wood duck, <i>Aix sponsa</i> ; eggs; adverse effects on survival	>20–50 ng/kg FW	13
MAMMALS		
Diet		
No effect on carcinogenicity or reproduction in laboratory white rat, <i>Rattus</i> sp.	Equivalent to <1.0 ng/kg BW daily	5
Safe; laboratory white rat; exposure for 3 generations	12–30 ng/kg FW ration, equivalent to about 1.0 ng/kg BW daily	9
Safe; mammalian wildlife	10–12 ng/kg FW ration	8, 9
Acceptable; daily intake; lifetime exposure	<0.01 ng/kg BW ^d	5
Unacceptable, monkeys	>50 ng/kg FW ration equivalent to >1.7 ng/kg BW daily	10, 14, 15
Subcutaneous injection; marmoset monkey, <i>Callithrix jacchus</i> ; adverse sublethal effects	Persistent altered blood chemistry after single injection of 10 ng/kg BW	16, 17
HUMAN HEALTH		
Daily intake, minimum risk level		
Acute	0.0002 µg	26
Intermediate	0.00002 µg	26
Chronic	0.000001 µg	26
Diet, acceptable		
Fish muscle		
New York	<10 ng/kg FW fillet	21
Canada	<20 ng/kg FW fillet	5, 21
Most U.S. states	<25 ng/kg FW fillet	2, 18, 20, 22
Diet, limited		
Fish muscle; may be eaten once weekly by occasional consumers of fish and up to twice monthly for those who eat contaminated fish year-round	25–50 ng/kg FW fillet	18, 22
Diet, unacceptable	>50 ng/kg FW ration	2, 20, 22, 26
Soils, acceptable		
Residential areas	<1000 ng/kg FW	20
Of grazing dairy cattle	<6 ng/kg FW	20
Cancer risk		
Lifetime cancer risk increases from drinking water and eating fish from 2,3,7,8-TCDD-contaminated waters		
Cancer risk of 1 in a million	0.000013 ng/L water	20

Table 18.7 (continued) Proposed 2,3,7,8-TCDD Criteria for the Protection of Natural Resources and Human Health

Resource, Criterion, and Other Variables	Effective 2,3,7,8-TCDD Concentration	Reference ^a
Cancer risk of 1 in 100,000	1.0 ng/L water	20
Drinking water, acceptable	<0.01–<0.02 ng/L	5, 26
Ambient water, acceptable	<0.01 ng/L	5
Ambient air, acceptable	<0.03 ng/m ³	5
Total daily intake from all sources; maximum allowed	<160 ng/kg BW	18
Total daily intake from all sources; recommended	<61–<100 ng/kg BW	5, 18, 19
Total daily intake from all sources; lifetime exposure; acceptable	<0.01 ng/kg BW ^d	5

^a 1, Miller et al. 1979; 2, USEPA 1984; 3, Mehrle et al. 1988; 4, Helder 1980; 5, Boddington et al. 1990; 6, Walker et al. 1991; 7, USEPA 1990; 8, McNulty 1977; 9, Murray et al. 1979; 10, NRCC 1981; 11, Gilbertson 1983; 12, Keenen et al. 1990; 13, White and Seginak 1994; 14, Ramel 1978; 15, Barsotti et al. 1979; 16, R. ^b 0.01 ng/L was the highest 2,3,7,8-TCDD concentration tested that had no measurable adverse effect on freshwater teleosts.

^c Based on bioconcentration factor of 5000.

^d Based on no-observable-adverse effect concentration of 1.0 ng/kg BW daily in a three-generation rat study and an uncertainty factor of 100.

18.6 SUMMARY

Polychlorinated dibenzo-*para*-dioxins (PCDDs) are present as trace impurities in some manufactured chemicals and industrial wastes. The chemical and environmental stability of PCDDs and their tendency to accumulate in fat have resulted in their detection within many ecosystems. In general, wherever high levels of PCDDs have been detected, the source has been a hazardous waste dump, an industrial discharge, or an application of PCDD-contaminated herbicide. There are 75 PCDD isomers; some are extremely toxic, while others are believed to be relatively innocuous. The most toxic and most extensively studied PCDD isomer is 2,3,7,8-tetrachlorodibenzo-*para*-dioxin (2,3,7,8-TCDD). In the United States and elsewhere, accidental contamination of the environment by 2,3,7,8-TCDD has resulted in deaths of many species of wildlife and domestic animals. High residues of 2,3,7,8-TCDD in fish (i.e., more than 50 ppt wet weight), have resulted in closing rivers to fishing. In the most seriously affected areas, hospitalization and permanent evacuation of humans have been necessary. Laboratory studies with birds, mammals, aquatic organisms, and other species have demonstrated that exposure to 2,3,7,8-TCDD can result in acute and delayed mortality as well as carcinogenic, teratogenic, mutagenic, histopathologic, immunotoxic, and reproductive effects. These effects varied greatly among species. No regulations governing PCDD contamination exist at present to protect sensitive species of wildlife and aquatic organisms. Data available suggest that 2,3,7,8-TCDD concentrations in water should not exceed 0.01 ppt to protect aquatic life, or 10 to 12 ppt in food items of birds and other wildlife. Additional data are needed in several areas:

- Concentrations of PCDDs in natural systems
- Identification of fish and wildlife populations at risk
- Relative importance of PCDD sources
- Toxicological effects of various PCDDs to aquatic biota and wildlife, especially reproductive and immunosuppressive effects
- Toxic and other interaction effects of PCDDs with other groups of polychlorinated chemicals having similar structure and properties, such as biphenyls, dibenzofurans, and biphenylenes.

CHAPTER 19

Famphur

19.1 INTRODUCTION

Famphur (phosphorothioic acid, *O*-[4-[(dimethylamino)sulfonyl], phenyl] *O,O*-dimethyl ester) also known as Warbex, is a systemic organophosphorus insecticide found effective against lice, grubs, flies, and gastrointestinal nematodes of ruminants. Introduced commercially in 1961, the compound is especially effective against cattle grubs (*Hypoderma* spp.) when fed in the diet, injected subcutaneously or intramuscularly, or applied as a pour-on and oral drench treatment (Gatterdam et al. 1967; Kaemmerer and Buntenkotter 1973; Black et al. 1979; Felton et al. 1981; Gallo and Lawryk 1991; Eisler 1994).

Many dead birds, including robins, hawks, and magpies were found after cattle were treated with pour-on applications of famphur (Henny et al. 1985; Smith 1987). The black-billed magpie (*Pica pica*) was especially sensitive; ranchers reported observations of magpies dying after famphur use on cattle as early as 1973 (Henny et al. 1985). Dead magpies usually had famphur in the gizzard contents and severely depressed brain cholinesterase activity — a characteristic of organophosphorus poisoning. Populations of the black-billed magpie in western states declined between 1968 and 1979, which coincides with widespread use of famphur in that region; however, factors other than famphur may have caused the decline (Henny et al. 1985).

19.2 USES

The cholinesterase-inhibiting and intoxicating properties of organophosphorus compounds have been known since these products were first synthesized about 60 years ago (Randell and Bradley 1980). During World War II, the more toxic organophosphorus compounds — such as soman, tabun, and sarin — were stockpiled for use as potential chemical warfare agents. More than 50,000 organophosphorus compounds have been synthesized and screened for possible insecticidal and antihelminthic activity, and several dozen, including famphur, are available commercially (Randell and Bradley 1980). During the 1970s, most organochlorine insecticides were removed from common use in North America, Europe, and most developed countries, and the removal increased reliance on carbamate and organophosphorus compounds, the two major classes of cholinesterase-inhibiting pesticides (Mineau 1991). The relative lack of target specificity of these compounds and their high acute toxicity to many nontarget organisms were ignored in favor of their short-term environmental persistence and lack of accumulation in organisms. The anticholinesterase insecticides now account for the majority of globally registered insecticides (Mineau 1991).

Famphur is not now applied to forests or crops but is used almost exclusively as a veterinary chemical (Smith 1987). A single treatment controls cattle grubs and reduces cattle-lice infestations

(American Cyanamid Company 1984). Famphur is especially effective against maggots of the botfly and warble fly (*Hypoderma* spp.) and of other oestrid dipterous flies (Seel 1985). Eggs from this group of insects are laid on the feet and legs of cattle and other mammals and licked off by the host and hatch in the mouth or esophagus. The resultant larvae burrow through the tissues to the skin of the animal's back where they live until ready to pupate and cause warbles or swellings (Seel 1985; Tarry 1986). When applied carelessly, famphur and other systemic insecticides are highly toxic and frequently produce acute poisonings in ruminants (Ballantyne and Marrs 1992). Famphur is not now registered or regulated by the U.S. Environmental Protection Agency.

Cholinesterase-inhibiting agents such as famphur vary widely in their effectiveness in controlling target pests and depend on the route of administration, dose rate, formulation, and timing and frequency of applications (Mineau 1991). Famphur can be administered to livestock by intramuscular injection, orally in the diet, as a dermal pour-on, or as a bolus. Intramuscular injections of a 35% famphur concentrate are usually given in the gluteal muscle (Loomis and Schock 1978). When fed in the diet, famphur is formulated as a 33.3% liquid feed premix (Pasarela et al. 1967; Smith 1987). The topical use of famphur as a systemic insecticide was recommended in 1970. As a pour-on over part of the backline of cattle at dosages between 15 and 35 mg/kg body weight (BW), 12.5 to 13.2% w/v famphur applied in the autumn controls warbles before they develop into grubs the following year (Henny et al. 1985) and controls various species of lice (Annand et al. 1976). When used as a pour-on for cattle-tick control, famphur may be transferred from treated cattle to untreated animals (Annand et al. 1976), presumably through body contact. The solvent used in preparing dermal formulations of famphur significantly affects absorption hazards. In the case of the laboratory white rat (*Rattus* spp.), corn oil proved to be the least hazardous solvent and acetone the most hazardous; benzene was intermediate (Durham 1967). Famphur can also be administered in a rumen bolus as a systemic insecticide against ticks in cattle. Boluses have been designed to release 200 mg famphur/bolus daily over a 65- to 75-day postingestion period; actual release rates range from 207 to 308 mg daily (Hair et al. 1979).

Technical information by the American Cyanamid Company (1984) lists five precautions and warnings for the use of famphur.

1. Famphur is "Toxic to fish, birds, and other wildlife. Keep out of lakes, ponds, and streams. Do not apply to areas where run-off occurs. Do not contaminate water by cleaning of equipment or disposal of wastes."
2. After use, all containers should be drained and rinsed several times with a solution of water, detergent, and lye ("bury rinse solution deeply in an isolated location with 18 inches [7 cm] of cover"); the empty container should be punctured and crushed to prevent reuse.
3. Famphur should not be used in combination with any compound having cholinesterase-inhibiting activity, either simultaneously or within a few days before or after treatment.
4. Famphur use on livestock is contraindicated for less than 3-month-old calves; animals stressed from castration, dehorning, or overexcitement; and sick or convalescent animals. Brahman and Brahman crossbreeds are less tolerant of cholinesterase-inhibiting insecticides than other breeds, and Brahman bulls are especially sensitive and should not be treated with famphur. Cattle should not be slaughtered for at least 35 days after treatment with famphur.
5. For humans, famphur is considered harmful or fatal if swallowed or absorbed through the skin, especially by children. If poisoning should occur, physicians are advised that atropine is antidotal and that pralidoxime chloride may be effective as an adjunct to atropine. Pour-on formulations are flammable, and users should keep them away from heat, sparks, and open flames including hot branding irons and cautery dehorning devices (American Cyanamid Company 1984).

19.3 CHEMISTRY AND METABOLISM

Some physical and chemical properties of famphur are listed in [Table 19.1](#). Gas chromatography is used to measure famphur and its oxygen analog famoxon in bovine milk, blood, and edible

tissues; detection limits are 0.005 mg/L milk and <0.01 mg/kg tissue (Pasarela et al. 1967; Annand et al. 1976). The main degradation routes of famphur in mammals occur through hydrolysis of the P-O phenyl, P-O methyl, and N-methyl bonds; oxidative desulfuration and N-demethylation take place to a small extent (Figure 19.1) (Kaemmerer and Buntenkotter 1973; Eto 1974). In the metabolic scheme for famphur in mammals (Figure 19.1), only famphur and its oxygen analog, famoxon, were of toxicological significance, as judged by acute oral toxicity in mice (Gatterdam et al. 1967). In studies with mice, acute oral LD₅₀ values in mg/kg BW were 27 for famphur; 18 for famoxon; 2270 for *O*-desmethylfamphur; 860 for *O,N*-bisdesmethylfamphur; 2290 for *p*-(*N,N*-dimethylsulfamoyl)phenol; 2500 for *p*-(*N*-methylsulfamoyl)phenol; 6400 for *p*-hydroxybenzenesulfonic acid; and >5000 for *p*-(*N,N*-dimethylsulfamoyl)phenyl glucuronide.

Table 19.1 Chemical and Other Properties of Famphur

Variable	Datum

Alternate names	AC 38023, American Cyanamid 38023, Bo-Ana, CL 38023, Cyflee, Dovip, ENT 25644, Famaphos, Famfos, Famophos, Famphos, Fanfos, Warbex, 38023
Primary use	Systemic livestock insecticide
CAS Number	52-85-7
Empirical formula	C ₁₀ H ₁₆ NO ₅ PS ₂
Molecular weight	325.36
Melting point, crystals vs. powder	52.5–53.5°C vs. 55°C
Solubility	
Chlorinated hydrocarbons	Highly soluble
Water	~100 mg/L
Polar solvents	Slightly soluble
Aliphatic hydrocarbons	Insoluble

^a O'Brien et al. 1965; Gatterdam et al. 1967; Pasarela et al. 1967; Tucker and Crabtree 1970; Schafer 1972; Kaemmerer and Buntenkotter 1973; Eto 1974; Black et al. 1979; Ryan and McLeod 1979; Hudson et al. 1984; Hill and Camardese 1986; Smith 1987; Gallo and Lawryk 1991.

Famphur residues of 1 to 3 mg/kg fresh weight (FW) are common in cattle tissues after normal pour-on applications of the chemical (Annand et al. 1976). The half-time persistence of famphur in subcutaneous fat of cattle after a single pour-on application was 0.9 days and was independent of dose within the range of 25 to 150 mg/kg BW or initial tissue residues between 1.8 and 12.3 mg/kg FW; fat residues were <0.08 mg/kg FW 5 days after treatment and <0.01 mg/kg FW after 11 days. These observations suggest that famphur tissue residues are near or below detection levels within 1 week after treatment, even with gross misuse of the chemical (Annand et al. 1976). However, because famphur persists on cattle hair for >90 days at concentrations >1000 mg/kg, this has serious implications for local populations of birds (Henny et al. 1985).

Famphur and other organophosphorus compounds are metabolized and excreted with greater efficiency by mammals than the target pests before these compounds can bind to and ultimately inhibit the cholinesterase enzyme (Randell and Bradley 1980). Mice, for example, degrade famphur rapidly. Less than 1 h after an intraperitoneal injection of 1 mg famphur/kg BW, only 8.34% of

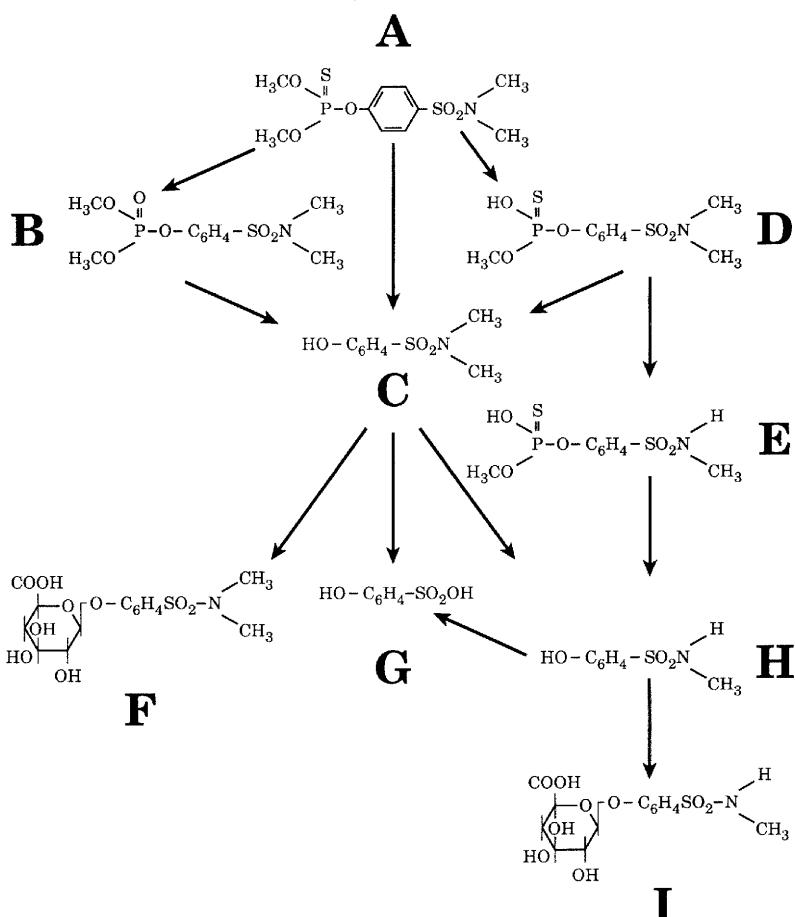

Figure 19.1 Metabolic scheme for famphur in mammals. (Adapted from Gatterdam, P.E., L.A. Wozniak, M.W. Bullock, G.L. Parks, and J.E. Boyd. 1967. Absorption, metabolism, and excretion of tritium-labeled famphur in the sheep and calf. *Jour. Agricul. Food Chem.* 15:845-853.) Major metabolic routes are indicated by an asterisk (*). **A**, famphur; **B**, famoxon; **C**, *p*-(*N,N*-dimethylsulfamoyl)phenol; **D**, *O*-desmethylfamphur; **E**, *O,N*-bisdesmethylfamphur; **F**, *p*-(*N,N*-dimethylsulfamoyl)phenyl glucuronide; **G**, *p*-hydroxybenzene sulfonic acid; **H**, *p*-(*N*-methylsulfamoyl)phenol; and **I**, *p*-(*N*-methylsulfamoyl)phenyl glucuronide. According to this scheme, famphur (**A**) initially undergoes oxidation at the P=S bond to yield famoxon (**B**), hydrolysis at the P-O-phenyl bond to yield the transitory *p*-(*N,N*-dimethylsulfamoyl)phenol (**C**)*, or hydrolysis at one of the P-O-methyl bonds to yield *O*-desmethylfamphur (**D**)*. *p*, *N,N*-dimethylsulfamoylphenol (**C**) may also arise by hydrolysis of famoxon (**B**) or *O*-desmethylfamphur (**D**)*. *p*-(*N,N*-dimethylsulfamoyl)phenol (**C**) is immediately conjugated to form *p*-(*N,N*-dimethylsulfamoyl)phenyl glucuronide (**F**)* or transformed to *p*-hydroxybenzene sulfonic acid (**G**) or *p*-(*N*-methylsulfamoyl)phenol (**H**). *O*-desmethylfamphur (**D**) can also give rise to *O,N*-bisdesmethylfamphur (**E**)* by removal of one of the methyl groups of the sulfonamide moiety. *O,N*-bisdesmethylfamphur (**E**) is hydrolyzed to the corresponding transitory *p*-(*N*-methylsulfamoylphenol) (**H**)* which is immediately conjugated to yield the corresponding glucuronide, *p*-(*N*-methylsulfamoyl)phenyl glucuronide (**I**)*.

the original administered dose remained in the mouse: 8.11% as the parent famphur, 0.22% as famoxon, and 0.01% as desmethylfamphur (Kaemmerer and Buntenkotter 1973). Famphur's biocidal properties are associated with its ability to inhibit cholinesterase activity, blocking synapses at the neuromuscular junction. Useful reviews of ecological and toxicological properties of cholinesterase-inhibiting agents in the environment — including organophosphorus insecticides — are given by Gallo and Lawryk (1991), Mineau (1991), and Ballantyne and Marrs (1992). Brain cholinesterase inhibition is often used to diagnose death of wildlife after exposure to famphur and

other organophosphorus insecticides (Mineau 1991). It is emphasized that the type and number of cholinesterase compounds and cholinesterase activities vary widely between species and tissues, and activities are further modified by metabolic factors, age, genotype, circadian rhythms, sex, reproductive status, nutritional status, ambient temperature, and disease (Mineau 1991).

19.4 LETHAL AND SUBLETHAL EFFECTS

19.4.1 General

Famphur controls many species of pestiferous insects that afflict poultry and livestock. The LD₅₀ values for target insects ranged from 2.4 to 4.1 mg/kg BW from a dermal route and 8.0 to 11.8 mg/kg BW from abdominal injection. Toxicity of famphur is often associated with differential degradation and cholinesterase sensitivity among various species of target pests. Famoxon is more effective than famphur in producing cholinesterase inhibition and death, and this confirms the generalization that the corresponding oxons are the more potent anticholinesterase agents.

No published data were available on famphur toxicity to aquatic life. Other data, however, suggest that acute famphur toxicity to fishes may be comparable to that of other phosphorothioate insecticides. Among birds, sensitive species had reduced survival after single oral doses of 1.8 to 3.0 mg famphur/kg BW or when fed diets containing 35 to 49 mg famphur/kg ration. Daily oral doses as low as 0.3 mg famphur/kg BW caused depressed cholinesterase activity in the brain and in plasma. Secondary poisoning of eagles and hawks foraging on famphur-killed vertebrates and tertiary poisoning of a great horned owl (*Bubo virginianus*) feeding on a famphur-poisoned hawk are documented. Famphur has also been used illegally to kill birds — including migratory waterfowl and other federally protected species — thought to be depredating crops. Famphur-induced mortality in mammals was documented at concentrations as low as 11.6 mg/kg BW in intraperitoneal injection (mouse), 27 mg/kg BW in oral exposure (mouse), >33.3 mg/kg BW in intramuscular injection (Brahman cattle), and 400 mg/kg BW in dermal application (rat). In reindeer, altered blood chemistry was evident 1 year after famphur exposure. Famphur is metabolized rapidly by mammals; residues in animal tissues and milk — regardless of mode of administration, length of exposure, or dose — were usually not detectable within 4 days of final exposure.

19.4.2 Terrestrial Invertebrates

Famphur controls many species of pestiferous insects that afflict poultry and livestock, especially warble flies (*Hypoderma* spp.). Famphur is one of the most toxic compounds for the control of adults and late instars of the lesser mealworm (*Alphitobius diaperinus*), the most abundant beetle inhabiting poultry litter and manure (Vaughan and Turner 1984). *Alphitobius* can transmit several diseases to poultry, including avian leukosis — one of the most costly diseases for the poultry industry. By tunneling, *Alphitobius* can destroy polyurethane and polystyrene panels adjacent to manure. Famphur also controls the lesser mealworm in nests of birds and in bat roosts (Vaughan and Turner 1984). The northern fowl mite (*Ornithonyssus sylviarum*) is the most important ectoparasite of commercial breeders and laying hens in the United States. However, attempts to control northern fowl mite with famphur were ineffective regardless of tested mode of administration (De Vaney and Ivie 1980).

Cattle lice (*Haematopinus* spp.) were controlled when the equivalent of 2.5 mg famphur/kg BW in diets was fed to cattle for at least 30 days (Ivey et al. 1976); 40.5 mg/kg BW were applied as a topical pour-on (Randell and Bradley 1980). Famphur was used in 1971 to control cattle lice at pour-on applications equivalent to 15 to 35 mg/kg BW (Annand et al. 1976). Pour-on treatments of Australian yearling heifers were especially effective in controlling the long-nosed sucking louse (*Linognathus vituli*) and the short-nosed sucking louse (*Haematopinus eurysternus*); untreated heifers grew more slowly than famphur-treated heifers (Bailey et al. 1984). Larvae of the hornfly

(*Haematobia irritans*) were controlled in manure of cattle fed famphur at 2.5 to 5.0 mg/kg BW daily (Ivey et al. 1976). Manure of treated cows contained low concentrations of famphur (as much as 0.14 mg/kg FW) 1 day after diet cessation, but residues were nondetectable thereafter (Henny et al. 1985).

In Alaska, reindeer (*Rangifer tarandus*) infested with reindeer warble fly (*Oedemagena tarandi*) produced hides of little value and low quality meat. Reindeer warble flies were not controlled by pour-on applications of famphur because the product was unable to penetrate the hair coat of reindeer; however, intramuscular injections were effective (Ivey et al. 1976). In Norway, Sweden, and Finland, famphur was the most promising control agent against reindeer warble fly and reindeer nostril fly (*Cephenomyis trompe*) — two parasites that together caused a 15 to 20% annual loss of total yield in reindeer husbandry (Niemenen et al. 1980).

Famphur was not very effective in the control of ticks. The tropical horse tick (*Anocentor nitens*) is a species of serious concern to horse breeders and raisers in Florida mainly because it transmits *Babesia caballi*, the causative agent of equine piroplasmosis. A secondary concern is that heavy tick infestations may cause injury to the ears of the horse (Gladney et al. 1972). Data were unavailable on famphur control of ticks in horses; however, famphur was 99.9 to 100% effective in controlling *A. nitens* in Hereford steers and heifers when fed in the diet at 5 mg/kg BW for 14 to 21 days. Famphur at 2.5 mg/kg BW in cattle diets for 7 days was only partially effective (39 to 87.5%) in controlling horse ticks (Gladney et al. 1972). Famphur — despite multiple treatments — was not effective in controlling cattle ticks (*Haemaphysalis longicornis*) when used as a pour-on at recommended application rates in weaned Hereford calves (Heath et al. 1980).

Results of selected studies of famphur and insects indicate several trends:

- Males are more sensitive than females
- The oxygen analog, famoxon, is more toxic than the parent chemical
- Dermal LD₅₀ values range from 2.4 to 4.1 mg/kg BW
- Abdominal injection LD₅₀ values range from 8.0 to 11.8 mg/kg BW
- Metabolic degradation rates vary widely between species ([Table 19.2](#)).

Famoxon is about 100 times more effective than famphur in controlling houseflies (*Musca* spp.), which confirms the generalization that the corresponding oxons are the most effective anticholinesterase agents and are, in fact, the actual toxicants (O'Brien et al. 1965).

Differences in toxicity of organophosphorus compounds among species is often associated with differential degradation rates, pathways, and metabolites. Although injections of famphur were equally toxic to mice (*Mus* sp.), the American cockroach (*Periplaneta americana*), and the milkweed bug (*Oncopeltus fasciatus*), famphur was rapidly degraded by mice (91.7% degraded within 1 h after injection) and cockroaches (81.5% in 1 h); however, milkweed bug degraded only 15.4% during a similar period (O'Brien et al. 1965). The variations in degradation rate among mice and cockroaches were relatively small, about 1.9-fold. Despite the great similarity in famphur toxicity to mice and cockroaches, net famoxon production — like famphur persistence — was very low in the mouse but 10 times higher in the milkweed bug. The cholinesterase activity in the milkweed bug was 32 times more resistant to inhibition by famoxon than either mouse or cockroach cholinesterase, and this could account for the comparatively slow breakdown of famphur by the milkweed bug (O'Brien et al. 1965).

There is a correlation among cholinesterase activity depression in rabbit blood, depression of cholinesterase activity in ectoparasites feeding on the blood of the host, and mortality of ectoparasites (Smith and Goulding 1970). In one case, rabbits (*Oryctolagus* sp.) parasitized by the yellow fever mosquito (*Aedes aegypti*) and Rocky mountain wood tick (*Dermacentor andersoni*) were treated with 5 to 50 mg of famphur/kg BW administered orally, subcutaneously, or intravenously. Regardless of dose or route of administration, tick and mosquito mortality was related to cholinesterase activity levels in rabbit plasma and erythrocytes. Some ectoparasite deaths were noted when

cholinesterase levels in rabbits were depressed 32%; ectoparasite mortality increased to 90% at 33% depression and to 100% at 68% cholinesterase inhibition. In general, wood ticks and mosquitoes reflected cholinesterase activity levels of the host rabbit. Surviving female ticks that fed on dosed hosts laid no eggs during a 32-day postremoval observation period. Mosquitoes that had fed on famphur-dosed hosts were more susceptible to cold than those that fed on control hosts (Smith and Goulding 1970).

Table 19.2 Famphur Effects on Selected Terrestrial Invertebrates

Organism, Dose, and Other Variables	Effect	Reference ^a
LESSER MEALWORM, <i>Alphitobius diaperinus</i>, topically applied		
3.44 mg/kg body weight (BW), 95% confidence interval (CI) 2.4–3.8 mg/kg BW	LD50 (24 h), adults	1
3.61 (95% CI of 3.32–4.08) mg/kg BW	LD50 (24 h), late instars	1
MILKWEED BUG, <i>Oncopeltus fasciatus</i>		
Abdominal injection, various doses		
Famoxon, 3.0 mg/kg BW	LD50	2
Famphur, 8.0 mg/kg BW	LD50	2
Single abdominal injection of 1 mg famphur/kg BW; whole-body residues of famphur, famoxon, and N-desmethylfamphur measured 1 h after injection	Of total amount injected, 84.6% remained after 1 h: 79.4% famphur, 2.2% famoxon, and 3.1% N-desmethylfamphur	2
AMERICAN COCKROACH, <i>Periplaneta americana</i>		
Abdominal injection, various doses		
Famoxon, 4.6 (males) or 8.6 (females) mg/kg BW	LD50	2
Famphur, 9.0 (males) or 11.8 (females) mg/kg BW	LD50	2
Single abdominal injection of 1 mg famphur/kg BW; whole-body residues of famphur, famoxon, and N-desmethylfamphur measured 1 h after injection	Of total amount injected, 18.5% remained after 1 h: 16.8% famphur, 0.5% famoxon, and 1.2% N-desmethylfamphur	2

^a 1, Vaughan and Turner 1984; 2, O'Brien et al. 1965.

19.4.3 Aquatic Organisms

An extensive literature search revealed no published data on famphur toxicity to aquatic animals. Unpublished studies of acute lethality were, however, conducted with the bluegill (*Lepomis macrochirus*) and rainbow trout (*Oncorhynchus mykiss*). In those studies, the range in LC50 values at 96 h was 18 to 21 mg/L in bluegills and 4.9 to 5.3 mg/L in rainbow trout. The no-observable-effect concentration at 96 h ranged from 14 to 18 mg/l in bluegills and was 2.1 mg/L in rainbow trout (U.S. Environmental Protection Agency, OPPTS/OPP/EFED/EEB, personal communication, 30 June 1993).

Although no data were available on the effects of famphur in aquatic ecosystems, there is a substantial database on other organophosphorus insecticides. For example, methyl parathion (*O,O*-dimethyl *O*-(*p*-nitrophenyl)phosphorothioate), another phosphorothioate organophosphorus insecticide, had LC50 (96 h) values for bluegills and rainbow trout that were similar to those of famphur: 5.7 mg/L and 2.7 mg/L, respectively (Khan 1977). But exposure for 96 h is not sufficient to satisfactorily evaluate the aquatic toxicity of organophosphorus insecticides. The mortality of adult northern puffers (*Sphaeroides maculatus*) continuously exposed to 20.2 mg/L of methyl parathion was <5% in 96 h but 100% in 40 days. Puffers refused to eat during exposure, and survivors between days 10 and 40 showed complete inhibition of serum esterase activity, zinc-depleted liver and gills, and altered blood chemistry (Eisler 1967, 1972). In another study, male guppies (*Poecilia reticulata*)

held in sublethal concentrations (0.01 to 1.0 mg/L) of methyl parathion for 40 days or longer showed a dose-dependent decrease in spermatogenesis (Billard and de Kinkelin 1970). Pesticide-induced mortality patterns of representative organophosphorus compounds are also modified by water temperature, pH, and salinity. The mummichog (*Fundulus heteroclitus*), an estuarine cyprinodontiform teleost, was most sensitive to organophosphorus compounds at elevated temperatures, reduced salinities, and low pH (Eisler 1970b). Duration of exposure to organophosphorus compounds also affects mummichog survival: fish exposed to high (LC₇₅, 24-h) concentrations of representative insecticides for more than 30 min died by day 21 postexposure. Some insecticides were as much as 8.3 times more toxic after exposure for 240 h than 96 h, as judged by LC₅₀ values (Eisler 1970b). In general, crustaceans were more sensitive than teleosts — sometimes by several orders of magnitude — to organophosphorus insecticides in 96-h tests. Grass shrimp (*Palaemonetes vulgaris*) and fishes were most sensitive to organophosphorus insecticides at high salinities in the 1.2 to 3.6% test range and high temperatures in the 10 to 30°C test range (Eisler 1969; 1970c, 1972). Marine clams and gastropods were comparatively resistant to organophosphorus insecticides; none died in 96-h exposure to 25 mg/L of five organophosphorus insecticides, including methyl parathion. But during a postexposure observation of 133 days, some bivalves and gastropods died (Eisler 1970a), and these deaths are similar to the delayed mortality for some species of mammals and invertebrates after exposure to certain organophosphorus insecticides (Negherbon 1959).

The expected continued use of famphur in the environment and its vehicular transport along roads that border navigable waters suggest a need for aquatic toxicity data. Famphur data — like those on other organophosphorus insecticides — should reflect the influence of dose, exposure duration, formulation, and other biological and abiotic variables on growth, survival, and metabolism of representative species of aquatic organisms.

19.4.4 Birds

The avian acute oral LD₅₀ of famphur is usually between 1 and 9.5 mg/kg BW (Schafer 1972; Hill and Mendenhall 1980). Laboratory studies with sensitive species of birds show reduced survival after a 5-day consumption of diets containing 35 to 49 mg famphur/kg ration (Hill et al. 1975) (Table 19.3). Depressed cholinesterase activity in the brain and in plasma of European starling (*Sturnus vulgaris*) nestlings occurred after 15 daily oral exposures of concentrations as low as 0.3 mg famphur/kg BW (Powell and Gray 1980) (Table 19.3). Signs suggesting famphur poisoning in mallards (*Anas platyrhynchos*) included regurgitation, goose-stepping, ataxia, wing drop, tremors, and tonic seizures (Tucker and Crabtree 1970; Hudson et al. 1984).

Famphur is considered a Class II toxic compound to the Japanese quail (*Coturnix japonica*) according to the classification of Hill and Camardese (1986). Class II compounds (very toxic) kill 50% of the test organisms on diets containing 40 to 200 mg chemical/kg ration for 5 days followed by a 3-day observation. By comparison, the 50% kill in other classes (in mg/kg diet) is <40 in Class I (highly toxic), >200 to 1000 in Class III (moderately toxic), >1000 to <5000 in Class IV (slightly toxic), and >5000 in Class V (practically nontoxic) (Hill and Camardese 1986). Smith (1987) rates famphur as a Class I toxic compound, as judged by results of dietary tests with mallards.

Birds killed by organophosphorus compounds in the wild consistently show 80 to 95% depression of brain cholinesterase activity (Hill 1992). Depression of brain cholinesterase activity by >20% in birds has been used as a conservative criterion to indicate significant exposure to organophosphorus chemicals. Depression of brain cholinesterase activity by >50% and confirmation of suspected organophosphorus chemical residues in tissues or ingesta are criteria for cause–effect diagnosis of death in birds exposed to cholinesterase-inhibiting chemicals (Henny et al. 1985; Hill 1992). Death occurs in many avian species when brain-cholinesterase inhibition is 60 to 90%. However, no barn owls (*Tyto alba*) died or showed signs of intoxication after consuming famphur-poisoned Japanese quail, although 70% of the owls had brain cholinesterase inhibition within these lethal bounds (Hill and Mendenhall 1980). Barn owls fed famphur-poisoned quail, the digestive

tracts of which had been removed, showed significant but lesser brain cholinesterase activity inhibition than owls fed intact poisoned quail, indicating that famphur or cholinesterase-inhibiting metabolites were most heavily concentrated in digestive tracts (Table 19.3).

The black-billed magpie seems unusually sensitive to famphur. Dead famphur-poisoned magpies contained as much as 290 mg famphur/kg liver FW, 4770 mg/kg gizzard FW, and <0.2 mg/kg muscle or fat (Hill and Mendenhall 1980). There is a growing body of literature on adverse effects on magpies from pour-on (13.2% famphur) applications along the backline of cattle to control cattle warbles at the recommended rate of 0.326 mL/kg BW, not to exceed 118 mL/animal — equivalent to 43 mg/kg BW, not to exceed 15.6 g/animal (Felton et al. 1981; Henny et al. 1985; Seel 1985; Smith 1987). Felton et al. (1981) documented three occasions when dead birds were found after pour-on-famphur treatment of cattle against warble flies:

1. 12 black-billed magpies in a nearby field 2 to 3 days after cattle were treated
2. 6 magpies during a 14-day period (although other species of corvids were present, only magpies were affected)
3. 8 robins (*Erythacus rubecula*) and a single dunnock (*Prunella modularis*) near a cattle crush a few days after famphur treatment.

The dead birds had no measurable brain-cholinesterase activity, and famphur was detected in the gizzards of birds in all three incidents (Felton et al. 1981). Partially paralyzed magpies containing as much as 3500 mg famphur/kg gizzard contents were found in the vicinity of cattle recently treated with a pour-on formulation of famphur to control an infestation by warble flies; another 20 to 30 dead magpies were found in the immediate area (Seel 1985). Magpies and one red-tailed hawk (*Buteo jamaicensis*) were the only birds found dead where cattle had been topically treated with famphur, although several other species, including killdeers (*Charadrius vociferus*) and European starlings, were common in these pastures (Henny et al. 1985). Famphur residues were detected in all dead magpies and hawks, and brain cholinesterase activity depression ranged from 70 to 92%. Based on residue concentrations in the gizzards, dead magpies contained 5.2 to 6.1 mg famphur/kg whole body; these values were above the acute oral LD₅₀ values for several species of birds (Henny et al. 1985) (Table 19.3).

The most probable explanation for the sensitivity of magpies to famphur is associated with the contents of the poisoned magpies, which consisted of as much as 12% cattle hair (Henny et al. 1985). Although most organophosphorus compounds degrade rapidly, famphur persists for >90 days on hair of Hereford bulls and steers and Angus yearlings. Famphur concentration in hair of a Hereford bull averaged 38,000 mg/kg FW 1 week after a single pour-on treatment and a maximum of 12,000 mg/kg FW 60 days posttreatment. High concentrations of famphur in the gizzards of magpies indicated that the material was ingested and not from dermal contact or inhalation. Tissue residues, in mg famphur/kg FW, in famphur-poisoned magpies were as much as 550 in the upper GI tract, 4.3 in the lower GI tract, and 3 in the whole body. Cow hair from gizzards of dead magpies averaged 4600 mg famphur and famoxon/kg FW; other animal matter in the gizzard contained 620 mg famphur and famoxon/kg FW and plant matter 340 mg famphur and famoxon/kg FW. A potentially lethal dose to magpies would be 8 to 19 mg of treated hair at day 7 and 26 to 60 mg of treated hair after 60 days. Coincidentally, magpie mortality persisted for more than 3 months; most deaths occurred 5 to 13 days after cattle were treated (Henny et al. 1985). The manure-insect-bird pathway of famphur translocation is untenable because of extremely low (<0.14 mg/kg FW) concentrations of famphur in cow manure (Henny et al. 1985).

Secondary poisoning of flesh-eating birds foraging on famphur-killed vertebrates is well documented. The degree of hazard to the predator is related to the amount and type of consumed tissues and famphur concentrations in the prey tissues (Heinz et al. 1979; Hill and Mendenhall 1980; Henny et al. 1985, 1987; Hill 1992). Secondary poisoning of raptors killed by famphur that was topically applied to livestock include the bald eagle (*Haliaeetus leucocephalus*) — after eating

cattle that died within 100 days of famphur treatment or famphur-poisoned brown-headed cowbirds (*Molothrus ater*) and European starlings — and a red-tailed hawk after eating famphur-poisoned black-billed magpies or European starlings (Henny et al. 1987). In one case, an adult female bald eagle that was unable to fly near Lewes, Delaware, was brought to a national wildlife refuge where it died after a few days (Franson et al. 1985). Stomach contents included one lead shot and remains of brown-headed cowbirds and European starlings. A necropsy showed no signs of lead poisoning. Clinical signs, physical examination, and presence of a full crop suggested acute poisoning. Crop and stomach contents were analyzed for a variety of pesticides, metals, and herbicides, but only famphur was elevated at 1.9 mg/kg FW. As judged by famphur residues in the GI tract and by brain cholinesterase activity inhibition of 85%, the authors concluded that famphur was the probable cause of death (Franson et al. 1985). There is also a case of tertiary poisoning in which a great horned owl (*Bubo virginianus*) died after consuming a dead famphur-poisoned red-tailed hawk. In all of these cases, brain cholinesterase activity of poisoned birds was depressed >50% and undigested remains contained famphur (Henny et al. 1987).

Famphur has also been used to intentionally kill birds, including migratory waterfowl and other protected species, and should be added to the list of other toxic organophosphorus insecticides, such as monocrotophos, dicrotophos, and parathion, that have been used for this purpose (White et al. 1989). In 1988, for example, famphur was used illegally by farmers in Georgia and West Virginia to kill birds thought to be depredating crops. Corn and grain at the mortality sites contained between 4240 and 8500 mg famphur/kg. Dead birds at these locations included Canada geese (*Branta canadensis*), mallards, American black ducks (*Anas rubripes*), American crows (*Corvus brachyrhynchos*), common grackles (*Quiscalus quiscula*), red-winged blackbirds (*Agelaius phoeniceus*), sandhill cranes (*Grus canadensis*), and a single red-tailed hawk. Most of the poisoned waterfowl, cranes, raptors, corvids, and songbirds from the five sites had severely depressed brain cholinesterase activity (i.e., >50%), poisoned bait in the gizzards, and famphur concentrations in the gastrointestinal tracts ranging from 5 mg/kg FW in the red-tailed hawk to 1480 mg/kg FW in Canada geese. It was concluded that all birds died from direct ingestion of the poisoned bait, except the red-tailed hawk that had eaten one or more famphur-poisoned crows (White et al. 1989).

Table 19.3 Famphur Effects on Birds

Route of Administration, Organism, Dose, and Other Variables	Effect	Reference ^a
DIETARY EXPOSURE		
Treated feed for 5 days, then untreated feed for 3 days		
Mallard, <i>Anas platyrhynchos</i> ; 35 mg/kg diet Japanese quail, <i>Coturnix japonica</i> ; 69 mg/kg diet, 95% confidence interval (CI) of 49–97 mg/kg diet	About 50% survived; ducklings age 10 days 50% dead; 14-day-old quail	1 2
Ring-necked pheasant, <i>Phasianus colchicus</i> ; 49 mg/kg diet, 95% CI of 40–61 mg/kg diet	50% dead; 10-day-old chicks	1
Domestic chicken, <i>Gallus</i> sp. Fed 50 mg/kg ration for 10 days (in attempt to control northern fowl mite, <i>Ornithonyssus sylviarum</i>)	Ineffective in controlling mites. Feed consumption, body weight, and egg production significantly decreased	3
Barn owl, <i>Tyto alba</i> , adults, 475 g body weight (BW)	Owls did not avoid famphur-poisoned <i>Coturnix</i> , fed normally, and did not lose weight. By the tenth day, plasma-cholinesterase activities in owls were depressed 45–81%, and brain cholinesterase activities were depressed 32–73%	4
Owls were fed whole famphur-poisoned Japanese quail. Quail received multiple doses of famphur (a total of 1 mg over a 3-day period). One poisoned <i>Coturnix</i> was fed daily for 10 days. If no famphur was lost or metabolized by <i>Coturnix</i> prior to death, then owls received a maximum of 21 mg/kg BW for the 10-day period or 2.1 mg famphur/kg BW daily		

Table 19.3 (continued) Famphur Effects on Birds

Route of Administration, Organism, Dose, and Other Variables	Effect	Reference ^a
As above, except digestive tract was removed from famphur-poisoned <i>Coturnix</i> before presentation to owls	Owls had brain cholinesterase activity values intermediate between controls and those fed poisoned whole <i>Coturnix</i>	4
MULTIPLE ORAL DOSES		
Japanese quail; dosing by gavage over 3 days: 300 µg on days 1 and 2 and 400 µg on day 3; mean weight of 120 g	Some deaths; cumulative dose received at day 3 = 8.33 mg/kg BW	4
Domestic chicken; 2.5 mg/kg BW once daily for 8 days; observed for 10 days posttreatment	Egg production, body weight, and feed consumption decreased significantly; ineffective in controlling northern fowl mite	3
European starling, <i>Sturnus vulgaris</i> , free-living nestlings, age 4 days. Dosed perorally with famphur dissolved in corn oil at 0.3, 1.0, or 3.0 mg famphur/kg BW daily for 15 days, then killed at age 19 days	At 0.3 mg/kg BW, 1 nestling died after the second dose (age 6 days) and another after the fifth dose vs. no deaths in controls; at day 19, brain cholinesterase activity was depressed 51% and plasma activity 49%. At 1.0 mg/kg BW, 1 died after the third dose; at day 19, brain cholinesterase activity level was depressed 75% and plasma cholinesterase 25%. At 3.0 mg/kg BW, 9 of 11 tested nestlings died within 8 h of the first dose, another within 8 h of the second dose, and the last was killed by a predator after the second dose. The 2 nestlings that survived a single dose were moribund and their brain cholinesterase activity was depressed 85%	5
SINGLE ORAL DOSE		
Red-winged blackbird, <i>Agelaius phoeniceus</i> ; 1.8 mg/kg BW, 95% CI of 1.0–3.2 mg/kg BW	LD50	6, 9
Mallard; 9.87 mg/kg BW, 95% CI of 5.88–16.6 mg/kg BW	LD50 for 3–4-month-old hens	7, 8
Domestic chicken; 10 mg/kg BW in gelatin capsule to control northern fowl mite; observed for 10 days posttreatment	Ineffective in controlling mites. On day 2 posttreatment, 1 of 12 chickens had died and 9 others showed muscular incoordination, especially in the legs. By day 3 posttreatment, most of the 9 were again standing and feeding and feces had reverted from a greenish diarrheic discharge to the normal consistency. By day 10 posttreatment, body weight and egg production was significantly decreased, although egg weight was unaffected	3
European starling; 4.2 mg/kg BW, 95% CI of 1.99–9.50 mg/kg BW	LD50	6, 9

^a 1, Hill et al. 1975; 2, Hill and Camardese 1986; 3, DeVaney and Ivie 1980; 4, Hill and Mendenhall 1980; 5, Powell and Gray 1980; 6, Smith 1987; 7, Tucker and Crabtree 1970; 8, Hudson et al. 1984; 9, Schafer 1972.

19.4.5 Mammals

Famphur is a group-D compound that is not classifiable as a human carcinogen (Sine 1991). However, a study of leukemia risk among males in Iowa and Minnesota indicated a slight but significant elevation in risk — especially chronic lymphocyte leukemias — for farmers but not for nonfarmers. Moreover, a significantly elevated leukemia risk was seen from exposure to specific animal insecticides, including famphur (Brown et al. 1990). It is clear that more research is needed on the potential carcinogenicity of famphur.

Signs of famphur toxicosis in cattle include ataxia, muscular fasciculations, general weakness, lacrimation, salivation, and diarrhea (Randell and Bradley 1980). In comparison with European breeds of cattle (*Bos taurus*), the Brahman (*Bos indicus*) and European X Brahman hybrids are more sensitive to famphur, and Brahman bulls are more sensitive than cows (Johnson et al. 1972; Randell and Bradley 1980) (Table 19.4). At a comparatively low dose of 16.6 mg famphur/kg BW, both *B. taurus* and *B. indicus* are tolerant of intramuscular injectable famphur. However, *B. indicus* is more sensitive, and bulls sometimes died when treatment levels exceeded 33.3 mg/kg BW (Randell and Bradley 1980) (Table 19.4). In addition to cattle, famphur-induced mortality in other species of mammals has been documented (Table 19.4). Single exposures of famphur, in mg/kg BW, killed rabbits (*Oryctolagus* sp.) at 2730 in dermal exposure; mice (*Mus* sp.) at 27 in oral dose or 11.6 by intraperitoneal injection; domestic sheep (*Ovis aries*) at 400 in oral dose; and laboratory white rats (*Rattus* sp.) at 400 dermal exposure or >28 in oral dose (Table 19.4). Mice receiving fatal or near-fatal intraperitoneal injections of famphur or famoxon began to convulse 10 to 20 min postinjection; death came within 45 min postinjection, usually from respiratory failure. Mice remaining alive at 60 min postinjection usually recovered (O'Brien et al. 1965).

Latent effects of famphur exposure in reindeer hinds (Nieminen et al. 1980) strongly indicate a need for additional studies in this subject area. Intramuscular injections of reindeer hinds and their 4-week-old calves controlled warble-fly infection in treated animals. Treated calves did not differ significantly from controls during the following year in body weight, body temperature, or blood chemistry. Treated hinds, however, had significantly lower erythrocyte sedimentation rates and serum gamma-globulin concentrations and significantly higher hemoglobin, serum calcium, serum inorganic phosphorus, and serum magnesium than untreated hinds 1 year after treatment (Nieminen et al. 1980).

Reduced brain cholinesterase activity in avian and mammalian wildlife is associated with adverse effects on metabolism, reproduction, sensory behavior, motor activity, food and water intake, learning, and memory (Mineau 1991). Cholinesterase activity in mammals regenerates rapidly after a cessation from treatment with famphur (Kaemmerer and Buntenkotter 1973). In humans, typical symptoms of organophosphorus-induced cholinesterase inhibition include headache, giddiness, nervousness, blurred vision, weakness, nausea, cramps, diarrhea, chest discomfort, sweating, salivation, vomiting, and tremors (Gallo and Lawryk 1991). In severe cases, victims show muscular weakness, convulsions, coma, loss of reflexes, loss of sphincter control, and eventually death. Effects of cholinesterase-inhibiting agents in humans are usually counteracted with repeated intravenous injections of atropine sulfate (2 to 4 mg), intravenous injections of pralidoxime chloride (1 g), and oxygen (Gallo and Lawryk 1991). Rats had depressed plasma cholinesterase activity when fed diets containing as little as 1 mg famphur/kg for as many as 90 days, although growth and appetite seemed normal (Black et al. 1979). Brahman bulls had maximum erythrocyte cholinesterase inhibition 14 days after intramuscular injection of famphur. Cholinesterase activity levels recovered toward normal during the next 14 days, and recovery correlated with the formation of new erythrocytes (Randell and Bradley 1980). Except for cholinesterase activity inhibition, there were no signs of organophosphate intoxication in Brahman heifers and steers given single dermal doses of 20 to 61 mg famphur/kg BW. Cholinesterase activity was inhibited for as many as 14 days posttreatment at the lower (20 to 41 mg/kg BW) doses and for at least 7 weeks at 61 mg/kg BW (Table 19.4).

Famphur is metabolized rapidly in mammals. In cattle, famphur controlled target insect pests when administered as a bolus, in the diet, as an oral paste, by intramuscular injection, or by pour-on. Regardless of mode of administration, length of exposure, or dose, famphur residues in tissues and milk were usually nondetectable within 4 days of final exposure. A similar pattern was evident in other species of mammals (Table 19.4). Rats and sheep metabolize famphur differently. During the first 24-h postdosing period, urine of rats contained as much as 2 times more of the unchanged *O*-desmethyl compound than urine of sheep, about the same amount of dimethylsulfamoylphenyl glucuronide, about 0.3 times as much *O,N*-bisdesmethylfamphur, and about 0.5 times less methylsulfamoylphenyl glucuronide (Gatterdam et al. 1967). With the exception of the oxon, metabolites of famphur were considerably less toxic to mammals than the parent chemical. In general, famoxon

was 100 times more effective than famphur in depressing erythrocyte cholinesterase activity (Kaemmerer and Buntenkotter 1973).

Famphur in pour-on applications penetrates skin at different rates, depending on the solvent. In rat skin, penetration was most rapid when the solvent was acetone and least rapid in corn oil and benzene; the percent of remaining famphur in rat skin 3 h after a single dermal application was 38% from the acetone mixture, and 67% from both benzene and corn oil solvents (O'Brien and Dannelley 1965). The penetrability of famphur pour-on formulations used in lice control on Angora goats was enhanced when applied in combination with a liquid-detergent wetting agent (Fuchs and Shelton 1985). Laboratory screening tests in which small mammals are treated with chemicals and parasitized by insects are now used to predict the effectiveness of systemic insecticides. Tests with mice and rodent botfly (*Cuterebra* sp.) were useful in predicting the effectiveness of famphur against larvae of the common cattle grub (*Hypoderma lineatum*) in cattle (Gingrich et al. 1972) (Table 19.4), and show promise for screening additional chemicals.

Table 19.4 Famphur Effects on Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect	Reference ^a
CATTLE, <i>Bos</i> spp.		
Bolus		
Given to 180-kg heifer calves 12 days before infestation by 30–60-day-old larvae of ticks. Sustained release equivalent to 3, 5, or 6.8–10.1 mg famphur/kg body weight (BW) daily	Ineffective at 3 mg/kg BW against fever ticks (<i>Boophilus annulatus</i> , <i>B. microloplus</i>) and the American dog tick (<i>Dermacentor variabilis</i>). At 5 mg/kg BW, famphur was effective (87–97%) against fever ticks but ineffective against the dog tick. At the highest daily release rate, famphur was 100% effective against fever ticks between days 12 and 41, but remained ineffective against the dog tick	1
7 mg/kg BW daily (range 4.5–11.5 mg/kg BW daily)	Bolus was 99–100% effective against Gulf Coast tick (<i>Amblyomma maculatum</i>) and 60–86% effective against the lone star tick (<i>A. americanum</i>). Heifers showed no signs of organophosphorus insecticide poisoning, but had slight reduction in erythrocyte cholinesterase activity	2
Diet		
Lactating cows fed diets equivalent to 3.3 mg famphur/kg BW for 90 days	Concentrations in milk on day of withdrawal were 0.025 mg famphur/L and 0.023 mg famoxon/L. During the next four milkings (i.e., through day 8 posttreatment), famphur and famoxon residues in milk were always <0.005 mg/L	3
Calves fed rations equivalent to 3.3 or 9.9 mg famphur/kg BW for 90 days	Within 2 days of cessation of the low-dose-contaminated diet all calf tissues were free of famphur and famoxon; this value was 4 days for the 9.9-mg/kg BW group. Concentrations of famphur (famoxon) in mg/kg FW in the high-dose group at the end of the 90-day feeding study were 0.31 (0.03) in muscle, 1.6 (0.23) in fat, 5.6 (0.5) in liver, and 0.49 (0.19) in kidney	3
Adult rations contained equivalent of 5 mg famphur/kg BW daily	99.5–100% effective in control of Gulf Coast tick and lone star tick; ineffective against the American dog tick	1
Adults given equivalent of 5 mg famphur/kg BW daily	Effective against tropical horse tick (<i>Anocentor nitens</i>), but not completely effective against 3 other species of ticks	2
Adults given equivalent of 5 mg/kg BW daily for 10 days, administered as a 33%-feed premix	>90% control of cattle grubs (<i>Hypoderma</i> spp.). Manure from treated cattle controlled larvae of horn fly (<i>Haematobis irritans</i>), but was ineffective against larvae of the house fly (<i>Musca domestica</i>)	4
Intramuscular injection		
15 mg/kg BW; Hereford steers and calves, Angus cows; to control cattle grubs (<i>Hypoderma lineatum</i> , <i>H. bovis</i>)	97% grub reduction in calves, 93% in cows, 94% in steers	5

Table 19.4 (continued) Famphur Effects on Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect	Reference ^a
16.6, 33.3, or 49.9 mg/kg BW, single injection; Brahman bulls, steers, and heifers 6–8 months old, 169–200 kg BW. Observed for 28 days posttreatment	All doses inhibited erythrocyte cholinesterase levels by 45–95%. All groups tolerated 16.6 mg/kg BW. Severe toxicosis in the two high-dose groups (9 of 20) in bulls but not in heifers and steers; 7 of the 9 bulls died or had to be euthanized; necropsy showed severe pulmonary edema	6
18 mg/kg BW, single injection	Residues <0.7 mg/L in blood 2 h postinjection	7
36 mg/kg BW, single injection	Residues in blood >0.7 mg/L 2 h postinjection, but <0.7 mg/L after 4 h	7
54 mg/kg BW, single injection	Residues in blood >0.7 mg/L 1–2 h postinjection, but <0.7 mg/L after 4 h	7
60.7 mg/kg BW, single injection of radiolabeled famphur	Blood plasma levels in mg/kg fresh weight (FW) were 0.4 after 4 h and 0.18 after 72 h; for famoxon, these values were not detectable at 4 h and 0.05 at 72 h. Plasma and urine radioactivity levels reached maxima after 24 h	7, 8
83.2 mg/kg BW; Brahman bulls and Angus bulls, 7–9 months old, 174–184 kg BW	5 of 6 injected Brahman bulls showed severe signs of toxicosis and 4 died within 48 h; recovery of the 5th bull took 10 days. Only 1 of 5 Angus bulls showed clinical signs of toxicosis, but it recovered	6
Oral		
9.9 mg/kg BW; single application, residues measured 24 h posttreatment; control values always <0.05 mg/kg FW of famphur and famoxon		
Fat; famphur vs. famoxon (mg/kg FW)	0.14 vs. <0.05	3
Kidney; famphur vs. famoxon (mg/kg FW)	<0.05 vs. <0.05	3
Liver; famphur vs. famoxon (mg/kg FW)	0.08 vs. 0.05	3
Muscle; famphur vs. famoxon (mg/kg FW)	<0.05 vs. <0.05	7
18 mg/kg BW	Residues in blood >0.7 mg/L 18–24 h after ingestion	7
20, 30, or 40 mg/kg BW, each with 8 mg levamisole/kg BW; administered as a paste to cattle yearlings in California, Nebraska, and Kentucky	As much as 85% reduction in cattle grubs and nematode gastrointestinal worms at 20 mg/kg BW + levamisole; as much as 98.2% reduction in 30 or 40 mg/kg BW groups	9
36 mg/kg BW, single dose	Residues in blood >0.7 mg/L 6–72 h after intake, but <0.7 mg/L after 96 h	7
Pour-on		
15–35 mg/kg BW, cows	Controls cattle-biting lice (<i>Damalinia bovis</i>), long-nosed cattle lice (<i>Linognathus vituli</i>), and short-nosed cattle lice (<i>Haematopinus eurysternus</i>)	10
20.25, 40.5, or 60.75 mg/kg BW; Holstein Friesian calves; blood cholinesterase activity levels measured up to 49 days posttreatment	At the 2 lowest doses, significant depression from day 2 through day 14; blood cholinesterase normal at day 21. At 60.75 mg/kg, blood cholinesterase decreased for entire 49-day posttreatment. No outward signs of organophosphate intoxication and normal food intake and demeanor	11
23 mg/kg BW, cows	At 24 h, whole milk had 0.24 mg famphur/L of which 76% was in the butterfat fraction; after 72 h, residues in milk were <0.008 mg/L	10
25 mg/kg BW, cows	After 24 h, mean residue of famphur in subcutaneous fat was 1.8 mg/kg FW, maximum was 2.46 mg/kg FW	10
40 mg/kg BW; Hereford steers and calves, Angus cows	87% effective in controlling cattle grubs in calves; 100% effective in cows and steers	5
40 mg/kg BW, cattle yearlings	100% effective in controlling cattle grubs and nematode gastrointestinal worms	9

Table 19.4 (continued) Famphur Effects on Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect	Reference ^a
40 or 50 mg/kg BW; yearling steers; Canada, late autumn; single treatment	Although not completely satisfactory for control of <i>Hypoderma</i> spp. (52–68% reduction in grubs) — possibly because of low absorption associated with low ambient temperatures at time of treatment — and some inhibition in blood cholinesterase activity (maximum inhibition of 31–38% reached 15 days after treatment), both groups of treated steers gained significantly more weight than a control group during the posttreatment of 181 days and were otherwise normal	12
Brahman bulls, steers, and heifers; mean weight of 117 kg		
40 mg/kg BW	Erythrocyte cholinesterase depression after 24 h was 43% in bulls and 33–34% in steers and heifers	13
80 mg/kg BW	After 5 h, 1 of 13 bulls was anorexic and salivating	13
209 mg/kg BW	After 48 h, erythrocyte cholinesterase depression was 56% in bulls, 55% in steers, and 51% in heifers	13
40.5 mg/kg BW, Brahman bull calves	2 of 3 famphur-treated calves died	11
45 mg/kg BW, cows	Famphur concentrations, in mg/kg FW, after 24 h were <0.05 in liver and kidney, 1.25 in fat, and 1.41 in muscle. After 7 days, these values were 0.53 in fat and 0.71 in muscle. By day 14, maximum values were 0.11 mg/kg FW in fat and <0.02 in other tissues	10
50 mg/kg BW, cows	After 24 h, mean residue of famphur in subcutaneous fat was 2.08 mg/kg FW, maximum was 3.00 mg/kg FW	10
150 mg/kg BW, cows	After 24 h, famphur concentrations in subcutaneous fat ranged from 6.3–12.3 mg/kg FW	10
ANGORA GOAT, <i>Capra</i> sp.		
Pour-on, 4.1–4.8 mg/kg BW; nannies 27–41 kg; single application	100% effective in 14-day control of Angora goat-biting louse (<i>Bovicola limbatus</i>) and hairy goat louse (<i>B. crassipes</i>); significant protection after 45 days	14
LABORATORY MOUSE, <i>Mus</i> sp.		
Dermal		
Mice infected nasally or orally with rodent botfly (<i>Cuterebra</i> sp.) were dipped 48 h postinfestation for 30 s in 25% emulsifiable famphur solutions (0.001–10%) and examined 1 week later. Entire body was submersed, except head	50% kill of larvae after immersion in 0.0072% solution (18 mg famphur/L); 90% control in 0.051% solution (127.5 mg/L)	16
Oral		
Male mice, 8–12 weeks old, orally and nasally infected with 1st-stage larvae of rodent botfly. Two days after infection, mice were given single doses of 1.46 or 3.38 mg famphur/kg BW	Low dose killed 50% of larvae; high dose killed 90%	17
As above, except that mice were given 1.5 mg famphur/kg BW at 1, 2, or 3 days after infestation	Most effective control (71% dead larvae) when administered at 3 days	17
18 mg/kg BW	Acute LD50, famoxon	7
27–30 mg/kg BW	Acute LD50, famphur	7, 15

Table 19.4 (continued) Famphur Effects on Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect	Reference^a
Intraperitoneal injection		
Single injection of 1 mg famphur/kg BW; residues of famphur, famoxon, and <i>N</i> -desmethylfamphur measured 1 h postinjection	Only 8.3% of the injected dose was measurable 1 h postinjection: 8.1% as the parent famphur, 0.2% as famoxon, and 0.01% as <i>N</i> -desmethylfamphur	18
5.8 mg famoxon/kg BW	LD50	18
11.6 mg famphur/kg BW	LD50	18
RABBIT, <i>Oryctolagus</i> sp.		
50 mg/kg BW; oral, subcutaneous, or intravenous route	No effect on reproduction	25
2730 mg/kg BW, dermal route	LD50	15
DOMESTIC SHEEP, <i>Ovis aries</i>		
Bolus; sustained release of 7 mg famphur/kg BW daily	Completely effective against Gulf Coast tick, partial control of lone star tick, ineffective against American dog tick	2
Intravenous injection		
Single injection of radiolabeled famphur equivalent to 22.3 mg famphur/kg BW. Sheep killed at 96 h and tissues analyzed for residual radioactivity	More than 50% of the administered dose was excreted within 6 h and 98% within 48 h. About 97% was excreted in urine and <3% in feces. Residues, in mg/kg FW, were 1.4 in blood; 0.3–0.6 in kidney, liver, spleen, lung, and cerebrospinal fluid; and <0.1 in bile, fat, brain, and muscle	7, 8
Single injection, 22.3 mg/kg BW	Famphur (famoxon) residues in blood plasma in mg/kg FW were 0.6 (5.6) at 2 h, and nondetectable (0.01) at 24 h	7
Intravenous or intramuscular injection; urine collected over 24-h period after single application of radiolabeled famphur	Urinary radioactivity was due to the unchanged O-desmethyl compound (13–24%); <i>N,N</i> -dimethyl sulfamoylphenyl glucuronide (32–33%); <i>O,N</i> -bisdesmethylfamphur (31–34%); and <i>N</i> -methyl sulfamoylphenyl glucuronide (8–15%)	8
Intramuscular injection		
Single injection of radiolabeled famphur, equivalent to 55.1 mg/kg BW. Sheep killed at 72 h and tissues analyzed for residual radioactivity	About 64% of the administered dose was recovered in excreta after 72 h. Residues in mg/kg FW were 15 at the muscle injection site; 5–8 in kidney, bile, and fat; 1.6–2.3 in liver, spleen, lung, and blood; and 0.7–0.9 in brain, muscle, and cerebrospinal fluid.	7, 8
Single injection, 55.1 mg/kg BW	Famphur (famoxon) residues in blood plasma, in mg/kg FW, were 0.9 (0.1) at 2 h and 0.06 (0.01) at 72 h	7, 8
Oral, single dose; 400 mg/kg BW	LD50	15, 19, 20
Rumen infusion; peroral administration by cannulation for 72 h of ewes given doses equivalent to 5 or 7 mg famphur/kg BW daily. After infusion for 72 h, sheep were challenged by various blood-sucking arthropods	At 5 mg/kg BW, famphur caused a significant increase in mortality and decrease in percent egg hatch of adult Gulf Coast ticks and complete control of the bedbug (<i>Cimex lectularius</i>). At 7 mg/kg BW daily, Gulf Coast ticks were completely controlled, but dose was ineffective against the lone star tick and the American dog tick	21
REINDEER, <i>Rangifer tarandus</i>		
Intramuscular injection		
15 mg/kg BW, single injection	At 24 h residues were highest (8.1–9.1 mg/kg FW) in fatty tissues; at muscle injection site, residues ranged as high as 635 mg/kg FW vs. 0.6 mg/kg FW in normal muscle. At 7 days posttreatment, residues in mg/kg FW, were 0.03–0.19 in fat,	22

Table 19.4 (continued) Famphur Effects on Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect	Reference ^a
30 mg/kg BW, single injection	0.03 in injection-site muscle, and 0.03 in liver. At 5 weeks, famphur was detectable only in fat; by 7 weeks, no famphur was detectable in any tissue. Famoxon was not found in any tissue at any time	22
30 mg/kg BW, single injection	Residues at 24 h in mg/kg FW were as high as 38 in fat, 8 in muscle, 5 in liver and 2.5 in kidney	23
Accidental overdose (usually double-dosed), 60 mg/kg BW	90–95% reduction in larvae of warble fly (<i>Oedemagena tarandi</i>) and nostril fly (<i>Cephenomyia trompe</i>)	23
	Atropine sulfate is recommended antidote	23
LABORATORY WHITE RAT, <i>Rattus</i> sp.		
Dermal		
Single application, mg/kg BW		
400	LD50, adult males	19
533	LD50, adult females	19
Diet		
Rations containing 1, 3, or 25 mg famphur/kg for as many as 90 days	At 90 days, all groups had depressed plasma cholinesterase, although growth and appetite seemed normal. Whole-blood cholinesterase was depressed in the 3- and 25-mg/kg groups; brain cholinesterase was significantly reduced in the 25-mg/kg group	24
Diet containing 25 mg famphur/kg for 90 days, then famphur-free diet for 42 days	Blood chemistry and histology normal at necropsy on day 132. Rats avoided diets during famphur-free phase	24
Oral		
Single dose, in mg/kg BW		
28	LD50, adult males	19
35	LD50	7, 20
36–62	LD50	15
51	LD50, adult females	19
73	LD50, weanling males	19
Subcutaneous injection; urine collected during 24-h period after single application of radiolabeled famphur	Urinary radioactivity was due to the unchanged O-desmethyl compound (>50%); <i>N,N</i> -dimethyl sulfamoylphenyl glucuronide (30%); (O, <i>N</i> -bisdesmethylfamphur (12%), and <i>N</i> -methyl sulfamoylphenyl glucuronide (7%)	8

19.5 RECOMMENDATIONS

The four primary areas of concern about famphur use are:

1. Mortality of birds associated with topical applications to cattle
2. Latent effects on domestic livestock
3. The absence of aquatic toxicity data
4. Potential carcinogenicity

Because of its high toxicity to birds and field and experimental evidence of primary and secondary poisoning of birds, famphur is considered hazardous to avian wildlife — especially magpies — where cattle are topically treated with this insecticide (Felton et al. 1981; Henny et al. 1985, 1987). The pour-on application for cattle is now preferred to systematic dipping or intramuscular injection; dipping is reportedly labor intensive and costly (Hair et al. 1979). Intramuscular injection is more labor intensive, causes greater tissue damage and higher famphur absorption at the injection site, and produces a greater depression in blood cholinesterase levels and a lower rate of weight gain in cattle than pour-on application (Loomis and Schock 1978). Nevertheless, famphur-induced mortality of magpies and other birds can be significantly reduced or eliminated by changing the insecticide application from the present pour-on method to other, now-available modes of administration such as by diets, bolus, and intramuscular injection (Henny et al. 1985, 1987). Furthermore, a warning should be added to famphur labels; livestock dying within 3 months of famphur treatment should be removed from the range or farmland; this would offer partial protection to carrion-feeding raptors such as eagles and vultures (Henny et al. 1987).

Reindeer are considered safe for human consumption 6 to 7 weeks after famphur treatment by intramuscular injection (dermal applications of famphur seldom penetrate the thick hair coat of reindeer). Treated reindeer had no detectable residues in liver, kidney, and muscle after 3 weeks (Ivey et al. 1976) and none in fat and other tissues after 6 to 7 weeks (Nordkvist 1975; Ivey et al. 1976). However, treated hinds during the following year had a significantly altered blood chemistry profile when compared to untreated hinds (Nieminen et al. 1980), suggesting a need for additional research on latent effects of famphur exposure. A safe dosage for cattle (*Bos* spp.) is 7 to 25 mg/kg BW by intramuscular injection or 40 to 55 mg/kg BW by pour-on (Loomis and Schock 1978). The maximum concentration of famphur and famoxon allowed in cattle meat, fat, and meat by-products in the United States is 0.1 mg/kg (Kaemmerer and Buntenkotter 1973; Ryan and McLeod 1979). In Australia, the maximum value is 0.05 mg/kg FW (Annand et al. 1976). The recommended minimum time between famphur treatment and slaughter of Australian cattle is 14 days. The half-time persistence of famphur in cattle tissues is 0.9 days, implying that even with gross misuse of the chemical, residues fall to low levels within a week (Annand et al. 1970). At present, no published studies are available on the latent effects of famphur to cattle. Evidence of latent effects of famphur in reindeer (Nieminen et al. 1980) strongly suggest initiation of research into this subject area with cattle and other treated livestock.

No published data were available on effects and fate of famphur in aquatic ecosystems. This seems to be a high-priority research need in view of the increasing and illegal use of famphur to kill migratory waterfowl (White et al. 1989). In the absence of these data, it is recommended that concentrations of famphur and famoxon in water and in tissues of aquatic organisms not exceed current analytical detection limits of 0.005 mg/L in water or 0.01 mg/kg FW tissue.

The carcinogenicity of famphur has not been satisfactorily resolved. Studies indicate a significantly elevated risk for leukemias among farmers handling famphur (Brown et al. 1990), but this needs verification.

19.6 SUMMARY

Famphur (phosphorothioic acid, *O*-[4-[(dimethylamino)sulfonyl], phenyl] *O,O*-dimethyl ester), also known as Warbex, is a systemic organophosphorus insecticide used almost exclusively as a veterinary chemical to control parasites in livestock. Famphur has proven effective in controlling maggots of the botfly and warble fly (*Hypoderma* spp.), lice (*Haematopinus* spp., *Linognathus* spp.), hornfly (*Haematobia* spp.), reindeer warble fly (*Oedemogena* spp.), reindeer nostril fly (*Cephanomyia* spp.), and mealworms (*Alphitobius* spp.). The LD₅₀ values for target insects ranged from 2.4 to 4.1 mg/kg body weight (BW) from a dermal route and 8.0 to 11.8 mg/kg BW from abdominal injection.

Only famphur and its oxygen analog, famoxon, were of toxicological significance. Other famphur metabolites were 31 to 237 times less toxic, as judged by acute oral toxicity tests in the mouse (*Mus* sp.). Famoxon was more effective than famphur in producing cholinesterase inhibition and death and confirms the generalization that the corresponding oxons are the more effective anticholinesterase agents. Differential toxicity of famphur to target pests and nontarget species was often associated with differential degradation and cholinesterase sensitivity.

Famphur is administered to livestock by intramuscular or subcutaneous injection, through the diet, as a dermal pour-on, or as an oral bolus. In mammals, famphur induced mortality at concentrations as low as 11.6 mg/kg BW in intraperitoneal injection (mouse), 27 mg/kg BW in a single oral exposure (mouse), >33.3 mg/kg BW in an intramuscular injection (Brahman cattle, *Bos indicus*), and 400 mg/kg BW in a dermal application (rat, *Rattus* sp.). Latent effects of famphur exposure were reported in reindeer (*Rangifer tarandus*) hinds 1 year posttreatment (altered blood chemistry). Famphur is rapidly metabolized by mammals. The half-time persistence of famphur and famoxon in subcutaneous fat of cattle after a single pour-on application is 0.9 days and is independent of dose between 25 and 150 mg/kg BW or initial tissue residues between 1.8 and 2.3 mg/kg BW.

Famphur has been used illegally by U.S. farmers to kill wild birds — including migratory waterfowl — thought to be depredating crops. Pour-on applications of famphur to cattle at recommended doses are sometimes associated with bird die-offs, especially the black-billed magpie (*Pica pica*). Magpie mortality — which persisted for 3 months — was probably associated with the lengthy persistence (>90 days) of famphur on cattle hair, and the ingestion of cattle hair by magpies. Cattle hair comprised as much as 12% of gizzard contents of dead magpies, and hair in the gizzards of dead magpies averaged 4600 mg famphur and famoxon/kg. Secondary poisoning of eagles and hawks foraging on famphur-killed vertebrates and tertiary poisoning of a great horned owl (*Bubo virginianus*) feeding on a famphur-poisoned hawk are documented. In the laboratory, sensitive species of birds died after single oral doses of 1.8 to 3.0 mg famphur/kg BW or when fed diets containing 35 to 49 mg famphur/kg ration. Depressed cholinesterase activity in the brain and in plasma occurred in nestlings at daily oral concentrations as low as 0.3 mg famphur/kg BW.

No published data were available on the fate or effects of famphur in aquatic ecosystems. In the absence of aquatic toxicity data on famphur, it is recommended that famphur and famoxon concentrations do not exceed the analytical detection limits of these compounds in water (0.005 mg/L) or in tissues of aquatic organisms (<0.01 mg/kg fresh weight).

Current recommendations include the discontinuance of topical applications of famphur to cattle because of its association with primary and secondary poisoning of birds — especially magpies, hawks, and eagles — and more research on famphur in the three areas of latent effects on treated livestock, fate and effects in aquatic ecosystems, and carcinogenicity evaluation.

CHAPTER 20

Fenvalerate

20.1 INTRODUCTION

Synthetic pyrethroids, including fenvalerate [(*RS*) α -cyano-3-phenoxybenzyl (*RS*) 2-(4-chlorophenyl)-3-methylbutyrate]^{*}, are broadly recognized as a major class of synthetic organic insecticides (Gray and Soderlund 1985). Introduced commercially less than 40 years ago, synthetic pyrethroids now account for more than 30% of insecticide use worldwide (Flannigan et al. 1985; Gilbert et al. 1989), in household, agricultural, and veterinary applications (Haya 1989; Williamson et al. 1989). More than 1000 pyrethroids have been synthesized since 1973 (Flannigan et al. 1985). They include compounds containing nitrogen, sulfur, fluorine, chlorine, and bromine, in addition to carbon, hydrogen, and oxygen (Glickman and Casida 1982). The most potent synthetic pyrethroid insecticides are the cyanophenoxybenzyl pyrethroids (Casida and Lawrence 1985); and fenvalerate is the most widely used compound in this group (Clark et al. 1985).

Pyrethroid insecticides are synthetic analogs of natural pyrethrins. Natural pyrethrins were widely used in Europe during the 19th century when few effective insecticides were available (Elliott and Janes 1978). Natural pyrethrins, which contain six insecticidally active components extracted from the dried heads of the pyrethrum flower (*Chrysanthemum cinariaefolium*), have high insecticidal properties and low mammalian toxicity. However, they are expensive to produce and have low photostability and high biodegradability (Wouters and Bercken 1978; Gray and Soderlund 1985; Haya 1989; Williamson et al. 1989). Modern synthetic pyrethroids have been designed to provide enhanced residual activity through greater photostability and greater resistance to chemical and biological degradation, greater insecticidal activity, diminished mammalian toxicity, and greater cost effectiveness (Elliott and Janes 1978; Vijverberg and Bercken 1982; Gray and Soderlund 1985; Smith and Stratton 1986; Coats et al. 1989; Haya 1989). The first synthetic pyrethroids — allethrin and cycloethrin — were produced around 1950, but lacked adequate photostability and were not as effective insecticidally as the natural pyrethrins. Tetramethrin was introduced in 1964, but it had inferior insecticidal activity. The first synthetic pyrethroids with greater insecticidal activity than natural pyrethrins were resmethrin and cismethrin, produced in 1968. Photostable pyrethroids were produced in the mid-1970s and included deltamethrin, cypermethrin, fenpropathrion, and fenvalerate (Smith and Stratton 1986).

Pyrethroid insecticides are generally recognized as potent neurotoxicants that interfere with nerve membrane function by interaction with the sodium channel (Elliott and Janes 1978; Vijverberg et al. 1982; Gilbert et al. 1989; Haya 1989). Synthetic pyrethroids are more toxic against insect pests, up to 10 times more potent in some cases, than other insecticides now in general use (Bradbury

* The technical fenvalerate formulation is no longer being manufactured by the Dupont Company, although existing stocks may be used until exhausted. The new fenvalerate formulation is sold as Asana or Esfenvalerate, and contains only the 2S, α S isomer (A. Stavola, U.S. Environmental Protection Agency, personal communication, January 28, 1991).

and Coats 1989a). However, the stereochemical structure of pyrethroid insecticides greatly influences their toxicity to insects and mammals, and this phenomenon is especially pronounced for fenvalerate (Bradbury et al. 1987b).

As broad-spectrum insecticides, the synthetic pyrethroids are necessarily toxic to a wide range of arthropods. Most insect orders are extremely susceptible, including many types of beneficial predator and parasite species (Bradbury and Coats 1989a). Synthetic pyrethroids are also toxic to fish and nontarget aquatic insects and crustaceans (Muir et al. 1985). Fenvalerate, for example, enters freshwater aquatic environments in runoff from food crop use, in drift from forest-spray procedures, and by direct spraying of water bodies (Haya 1989). Estuarine organisms may be exposed to fenvalerate and other pyrethroids after applications to corn, cotton, rice, and vegetables in coastal areas or by discharges from pyrethroid manufacturers or formulating and distribution centers (Clark et al. 1989). Fenvalerate has been implicated in kills of coastal organisms in South Carolina, primarily from agricultural runoff into estuarine tidal creeks (Scott et al. 1987).

Detailed information on ecological and toxicological aspects of fenvalerate and other synthetic pyrethroid insecticides is provided in reviews by Elliott (1977), Elliott and Janes (1978), Wouters and Bercken (1978), Glickman and Casida (1982), Vijverberg and Bercken (1982), Gray and Soderlund (1985), Leahey (1985), Smith and Stratton (1986), Coats et al. (1989), Bradbury and Coats (1989a), and Eisler (1992).

20.2 ENVIRONMENTAL CHEMISTRY

20.2.1 General

Synthetic pyrethroids now account for at least 30% of the world insecticide market and are rapidly replacing other agricultural chemicals for control of insect pests. Fenvalerate is one of the more widely used synthetic pyrethroid insecticides. It is derived from a combination of α -cyano-3-phenoxybenzyl alcohol and α -isopropyl phenylacetate ester. Technical fenvalerate is a mixture of four optical isomers, each occurring in equal amounts but with different efficacies against insect pests. Fenvalerate does not usually persist in the environment for >10 weeks, and it does not accumulate readily in the biosphere. Time for 50% loss (T_b 1/2) in fenvalerate-exposed amphibians, birds, and mammals was 6 to 14 h; for reptiles, terrestrial insects, aquatic snails, and fish it was >14 h to <2 days; and for various species of crop plants, it was 2 to 28 days. Fenvalerate degradation in water is due primarily to photoactivity, and in soils to microbial activity. Half-time persistence in nonbiological materials is variable, but may range up to 6 days in freshwater, 34 days in seawater, 6 weeks in estuarine sediments, and 9 weeks in soils.

20.2.2 Chemical Properties

Synthetic pyrethroid insecticides are photostable analogs of the natural pyrethrins of botanical origin. They consist of a series of related esters derived from alcohols and acids that maintain critical isosteric relations with the natural product prototype (Glickman and Casida 1982; Bradbury and Coats 1989a). Small changes in substituents and stereochemistry are sufficient to produce compounds differing in their insecticidal potency, spectrum of activity, and mammalian toxicology (Gray and Soderlund 1985). These halogenated, lipophilic, photostable compounds are exceptionally active against many species of insects. Although these compounds are relatively safe to birds and mammals, they are usually extremely toxic to certain freshwater and marine groups, including fish (Leahey 1985; Coats et al. 1989).

The first significant success in creating a photostabilized pyrethroid with high insecticidal activity was achieved through use of the 3-phenoxybenzyl alcohol moiety. A further step was the finding that 2-aryl-3-methylbutyric acid esters of pyrethroid alcohols were both photostable and

Table 20.1 Chemical and Other Properties of Fenvalerate^a

Variable	Data
Chemical name	(RS)- α -cyano-3-phenoxybenzyl(RS)-2-(4-chlorophenyl)-3-methylbutyrate; cyano(3-phenoxyphenyl) methyl 4-chloro- α -(1-methylethyl) benzeneacetate; α -cyano-3-phenoxybenzyl 2-(4-chlorophenyl)-3-methylbutyrate; 4-chloro- α -(1-methylethyl) benzeneacetic acid cyano(3-phenoxyphenyl) methyl ester; α -cyano-3-phenoxybenzyl α -(4-chlorophenyl) isovalerate
Alternate names	Agmatrin, Belmark, Ectrin, Fenkill, Phenvalerate, Pydrin, S-5602, Sanmarton, SD 43775, Sumicidin, Sumifly, Sumipower, Sumitox, WL 43775
CAS Number	51630-58-1
Chemical formula	C ₂₅ H ₂₂ CINO ₃
Molecular weight	419.92
Physical state	Clear yellow, viscous, liquid at 23°C
Purity	Technical grade compound is about 92% pure; nature and extent of impurities unknown
Vapor pressure at 25°C	1.1 × 10 ⁻⁸ mm mercury
Density at 23°C	1.17 g/mL
Stability	Stable in most solvents except alcohols at ambient temperature. Unstable in alkaline media. No significant breakdown after 100 h at 75°C; gradual degradation occurred in range 150–300°C
Degradation	Cleavage of the ester linkage is the primary route
Formulations	Emulsifiable concentrate, dust, granules, wettable powder
Log K _{ow}	6.2
Solubility at 20°C	
Acetone	>450 g/L
Chloroform	>450 g/L
Methanol	>450 g/L
Hexane	77 g/L
Water	2–85 µg/L
Seawater	24 µg/L

Data from Elliott 1977; Coats and O'Donnell-Jefferey 1979; Reed 1981; Tagatz and Ivey 1981; Akhtar 1983; Schimmel et al. 1983; Windholtz et al. 1983; Clark et al. 1987, 1989; Crofton and Reiter 1988; Sine 1988.

insecticidal (Gray and Soderlund 1985). Fenvalerate is one of the more recently developed and widely used synthetic pyrethroid insecticides, and it is a highly active phenylacetate ester of known pyrethroid alcohols, specifically, a combination of α -isopropyl phenyl acetate ester and α -cyano-3-phenoxybenzyl alcohol (Wouters and Bercken 1978). The phenoxybenzyl group and the halogenated phenyl ring increase the photostability of the molecule. The cyano group, substituted on the benzylic carbon, stabilizes the ester bond against hydrolysis (Coats et al. 1989).

Fenvalerate, like most other synthetic pyrethroids, is a halogenated, lipophilic, stable compound with low solubility in water and high solubility in organic solvents (Table 20.1). Technical fenvalerate is a racemic mixture of four isomers, composed of equal amounts of dextrorotatory and levorotatory forms. However, the four optical isomers (Figure 20.1) have very different efficacies against pest species. In general, fenvalerate stereoisomers with *S*-configurations in both the acid and alcohol moieties are more active pharmacologically and toxicologically than those with *R*-configurations (Wouters and Bercken 1978). Fenvalerate can be isolated and concentrated from pond water and other solutions using solid-phase extraction, and analyzed to 1.0 µg/L on a capillary gas chromatograph equipped with an electron-capture or flame photometric detector (Swineford and Belisle 1989).

20.2.3 Uses

Pyrethroids are used primarily for the control of household and agricultural insect pests, and secondarily in industrial, stored product, and veterinary applications. They are especially advantageous for use in northern climates because their toxicity is enhanced at low temperatures (Smith and Stratton 1986). Synthetic pyrethroid insecticides, including fenvalerate, are used as alternatives

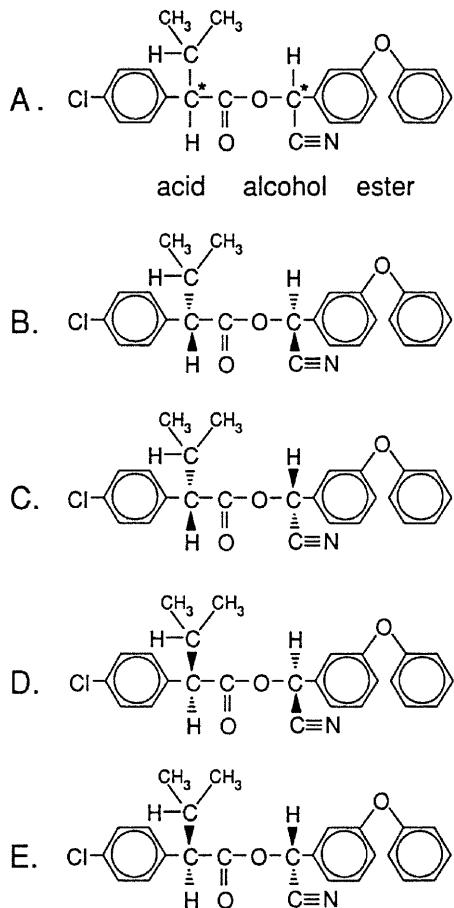

Figure 20.1 Fenvalerate and its isomers (Ohkawa et al. 1979; Hill 1981; Kaneko et al. 1981, 1986; Vijverberg and Bercken 1982; Miyamoto et al. 1986; Bradbury et al. 1987; Bradbury and Coats 1989a, 1989b; Coats et al. 1989). **A.** Chemical structure of fenvalerate denoting two asymmetric carbon atoms (*): the 2C position of the acid moiety, and the αC position of the α-cyano-3-phenoxybenzyl alcohol moiety. These two chiral centers, at the 2C and αC positions, yield a mixture of four stereoisomers, in approximately equal amounts, but with greatly different biological properties. **B.** (2S)-α-cyano-3-phenoxybenzyl (αS)-2-(4-chlorophenyl)-3-methylbutyrate. The 2S,αS-isomer is extremely toxic to insects, and is the most active form of fenvalerate. **C.** (2S)-α-cyano-3-phenoxybenzyl (αR)-2-(4-chlorophenyl)-3-methylbutyrate. The 2S,αR-isomer has markedly reduced insecticidal activity when compared with the 2S,αS-isomer, but is greatly elevated in this respect when compared with fenvalerate stereoisomers with an *R* configuration in the acid moiety, that is, the 2R,αS- and the 2R,αR-isomers. **D.** The 2R,αS-isomer is the only fenvalerate isomer that caused granulomatous changes in liver, spleen, and mesenteric lymph node in rodents. **E.** The 2R,αR-isomer has greatly reduced biological and toxicological properties when compared with other fenvalerate isomers. Isomers with an *R* configuration in the acid moiety degraded slightly faster than the insecticidally active 2S,αS- and 2S,αR-isomers.

to organochlorine, organophosphorus, carbamate, and natural pyrethrum insecticides because they are highly toxic to insect pests, low to intermediate in persistence, and low in toxicity to warm-blooded organisms, although extremely toxic to many aquatic organisms (Hansen et al. 1983; Coats et al. 1989). By 1982, more than 30% of the world market for insecticides consisted of synthetic pyrethroids, and this percentage is increasing (Smith and Stratton 1986).

Outside of the United States, fenvalerate is used on cotton (*Gossypium hirsutum*) in Australia, Greece, and South Africa, and on apples (*Malus* sp.), pears (*Pyrus* sp.), and potatoes (*Solanum* sp., *Ipomea* sp.) in Canada (Reed 1981); uses in other countries, including Mexico, are anticipated (Reed 1981), as is increased use against agricultural, poultry, dairy, and household pests (Mumtaz

and Menzer 1986). In agricultural use, recommended application rates of fenvalerate range between 0.055 and 0.224 kg/ha for control of a broad spectrum of pestiferous insects (Bennett et al. 1983).

Domestically, about 6500 kg fenvalerate were used in 1979; all of this amount was imported (Reed 1981). In 1980, in addition to registered use, the U.S. Environmental Protection Agency (USEPA) allowed an additional 80,000 kg for crisis and experimental use (Reed 1981). By 1981, fenvalerate had been registered for domestic use on apples, cotton, peanuts (*Arachis* sp.), pears, and potatoes. Additional uses were allowed under various experimental or crisis exemptions on beans (*Phaseolus* spp.), peppers (*Piper* spp.), broccoli, cabbage, cauliflower (*Brassica* spp.), celery (*Apium* sp.), corn (*Zea mays*), cucumbers (*Cucumis* sp.), eggplant (*Solanum melongena*), grapes (*Vitis* spp.), lettuce (*Lactuca* sp.), peas (*Pisum* sp.), squash (*Cucurbita* spp.), and tomatoes (*Lycopersicon esculentum*) (Reed 1981). By 1989, this list was expanded to include tobacco (*Nicotiana tabacum*), soybeans (*Glycine max*), sugarcane (*Saccharum* sp.), a wide variety of nuts, fruits, and vegetables, pine seed orchards, forest tree nurseries, mosquitoes, biting insects, insect vectors of disease, mite control in poultry, and fly and tick control in cattle (Spehar et al. 1982; Akhtar 1983; Bennett et al. 1983; Hansen et al. 1983; Sine 1988; Clark et al. 1989; Smith et al. 1989).

The delivery vehicle of fenvalerate-containing insecticide may account for wide variations in toxic action. For example, fenvalerate microcapsules used to control caterpillar pests (*Plutella xylostella*, *Spodoptera litura*) were most effective with thin-walled capsules and small particles. However, significant protection to nontarget organisms, such as fish, occurred with thicker-walled capsules and larger particles (Ohtsubo et al. 1989). The popularity of commercial synthetic pyrethroids and their widespread replacement of older, more-toxic compounds in various settings mandates a thorough understanding of the formulation used and of the active and inert components (Williamson et al. 1989).

20.2.4 Persistence

In nonbiological samples, half-time persistence of fenvalerate is variable, but frequently ranged between 2 and 6 days in freshwater, between 27 and 34 days in seawater, between 3 and 9 weeks in soils, and up to 6 weeks in estuarine sediments (Table 20.2). Persistence was longer at higher initial application rates and under conditions of reduced light, low microbial activity, and high organic content (Table 20.2). Fenvalerate is not readily transported from upland field application sites into the aquatic environment. Fenvalerate that directly enters the aquatic environment by way of runoff has limited bioavailability to aquatic organisms, owing to rapid adsorption onto soil particles, organic matter, or plants, and to chemical hydrolysis and photodecomposition (Ohkawa et al. 1980). Under acidic conditions, fenvalerate in water is stable to hydrolysis for 100 h at 75°C; Tb 1/2 at elevated recommended application rates is about 21 days, primarily as a result of photo-degradation (Reed 1981).

Fenvalerate is one of the more persistent synthetic pyrethroids in soils (Klaassen et al. 1986). In agricultural soils, fenvalerate is tightly adsorbed to soil particles, does not easily move laterally or to lower soil layers with groundwater, and almost always localizes in the application site because of its extremely low solubility in water (Ohkawa et al. 1980; Hill 1981; Miyamoto 1988). Fenvalerate degradation rates from mineral soil surfaces are dependent on soil type, moisture, temperature, and microbial activity. Half-time persistence in soils usually ranged between 2 and 18 days, but 3 months has also been recorded (Harris et al. 1981; Reed 1981; Bennett et al. 1986). Although fenvalerate is susceptible to chemical degradation by hydrolysis and oxidation, most authorities agree that degradation in soils is due primarily to microbial activity, that microbial degradation is most rapid under aerobic conditions, and that transformed products do not persist longer than the parent compound (Ohkawa et al. 1980; Chapman et al. 1981; Bennett et al. 1986).

In biological samples, fenvalerate neither persists for lengthy periods nor is readily accumulated (Smith and Stratton 1986; Cooper 1991). In general, fenvalerate is rapidly (i.e., Tb 1/2 of 6 to 14 h) excreted by amphibians, birds, and mammals; has low persistence in various reptiles, terrestrial

Table 20.2 Fenvvalerate Persistence in Water, Sediments, and Soils

Sample and Other Variables	Persistence	Reference ^a
FRESHWATER		
Various concentrations	Half-time persistence (Tb 1/2) of 3.2 days (range 1.9–5.8 days); longer for higher initial doses	1
0.1 µg/L	Tb 1/2 of 4.1 days; 90% loss in 13.5 days	11
3.9 µg/L	Maximum concentration was 2.3 µg/L 48 h after application; at 168 h it was 0.6 µg/L	1
8.3 µg/L	Concentration declined from 5.3 µg/L at 24 h to 1.8 µg/L at 168 h	1
16.5 µg/L	Concentration declined from 17.6 µg/L at 24 h to 9.1 µg/L at 168 h	1
30.6 µg/L	Concentration declined from 54.4 µg/L at 24 h to 21.2 µg/L at 168 h	1
SEAWATER	Tb 1/2 of 8 days in light, >14 days in dark; 27–34 days under alternating light and dark	2, 3
ESTUARINE SEDIMENTS		
Sterilized	No degradation in 28 days	2
Natural "Low" concentrations	Tb 1/2 of 4.5–9 days	1, 3
"Various" concentrations	Tb 1/2 of 24–42 days	2, 4–6
0.1–10 mg/kg dry weight (DW)	73% loss in 8 weeks at initial nominal concentration of 0.1 mg/kg DW, 78% at 1.0 mg/kg, and 96% loss in 8 weeks at 10 mg/kg DW	4
SOILS		
Initial concentration of 1.0 mg/kg DW soil		
Natural mineral, pH 8.0–8.1	12% remaining after 8 weeks; about 5% after 16 weeks	7
Sterilized mineral, pH 7.7–8.1	91% remaining after 8 weeks, 87% after 16 weeks	7
Natural organic, pH 7.1–7.2	58% remaining at 8 weeks, about 32% after 16 weeks	7
Sterilized organic, pH 6.5–6.9	100% remaining after 16 weeks	7
Various (clay, silt, sand), dose unknown	Tb 1/2 of 22–40 h	8
Mineral soils, dose unknown	Tb 1/2 of 6 weeks	9
Moist sand, dose unknown	Tb 1/2 of 9 weeks; 88% loss in 48 weeks	9
Lethbridge surface soil, agricultural, British Columbia		
Field conditions, initial application of 150 g/ha	Tb 1/2 of 6 weeks; 89% loss in 45 weeks	10
Laboratory study, 70 g/ha equivalent	Tb 1/2 of 5.2 weeks	10

^a 1, Coulon 1982; 2, Schimmel et al. 1983; 3, Smith and Stratton 1986; 4, Tagatz et al. 1987; 5, Tagatz and Ivey 1981; 6, Hansen et al. 1983; 7, Chapman et al. 1981; 8, Muir et al. 1985; 9, Harris et al. 1981; 10, Hill 1981; 11, Day et al. 1987.

insects, aquatic snails, and fish; and has moderate (i.e., Tb 1/2 of 2 to 28 days) persistence in various species of target plants (Reed 1981; Mumtaz and Menzer 1986; Bradbury and Coats 1989a, 1989b; Muir et al. 1994) (Table 20.3). Animals collected after 5 days from a cotton field sprayed with 0.112 kg/ha, or from the immediate vicinity, had very low fenvvalerate residues (Table 20.3) (Bennett et al. 1983). In that study fenvvalerate was detected in one of nine bird species sampled, in one of four mammals, in the western ribbon snake (*Thamnophis* sp.), in one of four amphibian species, and in fish and insects. The bird was a male dickcissel (*Spiza americana*) that had established a breeding territory within the sprayed cotton field. Carnivorous ground beetles, found moribund on the ground, contained the highest mean fenvvalerate residue of 0.55 mg/kg fresh weight (FW) whole body; large numbers of dead insects were found in the fields during collection. The highest residues (0.32 to 0.55 mg/kg) in fish and invertebrates were in those collected from a small pool in a drainage ditch, which compares with 0.92 mg/kg found in common carp (*Cyprinus carpio*) after exposure in the laboratory for 7 days to 0.8 µg fenvvalerate/L (Bennett et al. 1983).

Fenvalerate is not significantly absorbed or translocated in plants. Cotton, apples, and lettuce treated with fenvalerate contained surface residues of parent fenvalerate 8 weeks after treatment (Reed 1981). In addition to the parent compound, which accounted for 80% of all residues, identified metabolites included 3-phenoxybenzaldehyde, 3-phenoxybenzyl methylbutyric acid, and conjugates of these compounds. Half-time persistence of fenvalerate on plant surfaces is between 2 and 4 weeks, and degradation is primarily a result of weathering (Reed 1981).

Various plants sprayed with 0.25 kg fenvalerate/ha all had measurable residues 7 days after application, and nondetectable residues 15 to 30 days after treatment (Jain et al. 1979). Washing plants in cold water to remove the pesticide was effective only on the initial day of application, removing 30 to 50%. Afterward, only 3 to 13% could be removed by washing. Cooking removed 71 to 88% of the fenvalerate residues on the initial day of treatment; but in later samplings, removal was 68 to 70% in spinach (*Spinacea oleracea*) and tomatoes, and 38 to 40% in okra (*Abelmoschus esculentus*) and cauliflower (*Brassica oleracea botrytis*) (Jain et al. 1979).

Adsorption and persistence in plants can be modified by other chemicals or by selected carriers, although mechanisms to account for these phenomena are unclear. The application mixture influences adsorption and persistence of fenvalerate. For example, interception and persistence in sugarcane were increased when fenvalerate was applied in a 25% water/75% soybean oil mixture vs. water or soybean oil alone (Smith et al. 1989). Also, biocidal properties of fenvalerate residues on cotton foliage were increased up to 100% due to enhanced persistence of fenvalerate in the presence of toxaphene (Brown et al. 1982).

Fenvalerate photoproducts merit consideration, as some may be comparatively toxic. Decarboxyfenvalerate is a major degradation product of fenvalerate that is formed by photochemical reactions in water and on plant foliage (Mikami et al. 1985). This photoproduct comprises up to 10% of the total residues in forage crops that have been exposed to prolonged sunlight and drying. Decarboxyfenvalerate did not persist in tissues of hens, rats, and cows when consumed with feed for extended periods; its residue levels in ova, milk, and meat were negligible (Mikami et al. 1985).

Photolysis of fenvalerate in various solvents by sunlight yields products resulting from ester cleavage, primarily decarboxyfenvalerate, but also 15 other products. All sunlight photoproducts were relatively harmless to mice; LD₅₀ values were >500 mg/kg body weight (Holmstead et al. 1978). When photolysis was by way of ultraviolet light, however, two of the photoproducts formed (3-phenoxybenzoyl cyanide and 3-phenoxybenzyl cyanide) were considerably more toxic than fenvalerate. LD₅₀ values for intraperitoneal injection in mice were >500 mg/kg BW for fenvalerate, 2 mg/kg BW for 3-phenoxybenzoyl cyanide, and 105 mg/kg BW for 3-phenoxybenzyl cyanide (Holmstead et al. 1978). This finding strongly suggests a need for additional research on fenvalerate photoproduct persistence and toxicity.

Table 20.3 Fenvalerate Persistence in Plants and Animals under Field Conditions

Sample and Other Variables	Persistence	Reference ^a
Alfalfa, <i>Medicago sativa</i>	Half-time persistence (Tb 1/2) of 9–11 days	1
Cotton (<i>Gossypium hirsutum</i>) treated with 0.224 kg/ha, residues on foliage 12 days later		
In combination with 2.24 kg/ha toxaphene	Fenvalerate residues were 11.6 mg/kg	2
Fenvalerate alone	Residues were 5.9 mg/kg	2
Cotton, foliage	Tb 1/2 of 2 days, 96% lost in 17 days	3, 7
Cotton field sprayed with 0.112 kg/ha (0.1 pound/acre), Garland, Arkansas, July 1979. Animals collected from field 5 days later		
Mammals		
Deer mouse, <i>Peromyscus maniculatus</i> ; white-footed mouse, <i>P. leucopus</i> ; cotton rat, <i>Sigmodon hispidus</i>	<0.01 mg/kg whole-body fresh weight (FW), less skin and GI tract	3
House mouse, <i>Mus musculus</i>	0.01 mg/kg whole-body FW, less skin and GI tract	3

Animals collected from location near cotton field 5 days later		
Insects		
Cicada, Cicadidae	<0.01 mg/kg FW whole body	3
Short-horned Acrididae	0.18–0.24 mg/kg FW whole body	3
Ground beetle, <i>Calosoma</i> sp.	0.55 mg/kg FW whole body	3
Molluscs		
Aquatic snail, unidentified	0.53 mg/kg FW soft parts	3
Fish		
Mosquitofish, <i>Gambusia affinis</i>	0.3 mg/kg FW whole body	3
Golden shiner, <i>Notemigonus crysoleucas</i>	0.47 mg/kg FW whole body	3
Amphibians		
Southern leopard frog, <i>Rana utricularia</i> ; green frog, <i>Rana clamitans</i> ; green treefrog, <i>Hyla cinerea</i>	<0.01 mg/kg FW whole body, less skin and GI tract	3
Fowler's toad, <i>Bufo fowleri</i>	0.02 mg/kg FW whole body, less skin and GI tract	3
Old field site, Iowa, 0.112 kg/ha (0.1 pound/acre) applied on June 9, 1980, and again on August 5, 1980, June 10, 1981, and July 21, 1981		
Vegetation	Maximum immediately after each application was 12.1 mg/kg FW; residues after 24 days were always <1 mg/kg FW	1
Short-horned grasshopper, whole		
Applied June 9, 1980	Residues were 0.03 mg/kg FW after 36 days, and nondetectable (ND) in 49 days	1
Applied August 5, 1980	Residues were 0.33 mg/kg FW after 7 days, 0.19 after 14 days, and 0.12 after 21 days	1
Ground beetles, Carabidae, whole		
Applied June 1980	After 10 days, beetles contained 0.12 mg/kg FW; after 17 days, residues were ND	1
Applied August 5, 1980	After 6 days, residues were 0.14 mg/kg FW, and ND in 17 days	1
Applied July 21, 1981	Maximum residue after 24 days was 0.15 mg/kg FW	1
Deer mice, <i>Peromyscus maniculatus</i> , whole		
Applied July 21, 1988	Residues were 0.1 mg/kg FW after 2 days, and 0.01 after 21 days	1
Meadow vole, <i>Microtus pennsylvanicus</i> , whole		
Applied July 21, 1988	Residues were variable: 0.07 mg/kg FW after 2 days, 0.12 after 4 days, 0.46 after 8 days, and 0.04 after 21 days	1
Plants, 4 species, sprayed with 0.05% emulsifiable concentrate equivalent to 0.25 kg/ha		
Okra, <i>Abelmoschus esculentus</i> , initial concentration of 4 mg/kg FW	After 5 days, residue was 1.6 mg/kg FW, after 7 days it was 0.8, and after 15 days it was ND	4

Table 20.3 (continued) Fenvalerate Persistence in Plants and Animals under Field Conditions

Sample and Other Variables	Persistence	Reference ^a
Cauliflower, <i>Brassica oleracea botrytis</i> , initial deposit of 0.86 mg/kg FW	Initial deposit degraded to 0.3 mg/kg in 7 days, and was ND in 15 days	4
Tomato, <i>Lycopersicon esculentum</i> , initial residue of 0.85 mg/kg FW	Initial residue degraded to 0.67 mg/kg in 5 days, 0.3 in 15 days, and ND in 30 days	4
Spinach, <i>Spinacea oleracea</i> , initial residue of 9.5 mg/kg FW	Initial residue degraded to 2.8 mg/kg in 15 days, and ND in 30 days	4
Plants, various, foliage	Mean Tb 1/2 of 8.2 days, range 2.8–14 days	6
Bean, <i>Phaseolus</i> , sp.	Tb 1/2 of 14 days, essentially no translocation from leaf surface	1
Sugarcane, <i>Saccharum officinarum</i>, initial residue immediately after application was 18.8–28.2 mg/kg dry weight leaf	Residues after 7 days were 2.1–5.4 mg/kg DW; Tb 1/2 of 2.2–2.4 days	5

20.3 MODE OF ACTION

20.3.1 General

Two types of synthetic pyrethroids have been identified, as judged by different behavioral, neurophysiological, chemical, and biochemical profiles:

- Type I: those pyrethroids lacking the α -cyano group
- Type II: those possessing the α -cyano group (i.e., fenvalerate)

Induction of repetitive activity in the nervous system is the principal effect of pyrethroids. Repetitive activity originates from a prolongation of the transient increase in sodium permeability of the nerve membrane associated with excitation. All pyrethroids affect sodium channel gating in a similar manner, although Type II pyrethroids are significantly more neurotoxic than Type I pyrethroids.

Metabolism of fenvalerate proceeds by way of oxidation and hydrolysis to produce metabolites considered pharmacologically inactive or inferior to the parent compound. Insects and fish are extremely susceptible to fenvalerate when compared to mammals and birds. Interspecies differences are associated with rates of metabolism, excretion, absorption, esterase activity, and neurosensitivity.

Fenvalerate is neither mutagenic nor teratogenic. Tumor-like growths in rodent tissues, however, were associated with the $2R,\alpha S$ isomer — heretofore believed innocuous — more specifically, with its cholesterol conjugate.

20.3.2 Types of Pyrethroids

Two distinct types of synthetic pyrethroids have been identified, as judged by different behavioral, neurophysiological, chemical, and biochemical profiles in rodents (Wouters and Bercken 1978; Verschoyle and Aldridge 1980; Glickman and Casida 1982; Gray 1985; Gray and Soderlund 1985; Klaassen et al. 1986; Crofton and Reiter 1988; Bradbury and Coats 1989a; Gilbert et al. 1989; Williamson et al. 1989):

- Type I, also known as Class 1, or T — for tremor
- Type II, also known as Class 2, or CS — for choreoathetosis/salivation

In general, these authorities agree that pyrethroids containing both a halogenated acid esterified with the α -cyano-3-phenoxybenzyl alcohol — such as fenvalerate, deltamethrin, and cyper-

methrin — produce the Type II poisoning syndrome, and that pyrethroids lacking either or both of these moieties (i.e., permethrin, resmethrin, cismethrin, allethrin, bromphenothrin, phenothrin, kadeithrin, and tetramethrin) tend to produce the Type I syndrome. Type I is characterized by sparring, aggressive behavior (in rats, but not mice), rapid onset of tremor in the extremities, increased body temperatures, and whole-body tremors. As toxicity progresses, mice show hyperactivity, whereas rats become prostrate and die with immediate onset of rigor mortis; in mice, death is often associated with spasmodic seizures. The Type I syndrome is very similar to that produced by *p,p'*-DDT. Type II is characterized by pawing and burrowing behavior, profuse salivation, a decrease in body temperature of rats (due partially to evaporation of saliva), tremors progressing to choreoathetosis (i.e., a sinuous, writhing movement), muscular contractions and seizures, and death. With repeated high doses sufficient to kill some rats, degenerative changes in sciatic and posteriad tibial nerves were observed. The same two types of pyrethroid actions are also evident among insects.

Regardless of route of administration, signs of fenvalerate poisoning in rodents were similar. Doses administered by intercerebroventricular injection of comparatively low concentrations were more toxic than higher doses given orally, or by intravenous or intraperitoneal injection, suggesting greater central nervous system involvement in Type II than in Type I poisoning. In fact, pyrethroids that produce the Type II syndrome — including fenvalerate — are 5 to 10 times more potent neurotoxicants than Type I pyrethroids, which suggests different sites of action in the central nervous system.

20.3.3 Sodium Gating Kinetics

Pyrethroids have an action at or near the sodium channel in the nerve, resulting in greatly altered ionic currents and disrupted nerve function through membrane depolarization. Based on studies with insects, crustaceans, frogs, and small mammals, there is general agreement that (Wouters and Bercken 1978; Gammon et al. 1981; Vijverberg and Bercken 1982; Vijverberg et al. 1982; Parker et al. 1984b; Flannigan et al. 1985; Gray and Soderlund 1985; Ruigt and Bercken 1986; Eells and Dubocovich 1988; Flodstrom et al. 1988; Clark and Brooks 1989; Gilbert et al. 1989; Holloway et al. 1989; Salgado et al. 1989; Theophilidis et al. 1997):

- The sodium channel in the nerve membrane is the major target site for all synthetic pyrethroid insecticides (and many other neurotoxicants)
- Synthetic pyrethroids prolong the transient increase in sodium permeability of the nerve membrane during excitation, resulting in spontaneous depolarization and repetitive discharges
- Persistent repetitive discharges lead to muscular fasciculations, acetylcholine depletion, and muscular weakness
- Effects are enhanced at lower temperatures
- α -cyano (Type II) pyrethroids are more potent neurotoxicants than noncyano (Type I) pyrethroids, differences in neurotoxic effects being attributed solely to the α -cyano substituent

Most authorities agree that fenvalerate was the most effective pyrethroid tested for inducing pronounced repetitive activity in nerve fibers and that the 2S, α S-isomer was up to 15 times more potent than other fenvalerate isomers. Pyrethroids induce the sodium channels to close more slowly than normal, resulting in a gradually decaying inward sodium current (called a tail current) after termination of membrane depolarization. Type I pyrethroids induce tail currents with time constants of decay in milliseconds, but Type II pyrethroids result in time constants of decay that are orders of magnitude longer and contain thousands of impulses, inducing a quickly reversible, frequency-dependent suppression of the action potential. Depolarization of axons by synthetic pyrethroids was most effective at low temperatures; the negative temperature dependence of the steady-state current seems to be due to the stabilizing effect of low temperature on the open-modified channel.

Myelinated nerves of vertebrates are thought to sequester the pyrethroid molecules, known to be soluble in the myelin sheath, thereby preventing a portion of their chemical effect on the nerve axon (Flannigan et al. 1985). Fenvalerate, unlike other α -cyano pyrethroids, had little effect on the electrophysiological function of single myelinated nerve fibers in the frog (*Rana esculenta*), suggesting that additional research is needed on mechanisms other than membrane sodium transport (Tippe 1987).

The role of calcium in pyrethroid interaction with nerve tissue is under active investigation. Fenvalerate affects calcium-ATPase enzyme and calmodulin-activated enzyme activities, such as phosphodiesterase (Flodstrom et al. 1988). Fenvalerate inhibits calcium uptake by nerve cord of crayfish (*Procambarus clarkii*) and axon of spiny lobster (*Panulirus japonicus*), an action that seems to be related to its lipophilic properties (Doherty et al. 1986). Fenvalerate enhances the calcium-dependent, potassium-stimulated release of norepinephrine from rat brain and could lead to an overall depletion of brain stores of this neurotransmitter, producing a convulsive state typical of Type II pyrethroid poisoning (Brooks and Clark 1987; Clark and Brooks 1989). Fenvalerate evoked a calcium-dependent release of dopamine and acetylcholine from rabbit brain that was concentration related and specific for the 2S, α S-isomer; release of dopamine and acetylcholine was antagonized completely by tetrodotoxin, a sodium channel blocker (Eells and Dubocovich 1988). The relatively low potency of fenvalerate and other Type II pyrethroids on potassium-stimulated calcium uptake in rat brain and other responses suggests that neither the sodium–calcium exchanger nor the voltage-dependent calcium channels are primary targets for pyrethroid toxicity (Ramadan et al. 1988).

Toxic isomers of Type II pyrethroids usually antagonize γ -aminobutyric acid (GABA) by interacting with the *t*-butyl-bicyclicphosphorothionate/picrotoxin binding site in brain; antagonism of GABA leads to a reduction in inhibition (Casida and Lawrence 1985). Fenvalerate seems to increase inhibition, however, and this may be explained by a differential effect on sodium channel kinetics (Gilbert et al. 1989). Fenvalerate also inhibits perhydrohistrionicotonin binding with electric organ membrane of the electric ray (*Torpedo* sp.) (Abassy et al. 1983) and interacts with binding sites for dihydropicrotoxin and kainic acid in the brain (Gammon et al. 1982), but the significance of these observations is unclear.

20.3.4 Metabolism

The most important metabolic degradation pathways for synthetic pyrethroids are oxidation on the phenoxy ring, hydrolysis of the ester linkage, and conjugation of metabolites. Rates and pathways differ among taxonomic animal groupings, resulting in large differences in sensitivity (Holmstead et al. 1978; Kaneko et al. 1981; Akhtar 1983; Miyamoto 1988; Bradbury and Coats 1989a).

All metabolic degradation products of fenvalerate are pharmacologically inactive or inferior to the parent compound, implying that metabolic modifications lead to detoxication (Miyamoto 1988). Fenvalerate and other α -cyano pyrethroids, however, are consistently more resistant to oxidative attack than their non-cyano analogs (Gray and Soderlund 1985). Liver is the predominant site of fenvalerate metabolism via hydrolysis by one or more hepatic microsomal esterases. Inhibition of these enzymes results in enhanced toxicity (Ghiasuddin and Soderlund 1984). Hydrolysis has also been demonstrated in plasma, kidney, stomach, and brain tissues. Except for brain, however, these tissues were relatively unimportant in the detoxification process (Ghiasuddin and Soderlund 1984; Gray and Soderlund 1985).

Metabolism of the 2S-isomers proceeds sequentially: hydroxylation at the phenoxy group, hydrolysis of the cyano group, and cleavage of the ester linkage (Coats et al. 1989). Fenvalerate and the 2S-isomers yield two ester metabolites in feces from hydroxylation at the 4'- and 2'-phenoxy positions. Other significant metabolites were 3-phenoxybenzoic acid and its hydroxy derivatives from the alcohol moiety, 3-(4-chlorophenyl) isovaleric acid and its hydroxy derivatives from the acid moiety, and thiocyanate and carbon dioxide from the cyano moiety (Ohkawa et al. 1979). A slow elimination rate characterizes fenvalerate and other α -cyano pyrethroids when compared with

non-cyano pyrethroids; it seems to be due to the release of the cyano group during ester cleavage, which is then incorporated into the body thiocyanate pool and retained in the skin and stomach (Gray and Soderlund 1989). Decarboxyfenvalerate, a photolysis product of fenvalerate, is present in water and on plant surfaces, but it is extensively hydroxylated in mammals, and excreted rapidly and completely into feces, with no apparent toxic effects (Miyamoto 1988).

Signs of fenvalerate intoxication are similar in birds, fish, mammals, and insects, but insects and fish are extremely sensitive when compared with warm-blooded organisms, frequently by one to three orders of magnitude (Bradbury and Coats 1989a,b). Increased resistance to fenvalerate and other synthetic pyrethroid insecticides in mammals and birds, when compared with aquatic organisms and terrestrial insects, is attributed to their higher metabolism, more rapid excretion, lower absorption from diet or the surrounding envirosphere, higher esterase activity, higher fat content, and lower neurosensitivity (Wouters and Bercken 1978; Ohkawa et al. 1979; Glickman and Casida 1982; Flannigan et al. 1985; Gray and Soderlund 1985; Klaassen et al. 1986; Bradbury and Coats 1989a,b; Coats et al. 1989). For example, rainbow trout (*Oncorhynchus mykiss*) — one of the more sensitive aquatic species — have significantly lower rates of metabolism and elimination of fenvalerate than those reported for birds and mammals (Bradbury et al. 1986; Bradbury and Coats 1989a,b); show little or no esterase activity toward pyrethroids and substantially lower oxidative activity than warm-blooded animals (Bradbury and Coats 1989a,b); efficiently accumulate fenvalerate from the medium (Gray and Soderlund 1985), and show greater intrinsic sensitivity of the central nervous system when compared with birds and mammals (Gray and Soderlund 1985; Bradbury and Coats 1989a).

Fenvalerate effects are antagonized or synergized by various compounds or chemicals. Dermal exposure to fenvalerate in mammals may produce a skin sensory response, most frequently on the face, characterized by itching and tingling. Administration of Vitamin E up to 29 h before fenvalerate exposure partially reduced the fenvalerate-mediated skin sensation in guinea pigs (*Cavia* sp.; Malley et al. 1985). The effectiveness of Vitamin E may be associated with its membrane stabilizing property, although the exact mode of action is unknown. Fenvalerate skin sensations were also reduced by piperonyl butoxide when applied directly to the skin or in conjunction with fenvalerate (Malley et al. 1985). Delayed toxic effects in rodents and insects were produced with various muscle relaxants, including propranolol and diazepam, perhaps through depolarization of nerve terminals (Gammon et al. 1982; Gray 1985; Gray and Soderlund 1985). Mice given profenofos, an esterase inhibitor, were up to 27 times more susceptible than were nontreated animals (Glickman and Casida 1982).

20.3.5 Mutagenicity, Teratogenicity, and Carcinogenicity

Fenvalerate and other synthetic pyrethroids caused no oncogenic, reproductive, mutagenic, or teratogenic effects, as judged by results of 2-year feeding studies with rodents at 250 to 300 mg/kg diet, three-generation rodent reproduction studies at 250 mg/kg diet, various mutagenicity assays, bone marrow cytogenicity up to 150 mg/kg BW, the dominant lethal bioassay at 100 mg/kg, and a host-mediated bioassay in mice at 50 mg/kg BW (Reed 1981; Pluijmen et al. 1984; Flannigan et al. 1985; Gray and Soderlund 1985). Some chromosomal aberrations and alterations in the mitotic index were noted, however, in bone marrow and testis cells of rats given 100 mg fenvalerate/kg BW orally, a dose that killed 71% of the rats (Gray and Soderlund 1985). A similar pattern was noted in mice (Flodstrom et al. 1988; Pati and Bhunya 1989), indicating that additional research is needed to establish the mutagenicity of fenvalerate.

The carcinogenic potential of fenvalerate is based on negative or inconclusive evidence and centers on its ability to produce microgranulomas in various tissues, especially liver, in dogs and rodents. Beagle dogs exposed to 250, 500, or 1000 mg fenvalerate/kg diet for 6 months showed treatment-related microscopic effects, including histiocytic cell infiltrates in mesenteric lymph nodes and multifocal microgranulomas in liver (Parker et al. 1984b). Female rats fed a diet containing 1000 mg fenvalerate/kg ration for 2 years showed a statistically significant increase in the

incidence of mammary tumors; however, this was judged by the authors (Parker et al. 1984a) to be of unlikely biological significance. Their unusual conclusion was based on four points:

1. None of the mammary tumor incidences exceeded those expected or reported on aged female rats of this strain
2. Time and appearance of tumors in control and treated groups were unchanged by treatment
3. The benign:malignant ratio of mammary tumors was the same in control and treated groups
4. The tumors were common in this strain of rat and did not seem to be related to treatment

Fenvalerate inhibits intercellular communication between fibroblast cells and enhances the development of hepatocyte foci in rat liver at nonhepatotoxic dose levels. Chemicals that possess these properties are likely to be tumor promoters (Flodstrom et al. 1988). Fenvalerate alone induced no hepatotoxic effects in rat liver, as judged by transaminase activities and histology. However, some rats that were partially hepatectomized and insulted with nitrosodiethylamine — a carcinogen and tumor initiator — had significantly elevated numbers of liver foci after administrations of fenvalerate. This response suggests that fenvalerate is a potential tumor promoter (Flodstrom et al. 1988).

Linkage of the tumor-like formations in rodents with a specific fenvalerate stereoisomer was an important breakthrough (Kaneko et al. 1986; Okuno et al. 1986; Miyamoto et al. 1986; Miyamoto 1988). Granulatomous cells in spleen, lymph node, and liver of fenvalerate-stressed rats and mice tended to fuse, forming large multinucleated cells called giant cells. Researchers convincingly demonstrated that the $2R,\alpha S$ -isomer, heretofore believed innocuous, was solely responsible for the observed microgranulomas. The residual metabolite in this instance is the cholesterol conjugate [cholesterol ($2R$)-2-(4-chlorophenol) isovalerate] known as CPIA-cholesterol ester. This lipophilic conjugate forms rapidly, usually peaking within 60 min, and tends to persist in tissues, especially in adrenal, spleen, liver, and mesenteric lymph node. Of the four fenvalerate isomers, only the $2R,\alpha S$ -isomer yielded CPIA-cholesterol ester in tissue homogenates of mice, rats, dogs, and monkeys. Mouse tissues showed relatively higher activities than those of other animals. Kidney, brain, and spleen of mice showed relatively higher capacities to form CPIA-cholesterol ester when compared with other mouse tissues; in all cases, enzyme activity localized mainly in microsomal fractions. Researchers concluded that stereoselective formation of the CPIA-carboxyesterase complex only from the $2R,\alpha S$ -isomer, which subsequently undergoes cleavage by cholesterol to yield the CPIA-cholesterol ester that produced giant cells in mice (Kaneko et al. 1986; Okuno et al. 1986; Miyamoto et al. 1986; Miyamoto 1988). These findings strongly support the need for more research on the carcinogenic potential of fenvalerate stereoisomers.

20.4 EFFECTS

20.4.1 General

Fenvalerate is extremely toxic to representative nontarget aquatic organisms and to some beneficial terrestrial arthropods at concentrations substantially lower than those recommended to control pestiferous insects. Toxic effects are associated primarily with the $2S,\alpha S$ -isomer and are exacerbated at low temperatures. Birds, mammals, and terrestrial plants are normally tolerant.

Target insect species are usually killed at fenvalerate concentrations of 0.015 µg whole body, 0.11 kg/ha by way of aerial application, 5.4 mg/kg in the soil, or 50 mg/kg in the diet. Adverse effects on survival of sensitive aquatic organisms occur at 0.003 to 0.03 µg/L for crustaceans and 0.09 to 1.1 µg/L for fish and amphibians. Younger stages of sensitive birds had reduced survival at acute oral doses >500 mg/kg BW, and reduced growth at diets containing >750 mg/kg ration; poultry diets containing <50 mg fenvalerate/kg feed produced no appreciable residues in eggs and

meat of exposed birds. Among sensitive mammals, adverse effects on survival were noted at acute oral doses of 50 to 450 mg/kg BW, dietary concentrations of 50 to 1000 mg/kg, and dermal applications of 1800 mg/kg BW.

20.4.2 Terrestrial Plants and Invertebrates

Terrestrial plants are relatively unaffected by fenvalerate at recommended application rates, as judged by negligible uptake of fenvalerate from treated soils, formation of numerous fenvalerate conjugates that are pharmacologically inactive, and metabolism of the liberated cyano group into amino acids and eventually carbohydrate and protein (Miyamoto 1988).

Adverse effects of fenvalerate on survival of terrestrial arthropods were observed at 0.002 to 0.015 µg whole-body topical application, 0.11 kg/ha aerial application, 5.4 mg/kg in the soil, 50 mg/kg in the diet, and 1.4 g/ant mound (Table 20.4). Synthetic pyrethroids are more effective in biological systems at low temperatures. The relative sensitivity of insects when compared with mammals is attributed in part to this negative temperature coefficient. Thus, warm-blooded animals are less affected than insects and other poikilotherms (Klaassen et al. 1986). Fenvalerate, for example, showed a negative correlation between temperature and toxicity to crickets (*Acheta pennsylvanicus*), being up to 1.9 times more toxic at 15°C than at 32°C (Harris et al. 1981). A similar case is made for honey bees (*Apis mellifera*) (Mayer et al. 1987) and for many species of aquatic invertebrates and fish (Mayer 1987).

Signs of lethal pyrethroid poisoning in insects and other arthropods generally include hyperexcitation, tremors, and convulsions, culminating in paralysis and death (Wouters and Bercken 1978). At sublethal doses, equivalent to about 10% of a lethal dose, signs of poisoning in sensitive insects include cessation of feeding, wandering, hyperactivity, restlessness, and flushing out of hiding (Bradbury and Coats 1989a). The American cockroach (*Periplaneta americana*) exposed to topical lethal concentrations of fenvalerate had uncoordinated rapid movements followed by inactivity, appearance of water drops under wings and abdomen, and blackening of the abdomen (Yellamma and Reddy 1987). Signs appeared in <1 h at lethal concentrations and <3 h at sublethal concentrations. Roaches exposed to sublethal doses began recovery 6 h after exposure, attaining full recovery at 24 h (Yellamma and Reddy 1987).

Field application rates of 0.05 to 0.2 kg fenvalerate/ha are recommended for insect control on many food crops. Under these conditions, fenvalerate remained completely effective for 5 days against adults and nymphs of aphids (*Lipaphis erysimi*), jassids (*Amrasca biguttula biguttula*), and white fly (*Bemisia tabaci*) (Jain et al. 1979). Fenvalerate, applied as a drench to mounds, shows promise as an effective control agent of the fire ant, *Solenopsis invicta* (Phillips et al. 1984). Foliar applications of fenvalerate sprays at 135 mg/L effectively controlled various pests in pear orchards of northern California, including pear psylla (*Psylla pyricola*), codling moth (*Laspeyresia pomonella*), and pear rust mite (*Epitrimerus pyri*); populations of spider mites increased, especially the two-spotted spider mite, *Tetranychus urticae* (Riedl and Hoying 1980).

A concentration of 2 mg fenvalerate/L is frequently applied to soils to control insect pests (Schreiber and Brink 1989). However, several species of soil protozoans (*Blepharisma undulans*, *Colpoda cucullus*, *Oikomonas termo*) have LC10 (9 h) values in the range of 0.1 to 0.18 mg/L, suggesting that some damage occurs to this group under recommended application protocols (Schreiber and Brink 1989). In fact, all fenvalerate treatments applied to control insect pests of crops also reduced populations of beneficial nontarget organisms, including spiders, ground beetles, and crickets (Smith et al. 1989). For example, spiders (*Chiracanthium mildei*) exposed for 48 h to grapefruit leaves that had been dipped 1 h previously for 5 s in aqueous emulsions of fenvalerate at field-recommended application rates all died within 2 days postexposure (Mansour 1987).

Fenvalerate-tolerant strains of arthropods include insect vectors of disease, flies and cockroaches, arthropods of veterinary importance, and agricultural pests (Sawicki 1985). But serious

control problems are restricted to only a few areas, such as Central America and Thailand, where insecticidal usage is often excessive (Sawicki 1985). The exact mechanisms of resistance are unknown, although tolerance to fenvvalerate in the diamondback moth (*Plutella xylostella*), a worldwide pest of cabbage-type crops, is about 20% genetic, involving several genes and multiple loci (Tabashnik and Cushing 1989). Estimates of heritability in tolerance of insects to all biocides ranges between 14 and 47% (Tabashnik and Cushing 1989). Tolerant insect species, such as larvae of the common green lacewing, and resistant strains of houseflies and lepidopterous larvae may hydrolyze fenvvalerate faster than sensitive species or susceptible strains (Glickman and Casida 1982). Fenvvalerate-resistant strains of domestic houseflies (*Musca domestica*), for example, when compared with susceptible strains, absorbed up to 3 times less fenvvalerate, had a metabolic rate up to 8 times faster, began excretion of metabolites 5 times faster, and were twice as resistant to piperonyl butoxide, a synergist applied with fenvvalerate (Golenda and Forgash 1989).

The alfalfa leaf cutter bee (*Megachile rotundata*) is the most important insect pollinator of alfalfa grown for seed production in France. Alfalfa is parasitized by many insects, including the flower midge (*Contarinia medicaginis*). Fenvvalerate, at 0.05 kg/ha, controls the flower midge without harm to alfalfa leaf cutter bees (Tasei and Debray 1985). In general, fenvvalerate-treated plants were usually nontoxic to bees after 24 h (Mayer et al. 1987). Fenvvalerate does not poison bees when they are in contact with contaminated (100 mg/kg) wax in combs (Stoner et al. 1985). Fenvvalerate does not pose a serious threat to honey bees except when dietary levels exceed 50 mg fenvvalerate/kg (Stoner et al. 1984). Field application of 0.22 kg fenvvalerate/ha on blooming alfalfa, pollen-shedding corn, and blooming red raspberry resulted in reduced honey bee visitation and low-to-moderate adult bee mortality (Mayer et al. 1987). Caged honey bees exposed to an equivalent dose of 0.11 kg fenvvalerate/ha experienced >50% mortality within 24 h (Table 20.4). However, field studies showed that 0.11 kg/ha caused no observable adverse effects to bee colonies located adjacent to a treated alfalfa field; researchers concluded that fenvvalerate temporarily repelled bees, as judged by a 70% reduction in bee visits to the alfalfa field in the afternoon after application when compared with periods 24 h before and after application (Moffett et al. 1982). Impaired response to scent stimuli, in addition to repellency, may account for a reduction in bee visits. Studies by Taylor et al. (1987) suggested that bees surviving LD₅₀ doses of fenvvalerate were unable to distinguish odor-mediated learned responses for up to 6 days after treatment. This finding indicates that more research is needed on fenvvalerate-associated olfactory inhibition.

Table 20.4 Lethal and Sublethal Effects of Fenvvalerate on Terrestrial Invertebrates

Organism, Dose, and Other Variables	Effect	Reference ^a
CRICKET, <i>Acheta pennsylvanicus</i>		
5.4 mg/kg mucky soil	LD ₅₀ (18 h)	1
6.5 mg/kg moist sand	LD ₅₀ (18 h)	1
MOSQUITO, <i>Anopheles stephensi</i>		
0.002 µg whole body	LD ₅₀	12
INDIAN HIVE BEE, <i>Apis cerama indica</i>		
0.128–0.14 µg/bee	LD ₅₀ , topical application	2
HONEY BEE, <i>Apis mellifera</i>		
0.11 kg/ha, caged bees	57% dead in 24 h	3
Bees caged with alfalfa treated previously with 0.22 kg/ha, and held under various photothermal regimens for 24 h	Bees held at 10°C in the dark experienced 96% mortality; bees held at 29°C in the dark had 58% dead; those held at 18–35°C with normal photoperiod had 40% dead	3
0.22 kg/ha	Repelled bees for 10 h	4

Table 20.4 (continued) Lethal and Sublethal Effects of Fenvalerate on Terrestrial Invertebrates

Organism, Dose, and Other Variables	Effect	Reference ^a
0.4 kg/ha	Increased mortality for 3 days after exposure	4
0.43 kg/ha, caged bees	All dead in 24 h	3
0.9 kg/ha	Hazardous for 2 h after application	5
Fed sucrose syrup for 7–8.5 weeks containing 0.1, 1, 10, 50, or 100 mg fenvalerate/kg	At 100 mg/kg, survival was lower and honey production declined. At 50 mg/kg diet, bees consumed less syrup, suggesting repellency. No measurable effect at 10 mg/kg diet, and lower. Queens were not affected at any dose level	5
Colonies exposed for several weeks to 1, 10, 100, or 1000 mg/kg incorporated into beeswax foundation	Adverse effects noted only at 1000 mg/kg, namely, lower egg hatch and survival. Fenvalerate degradation in beeswax was 11% in 15 days, 21% in 75 days, and 81% in 130 days	6
MITE, <i>Chorioptes bovis</i>		
0.05% dip (500 mg/L) for 1 min	Kills all mites and their eggs on Angora goats (<i>Capra</i> sp.) within 7 days	7
ALFALFA LEAFCUTTING BEE, <i>Megachile rotundata</i>		
0.05 kg/ha	No effect on survival or reproduction	8
0.11 kg/ha	82% dead in 24 h	3
0.22 kg/ha	92% dead in 24 h	3
0.43 kg/ha	All dead within 24 h	3
HOUSEFLY, <i>Musca domestica</i>		
Susceptible strain		
0.013–0.015 µg/fly	LD5, topical dose	12, 13
0.028 µg/fly	LD30, topical dose	13
Resistant strain		
0.150 µg/fly	LD5, topical dose	13
ALKALI BEE, <i>Nomia melanderi</i>		
0.11 kg/ha	64% dead in 24 h	3
0.43 kg/ha	All dead in 24 h	3
AMERICAN COCKROACH, <i>Periplaneta americana</i>		
3.5 µg/roach	Nonlethal	9
10.5 µg/roach	LD50, topical	9
100 µg/kg BW	LD50, topical	12
200 µg/kg BW	LD95, topical. Diazepam delayed onset of action	10
FIRE ANT, <i>Solenopsis invicta</i>		
0.73–1.4 g/mound, applied as drench	All mounds viable after 4 weeks; 70–100% of mounds nonviable after 8 weeks	11
112 or 224 g/ha, aerial application	Ineffective control. After 4 weeks, population levels were 29–35% of controls	11

20.4.3 Aquatic Organisms

“Supertoxic” compounds are those with LC50 (96 h) values <10 µg/L (Scott et al. 1987). Fenvalerate is considered supertoxic, as judged by LC50 (96 h) values of <1.0 µg/L for sensitive aquatic organisms, and <10 µg/L for representative aquatic species (Table 20.5).

Signs of fenvalerate poisoning in fish include loss of schooling behavior, swimming near the water surface, hyperactivity, erratic swimming, seizures, loss of buoyancy, elevated cough rate, increased gill mucus secretions, flaring of the gill arches, head shaking, and listlessness prior to death (Bradbury and Coats 1989a, 1989b). Fenvalerate mainly affects the nervous system in fishes, as discussed earlier. It also produces osmoregulatory imbalance, as judged by altered calcium uptake (Symonik et al. 1989), abnormal sodium and potassium excretion rates, and elevated urine osmolality (Bradbury et al. 1987a; Bradbury and Coats 1989a, 1989b). Histological damage to gill surfaces by fenvalerate is attributed to high accumulations in gills, irritation due to elevated mucus secretion, increased ventilation volume, and decreased gill-oxygen uptake efficiency (Bradbury et al. 1986, 1987a; Bradbury and Coats 1989a,b). In fish, as in mammals, fenvalerate toxicity is primarily dependent on the *2S,αS*-component of the technical mixture. Studies with individual isomers and various freshwater fishes indicate that the *2S,αS*-isomer is 96 times more toxic than the *2S,αR*-isomer, and at least 1766 times more toxic than the *2R,αS*- or *2R,αR*-isomers ([Table 20.5](#)).

Laboratory studies with fenvalerate and aquatic organisms indicate marked differences in sensitivity among taxonomic groups ([Table 20.5](#)). Crustaceans were the most sensitive group: reduced survival was evident between 0.0032 and 0.03 µg/L, and impaired feeding and reproduction between 0.0016 and 0.01 µg/L. Fish and amphibians were more tolerant to fenvalerate than were crustaceans. Increased mortality was evident between 0.088 and 1.1 µg/L, and no adverse effects were demonstrated in several species between 0.062 and 0.083 µg/L, although certain salmonids showed high uptake at concentrations as low as 0.0003 µg/L. Algae, molluscs, and chordates were comparatively resistant to fenvalerate ([Table 20.5](#)). Survival patterns of fenvalerate-stressed aquatic organisms are significantly altered, sometimes by an order of magnitude or greater, by selected biological, chemical, and physical variables. In general, increased mortality was associated with the following:

- Reduced metabolism and excretion (Bradbury et al. 1986; Bradbury and Coats 1989a; Coats et al. 1989; Haya 1989)
- Depleted glycogen stores due to starvation (Haya 1989)
- Larval and juvenile stages of development (Spehar et al. 1982; Bradbury and Coats 1989a; Haya 1989)
- Low concentrations of humic acid and other dissolved materials (Coats et al. 1989)
- Low particulate loadings (Coulon 1982; Coats et al. 1989; Fairchild et al. 1992)
- Increased water hardness (Dyer et al. 1989; Coats et al. 1989)
- Increased exposure time and bioavailability (Spehar et al. 1982; Curtis et al. 1985)
- Emulsifiable formulations (Trim 1987; Haya 1989)
- Low temperatures (Cole and Casida 1983; Bradbury and Coats 1989a; Coats et al. 1989; Materna 1991)
- The *2S,αS*-component (Ohkawa et al. 1980; Bradbury and Coats 1989a; Coats et al. 1989; Haya 1989).

Fenvalerate intoxication effects may be reversible. Tadpoles of the northern leopard frog (*Rana pipiens*) that survived LC₅₀ concentrations of the *S,S*-isomer for 96 h appeared normal 7 days after being placed in clean water (Materna 1991). Fenvalerate-protective agents include diazepam and endosulfan. Diazepam provides up to 14-fold protection to frogs against toxic doses of fenvalerate (Cole and Casida 1983); endosulfan provides limited protection to estuarine fish and shrimp (Scott et al. 1987; Trim 1987).

Bioaccumulation factors for fenvalerate by representative freshwater and estuarine organisms during exposure for 28 to 30 days to various sublethal doses ranged from 40 to 570 for fish, 356 to 4700 for invertebrates, and 477 to 933 for algae (Smith and Stratton 1986). Because of its unusually high lipophilicity, fenvalerate is accumulated at only 30% efficiency by aquatic fauna, and uptake is not dose dependent (Coats et al. 1989). Contamination of algal food of daphnids with fenvalerate does not seem to contribute to an increase in whole-body burdens, although reduced filtration rates

due to toxicity could also account for a reduced intake of fenvalerate adsorbed to algae ([Table 20.5](#)) (Day and Kaushik 1987b,c).

Fenvalerate applications of 0.055 to 0.220 kg/ha are recommended for control of pestiferous crop insects, but these levels are rapidly fatal to nontarget organisms if introduced accidentally into aquatic environments (Day et al. 1987). In one study, large earthen ponds containing red crawfish (*Procambarus clarkii*) were treated with fenvalerate at concentrations equivalent to 28, 56, 112, or 224 g/ha. All crawfish died within 24 h at all concentrations tested (Coulon 1982). After 3 days, ponds dosed with 112 g/ha and lower were not lethal to crawfish exposed for 24 h. The 224-g/ha pond remained toxic to crawfish after 72 h (71% dead) and 120 h (32% dead); mortality was negligible (<10%) after 168 h (Coulon 1982). Fenvalerate applications of 28 to 112 g/ha (0.025 to 0.1 pounds/acre) usually control 90 to 100% of floodwater mosquitoes and stagnant water mosquitoes. But at 2 to 11 g/ha equivalent, the following effects are reported (Mulla et al. 1978, 1980; Tagatz and Ivey 1981; Anderson 1982; Spehar et al. 1982; Hansen et al. 1983; Smith and Stratton 1986; Day et al. 1987; Bradbury and Coats 1989a; Day 1989):

- Mayfly naiads are eliminated
- Populations of diving beetles, cladocerans, and dragonfly naiads are suppressed for up to 3 weeks
- Zooplankton filtration rates are reduced
- Colonization processes are altered
- Algal and rotifer populations increase due to lack of cladoceran grazing and competition

Several large-scale mesocosm studies were conducted with esfenvalerate, the most active form of fenvalerate (Fairchild et al. 1992; Heinis and Knuth 1992; Lozano et al. 1992; Webber et al. 1992). These investigators demonstrated that:

1. The half-time persistence of fenvalerate in the water column is about 10 h
2. Initial concentrations of 1.0 or 5.0 µg/L were not detectable in the water column after 2 and 4 days, respectively
3. In the first 2 days after application, the water column contained the majority of the fenvalerate
4. By day 4 postapplication, the sediments and macrophytes were the major reservoirs of fenvalerate
5. Fish usually contained less than 1% of the esfenvalerate at any time
6. Sensitive species of some copepod and insect genera showed declines in abundance at 0.08 to 0.2 µg/L and were unable to recover
7. Most species of zooplankton and benthic invertebrates decreased in abundance at 0.25 µg/L and higher
8. At 1.0 to 5.0 µg/L, there were drastic reductions or elimination of most species of crustaceans and chironomids, juvenile bluegills, and larval cyprinid fishes.

Sediment/water interactions are important to the understanding of fenvalerate toxicokinetics. Addition of soil to fenvalerate-treated waters reduced toxicity to channel catfish (*Ictalurus punctatus*) through adsorption of fenvalerate to clay and organic components of soil; however, crayfish (*Procambarus spp.*) were not protected (Coulon 1982). Chironomid larvae held in water on sand initially spiked with 50 µg fenvalerate/kg accumulated up to 15 times more fenvalerate than did larvae held in water above spiked silt or clay. A similar pattern was evident at an initial concentration of 5 µg/kg (Muir et al. 1985). This phenomenon is attributed to the greater bioavailability of fenvalerate in sand, as judged by elevated sediment interstitial water concentrations in sand when compared with those of silt or clay ([Table 20.5](#)) (Muir et al. 1985). Mortality was observed in systems where fenvalerate concentrations in sediments were sufficient to establish lethal concentrations in the overlying water through sediment/water partitioning; lethal effects at nominal sediment concentrations of 0.1 mg fenvalerate/kg were observed for mysids (*Mysidopsis bahia*) and grass shrimp (*Palaemonetes pugio*), and at 10 mg/kg for pink shrimp (*Penaeus duorarum*) (Clark et al. 1989). Because fenvalerate readily sorbs and binds to organic and inorganic particulate matter, it is difficult to predict its toxic effects on aquatic biota after runoff from agricultural areas or from discharges into particulate-laden habitats (Clark et al. 1989).

Table 20.5 Lethal and Sublethal Effects of Fenvalerate on Aquatic Organisms

Taxonomic Group, Organism, Dose or Concentration, and Other Variables	Effect	Reference ^a
ALGAE		
Alga, <i>Chlamydomonas reinhardtii</i> 0.109–5.17 µg/L	Up to 93% of all fenvalerate was adsorbed by algae in 48 h in a biomass-dependent manner when cells increased from 100/mL to 2 million/mL. In absence of alga, up to 33% of fenvalerate added to glass containers was adsorbed to container walls in 48 h	1
Marine algae, 4 species: <i>Isochrysis galbana</i> , <i>Skeletonema costatum</i> , <i>Thalassiosira pseudonana</i> , <i>Nitzchia angularis</i> 1000 µg/L	Insufficient to produce 50% growth inhibition in 96 h	2
INVERTEBRATES		
Mosquito, <i>Aedes nigromaculatus</i> Multi-resistant strain, fourth-stage larvae 5.6 g/ha (0.005 pounds/acre) 11.2 g/ha (0.01 pounds/acre) 28.0 g/ha (0.025 pounds/acre)	58% reduction 6 h after treatment 81% reduction 6 h after treatment 88% reduction 6 h after treatment	3 3 3
Mosquito, <i>Aedes</i> spp. 0.9–10.0 µg/L 1.5–4.0 µg/L	LC50–LC90 range for fourth-stage larvae LC50–LC90 range for 24-h-stage pupae	4 4
Rhagionid fly, <i>Atherix</i> sp. 0.021 µg/L 0.029 µg/L 0.032 µg/L	LC30 (28 days) LC50 (28 days) LC50 (96 h)	5 5 5
Cladoceran, <i>Ceriodaphnia lacustris</i> 0.01 µg/L 0.05 µg/L 0.21 µg/L	Filtration rate of alga (<i>Chlamydomonas reinhardtii</i>) significantly decreased after 24-h exposure Decreased food assimilation rate, 24-h exposure 50% immobilization of adults in 48 h	6 6 6
Chironomids 4.2–18.0 µg/L 4.2–80.0 µg/L	LC50 (24 h), 3 species LC50 (24 h), 8 species	7 7
Midge, <i>Chironomus tentans</i> , fourth-instar larvae 0.015–0.93 µg/L; exposed for 24 h in different sediment types containing initial concentration of 50 µg fenvalerate/kg fresh weight (FW) or 48 h in water above sediment; depuration for 96 h in each case	Normal burrowing behavior	8
Sand (water column and sediment interstitial water concentrations after 24 h were 1.02 and 4.82 µg/L, respectively) Silt (water column 0.17 µg/L, interstitial water 0.15 µg/L) Clay (water column 0.3 µg/L, interstitial water 0.34 µg/L)	Bioconcentration factor (BCF) of 69 for those held in water column and 102 for those held in sand BCF of 74 for water column, 116 for silt BCF of 32 for water column, 152 for clay	8 8 8
Snail, <i>Cipangopaludina japonica</i> 0.4–0.7 µg/L	BCF of 617 in 30 days	9
Sand shrimp, <i>Crangon septemspinosa</i> 0.04 µg/L	LC50 (96 h)	10, 11
American oyster, <i>Crassostrea virginica</i> 1.0 µg/L	BCF of 4700 in 28 days; depuration to nondetectable levels in <7 days	12

Table 20.5 (continued) Lethal and Sublethal Effects of Fenvalerate on Aquatic Organisms

Taxonomic Group, Organism, Dose or Concentration, and Other Variables	Effect	Reference ^a
>1000 µg/L	Abnormal shell growth in 50% of larvae surviving exposure for 48 h	2, 11
Mosquito, 3 species of <i>Culex</i>		
1.2–30.0 µg/L	LC50–LC90 range for 24-h-stage pupae	4
4.0–10.0 µg/L	LC50–LC90 range for fourth-stage larvae	4
Mosquito, <i>Culex pipiens pipiens</i> , larvae		
0.45 µg/L	LC50 (24 h), technical grade	13
30.0 µg/L	LC50 (24 h), emulsifiable formulation	13
11.0 mg/kg diet	LC50 (24 h)	13
Mosquito, <i>Culex quinquefasciatus</i>		
7–8 µg/L	LC50–LC90 range for fourth-stage larvae	3
Daphnid, <i>Daphnia galeata mendotae</i>		
0.005 µg/L	Life cycle (28-day) exposure produced increased longevity but decreased production of young	1
0.01 µg/L, and higher	Decreased survival, reproduction, and generation time in lifetime exposure	1
0.042–0.084 µg/L	Whole-body fenvalerate residues in presence of alga (<i>Chlamydomonas reinhardtii</i>) ranged from 0.51–1.08 mg/kg FW after 48-h exposure	14
0.05 µg/L	Decreased filtering rate and assimilation rate of algae after exposure for 24 h; decrease in population numbers in 28-day exposure	1, 6
0.051–0.109 µg/L	In absence of algae, whole-body residues ranged from 1.46–2.66 mg/kg FW after 48 h	14
0.16 µg/L	50% of immatures immobilized in 48 h	6, 15
0.29 µg/L	50% of adults immobilized in 48 h	6, 15
Daphnid, <i>Daphnia magna</i>		
0.25 µg/L	No measurable effect after exposure for 21 days	16, 17
0.27 µg/L	LC50 (48 h)	50
0.5 µg/L	After 21 days, reduced survival and inhibited reproduction	16
0.83 µg/L	50% immobilization of immatures in 48 h	6
2.1–2.5 µg/L	50% immobilization of adults in 48 h	6, 18
Daphnid, <i>Daphnia pulex</i>		
0.4–0.7 µg/L	BCF of 683 in 30 days	19
Copepod, <i>Diaptomus oregonensis</i>		
0.05 µg/L	Decreased filtration rate and food assimilation rate after 48-h exposure	6
0.12 µg/L	50% of adults immobilized in 48 h	6
Mayfly, <i>Ephemerella</i> sp.		
0.022 µg/L	LC80 (14 days)	5
0.07 µg/L	50% reduction in swimming ability in 96 h	20
0.08 µg/L	LC50 (96 h)	20
0.93 µg/L	LC50 (24 h)	5, 20
Amphipod, <i>Gammarus pseudolimnaeus</i>		
0.022 µg/L	LC65 (6 days)	5
0.03 µg/L	LC50 (96 h), adults	5
0.05 µg/L	LC50 (96 h), juveniles	5
0.93 µg/L	All dead or immobilized within 5 h	5
Snail, <i>Helisoma trivolis</i>		
0.021 µg/L	BCF of 1167 in 28 days	5, 7
0.054 µg/L	BCF of 592 in 28 days	5, 7
0.79 µg/L	BCF of 386 in 28 days; no adverse effects on survival or behavior	5, 7
American lobster, <i>Homarus americanus</i>		
0.14 µg/L	LC50 (96 h)	10, 11
Mosquito, 4 species, larvae		
0.9–28.0 µg/L	LC50 (24 h)	7, 21

Table 20.5 (continued) Lethal and Sublethal Effects of Fenvalerate on Aquatic Organisms

Taxonomic Group, Organism, Dose or Concentration, and Other Variables	Effect	Reference ^a
Mysid shrimp, <i>Mysidopsis bahia</i>		
0.008–0.021 µg/L	LC50 (96 h)	2, 11, 12, 18, 22
97–190 µg/kg sediment, equivalent to 0.03 µg/L water column	58% dead in 4 days, 70% dead in 10 days	23
1200–1600 µg/kg sediment, equivalent to 0.06–0.17 µg/L water column	All dead in 4 days	23
Copepod, <i>Nitocra spinipes</i>		
0.38 µg/L	LC50 (96 h)	23
Rusty crayfish, <i>Orconectes rusticus</i>		
20 µg/L	LC100 (96 h)	24
Grass shrimp, <i>Palaemonetes pugio</i>		
0.0016 µg/L	No deaths of larvae in 20 days; larval development prolonged by 2 days	25
0.003–0.013 µg/L	LC50 (96 h)	18, 26
0.0032 µg/L	Larvae exposed for 20 days had reduced survival and inhibited metamorphosis	25
0.007 µg/L	LC50 (96 h), emulsifiable concentrate, zoeae, 10‰ salinity	27
0.02 µg/L	LC50 (96 h), emulsifiable concentrate, zoeae, 20‰ salinity	27
0.040 µg/L	LC50 (96 h), adults, emulsifiable concentrate	27
0.044 µg/L	LC50 (96 h), adults, technical grade	27
0.046 µg/L	Maximum tolerated dose in 6-h exposure, adults	27
0.1–0.15 µg/L	LC50, 90 h after 6-h exposure, adults	27
10 µg/kg sediment	After exposure for 28 days, body burdens of carbon and nitrogen were reduced	56
88–200 µg/kg sediment	LC50 (96 h)	18, 23
97–190 µg/kg sediment	48% dead in 4 days	18, 23
100 µg/kg sediment	After exposure for 28 days, larval metamorphosis of survivors was inhibited and growth reduced	56
1000–1200 µg/kg sediment	LC100 (96 h)	18, 23
Pink shrimp, <i>Penaeus duorarum</i>		
0.84 µg/L	LC50 (96 h)	12, 22
1200–1600 µg/kg sediment, equivalent to 0.06–0.17 µg/L	None dead in 10 days	23
10,000–13,000 µg/kg sediment equivalent to 0.2–1.9 µg/L water column	All dead in 4 days	23
Red crawfish, <i>Procambarus clarkii</i>		
0.37 µg/L	LC50 (24 h), juveniles	28
Mosquito, <i>Psorophora columbiae</i>		
28–50 µg/L	LC50–LC90 range for fourth-stage larvae	4
53–82 µg/L	LC50–LC90 range for 24-h-stage pupae	4
Stonefly, <i>Pteronarcys dorsata</i>		
0.11 µg/L	38% immobilized in 72 h	5
0.13 µg/L	50% immobilized in 72 h	5
0.44 µg/L	38% immobilized in 24 h; 25% dead in 72 h	5
1.02 µg/L	All immobilized in <4 h; most dead in 72 h	5
CHORDATES		
Amphioxus, <i>Branchiostoma caribaeum</i>		
760 µg/L	LC10 (10 days)	18
1000 µg/L	No deaths in 96 h	18
1600 µg/L	LC50 (96 h)	18
2500 µg/L	LC100 (96 h)	18, 23
100–1000 µg/kg sand	Effectively colonized in 8 weeks	29
10,000 µg/kg sediments	No deaths in 10 days	18
10,000 µg/kg sand	Unable to effectively colonize during 8-week study	29

Table 20.5 (continued) Lethal and Sublethal Effects of Fenvalerate on Aquatic Organisms

Taxonomic Group, Organism, Dose or Concentration, and Other Variables	Effect	Reference ^a
VERTEBRATES		
Bleak, <i>Alburnus alburnus</i> 0.3 µg/L	LC50 (96 h)	23
Topsmelt, <i>Atherinops affinis</i> 0.14 µg/L	Survival normal of embryos and fry after exposure for 30 days	51
0.34 µg/L	Survival 86% of embryos and fry after exposure for 30 days; bioaccumulation factor of 315	51
0.66 µg/L	LC50 (96 h) for juveniles	51
0.82 µg/L and higher	All fry dead within 96 h of hatch	51
3.2 µg/L	Normal hatch on day 7 of exposure	51
Desert pupfish, <i>Cyprinodon macularis</i> 25 µg/L	LC50 (48 h)	20
Sheepshead minnow, <i>Cyprinodon variegatus</i> 0.3–5.0 µg/L	Whole-body BCF values in fish surviving 28-day exposure were 460 (0.31 µg/L), 360 (0.62 µg/L), 500 (1.2 µg/L), 700 (2.5 µg/L), and 820 (5.0 µg/L)	22
0.56 µg/L	No effect on hatchability, survival or growth in 28-day exposure	17, 22
2.2 µg/L	Growth reduction in 28-day exposure	22
4.4–5.0 µg/L	LC50 (96 h), flowthrough assay	2, 12, 22, 30
120 µg/L	LC50 (96 h), static assay	2
Common carp, <i>Cyprinus carpio</i> 0.4–0.7 µg/L	BCF of 69–117 in 30-day exposure	19
0.8 µg/L	After exposure for 7 days, 50% excreted 5 days after exposure and 87% in 25 days	19
0.9 µg/L	No deaths in 48 h	31
3.8 µg/L	LC10 (48 h)	31, 32
10 µg/L	At 48 h, hypoproteinemia and altered enzyme activity in gills	31, 32
10 µg/L for 6–48 h	No deaths. Exposure-dependent decrease in tissue acetylcholinesterase activity and increase in acetylcholine content	54
21–30 µg/L	LC50 (48–96 h)	31, 32, 54
117 µg/L	LC90 (48 h)	31
Mummichog, <i>Fundulus heteroclitus</i> 1.2–1.8 µg/L	LC50 (96 h)	23, 26
Mosquitofish, <i>Gambusia affinis</i> 15.0 µg/L	LC50 (48 h)	20
Channel catfish, <i>Ictalurus punctatus</i> 1.8–1.9 µg/L	LC50 (24 h)	19, 28
16.5 µg/L, equivalent to 112 g/ha	Muscle residues in dead fish ranged up to 70 µg/kg FW	28
30.6 µg/L, equivalent to 224 g/ha	Muscle residues in dead fish collected 24 h after treatment ranged up to 160 µg/kg FW	28
Bluegill, <i>Lepomis macrochirus</i> 0.2 µg/L	Significant decline in adenylate energy charge in gills after 10 days exposure; normal by day 30 of exposure	52
0.3–1.1 µg/L	LC50 (96 h)	19, 50
0.7 µg/L	Elevated whole-body calcium content after 48 h	34
0.9–1.9 µg/L	LC50 (48 h) range for water hardnesses between 6 and 309 mg CaCO ₃ /L, or between 4.2 and 13.6‰ salinity	35
10 µg/L	LC100 (96 h)	24

Table 20.5 (continued) Lethal and Sublethal Effects of Fenvalerate on Aquatic Organisms

Taxonomic Group, Organism, Dose or Concentration, and Other Variables	Effect	Reference ^a
Intraperitoneal injection, in mg/kg body weight (BW)		
0.12	LD50 (48 h); 2S, α S-isomer	17, 36, 37
0.67	LD50 (48 h); technical fenvalerate — mixture of all isomers	13, 17, 36, 37
11.5	LD50 (48 h); 2S, α R-isomer	17, 36, 37
216	No deaths in 48 h; 2R, α S-isomer	17, 36, 37
264	No deaths in 48 h; 2R, α R-isomer	17, 36, 37
Crimson-spotted rainbow fish, <i>Melanotaenia fluviatilis</i> ; larvae		
0.32 µg/L	Some deaths after 1-h exposure to esfenvalerate	55
1.18 µg/L	LC50 (96 h); technical esfenvalerate	55
1.99 µg/L	LC50 (96 h); emulsified esfenvalerate	55
4.5 µg/L	Some deaths after exposure for 1 min to esfenvalerate	55
12.75 µg/L	LC50 (96 h); technical fenvalerate	55
30.25 µg/L	LC50 (96 h); emulsified fenvalerate	55
Freshwater fish, <i>Labeo rohita</i>		
10 µg/L for 6–48 h	Exposure-dependent decrease in respiration rate and content of sodium, potassium, and calcium in gill, brain, muscle and liver. At 48 h, whole animal respiration rate decreased 51%, tissue Na content by 28–40%, tissue K content by 28–34%, and tissue Ca content by 19–36%	53
30 µg/L	LC50 (48 h)	53
California grunion, <i>Leuresthes tenuis</i>		
0.06 µg/L	No-observable-effect concentration in 28-day early life history exposure	23
0.3–0.6 µg/L	LC50 (96 h)	2, 30
Inland silverside, <i>Menidia beryllina</i>		
1.0 µg/L	LC50 (96 h)	30
Atlantic silverside, <i>Menidia menidia</i>		
0.062 µg/L	No-observable-effect concentration in 28-day early life history exposure	23
0.31–0.69 µg/L	LC50 (96 h)	12, 17, 22
Tidewater silverside, <i>Menidia peninsulae</i>		
0.083 µg/L	No-observable-effect concentration in 28-day early life history exposure	23
1.0 µg/L	LC50 (96 h)	30
Striped mullet, <i>Mugil cephalus</i>		
0.58 µg/L	LC50 (96 h)	2, 12, 22
African catfish, <i>Mystus vittatus</i>		
0.13 µg/L	Safe concentration	38
6.3 µg/L	LC50 (96 h)	38
Rainbow trout, <i>Oncorhynchus mykiss</i>		
0.00028 µg/L, exposure for 48 h followed by depuration for 48 h	Tissue residues, in µg/kg FW, were 7.06 in bile; 0.2 in fat; 0.02–0.05 in blood, brain, carcass, gill, kidney, liver, muscle, ovary, erythrocytes, and spleen; and <0.02 in heart, plasma, and testes	39
0.23–2.1 µg/L	LC50 (96 h)	17–20, 41, 50
3.6 µg/L	Hyperactivity in 48 h	41
4.7–76 µg/L	LC50 (24 h)	20, 42
300 µg/L	All dead in 10 h. At death, brain residues of 150–160 µg/kg FW. Similar brain residues reported via lethal intraperitoneal and intravenous injection routes	13, 39, 43

Table 20.5 (continued) Lethal and Sublethal Effects of Fenvalerate on Aquatic Organisms

Taxonomic Group, Organism, Dose or Concentration, and Other Variables	Effect	Reference ^a
412 µg/L	All dead in 11 h. Prior to death, trout displayed elevated cough rate, tremors, seizures, elevated urine Na and K, and abnormal blood chemistry. At death, gill histopathology evident, and residues, in µg/kg FW, were 160 in brain, 250 in carcass, and 3620 in liver	40
Steelhead trout, <i>Oncorhynchus mykiss</i>		
Steelhead embryos and larvae exposed intermittently (4.5 h daily) or continuously for 70 days after fertilization to nominal concentrations of 0.018, 0.04, 0.08, 0.135, or 0.505 µg/L		
0.018 µg/L	No deaths. Whole-body BCF values at 70 days were 400 for intermittent exposure and 4100 for continuous exposure	40
0.04 µg/L, tested at intermittent exposure only	No deaths; BCF of 3200	40
0.08 µg/L	For continuous exposure, no effect on survival or growth; BCF of 3000. For intermittent exposure 32% dead, 50% reduction in growth, BCF of 10,700	40
0.135 µg/L, continuous exposure only	More than 90% dead, with most dying after 56 days; BCF of 11,800	40
0.505 µg/L, continuous exposure	All dead. Most died after 49 days	40
Steelhead juveniles exposed intermittently (4.5 h daily) or continuously		
0.088 µg/L	LC50 (96 h), intermittent exposure	40
0.172 µg/L	LC50 (96 h), continuous exposure	17, 40
Gulf toadfish, <i>Opsanus tau</i>		
1.2 µg/L	No observable effect concentration in 28-day early life history exposure	23
2.4–5.4 µg/L	LC50 (96 h)	2, 12, 23
Fathead minnow, <i>Pimephales promelas</i>		
0.14–0.19 µg/L	Whole-body residues of larvae in 28-day exposure ranged from 230 to 880 µg/kg FW. BCF values ranged from 1643 to 4631, in a dose-dependent manner	21
0.19 µg/L	No effect on larval survival or growth in 30-day exposure	45
0.33 µg/L	50% of larvae exposed for 96 h developed abnormally	45
0.34 µg/L	LC50 (48 h), adults, mixture of 2S,αS and 2S,αR-isomers	36, 37
0.36–0.43 µg/L	Exposure of eggs and resultant larvae for 30 days had no effect on hatchability, but adversely affected larval growth, survival, and swimming ability	21, 45
0.37 µg/L	Mean whole-body residue of survivors at 96 h was 598 µg/kg FW, equivalent to BCF of 1616	46
0.49 µg/L	After 96 h, survivors contained 911 µg/kg whole body, or BCF of 1859	46
0.75 µg/L	After 96 h, survivors contained 1680 µg/kg BW, or BCF of 2240	46
0.85 µg/L	LC50 (96 h), larvae	45
1.69 µg/L	LC50 (48 h), adults, technical fenvalerate	37
2.5 µg/L	Schooling behavior absent after 48 h exposure, adults	41
2.85 µg/L	Exposure of larvae for 5 h resulted in 50% deformities 96 h later	45

Table 20.5 (continued) Lethal and Sublethal Effects of Fenvalerate on Aquatic Organisms

Taxonomic Group, Organism, Dose or Concentration, and Other Variables	Effect	Reference ^a
3.6 µg/L	Hyperactivity after 48 h, adults	41
5.4 µg/L	LC50 (96 h), adults	17
>140 µg/L	LC50 (48 h), adults, mixture of 2R,αS- and 2R,αR-isomers	36, 37
1.0 mg/kg FW whole body	Residue at death of fenvalerate-poisoned fish	13
Northern leopard frog, <i>Rana pipiens</i> ; tadpoles		
1.0 µg/L and lower	Normal activity after 96 h	57
1.3 µg/L	Up to 40% had decreased activity in 96 h	57
3.6 µg/L	20% had spasms, uncoordinated swimming in 96 h	57
7.3 µg/L	LC50 (96 h)	57
Northern grassfrog, <i>Rana pipiens pipiens</i>		
3 µg/L	All dead in 72 h at 4°C	47
9 µg/L	None dead in 72 h at 20°C	47
130 µg/kg BW	LD50 (24 h), subcutaneous injection (sc)	47
1800 µg/kg BW	LD50 (24 h). Initially pretreated with sc dose of 10 mg diazepam/kg BW followed by sc dose of fenvalerate	47
Frog, <i>Rana</i> sp.		
450 mg/kg BW	Acute oral LD50	58
Atlantic salmon, <i>Salmo salar</i>		
0.8 µg/L	Some deaths during 96-h exposure; BCF of 200	10
1.2 µg/L	LC50 (96 h)	10
2.0–4.1 µg/L	Some deaths during 54-h exposure; BCF about 125	10
9.3 µg/L	Some deaths during 16-h exposure; BCF of 40	10
Mozambique tilapia, <i>Tilapia mossambica</i>		
9 µg/L	No deaths in 20 days, but significant decreases in activity of catalase superoxide dismutase in liver, gill, and muscle, and significant increases in activity (and presumably metabolism) of fructose-1, 6-diphosphate aldolase in liver, gill, kidney, and brain	48, 49
45 µg/L	LC50 (48 h)	48, 49

20.4.4 Birds

Birds that died of fenvalerate poisoning contained residues of 0.1 to 1.26 mg/kg brain fresh weight (FW) and 0.74 mg/kg liver FW, based on acute oral doses of 500 to 4000 mg/kg BW (Table 20.6); juveniles were more sensitive than adults (Bradbury and Coats 1989a). When compared to other synthetic pyrethroids tested in laying hens, fenvalerate provided higher, more persistent residues in tissues (Saleh et al. 1986). Birds given single oral doses as low as 250 mg

fenvalerate/kg BW experienced significant weight loss (adults) or a reduction in the rate of weight gain (immatures). Similar signs were noted at dietary levels of 15,000 mg/kg ration, but not at 7500 mg/kg feed (Bradbury and Coats 1982). Poultry diets that contain <50 mg fenvalerate/kg feed do not produce an appreciable concentration of residues in eggs or meat of exposed birds (Akhtar et al. 1989).

Adult Japanese quail (*Coturnix japonica*) given a single oral dose of 4000 mg/kg BW started feeding normally (Mumtaz and Menzer 1986); but in about 90 min, they became hyperactive. Hyperactivity increased until 2 h postdosing, at which time feeding ceased. At 4 h, they had convulsions, irregular movements, jerking, and twitching; they became progressively ataxic and uncoordinated. One quail died at 4 h, another at 8 h. By 24 h, most of the survivors had resumed feeding, but they had an odd standing posture: head held high above the body, legs extended as far straight as possible, and wings held in an upright position close to the body. By 48 h, the survivors seemed to be feeding and drinking regularly; growth was normal 14 days after exposure (Mumtaz and Menzer 1986). Signs of intoxication in fenvalerate-poisoned bobwhites (*Colinus virginianus*) usually appeared within 2 h and included hyperactivity, irregular locomotion, ataxia, and spastic muscle contractions (Bradbury and Coats 1982, 1989a). Bobwhites use croplands for feeding, and insects are an important dietary item of chicks and adults in summer months. Little potential exists for adverse effects of fenvalerate on bobwhite and other gallinaceous bird populations from dietary exposures, however, because insects from sprayed fields had maximum whole-body residues of only 0.5 mg/kg — a level far below that associated with adverse effects (Table 20.6) (Bradbury and Coats 1982).

Birds rapidly and efficiently metabolize fenvalerate by hydrolytic cleavage of the ester bond, followed by extensive hydroxylation of the acid moiety at the carbon adjacent to the carboxyl group, the methyl group, or both. Major metabolites identified in liver preparations were 2-(4-chlorophenyl)-3-methylbutyric acid, 4-hydroxyfenvalerate, 3-phenoxybenzaldehyde, and 3phenoxybenzoic acid (Akhtar 1983; Mumtaz and Menzer 1986; Akhtar et al. 1989; Bradbury and Coats 1989a). Liver microsomal drug-metabolizing enzymes usually play an important role in pesticide metabolism; however, fenvalerate and other synthetic pyrethroids are very weak inducers of avian microsomal enzymes (Riviere et al. 1983). Birds are more resistant to fenvalerate than are mammals, as judged by studies with Japanese quail and rats (*Rattus* sp.). Quail excreted fenvalerate more rapidly, had lower absorption, and faster metabolism; the oral LD₅₀ for quail was >4000 mg/kg BW vs. 450 mg/kg BW for rat, almost an order of magnitude higher (Mumtaz and Menzer 1986).

Table 20.6 Lethal and Sublethal Effects of Fenvalerate on Birds

Organism, Dose, and Other Variables	Effect	Reference ^a
COMMON BOBWHITE, <i>Colinus virginianus</i>		
0.1–1.26 mg/kg fresh weight (FW), brain	Residues in dead birds following single oral exposure; residues increased in dose-dependent manner in dose range of 500–4000 mg/kg body weight (BW)	1
0.74 mg/kg FW, liver	Mean residue in dead birds following single oral exposure; residue seemingly independent of dose	1
250 mg/kg BW, single oral dose, immatures, age 5 weeks	No deaths in 14 days	1
500 mg/kg BW, single oral dose, immatures	20% dead within 25 h	1
1785 mg/kg BW, single oral dose, immatures	LD ₅₀ . All deaths occurred 3–25 h after dosing	1
4000 mg/kg BW, single oral dose, immatures	70% dead within 24 h; remainder survived at least 14 days	1
4000 mg/kg BW, single oral dose, adults, age 19 weeks	No deaths in 14 days; all appeared normal 24 h after dosing	1
15,000 mg/kg diet, 5 days of exposure plus 3 days of clean feed	Insufficient to kill 50% of 2-week-old chicks	1

Table 20.6 (continued) Lethal and Sublethal Effects of Fenvalerate on Birds

Organism, Dose, and Other Variables	Effect	Reference ^a
JAPANESE QUAIL, <i>Coturnix japonica</i>		
4 daily treatments of 100 mg/kg BW, oral route	Maximum tissue residues 72 h after the last dose, in mg/kg FW, were 3.1 in fat, 0.9 in skin, 0.7 in liver, 0.2 in heart and kidney, 0.1 in lung, and 0.02 in brain	2
2000 mg/kg diet, 6-week-old females, 7-day feeding period	Increased liver aldrin epoxidase, intestinal cytochrome P-450, and intestinal ethoxyresorufin dealkylase	3
4000 mg/kg BW, single oral dose, 14-day observation period	75% excreted in <6 h, 90% within 24 h. Tissue residues were highest at 3 h in liver (9 mg/kg FW) and gradually declined, while in blood it peaked within 2 h and fell quickly to an equilibrium level of 1.5 mg/L	2
AMERICAN KESTREL, <i>Falco sparverius</i>		
Oral dose of 1000, 2500, or 4000 mg/kg BW; maintained at 22°C or minus 5°C for 10 h after dosing	No deaths. Mild intoxication and elevated plasma alanine amino-transferase activity; holding temperature did not affect toxicity	8
DOMESTIC CHICKEN, <i>Gallus</i> sp.		
0.03 mg/kg diet for 32 days	No detectable residues in tissue or eggs	6
5 mg/kg BW, single oral dose, residues measured in egg albumin and yolk, and various tissues during observation period of 144 h	Up to 85% of administered dose eliminated in 24 h, 88% in 72 h. Maximum residues, in mg/kg FW, were 0.5 in kidney (24 h), 0.48 in yolk (96 h), 0.46 in liver (24 h), 0.25 in plasma (24 h), 0.19 in abdominal fat (96 h), 0.18 in albumin (24 h), 0.14 in blood cells (24 h), 0.07 in both leg muscle and heart at 144 h, and not detectable in subcutaneous fat and breast muscle	4
10 mg/kg BW, single oral dose, laying hens, residues measured over 14 days	Maximum residues, in mg/kg FW, were 4.7 in blood (24 h), 4.0 in brain (7 days), 1.0 in kidney (48 h), 1.0 in heart (3 days), 0.3 in egg yolk (5 days), 0.25 in kidney (14 days), 0.23 in egg white (5 days), 0.2 in skin (5 days), 0.18 in liver (48 h), and <0.15 in fat and ovary	5
Oral doses of 1000 mg/kg BW for 5 days, and again at 21 days	No neurotoxic effects observed in hens	6
1500 mg/kg BW	Acute oral LD50	7

^a 1, Bradbury and Coats 1982; 2, Mumtaz and Menzer 1986; 3, Riviere et al. 1983; 4, Akhtar et al. 1989; 5, Saleh et al. 1986; 6, Reed 1981; 7, Smith and Stratton 1986; 8, Rattner and Franson 1984.

20.4.5 Mammals

In general, fenvalerate administered to mammals was rapidly eliminated and had little tendency to accumulate in tissues (Table 20.7). Fenvalerate killed sensitive species of mammals at a brain injection concentration of 1.0 mg/kg FW brain (equivalent to 14 µg/kg body weight = BW), an intraperitoneal injection concentration of 3.9 mg/kg BW, acute oral doses of 50 to 450 mg/kg BW, dietary levels of 50 to 1000 mg/kg feed, and an acute dermal concentration of 1800 mg/kg BW. In all cases, the 2S,αS-isomer was the most toxic (Table 20.7). Measurable residues of fenvalerate were detected in tissues of sensitive mammals at 0.15 mg/kg diet, 0.15 mg/kg BW applied dermally six times over a 3-week period, and at 2.5 mg/kg BW given orally; in all cases the 2R,αS-isomer was taken up 9 to 16 times over other isomers (Table 20.7). Behavioral alterations (e.g., change in drinking water preference) occurred in mice after a single oral dose of 0.3 mg/kg BW (Table 20.7). No significant adverse effects were observed in dogs on diets equivalent to 12.5 mg/kg BW daily for 90 days, or in rats on diets containing 250 mg fenvalerate/kg (equivalent to 12.5 mg/kg BW) for 2 years (Table 20.7).

At sublethal doses in rodents (i.e., 100 mg/kg BW), fenvaleate produces neurological toxicity but no histological damage. At higher doses, pathological alterations in peripheral nerves occur (Bradbury and Coats 1989a). Rats given acutely toxic doses of fenvaleate showed histopathological changes such as axonal swelling and degeneration, and myelin fragmentation of the sciatic nerve; the significance of these findings is unclear (Gray and Soderlund 1985).

Route of administration may account for wide variations in the toxic action of fenvaleate. Most authorities agree that fenvaleate is most toxic to rodents when administered by intercerebroventricular injection relative to other routes — indicating the importance of the brain in the Type II poisoning syndrome. Fenvaleate was decreasingly toxic when administered intravenously, intraperitoneally, orally, and dermally (Lawrence and Casida 1982; Flannigan et al. 1985; Grissom et al. 1985; Bradbury and Coats 1989a; Williamson et al. 1989).

Differences in fenvaleate metabolism occur, even among closely related species such as rats and mice (Kaneko et al. 1981). In both species, regardless of sex, dose level, or chiral isomer, fenvaleate is metabolized primarily by oxidation at the 2'-, 4'-phenoxy positions of the alcohol moiety and at the C-2 and C-3 positions of the acid moiety, by cleavage of the ester linkage, by conversion of the CN group to SCN⁻ and CO₂, and by conjugation of the resultant carboxylic acids and phenols with glucuronic acid, sulfuric acid, and amino acids. However, the taurine conjugate of 3-phenoxybenzoic acid was found in mice but not in rats; 4'-hydroxylation of the alcohol moiety and the sulfate conjugate of 3-(4'-hydroxyphenoxy) benzoic acid occurred to a greater extent in rats than in mice; and more thiocyanate was excreted in mice than in rats (Kaneko et al. 1981). Dogs (*Canis familiaris*) are remarkably different from rodents in their ability to metabolize fenvaleate (Kaneko et al. 1984). Four major differences have been observed:

1. Rats and mice show hydroxylation of the 2'-position of the alcohol moiety, whereas dogs do not.
2. Dogs produce 3-phenoxybenzyl alcohol and 3-(4'-hydroxyphenoxy) benzyl alcohol, whereas rodents do not.
3. The predominant conjugate of the alcohol moiety in dogs is 3-phenoxybenzoyl glycine, but this is only a minor conjugate in rodents.
4. Dogs produced more glucuronides of acid moiety and their hydroxy derivatives than did rats and mice.

The proposed fenvaleate metabolic pathways in dogs (Kaneko et al. 1984) suggest that species differences and pathways are important and require more research.

Cattle (*Bos* spp.) protected against various insect pests by fenvaleate-impregnated ear tags grow better than unprotected cattle. Beef cattle were protected against hornflies (*Haematobia irritans*) and other blood-sucking dipterans by fenvaleate-impregnated ear tags. During a 115-day grazing period, protected cattle had greater weight gain than unprotected cattle (Haufe 1982). This technique may have application in protecting fly-infested threatened or endangered species of mammals. Dairy cows tagged with 8% fenvaleate ear tags showed a 99.9% reduction in hornflies over a 16-week trial (Block and Lewis 1986). But other species of flies (housefly, *Musca domestica*; stablefly, *Stomoxys calcitrans*; facefly, *Musca autumnalis*) were not controlled to the same extent, and they increased as hornfly populations decreased. Protected cows produced 117 kg more milk in 16 weeks than did unprotected cows; fat and protein percentages in milk were the same for both groups. The higher milk production in the fenvaleate-tagged group was attributed to more uninterrupted forage time, greater forage consumption, and more efficient energy utilization because less energy was expended on avoiding or removing flies (Block and Lewis 1986). Similar results were reported in dairy cows in a 12-week study (Harris et al. 1987). Fenvaleate was adequately distributed over the entire body and persisted for at least 80 days on the hair of cattle with one ear tag containing 10.5 g active ingredients (Yeung et al. 1989). Residues in hair were highest at 14 days (18.4 mg/kg FW) and lowest at 80 days (1.3 to 3.0 mg/kg FW). All four stereoisomers were present

on cattle hair, and no stereoselective degradation occurred. Hair contained 14.8 mg/kg FW fenvalerate after 30 days with two ear tags (Yeung et al. 1989).

Cows fed fenvalerate in grain at 10 mg/kg diet for 4 days excreted most of the fenvalerate, essentially unchanged, in urine (Wszolek et al. 1981b). A secondary excretion route is feces, accounting for about 25% of the ingested dose. Milk accounted for 0.44 to 0.64% of the total excreted (Wszolek et al. 1980). Half-time persistence of fenvalerate in milk of treated cows is about 6.4 days (Frank et al. 1984). Effects of low concentrations (1.14 to 6.8 µg/L) of fenvalerate in milk of treated cows on newborn suckling calves are unknown and merit additional research (Frank et al. 1984).

Fenvalerate toxicity is antagonized by atropine sulfate or methocarbamol, which may be effective in treating severe cases of poisoning (Hiromori et al. 1986). Conversely, some compounds exacerbate the toxicity of fenvalerate and interfere with a desired use. Domestic cats (*Felis domesticus*) treated with Fendeet (an aerosol mixture of fenvalerate and *N,N*-diethyl-*m*-toluamide) to control fleas and ticks sometimes show signs of toxicosis, such as tremors, hypersalivation, ataxia, vomiting, depression, and seizures. Signs usually appeared within hours of topical application, and females and juveniles seem to be the most sensitive groups. The demonstrated ability of *N,N*-diethyl-*m*-toluamide to enhance the dermal absorption of fenvalerate is the probable cause of toxicosis (Dorman et al. 1990).

In occupational settings, fenvalerate produces temporary irritation and itching (Bradbury and Coats 1989a). Among human fenvalerate applicators, sensitive individuals complain of a burning and tingling skin sensation after using the insecticide, and sometimes they substitute a more toxic insecticide to nontarget species in order to avoid this uncomfortable sensation (Flannigan et al. 1985). This practice, if widespread, may compromise existing or proposed natural resource management practices.

Table 20.7 Lethal and Sublethal Effects of Fenvalerate on Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect	Reference ^a
CATTLE, <i>Bos</i> spp.		
Diet		
Fed 0.15 mg/kg feed for 21 days	Residues ranged up to 0.002 mg/L in milk, 0.022 mg/L in cream, 0.014 mg/kg fresh weight (FW) in fat, 0.006 mg/kg FW in liver, and <0.01 mg/kg FW in bone, brain, muscle, kidney, or lung	1
Dairy cows fed 5 or 15 mg/kg ration daily for 4 days; milk and feces collected during exposure and 6 days after exposure	Maximum concentrations of fenvalerate in milk during exposure were 48 µg/L (377 µg/kg dry weight = DW) in the 5 mg/kg group, and 250 µg/L (1950 µg/kg DW) in the 15 mg/kg group; fenvalerate was not detectable 2 days after exposure in the low-dose group and 6 days after exposure in the high-dose group. In feces, the maximum concentrations ranged between 34.9 and 50.4 mg/kg DW during exposure; detectable concentrations in both groups were evident 6 days after exposure	2
Fed 10.9 mg/kg feed for 28 days	Maximum residues, in mg/kg FW, were 0.13 in whole milk, 1.0 in cream, 0.8 in fat, and 0.06 in muscle	1
Dermal		
Dairy cows of mean weight 671 kg given 0.1 g topically (0.1 mg/kg body weight = BW) in 6 consecutive treatments at intervals of 3 or 4 days (total 0.6 g)	After last application, no detectable fenvalerate residues were found in milk after 6 h; maximum residues in milk were 1.14 µg/L after 3 days, 0.42 in 4 days, and not detectable after 7 days	3

Table 20.7 (continued) Lethal and Sublethal Effects of Fenvalerate on Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect	Reference^a
Dairy cows given three consecutive topical treatments of 0.5 g (0.5 mg/kg BW; total 1.5 g) at 2-week intervals	Maximum residues in milk, in µg/L, after last treatment were 6.8 after 6 h, 2.9 after 3 days, 2.5 at 7 days, 1.3 at 14 days, and <0.2 at 3 weeks. About 0.05% of the applied fenvalerate appeared in the milk as the intact insecticide over the 59-day study period	3
DOG, <i>Canis familiaris</i>		
Oral		
Male beagles, 7 months old, 1.7 mg/kg, single dose	About 84% eliminated from body within 3 days via urine and feces. Half-time persistence of 2 h in blood, and 0.7–1.0 day in whole body	4
Diet		
Fed up to 12.5 mg/kg BW equivalent for 90 days	No evidence of toxicity at any level	1
Groups of 12 beagles (6 males, 6 females), 5 months old, fed 250, 500, or 1000 mg fenvalerate/kg feed for 6 months	For all groups, dose-dependent increase in emesis, head shaking, biting of the extremities, blood chemistry alterations, ataxia, tremors, and hepatic multifocal microgranulomas. Some males in the 1000-mg/kg-group were killed after 2 weeks while in coma. Sex-related differences were noted: increased cholesterol and alkaline phosphatase in males; poor growth and enlarged adrenals, ovaries, liver, and kidneys in females. Lymph node histopathology was observed in female 500- and 1000-mg/kg-group and in the male 1000-mg/kg-group	5
HAMSTER, <i>Cricetus</i> sp.		
<i>In vitro</i>		
5–40 mg/L	Nontoxic to isolated cells	6
Oral		
12.5 or 25 mg/kg BW for 2 days	No chromosomal aberrations in bone marrow	1
DOMESTIC CAT, <i>Felis domesticus</i>		
Dermal		
Topical aerosol treatment of fenvalerate plus Deet (<i>N,N</i> -diethyl- <i>m</i> -toluamide) to control fleas and ticks	Kitten, 3 months old, died in 6 h following hypersalivation, ataxia, depression, and seizures. No histopathology at necropsy; brain AChE activity normal. Fenvalerate residues, in µg/kg, were 345,000 in skin, 230 in kidney, 150 in liver, 10 in brain. Adult (4-year-old) showed signs of toxicosis 4 h after topical application; by 30 h, animal had lowered body temperature, bradycardia, and other signs of fenvalerate poisoning. At death, shortly thereafter, fenvalerate residues were 1000 µg/kg in skin and 20 µg/kg in liver	7
DOMESTIC MOUSE, <i>Mus</i> spp.		
Intercerebroventricular injection		
0.2 mg/kg BW	95% dead; 50% show signs of poisoning within 6 min of brain injection	8
1.0 mg/kg FW brain, equivalent to 14 µg/kg BW	LD50; 2S,α-S-isomer	9
Oral, single dose		
0.3, 3, or 30 mg/kg	No deaths in any group. The 30 mg/kg group was hyperactive for 4 h after dosing. All mice preferred 0.3% saccharin solution to water	10

Table 20.7 (continued) Lethal and Sublethal Effects of Fenvalerate on Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect	Reference ^a
2.5 mg/kg BW of each of the 4 chiral isomers; tissue residues measured 6 days later	Residues of the <i>2R,αS</i> -isomer were 9–16 times higher in adrenal than the other 3 isomers (<i>2S,αS</i> ; <i>2S,αR</i> ; <i>2R,αR</i>), at least 20 times higher in heart, 6–14 times higher in kidney, 17–28 times higher in liver, at least 15 times higher in lung, 3–6 times higher in mesenteric lymph node, and >30 times higher in spleen	11
7 mg/kg BW, residues measured 6 days later	Maximum concentrations, in mg/kg FW, were 7.3 in hair, 0.9 in fat, 0.5 in skin, 0.3 in blood, and 0.08 in liver	12
8.4 mg/kg BW, residues measured 7 days later	Maximum concentrations, in mg/kg FW, were 2.3 in hair, 0.8 in fat, 0.3 in stomach contents, 0.1 in skin, and 0.05 in blood	12
50 mg/kg BW	LD50; <i>2S,αS</i> -isomer	13
72–845 mg/kg BW, various laboratory strains	LD50	1, 13–16
200 mg/kg BW	Slight increase in frequency of chromosome aberrations in bone marrow cells	17
>600 mg/kg BW	LD50; <i>2S,αR</i> isomer	13
>5000 mg/kg BW	LD50; <i>2R,αR</i> isomer	13
Dermal		
1 mg/kg BW, single application	Penetration through skin was 1.9% at 60 min, 2.2% at 6 h, and 9.1% at 24 h. Of penetrated dose, maximum percent distribution was 83% in carcass at 60 min, 1.3% in blood at 6 h, 11.5% in liver at 6 h, 2.2% in kidney at 6 h, 0.7% in fat at 6 h, and 73% in feces at 24 h	18, 19
60, 600, or 1800 mg/kg BW, single application	At 1800 mg/kg BW, 20% died in 96 h; no deaths in other groups. Survivors in 600 and 1800 mg/kg groups were hyperactive. All survivors preferred 0.3% saccharin solution to water	10
Intraperitoneal injection		
3.9 mg/kg BW	LD50; <i>2S,αS</i> -isomer	9
62 mg/kg BW	LD50	14
89 mg/kg BW	LD99	14
Diet		
Fed 5, 15, or 50 mg/kg on days 6–15 of gestation	Maternal toxicity at 50 mg/kg BW, but no effect on embryonic development	1
Fed 10, 50, 250, or 1250 mg/kg feed for 2 years	Increased mortality, reduced growth, disrupted enzyme activity at 1250 mg/kg. Nonneoplastic microgranulomas in lymph, liver, and spleen of 250 and 1250 mg/kg male mice; less severe microgranulomatous changes in mesenteric lymph node of 50 and 250 mg/kg groups; no observable effect at 10 mg/kg diet	34
Fed 50, 250, or 1250 mg/kg feed for 2 years	Nonneoplastic pathological changes diagnosed as multifocal microgranulomas in lymph nodes, liver, and spleen of males at all dose levels, and in females at the 250 and 1250 mg/kg diet level	20
Fed 100, 300, 1000, or 3000 mg/kg feed for 78 weeks	No evidence of carcinogenicity at any dose tested. No-observable-effect-level (NOEL) was 100 mg/kg diet (equivalent to 15 mg/kg BW); dose-related effects noted in liver at 300 mg/kg diet and higher	1
125 mg/kg diet, 8 weeks, <i>2R,αS</i> isomer	No deaths; 70% incidence of microgranulomas in liver	20
Fed 500 mg/kg diet of three isomers (<i>2S,αS</i> ; <i>2R,αS</i> ; <i>2R,αR</i>) for 2 weeks	Residues, in µg/kg FW, of the <i>2R,αS</i> isomer were significantly higher than that of other isomers tested in adrenal (173 vs. 10–21), heart (15 vs. 2), kidney (22 vs. 9–10), liver (105 vs. 13); lung (31 vs. 2–5), mesenteric lymph nodes (86 vs. 8–12), and spleen (21 vs. 1)	11

Table 20.7 (continued) Lethal and Sublethal Effects of Fenvalerate on Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect	Reference ^a
500 mg/kg diet, 13 weeks	No deaths; 100% incidence of microgranulomas or giant cell infiltration	20
500 mg/kg diet, 52 weeks, 2S, α S-isomer	No microgranulomas or giant cell infiltration in liver, spleen, or lymph nodes	20
500 or 1000 mg/kg diet, 52 weeks, 2S, α R isomer	No deaths; no microgranulomas	20
1000 mg/kg diet, 2 weeks, 2S, α S isomer	Severe hyperexcitability and tremors and 100% kill. No microgranulomas present	20
1000 mg/kg diet, 4 weeks, 2R, α S isomer	No deaths; 100% incidence of microgranulomas	20
1000 mg/kg diet, 13 weeks, 2R, α R isomer	No deaths; no microgranulomas or giant cell infiltration	20
2000 mg/kg diet, 2 weeks, 2S, α R isomer	All dead; no microgranulomas	20
Intraperitoneal (ip) injection		
40 mg/kg BW, 5 daily doses (total of 100 mg/kg BW)	Significant increase in frequency of chromosome aberrations induced in bone marrow cells — but frequency lower than single-dose ip injection of 200 mg/kg BW	17
Subcutaneous injection		
Given 5 daily doses totaling 100, 150, or 200 mg/kg BW	After 35 days, incidence of sperm abnormalities was significantly increased over controls: 3.3% abnormal sperm in 100-mg/kg-group, 5.9% in 150-mg/kg-group, and 6.3% in 200-mg/kg-group vs. 2.3% in controls	17
RABBIT, <i>Oryctolagus</i> spp.		
Dermal		
0.13 mg/cm ² skin, applied 5 days weekly for 16 weeks	Minor increases in cutaneous blood flow, skin reddening, and skin thickening	22
<i>In vitro</i>		
0.2–10 mg/L, liver and muscle tissues	Synthesis of protein and RNA inhibited in muscle in a dose-dependent manner; maximum inhibition was 0.2 mg/L for RNA synthesis and 10 mg/L for protein. The reverse was observed in liver; maximum stimulation was at 2 mg/L	23
DOMESTIC SHEEP, <i>Ovis aries</i>		
Diet		
3-month-old lambs fed 45 mg/kg feed for 10 days, equivalent to 20 mg daily	Tissue residues, in mg/kg DW, were 3.6–4.4 in renal fat, 0.2 in leg muscle, and 0.1 in liver	24
LABORATORY WHITE RAT, <i>Rattus</i> spp.		
Diet		
Fed 1, 5, 25, or 250 mg/kg ration for up to 2 years	No measurable effect on body weight, food consumption, hematology, clinical chemistry, or organ weights of any diet	25
Fed diets containing 1, 5, 25, or 250 mg/kg feed for 3 generations	No teratogenic or fetotoxic effects. Females in third generation fed highest dose had reduced growth	1
Fed 1, 5, 25, 250, or 500 mg/kg ration for 2 years	NOEL at 250 mg/kg, equivalent to 12.5 mg/kg BW; growth suppression at 500 mg/kg diet	1
Fed 50, 150, 500, or 1500 mg/kg feed for 15 months	NOEL at 50 mg/kg, equivalent to 2.5 mg/kg BW. Higher doses had adverse effects on growth, food consumption, and behavior	1
Fed 1000 mg/kg ration for 2 years	Growth inhibited; organ/BW ratios increased in brain, liver, spleen, kidney, heart (females), and testes. Mammary and pituitary tumors commonly observed in treated and in control groups. No statistically significant difference in number or type of neoplasms, except for mammary tumors	25

Table 20.7 (continued) Lethal and Sublethal Effects of Fenvalerate on Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect	Reference ^a
Oral		
1.7 mg/kg BW daily for 5 consecutive days, or single dose of 8.4 mg/kg BW. Technical fenvalerate and 2S, α S-isomer tested separately	No apparent differences in the nature and amount of metabolites and in the pattern of excretion and tissue residues between the racemic mixture and the 2S, α S isomer	26
Single dose, 2.5 mg/kg BW; residues, in μ g/kg FW, in tissues measured 6 days after exposure		
2R, α S isomer	Residues in tissues were usually much higher than those of other isomers tested: adrenal, 371; fat, 304; heart, 40; kidney, 25; liver, 72; lung, 25; mesenteric node, 318; and spleen, 62	11
2S, α S isomer	Residues were 511 in fat, 45 in mesenteric lymph node, and <22 in other tissues	11
2S, α R isomer	Fat contained 326, mesenteric lymph node 68, and other tissues <20	11
2R, α R isomer	Fat contained 756, in mesenteric lymph node 94, and other tissues <23	11
Single dose of 3 mg/kg BW, individual isomers tested, fat analyzed periodically during 21-day observation period	Half-time persistence of all 4 isomers in fat ranged between 7 and 10 days; mean residues at 24 h and 21 days after exposure were 0.64 and 0.08 mg/kg FW, respectively	27
Decarboxyfenvalerate, single dose, 4 mg/kg BW	Almost completely eliminated in a few days, mainly via the feces; little translocation from GI contents and liver to other tissues; Tb 1/2 of 10 h in pancreas and <7 h in all other tissues	28
Single dose, 7 mg/kg BW, residues measured 6 days later	Residues, in μ g/kg FW, were about 1250 in blood, 1200 in fat, 2300 in hair of females, 37,000 in hair of males, 370 in liver, and 5800 in skin	12
Single doses between 15–200 mg/kg BW	At 90 min, rats showed a dosage-dependent decrease in locomotor activity and operant response rates	29
Adults given 25 or 75 mg/kg BW, 5 days a week for 10 weeks	At low dose, no signs of neurotoxicity or significant hepatotoxicity. At high dose, neurotoxicity evident only during first week; liver contained significantly elevated number of foci/cm ² and a larger percentage of liver tissue occupied by foci when compared to controls	30
450–3000 mg/kg BW	LD50; variability due to solvent	1
451 mg/kg BW	LD50	15, 21, 31
Single dose of 850 mg/kg BW, observed for 7 days	Signs of toxicosis appeared in 2 h; if untreated, 80% died. Intraperitoneal injection of 400 mg/kg BW of methocarbamol followed by repeated doses of 200 mg/kg BW at every onset of signs eliminated signs of poisoning within 17 h and prevented mortality	32
Dermal		
31, 155, or 310 mg/kg BW, 5 days weekly for 2 weeks; observed for 2 weeks after last treatment	No deaths. Altered blood chemistry that returned to normal during observation period, except for elevated serum alkaline phosphatase activity	33
Intravenous injection		
50–100 mg/kg BW	LD50	21

20.5 RECOMMENDATIONS

Fenvalerate is listed under the Class IV Surveillance Index Classification, indicating a low hazard potential to humans from toxicological and exposure standpoints. This classification requires only nominal monitoring (Reed 1981). Monitoring efforts of regulatory agencies to the present time, however, have been limited and of marginal worth in evaluating background concentrations of fenvalerate. Additional monitoring is recommended to measure fenvalerate residues in tissues of birds and mammals of U.S. Fish and Wildlife Service concern.

Products that contain fenvalerate and are registered for use on corn, wheat, soybeans, sorghum, oats, barley, rye, or cotton are subject to the provisions of the Endangered Species Act (Sine 1988). The Endangered Species Act requires that actions of federal agencies not jeopardize threatened or endangered species or their habitats. Specifically, the U.S. Environmental Protection Agency, in consultation with the U.S. Fish and Wildlife Service, determines whether use of fenvalerate poses a threat to listed species of animals and plants in various locations (Sine 1988). Clearly, fenvalerate and other synthetic pyrethroid insecticides should be used with extreme caution in habitats of endangered species.

No regulations exist for protection of sensitive natural resources against fenvalerate, although current application rates to control pestiferous crop insects are lethal to many species of nontarget organisms, including bees, fish, and crustaceans ([Table 20.8](#)). Proposed fenvalerate guidelines for protection of livestock, poultry, and human health are as follows: <5 mg/kg in diets of livestock; <50 mg/kg in diets of poultry; <3 mg/kg in human diets (<1 mg/kg for vegetables, <0.5 mg/kg for meat, <0.25 mg/kg for milkfat); and <0.125 mg/kg BW for acceptable daily intake in man ([Table 20.8](#)).

Despite the high toxicity of fenvalerate and other pyrethroids to aquatic organisms, few environmental problems have been documented, presumably due to the very low application levels needed to control insects, adsorption onto soil and organic matter, and comparatively rapid degradation (Gray and Soderlund 1985). Nevertheless, fenvalerate is extremely toxic to aquatic organisms ([Table 20.8](#)), has high bioaccumulation, and is persistent in sediments. These patterns are most pronounced in estuaries and other wetland environments. Fenvalerate use in areas adjacent to estuarine systems poses unacceptable risks to those ecosystems at concentrations not detectable by analytical methods (Schimmel et al. 1983). It seems reasonable to prohibit all uses of fenvalerate directly into aquatic environments, and to severely restrict usage in areas adjacent to drainage systems.

Additional research is needed on sublethal effects of fenvalerate in the following areas:

1. Impaired response to scent stimuli as demonstrated in bees (Taylor et al. 1987)
2. Genotoxic potency as shown in positive genotoxic effects on mice bone marrow (Pati and Bhunya 1989)
3. Photoproduct formation — especially those formed through ultraviolet irradiation — wherein at least two photoproducts were more toxic than the parent chemical (Holmstead et al. 1978)
4. Enhanced tumor formation in rodent liver (Flodstrom et al. 1988)
5. Development of analytical procedures to detect minute and short-lived reactive metabolites (Miyamoto 1988)
6. Development of simplified and reliable laboratory test systems more representative of total natural ecosystems (Miyamoto 1988)
7. Interaction effects of fenvalerate degradation products with other chemicals (Smith and Stratton 1986).

More research is also needed on indirect effects on wildlife due to reductions in nontarget insects, and on bioavailability of fenvalerate to aquatic organisms from sediments and the sediment–water interface.

20.6 SUMMARY

Synthetic pyrethroids are the newest major class of broad-spectrum organic insecticides used in agricultural, domestic, and veterinary applications, and now account for more than 30% of global insecticide use. Fenvalerate [(*RS*) α -cyano-3-phenoxybenzyl (*RS*) 2-(4-chlorophenyl)-3-methylbutyrate] is one of the newer synthetic pyrethroid insecticides, and the one most widely used. Technical fenvalerate is a mixture of four optical isomers, each occurring in equal amounts, but with different efficacies against insect pests. Insecticidal properties are largely associated with the *2S,αS*-isomer, and to a minor extent with the *2S,αR*-isomer. Isomers with a *2R* configuration have negligible biocidal properties. However, tumor-like growths in rodent liver are associated with the comparatively innocuous *2R,αS*-isomer. Pyrethroid insecticides are potent neurotoxicants that interfere with nerve membrane function by interaction with the sodium channel. Fenvalerate is among the most effective pyrethroid neurotoxicants tested, and the *2S,αS*-isomer is up to 15 times more potent than other fenvalerate isomers.

Fenvalerate persists for <10 weeks in the environment and does not accumulate readily in the biosphere. Time for 50% loss (T_b 1/2) in fenvalerate-exposed amphibians, birds, and mammals is 6 to 14 h. For reptiles, terrestrial insects, aquatic snails, and fish, it is usually >14 h to <2 days; and for crop plants, it is 2 to 28 days. In nonbiological compartments, T_b 1/2 is up to 6 days in freshwater, 34 days in seawater, 6 weeks in estuarine sediments, and 9 weeks in soils.

At recommended application rates to control pestiferous crop insects, fenvalerate and other synthetic pyrethroids are relatively harmless to birds, mammals, and terrestrial plants. However, certain nontarget species, including bees, crustaceans, and fish, are at considerable risk, especially at low temperatures. Target insect species are usually killed at fenvalerate concentrations of 0.015 µg/insect, 0.11 kg/ha by way of aerial application, 5.4 mg/kg in soil, or 50 mg/kg in diet. Fenvalerate is especially toxic to aquatic organisms (e.g., crustaceans died at 0.003 to 0.03 µg/L and fish and amphibians at 0.09 to 1.1 µg/L), and its use in or near aquatic environments now seems contraindicated. Birds and mammals are significantly more resistant than fish and invertebrates. Adverse effects on birds occur at acute oral doses >500 mg/kg body weight (BW), and 750 mg/kg ration; <50 mg fenvalerate/kg feed produced no appreciable residues in eggs and meat of exposed birds. Among sensitive mammals, adverse effects on survival occur at acute oral doses of 50 to

450 mg/kg BW, dietary loadings of 50 to 1000 mg/kg feed, and dermal applications of 1800 mg/kg BW.

Criteria have not yet been formulated by regulatory agencies for protection of sensitive fish and wildlife resources against fenvalerate. Guidelines for protection of poultry, livestock, and human health include <50 mg/kg in poultry diets, <5 mg/kg in livestock diets, <3 mg/kg in human diets, and <0.125 mg/kg BW daily in humans.

CHAPTER 21

Mirex

21.1 INTRODUCTION

Fish and wildlife resources associated with approximately 51 million ha (125 million acres) in the southeastern United States, and with the Great Lakes, especially Lake Ontario, have been negatively affected by intensive or widespread use of mirex, a chlorinated hydrocarbon compound (Waters et al. 1977; Bell et al. 1978; Kaiser 1978; National Academy of Sciences [NAS] 1978; Lowe 1982; Eisler 1985; Hill and Dent 1985; Sergeant et al. 1993; Blus 1995; U.S. Public Health Service [USPHS] 1995). Contamination of the Southeast and of Lake Ontario by mirex probably occurred between 1959 and 1978. During that period, mirex was used as a pesticide to control the red imported fire ant (*Solenopsis invicta*) and the black imported fire ant (*Solenopsis richteri*), which infested large portions of Alabama, Arkansas, Florida, Georgia, Louisiana, Mississippi, North Carolina, South Carolina, and Texas. Under the trade name of Dechlorane, mirex was used as a fire retardant in electronic components, fabrics, and plastics; effluents from manufacturing processes resulted in the pollution of Lake Ontario. Regulatory agencies, environmentalists, and the general public became concerned as evidence accumulated demonstrating that mirex was associated with high death rates, numerous birth defects, and tumors, and that it disrupted metabolism in laboratory mammals, birds, and aquatic biota. Mirex also tends to bioaccumulate and to biomagnify at all trophic levels of food chains. Field studies corroborated the laboratory findings and showed that mirex appeared to be one of the most stable and persistent organochlorine compounds known, being resistant to chemical, photolytic, microbial, metabolic, and thermal degradation processes. Upon degradation, a series of potentially hazardous metabolites are formed, although it is generally acknowledged that the fate and effects of the degradation products are not fully understood. Mirex was also detected in human milk and adipose tissues at low concentrations, the levels related to the degree of environmental contamination. In 1978, the U.S. Environmental Protection Agency banned all uses of mirex. It is probable that mirex and its metabolites will continue to remain available to living organisms in this country for at least 12 years, although some estimates range as high as 600 years.

21.2 CHEMICAL PROPERTIES

Mirex is a white, odorless, free-flowing, crystalline, nonflammable, polycyclic compound composed entirely of carbon and chlorine. The empirical formula is $C_{10}Cl_{12}$, and the molecular weight 545.54 (Hyde 1972; Waters et al. 1977; Bell et al. 1978; NAS 1978; Menzie 1978; Kaiser 1978). In the United States, the common chemical name is dodecachlorooctahydro-1,3,4-metheno-2H-cyclobuta[c,d]pentalene. The systematic name is dodecachloropentacyclo 5.3.0.0^{2,6}.0^{3,9}.0^{4,8}decane. Mirex was first prepared in 1946, patented in 1955 by Allied Chemical Company, and introduced

in 1959 as GC 1283 for use in pesticidal formulations against hymenopterous insects, especially ants. It was also marketed under the trade name of Dechlorane for use in flame-retardant coatings for various materials. Mirex is also known as ENT 25719 (Tucker and Crabtree 1970), CAS 2385-85-5 (Schafer et al. 1983), Dechlorane 510, and Dechlorane 4070 (Kaiser 1978). Technical-grade preparations of mirex consist of 95.19% mirex and less than $2.58 \times 10^{-7}\%$ contaminants, mostly kepone $C_{10}Cl_{10}O$ (NAS 1978). Mirex is comparatively soluble in various organic solvents, such as benzene, carbon tetrachloride, and xylene, with solubilities ranging from about 4000 to 303,000 mg/L. However, mirex has very low solubility in water, not exceeding 1.0 µg/L in freshwater or 0.2 µg/L in seawater (Bell et al. 1978). In biological systems, mirex lipophilicity would account for the high concentrations observed in fatty tissues and reserves.

Mirex, which is composed of 22% carbon and 78% chlorine, is highly resistant to chemical, thermal, and biochemical degradation. It is reportedly unaffected by strong acids, bases, and oxidizing agents, and is resistant to photolysis in hydrocarbon solvents, but less so in aliphatic amines. Thermal decomposition begins at about 550°C and is rapid at 700°C. Degradation products include hexachlorobenzene, hexachlorocyclopentadiene, and kepone. Several additional degradation products of mirex have been isolated, but not all have been identified (Holloman et al. 1975; Menzie 1978). At least one photodegradation product, the 8-monohydro analogue, sometimes accumulates in sediments and animals, but the fate and effects of these photoproducts are unclear (Cripe and Livingston 1977).

Mirex is rapidly adsorbed onto various organic particles in the water column, including algae, and eventually removed to the sediments. Not surprisingly, mirex has a long half-life in terrestrial and aquatic sediments; large fractional residues were detected at different locations 12 and 5 years after initial application (Bell et al. 1978). Some degradation of mirex to the 10-monohydro analogue was reported in anaerobic sewage sludge after 2 months in darkness at 30°C (Menzie 1978). Other studies with mirex-contaminated anaerobic soils, anaerobic lake sediments, and soil microorganisms showed virtually no bacterial degradation over time (Jones and Hodges 1974). In Lake Ontario, mirex from contaminated sediments remained available to lake organisms for many years and, as judged by present sedimentation rates, mirex may continue to be bioavailable for 200 to 600 years in that system (Scrudato and DelPrete 1982). Disappearance of mirex from baits over a 12-month period was about 41% for those exposed on the ground, 56% from those exposed in soil, and 84% from those exposed in pond water (de la Cruz and Lue 1978b). Mirex disappearance is probably related to uptake by biological organisms, as has been demonstrated in marine ecosystems contaminated with mirex (Waters et al. 1977), and not to degradation.

Mirex is a highly stable chlorinated hydrocarbon with lipophilic properties, and its accumulation and persistence in a wide variety of nontarget biological species has been well documented. The biological half-life of mirex reportedly ranges from 30 days in quail to 130 days in fish and to more than 10 months in the fat of female rats (Menzie 1978); this subject area is further developed later. At this juncture, it is sufficient to state that most authorities agree on two points: there is little evidence of significant mirex metabolism, and mirex ranks among the more biochemically stable organic pesticides known.

21.3 LETHAL EFFECTS

21.3.1 Aquatic Organisms

Aquatic organisms are comparatively resistant to mirex in short-term toxicity tests. Among various species of freshwater biota, LC₅₀ (96 h) values were not obtained at the highest nominal concentrations tested of 1000 µg/L for insects, daphnids, and amphipods (Johnson and Finley 1980; Sanders et al. 1981) and 100,000 µg/L for five species of fish (Johnson and Finley 1980). Similar results were reported for other species of freshwater invertebrates (Muncy and Oliver 1963; Lue and de la Cruz 1978) and fishes (Van Valin et al. 1968), although waterborne mirex at concentrations of 1000 µg/L was lethal to postlarval freshwater prawns (*Macrobrachium rosenbergerii*) in 24 h

(Eversole 1980). It is probable that bioavailable concentrations from the water in each test did not exceed 1.0 µg/L. However, delayed mortality frequently occurs for extended periods after exposure, and the potential for adverse effects at the population level remains high (NAS 1978). Latent biocidal properties of mirex were documented for fish (Van Valin et al. 1968; Koenig 1977) and crustaceans (Ludke et al. 1971; Hyde 1972; Cripe and Livingston 1977). Crustaceans were the most sensitive group examined. For example, the crayfish (*Procambarus blandus*) immersed in nominal concentrations of 0.1 to 5.0 µg mirex/L for periods of 6 to 144 h died 5 to 10 days after initial exposure (Ludke et al. 1971). Immature crayfish were more sensitive than adults, and mortality patterns were similar when mirex was administered in the water or in baits (Ludke et al. 1971).

21.3.2 Birds and Mammals

Acute oral toxicity of mirex to warm-blooded organisms was low, except for rats and mice, which died 60 to 90 days after treatment with 6 to 10 mg mirex/kg body weight (Table 21.1). Birds were comparatively resistant. The red-winged blackbird (*Agelaius phoeniceus*) was unaffected at 100 mg mirex/kg body weight, although it was considered the most sensitive of 68 species of birds tested with 998 chemicals for acute oral toxicity, repellency, and hazard potential (Schafer et al. 1983).

Mortality due to dietary mirex is variable among species, although high death rates were usually associated with high dietary concentrations and long exposure periods (Table 21.2). One significant effect of mirex fed to breeding adult chickens, voles, and rats was a decrease in survival of the young (Naber and Ware 1965; Shannon 1976; Waters et al. 1977; Chu et al. 1981). Prairie voles (*Micropterus ochrogaster*) fed diets containing 15 mg mirex/kg ration bred normally, but all pups died by day 21 (Shannon 1976). Survival of the pups of prairie voles decreased in the first litter when the diet of the parents contained 10 mg mirex/kg ration, in the second litter when it contained 5 mg/kg, and in the third litter when it contained 0.1, 0.5, 0.7, or 1.0 mg/kg (Shannon 1976).

Table 21.1 Acute Oral Toxicity of Mirex to Birds and Mammals

Organism	Dose (mg/kg body weight)	Mortality	Reference ^a
Mice, <i>Mus</i> sp.	5	None, 60 days posttreatment	1
Rat, <i>Rattus</i> sp.; female	6	50%, 90 days posttreatment	1
Mice	10	100%, 60 days posttreatment	1

21.4 SUBLETHAL EFFECTS

21.4.1 Aquatic Organisms

The maximum acceptable toxicant concentration (MATC) values calculated for mirex and various freshwater species were:

- <2.4 µg/L for amphipods (*Gammarus* sp.), based on growth inhibition at higher concentrations (Sanders et al. 1981)
- 2 to 3 µg/L for fathead minnows (*Pimephales promelas*), as judged by disruption of swim bladder hydroxyproline content, Vitamin C metabolism, and bone collagen (Mehrle et al. 1981)
- 34 µg/L for fathead minnows, based on impaired reproduction (Buckler et al. 1981)
- >34 µg/L for daphnids (*Daphnia* sp.) and midges (*Chaoborus* sp.), predicated on daphnid reproduction and midge emergence (Sanders et al. 1981)

Other mirex-induced sublethal effects included reduced photosynthesis in freshwater algae (Hollister et al. 1975), gill and kidney histopathology in the goldfish (*Carassius auratus*) (Van Valin et al. 1968), reduced growth in the bluegill (*Lepomis macrochirus*) (Van Valin et al. 1968), cessation of reproduction in *Hydra* sp. (Lue and de la Cruz 1978), and disrupted behavior in the blue crab (*Callinectes sapidus*) (Shannon 1976) and the marine annelid (*Arenicola cristata*) (Schoor and Newman 1976). McCorkle et al. (1979) showed that channel catfish (*Ictalurus punctatus*) are particularly resistant to high dietary concentrations of mirex; juveniles fed 400 mg mirex/kg ration for 4 weeks showed no significant changes in enzyme-specific activities of brain, gill, liver, or muscle. However, yearling coho salmon (*Oncorhynchus kisutch*) fed 50 mg mirex/kg ration for 3 months showed significant reduction in liver weight and whole-body lipid content (Leatherland

et al. 1979). Additional studies with coho salmon and rainbow trout (*Salmo gairdneri*) fed 50 mg mirex/kg ration for 10 weeks demonstrated a significant depression in serum calcium, and significant elevation of skeletal magnesium in salmon; trout showed no measurable changes in calcium and magnesium levels in serum, muscle, or skeleton, although growth was reduced, muscle water content was elevated, and muscle lipid content was reduced (Leatherland and Sonstegard 1981). Interaction effects of mirex with other anthropogenic contaminants are not well studied, despite the observations of Koenig (1977) that mixtures of DDT and mirex produced more than additive deleterious effects on fish survival and reproduction.

21.4.2 Birds

Among captive American kestrels (*Falco sparverius*) fed 8 mg mirex/kg ration for 69 days by Bird et al. (1983), there was a marked decline in sperm concentration and a slight compensatory increase in semen volume, but an overall net decrease of 70% in sperm number. These investigators believed that migratory raptors feeding on mirex-contaminated food organisms could ingest sufficient toxicant to lower semen quality in the breeding season which, coupled with altered courtship, could reduce the fertility of eggs and the reproductive fitness of the individual. Altered courtship in ring-necked doves (*Streptopelia capicola*) fed dietary organochlorine compounds was reported by McArthur et al. (1983).

Most investigators, however, agree that comparatively high dietary concentrations of mirex had little effect on growth, survival, reproduction, and behavior of nonraptors, including chickens (*Gallus* sp.), mallards, several species of quail, and red-winged blackbirds. For domestic chickens, levels up to 200 mg mirex/kg ration were tolerated without adverse effects on various reproductive variables (Waters et al. 1977), but 300 mg mirex/kg diet for 16 weeks was associated with reduced chick survival, and 600 mg/kg for 16 weeks reduced hatching by 83% and chick survival by 75% (Naber and Ware 1965). Mallard ducklings experienced temporary mild ataxia and regurgitation when given a single dose of 2400 mg/kg body weight, but not when given 1200 mg/kg or less (Tucker and Crabtree 1970). Mallards fed diets containing as much as 100 mg mirex/kg ration for prolonged periods showed no significant differences from controls in egg production, shell thickness, shell weight, embryonation, hatchability, or duckling survival (Hyde 1972). However, in other studies with mallards fed 100 mg mirex/kg diet, eggshells were thinned and duckling survival was reduced (Waters et al. 1977), suggesting that 100 mg mirex/kg ration may not be innocuous to mallards. No adverse effects on reproduction were noted in the common bobwhite at 40 mg mirex/kg diet (Kendall et al. 1978), or in two species of quail fed 80 mg mirex/kg ration for 12 weeks (Waters et al. 1977). Red-winged blackbirds were not repelled by foods contaminated with mirex, but consumed normal rations (Schafer et al. 1983); a similar observation was recorded for bobwhites (Baker 1964).

21.4.3 Mammals

Mirex has considerable potential for chronic toxicity because it is only partly metabolized, is eliminated very slowly, and is accumulated in the fat, liver, and brain. The most common effects observed in small laboratory mammals fed mirex included weight loss, enlarged livers, altered liver enzyme metabolism, and reproductive failure. Mirex reportedly crossed placental membranes and accumulated in fetal tissues. Among the progeny of mirex-treated mammals, developmental abnormalities included cataracts, heart defects, scoliosis, and cleft palates (NAS 1978; Blus 1995).

Mirex has caused liver tumors in mice and rats and must be considered a potential human carcinogen (Waters et al. 1977; NAS 1978). Long-term feeding of 50 and 100 mg mirex/kg ration to rats of both sexes was associated with liver lesions that included neoplastic nodules and hepatocellular carcinomas; neither sign was found in controls (Ulland et al. 1977).

Adults of selected mammalian species showed a variety of damage effects of mirex:

- Enlarged livers in rats at 25 mg mirex/kg diet (Gaines and Kimbrough 1969) or at a single dose of 100 mg/kg body weight (Ervin 1982)
- Liver hepatomas in mice at 10 mg mirex/kg body weight daily (Innes et al. 1969)
- Decreased incidence of females showing sperm in vaginal smears, decreased litter size, and thyroid histopathology in rats fed 5 mg mirex/kg diet since weaning (Chu et al. 1981)
- Elevated blood and serum enzyme levels in rats fed 0.5 mg mirex/kg ration for 28 days (Yarbrough et al. 1981)
- Diarrhea, reduced food and water consumption, body weight loss, decreased blood glucose levels, and disrupted hepatic microsomal mixed function oxidases in mice receiving 10 mg/kg body weight daily (Fujimori et al. 1983).

In studies of field mice, decreased litter size was observed at 1.8 mg mirex/kg diet, and complete reproductive impairment at 17.6 mg/kg diet after 6 months (Wolfe et al. 1979). At comparatively high sublethal mirex concentrations, various deleterious effects were observed: thyroid histopathology and decreased spermatogenesis in rats fed 75 mg mirex/kg diet for 28 days (Yarbrough et al. 1981); abnormal blood chemistry, enlarged livers, reduced spleen size, and loss in body weight of beagles fed 100 mg mirex/kg ration for 13 weeks (Larson et al. 1979); and decreased hemoglobin, elevated white blood cell counts, reduced growth, liver histopathology, and enlarged livers in rats fed 320 mg/kg ration for 13 weeks (Larson et al. 1979).

Cataract formation, resulting in blindness, in fetuses and pups from maternal rats fed comparatively low concentrations of dietary mirex is one of the more insidious effects documented. Mirex fed to maternal rats at 6 mg/kg body weight daily on days 8 to 15 of gestation, or at 10 mg/kg body weight daily on days 1 to 4 postpartum, caused cataracts in 50% of fetuses on day 20 of gestation, and in 58% of pups on day 14 postpartum (Rogers 1982). Plasma glucose levels were depressed in fetuses with cataracts, and plasma proteins were depressed in neonates; both hypoproteinemia and hypoglycemia are physiological conditions known to be associated with cataracts (Rogers 1982). Mirex-associated cataractogenicity has been reported in female pups from rats fed 5 mg mirex/kg ration since weaning (Chu et al. 1981), in rat pups from females consuming 7 mg mirex/kg ration on days 7 to 16 of gestation or 25 mg/kg diet for 30 days prior to breeding (Chernoff et al. 1979), and in mice fed 12 mg mirex/kg ration (Chernoff et al. 1979). Offspring born to mirex-treated mothers, but nursed by nontreated mothers showed fewer cataracts (Waters et al. 1977). Other fetotoxic effects in rats associated with dietary mirex included:

- Edema and undescended testes (Chernoff et al. 1979)
- Lowered blood plasma proteins, and heart disorders, including tachycardia and blockages (Grabowski 1981)
- Hydrocephaly; decreases in weight of brain, lung, liver, and kidney; decreases in liver glycogen, kidney proteins and alkaline phosphatase; and disrupted brain DNA and protein metabolism (Kavlock et al. 1982)

In prairie voles exposed continuously to dietary mirex of 0.5, 0.7, 1.0, 5.0, or 10.0 mg/kg ration, the numbers of litters produced decreased (Shannon 1976). Maximum number of litters per year were four at 1.0 mg mirex/kg ration, three at 5.0 mg/kg, and two at 10.0 mg/kg ration. Furthermore, the number of offspring per litter also decreased progressively. Concentrations as low as 0.1 mg mirex/kg ration of adults were associated with delayed maturation of pups and with an increase in number of days required to attain various behavioral plateaus such as bar-holding ability, hind-limb placing, and negative geotaxis (Shannon 1976). On the basis of residue data from field studies, as is shown later, these results strongly suggest that mirex was harmful to the reproductive performance and behavioral development of prairie voles at environmental levels approaching 4.2 g mirex/ha, a level used to control fire ants before mirex was banned.

21.5 BIOACCUMULATION

21.5.1 Aquatic Organisms

All aquatic species tested accumulated mirex from the medium and concentrated it over ambient water levels by factors ranging up to several orders of magnitude. Uptake was positively correlated with nominal dose in the water column (Table 21.3). Other investigators have reported bioconcentration factors from water of 8025 in daphnids (Sanders et al. 1981), 12,200 in bluegills (Skaar et al. 1981), 56,000 in fathead minnows (Huckins et al. 1982), and 126,600 in the digestive gland of crayfish (Ludke et al. 1971). Rapid uptake of mirex by marine crabs, shrimps, oysters, killifishes, and algae was reported after the application of mirex baits to coastal marshes (Waters et al. 1977; Cripe and Livingston 1977). Mirex was also accumulated from the diet (Table 21.3) (Ludke et al. 1971; Zitko 1980), but not as readily as from the medium. Dietary bioaccumulation studies with guppies and goldfish show that mirex and other persistent hydrophobic chemicals are retained in the organism and biomagnify through food chains because of their hydrophobicity (Gobas et al. 1989, 1993; Clark and Mackay 1991). Mirex may also be accumulated from contaminated sediments by marine teleosts (Kobylinski and Livingston 1975), but such accumulation has not been established conclusively. Although terrestrial plants, such as peas and beans, accumulate mirex at field application levels, mangrove seedlings require environmentally high levels of 11.2 kg mirex/ha before accumulation occurs (as quoted in Shannon 1976).

There is general agreement that aquatic biota subjected to mirex-contaminated environments continue to accumulate mirex, and that equilibrium is rarely attained before death of the organism from mirex poisoning or from other causes. There is also general agreement that mirex resists metabolic and microbial degradation, exhibits considerable movement through food chains, and is potentially dangerous to consumers at the higher trophic levels (Hollister et al. 1975; NAS 1978; Mehrle et al. 1981; Eisler 1985). Marine algae, for example, showed a significant linear correlation between amounts accumulated and mirex concentrations in the medium. If a similar situation existed in nature, marine unicellular algae would accumulate mirex and, when grazed upon, act as passive transporters to higher trophic food chain compartments (Hollister et al. 1975). The evidence for elimination rates of mirex from aquatic biota on transfer to mirex-free media is not as clear. Biological half-times of mirex have been reported as 12 h for daphnids (Sanders et al. 1981), more than 28 days for fathead minnows (Huckins et al. 1982), about 70 days in Atlantic salmon (*Salmo salar*) (Zitko 1980), 130 days for mosquitofish (*Gambusia affinis*), and 250 days for pinfish (as quoted in Skea et al. 1981). However, Skea et al. (1981) averred that biological half-times may be much longer if organism growth is incorporated into rate elimination models. For example, brook trout (*Salvelinus fontinalis*) fed 29 mg mirex/kg ration for 104 days contained 6.3 mg/kg body weight or a total of 1.1 mg of mirex in whole fish. At day 385 postexposure, after the trout had tripled in body weight, these values were 2.1 mg/kg body weight, an apparent loss of 67%; however, on a whole-fish basis, trout contained 1.2 mg, thus showing essentially no elimination on a total-organism basis (Skea et al. 1981).

No mirex degradation products were detected in whole fathead minnow or in hydrosoils under aerobic or anaerobic conditions (Huckins et al. 1982). In contrast, three metabolites were detected in coastal marshes after mirex bait application, one of which, photomirex, was accumulated by fish and oysters (Cripe and Livingston 1977). The fate and effects of mirex photoproducts in the environment are unclear and merit additional research.

The significance of mirex residues in various tissues is unresolved, as is the exact mode of action of mirex and its metabolites. Minchew et al. (1980) and others indicated that mirex is a neurotoxic agent, with a mode of action similar to that of other chlorinated hydrocarbon insecticides, such as DDT. In studies with crayfish and radiolabeled mirex, mirex toxicosis was associated with neurotoxic effects that included hyperactivity, uncoordinated movements, loss of equilibrium, and

paralysis (Minchew et al. 1980). Before death, the most significant differences in mirex distributions in crayfish were the increases in concentrations in neural tissues, such as brain and nerve cord, by factors up to 14 (or 0.4 mg/kg) in low-dose groups held in solutions containing 7.4 µg mirex/L, and up to 300 (or 6.2 mg/kg) in high-dose groups held in solutions with 74.0 µg/L. With continued exposure, levels in the green gland and neural tissues approached the levels in the hepatopancreas and intestine (Table 21.3). Schoor (1979) also demonstrated that mirex accumulates in the crustacean hepatopancreas, but suggested that other tissues, such as muscle and exoskeleton, have specific binding sites that, once filled, shunt excess mirex to hepatopancreas storage sites.

21.5.2 Birds and Mammals

Like aquatic organisms, birds and mammals accumulated mirex in tissue lipids, and the greater accumulations were associated with the longer exposure intervals and higher dosages (Table 21.3). Sexual condition of the organism may modify bioconcentration potential. For example, in adipose fat of the bobwhite, males contained 10 times dietary levels and females only 5 times dietary levels; the difference was attributed to mirex loss through egg laying (Kendall et al. 1978).

Data on excretion kinetics of mirex are incomplete. Prairie voles fed mirex for 90 days contained detectable whole-body levels 4 months after being placed on a mirex-free diet (Shannon 1976). Levels of mirex in voles after 4 months on uncontaminated feed were still far above levels in their mirex diets. Humans living in areas where mirex has been used for ant control contained 0.16 to 5.94 mg/kg in adipose fat; 60% of the mirex was excreted and most of the rest was stored in body tissues, especially fat (28%), and in lesser amounts of 0.2 to 3% in muscle, liver, kidney, and intestines (Waters et al. 1977). Almost all excretion of mirex takes place through feces; less than 1% is excreted in urine and milk. The loss rate pattern is biphasic, the fast phase was estimated at 38 h and the slow phase at up to 100 days. Mirex binds firmly to soluble liver proteins and appears to be retained in fatty tissues, a property that may contribute to its long biological half-life. Chickens given single doses of mirex at 30 mg/kg intravenously or 300 mg/kg orally demonstrated a biphasic decline in blood concentrations (Ahrens et al. 1980). The fast component, constituting about 25% of the total, was lost during the first 24 h; the loss of the slow component was estimated to be at a constant rate of about 0.03% daily, suggesting a half-life of about 3 years. Growing chicks fed 1 or 10 mg/kg dietary mirex for 1 week lost the compound rather rapidly; disappearance half-times were 25 days for skin and 32 days for fat (Ahrens et al. 1980). It is clear that much additional research is warranted on loss rate kinetics of this persistent compound and its metabolites.

21.6 MIREX IN THE SOUTHEASTERN UNITED STATES

Between 1961 and 1975, about 400,000 kg mirex were used in pesticidal formulations, of which approximately 250,000 kg were sold in the southeastern United States for control of native and imported fire ants (*Solenopsis* spp.). Most of the rest was exported to Brazil for use in fire ant control in that country (NAS 1978). Mirex was also used to control big-headed ant populations in Hawaiian pineapple fields (Bell et al. 1978), Australian termites (Paton and Miller 1980), South American leaf cutter ants, South African harvester termites, and, in the United States, western harvester ants and yellow jackets (Shannon 1976). Chemical control measures for imported fire ants began in the southeastern United States during the 1950s with the use of heptachlor, chlordane, and dieldrin. The large mounds built by ants in cultivated fields were believed to interfere with mowing and harvesting operations; the “vicious sting” of the insects presented a hazard to workers harvesting the crops; and the species was considered to be a pest in school playgrounds and homes (Lowe 1982). In 1965, the use of organochlorine insecticides to control fire ants was discontinued, due partly to their high acute toxicity to nontarget biota and their persistence. Previously used compounds were replaced by mirex 4X bait formulations, consisting of 0.3% mirex by weight, dissolved in 14.7% soybean oil, and soaked into corncob grits (85%). Initially, the 4X baits were broadcast from low-flying airplanes at a total yearly rate of 1.4 kg bait/ha (1.25 lb total bait/acre) or 4.2 g mirex/ha. Usually, three applications were made yearly. More than 50 million ha in nine southeastern states were treated over a 10-year period. Later, dosages were modified downward, and mirex was applied to mounds directly. Ecologically sensitive areas, such as estuaries, prime wildlife habitats, heavily forested areas, and state and federal parks, were avoided. In 1977, for example, the formulation was changed to 0.1% mirex and the application rate lowered to 1.12 g/ha; about 8200 kg of the lower-concentration bait were manufactured in 1977 (Bell et al. 1978). Under ideal aerial application conditions, about 140 particles of mirex-impregnated bait were distributed per square meter. When an infested area is treated, the bait is rapidly scavenged by the oil-loving fire ant workers, placed in the mound, and distributed throughout the colony, including queen and brood, before any toxic effects become evident. Death occurs in several days to weeks. The exact mode of action is unknown, but is believed to be similar to that of other neurotoxic agents such as DDT (Waters et al. 1977; NAS 1978).

Widespread use of mirex may lead to altered population structure in terrestrial systems, with resurgence or escalation of nontarget pests due to selective mirex-induced mortality of predators (NAS 1978). For example, populations of immature horn flies and rove beetles, two species of arthropods normally preyed upon by fire ants, were higher in mirex-treated areas than in control areas (Howard and Oliver 1978). Conversely, other species, such as crickets, ground beetles, and various species of oil-loving ants, were directly affected and populations were still depressed or eliminated 14 months posttreatment (NAS 1978), whereas fire ants recovered to higher than pretreatment levels, as judged by mound numbers and mound size (Summerlin et al. 1977).

Field results from aquatic and terrestrial ecosystems receiving mirex bait formulations indicated, with minor exceptions, that mirex accumulates sequentially in food complexes and concentrates in animals at the higher trophic levels. In both ecosystems, omnivores and top carnivores contained the highest residues (Hyde 1972; Shannon 1976; Waters et al. 1977; de la Cruz and Lue 1978a; Hunter et al. 1980; Eisler 1985). In South Carolina, where the 4X formulation was used to control fire ants from 1969 to 1971, mirex was translocated from treated lands to nearby marshes and estuarine biota, including crustaceans, marsh birds, and raccoons (Lowe 1982). Juvenile marine crustaceans showed delayed toxic effects after ingesting mirex baits, or after being exposed to low concentrations in seawater. About 18 months posttreatment, mirex residues of 1.3 to 17.0 mg/kg were detected in shrimp, mammals, and birds (Table 21.4); however, 24 months after the last mirex treatment, less than 10% of all samples collected contained detectable residues (Lowe 1982). A similar study was conducted in pasturelands of bahia grass (*Paspalum notatum*) (Markin 1981). Within a month after application, the target fire ant colonies were dead. Of the 4.2 g mirex/ha

applied to the 164 ha block, 100% was accounted for on day 1, 63% at 1 month, and 3% at 1 year (Table 21.5). Unaccounted mirex residues could include loss through biodegradation; through movement out of the study area by migratory insects, birds, other fauna, and groundwater; and through photodecomposition and volatilization (Markin 1981).

Table 21.4 Mirex Residues in Water, Sediments, and Fauna in a South Carolina Coastal Marsh 18 months after Application of 4.2 g/ha

Sample	Maximum Mirex Residues (mg/kg)	Percent Samples with Mirex Residues

Mirex residues in bobwhites from a South Carolina game management area were documented after treatment with 4.2 g mirex/ha (Kendall et al. 1977). Pretreatment residues in bobwhites ranged from nondetectable to 0.17 mg mirex/kg breast muscle on a dry-weight basis, and 0.25 to 2.8 mg/kg in adipose tissues on a lipid-weight basis. Mirex residues in adipose tissue increased up to 5 times within 1 month posttreatment and declined thereafter; however, another residue peak was noted in the spring after mirex treatment and corresponded with insect emergence (Kendall et al. 1977).

Mirex concentrations in muscle and liver of mammalian wildlife in Alabama and Georgia during the period 1973 to 1976 from reference areas were always less than 0.04 mg mirex/kg FW in muscle and less than 0.07 mg/kg FW in liver (Hill and Dent 1985). In mirex-treated areas, conspecifics were collected up to 2 years posttreatment. Maximum concentrations of mirex in muscle and liver from mirex-treated areas were always less than 1.0 mg/kg FW in raccoons, bobcats (*Lynx rufus*), mink (*Mustela vison*), and foxes (*Urocyon* sp., *Vulpes* sp.). Higher concentrations of 3.7 mg/kg FW in muscle and 1.1 mg/kg FW in liver were measured in the river otter (*Lutra*

canadensis) 1 year posttreatment, 3.5 mg/kg FW in muscle of skunks (*Spilogale* sp., *Mephitis* sp.) 6 months posttreatment, and 1.1 to 1.5 mg/kg FW in embryos and muscle of the opossum (*Didelphis marsupialis*) 6 to 12 months after treatment (Hill and Dent 1985).

Heavily treated watershed areas in Mississippi were investigated by Wolfe and Norment (1973) and Holcombe and Parker (1979). After treatment, mirex residues were elevated in crayfish and stream fish. Among mammals, residues were highest in carnivores and insectivores, lower in omnivores, and lowest in herbivores (Wolfe and Norment 1973). Mirex residues in liver and eggs were substantially higher in the box turtle (*Terrapene carolina*), an omnivorous feeder, than in the herbivorous slider turtle (*Chrysemys scripta*); mirex did not accumulate for protracted periods in tissues of these comparatively long-lived reptiles (Holcombe and Parker 1979). Among migratory reptiles, mirex was detected in only 11% of the eggs of the loggerhead turtle (*Caretta caretta*) and not at all in eggs of the green turtle (*Chelonia mydas*) collected during summer 1976 in Florida (Clark and Kryniotsky 1980). However, DDT or its isomers were present in all eggs of both species, and PCBs were detected in all loggerhead turtle eggs. The low levels of mirex and other organochlorine contaminants suggest that these turtles, when not nesting, live and feed in areas remote from Florida lands treated with mirex and other insecticides (Clark and Kryniotsky 1980).

A 10-5 bait formulation containing 0.1% mirex was designed to make more of the toxicant available to the fire ant and less to nontarget biota. In one study, the 10-5 formulation was applied to a previously untreated 8000-ha area near Jacksonville, Florida, infested with fire ants (Wheeler et al. 1977). The bait was applied by airplane at 1.12 kg/ha, or 1.12 g mirex/ha. Insects accumulated mirex to the greatest extent during the first 6 months after application, and most of the mirex was lost by 12 months (Table 21.6). Other invertebrates accumulated only low levels during the first 9 months, and no residues were detected after 12 months. Fish also showed low concentrations for 9 months and no detectable residues afterward. Amphibians contained detectable residues after 12 months, but not at 24; and reptiles contained measurable, but low, residues for the entire 24-month study period. Mammals had higher residue levels than reptiles, particularly in fat, whereas birds contained low to moderate residues (Table 21.6). After 24 months, mirex was found infrequently and only at low concentrations in birds, mammals, reptiles, and insects. It was concluded that 10-5 mirex formulations were as effective in controlling fire ants as the 4X formulation and that residues in nontarget species were reduced from that following 4X treatment, or were lacking (Wheeler et al. 1977).

Eggs of the American crocodile (*Crocodylus acutus*) from the Florida Everglades contained up to 2.9 mg/kg fresh weight of DDE and 0.86 mg/kg of polychlorinated biphenyls, but less than 0.02 mg mirex/kg (Hall et al. 1979). Livers of the deep sea fish (*Antimora rostrata*) collected from 1971 to 1974 from a depth of 2500 m off the U.S. east coast, contained measurable concentrations of DDT and its degradation products, and dieldrin, but no mirex (Barber and Warlen 1979).

21.7 MIREX IN THE GREAT LAKES

Between 1959 and 1975, 1.5 million kg mirex were sold, of which 74%, or more than 1.1 million kg, were predominantly Dechlorane, a compound used in flame-resistant polymer formulations of electronic components and fabrics (Bell et al., 1978; NAS 1978). The total amounts are only approximate because almost half the mirex sold from 1962 to 1973 could not be accounted for (NAS 1978). Mirex loadings to Lake Ontario were estimated at 200 kg per year in 1960 to 1962, which decreased to 28 kg in 1980 (Halfon 1987). Mirex entered Lake Ontario mainly from the Niagara and Oswego Rivers. About 700 kg mirex were present in the bottom sediments of Lake Ontario in 1968, 1600 kg in 1976, and 1784 kg in 1981 (Halfon 1984). Kaiser (1978) reported that all fish species in Lake Ontario were contaminated with mirex, and that concentrations in half the species exceeded the Food and Drug Administration guideline of 0.1 mg/kg; other aquatic species had mirex residues near this level. Reproduction of the herring gull (*Larus argentatus*) on Lake Ontario was poor; mirex levels were an order of magnitude higher in gull eggs from Lake Ontario than in eggs from other Great Lakes locations (Kaiser 1978). It was concluded that the probable source of contamination was a chemical manufacturer that used mirex (Dechlorane) as a flame retardant, and that only Lake Ontario was contaminated (Kaiser 1978; NAS 1978). Until 1988, mirex had been reported for only a few locations in the Great Lakes, primarily Lake Ontario and the St. Lawrence River. Since 1988, however, mirex in water and fish samples has been measured from the other Great Lakes (Sergeant et al. 1993).

Gilman et al. (1977, 1978) observed poor reproductive success and declines in colony size of the herring gull at Lake Ontario at a time when dramatic increases of this species were reported along the Atlantic seaboard. In 1975, herring gull reproduction in Lake Ontario colonies was about one tenth that of colonies on the other four Great Lakes. In addition, in Lake Ontario colonies, there were reductions in nest site defense, the number of eggs per clutch, hatchability of eggs, and chick survival. Hatching success of Lake Ontario gull eggs was 23 to 26%, compared with 53 to 79% for eggs from other areas. Analysis of herring gull eggs from all colonies for organochlorine compounds and mercury demonstrated that eggs from Lake Ontario colonies had mean mirex levels of 5.06 mg/kg fresh weight (range, 2.0 to 18.6), or about 10 times more mirex than any other colony. Mean PCB and mercury levels were up to 2.8 and 2.3 times higher, respectively, in gull eggs from Lake Ontario than in those from other colonies, but only mirex levels could account for

the colony declines (Gilman et al. 1977, 1978). Short-term deviations from long-term trends in mirex concentrations in eggs of herring gulls from Lake Ontario seem to be correlated with weather patterns (i.e., warm spring weather conducive to phytoplankton growth produces relatively uncontaminated plankton, which results in less contamination for gulls during the critical period of egg yolk formation — and the reverse for cold spring weather) (Smith 1995). As judged by log-linear regression models, the half-life for mirex in herring gull eggs was 1.9 to 2.1 years, or essentially none was lost during egg incubation (Weseloh et al. 1979). Reproductive success of the Lake Ontario herring gull colonies improved after the early 1970s, an improvement that was directly paralleled by a decline in mirex, other organochlorine pesticides, and PCBs (Weseloh et al. 1979).

Concentrations of mirex and other contaminants in eggs of the Caspian tern (*Sterna caspia*) from the Great Lakes are declining, and tern populations are increasing (Struger and Weseloh 1985; Ewins et al. 1994). In Lake Huron, mirex concentrations in Caspian tern eggs declined from 0.51 mg/kg FW in 1976 to 0.12 mg/kg FW in 1991, equivalent to a decline of 8.6% annually. In Lake Ontario, mirex concentrations in tern eggs declined from 1.6 mg/kg FW in 1981 to 0.77 mg/kg FW in 1991, a decline of 7.1% annually (Ewins et al. 1994). Similar trends are reported for eggs of herring gulls from Lakes Michigan, Huron, and Ontario (Ewins et al. 1992, 1994), whole lake trout (*Salvelinus namaycush*) from Lake Ontario (Borgmann and Whittle 1991), and whole young-of-the-year spottail shiners (*Notropis hudsonicus*) throughout the Great lakes (Suns et al. 1993).

The fate of mirex in the environment and the associated transfer mechanisms have not been well defined (NAS 1978). One of the more significant works on this subject area was that by Norstrom et al. (1978), who documented levels of mirex and its degradation products in herring gull eggs collected from Lake Ontario in 1977 (Table 21.7). They concluded that photodegradation was the only feasible mechanism for production of the degradation compounds, although mirex and its photoproducts rapidly become sequestered in the ecosystem and protected from further degradation. Norstrom et al. (1980) found mirex degradation products in herring gull eggs from all of the Great Lakes and suggested that a high proportion of mirex and related compounds in herring gull eggs from Lakes Erie and Huron originated from Lake Ontario fish, whereas lower levels in eggs from Lakes Superior and Michigan originated from other sources. Mirex in sediments was considered an unlikely source because it was not being recycled into the ecosystem at an appreciable rate (Norstrom et al. 1980). Migrating salmon (*Oncorhynchus* spp.) make a significant contribution to the upstream transport of mirex from Lake Ontario, estimated at 53 to 121 g mirex annually (Lewis and Makarewicz 1988; Scrudato and McDowell 1989). Ingestion of salmon eggs by brown trout, decomposition of salmon carcasses by blowfly larvae, and ingestion of carcasses by aquatic and terrestrial scavengers are all means by which mirex is introduced to upstream environments (Scrudato and McDowell 1989). A harvest rate of 50% by fisherman represents a removal of an additional 61 g mirex annually from Lake Ontario (Lewis and Makarewicz 1988).

Table 21.7 Mirex and Its Degradation Products in Herring Gull Eggs Collected from the Great Lakes in 1977

Compound	Mirex Concentration, (mg/kg fresh weight)	Percent of Samples Containing Compound
Mirex	2.58	66.7
8-Monohydro mirex (photomirex)	0.95	24.5
10-Monohydro mirex	0.199	5.1
C ₁₀ C ₁₁ H(III), possibly 9-monohydro mirex	0.077	2.0

Table 21.8 Biomagnification of Mirex in Great Lakes Food Chains

From	To	Bioconcentration Factor (BCF)
Water	Whole rainbow smelt (<i>Osmerus mordax</i>) or whole alewife (<i>Alosa pseudoharengus</i>)	500,000
Water	Muscle of coho salmon (<i>Oncorhynchus kisutch</i>)	1,500,000
Water	Egg of herring gull (<i>Larus argentatus</i>)	25,000,000
Alewife or rainbow smelt	Muscle of coho salmon	2.6
Alewife or rainbow smelt	Egg of herring gull	50.0

Modified from Norstrom, R.J., D.J. Hallett, and R.A. Sonstegard. 1978. Coho salmon (*Oncorhynchus kisutch*) and herring gulls (*Larus argentatus*) as indicators of organochlorine contamination in Lake Ontario. *Jour. Fish. Res. Board Canada* 35:1401-1409.

Biomagnification of mirex through food chains was investigated by Norstrom et al. (1978). Their basic assumption was that both herring gulls and coho salmon ate alewives (*Alosa pseudoharengus*) and rainbow smelt (*Osmerus mordax*). Mirex residues in these organisms, in mg/kg (parts per million) fresh weight, were 4.4 in gull eggs, 0.23 in salmon muscle, 0.10 in salmon liver, and 0.09 in whole alewives and smelt retrieved from stomachs of salmon. Bioconcentration factors (BCFs) from prey to predator ranged up to 50, and those from water to gull egg were estimated to be near 25 million (Table 21.8). Norstrom et al. (1978) indicated that salmon muscle and gull eggs are complementary indicators of organochlorine contamination in the Great Lakes.

Among Great Lakes fishes, the highest mirex value recorded was 1.39 mg/kg FW in whole American eels (*Anguilla rostrata*) collected from Lake Ontario and was substantially in excess of the tolerated limit of 0.3 mg/kg FW for human consumption at that time (NAS 1978). In the early 1980s, mirex was detected in 100% of the American eels sampled from Lake Ontario (Dutil et al. 1985). High mirex values were also reported in chinook salmon (*Oncorhynchus tshawytscha*) and coho salmon (*Oncorhynchus kisutch*) from South Sandy Creek, a tributary of Lake Ontario, during autumn 1976. As a consequence, possession of all fish from that area was prohibited by the State of New York (Farr and Blake 1979). Mirex concentrations in coho and chinook salmon tissues from Lake Ontario in 1977/78 ranged between 0.07 and 0.24 mg/kg FW tissue and increased with individual fish weight in direct relation to lipid content (Insalaco et al. 1982). The significance of mirex residues in salmonid fishes is unclear. Skea et al. (1981), in laboratory studies with brook trout, showed that whole-body residues of 6.3 mg/kg fish weight were not associated with adverse effects on growth or survival and speculated that long-lived species, such as the lake trout, would probably continue to accumulate mirex in Lake Ontario as long as they were exposed, and may continue to contain residues for most of their lives, even after the source has been eliminated.

There was no widespread mirex contamination of urban environments near Lake Ontario as a result of Dechlorane use, although local contamination of the Lake Ontario area was high when compared with other Great Lakes areas (NAS 1978). Among humans living in the Great Lakes area, there was great concern that mother's milk might be contaminated, owing to the high lipophilicity of mirex. Bush (1983) found mirex concentrations in mother's milk from residents of New York state to be 0.07 µg/L in Albany, 0.12 µg/L in Oswego, and 0.16 µg/L in Rochester, confirming that mirex was present in human milk but that concentrations were sufficiently low to be of little toxicological significance. It is noteworthy that none of the mothers had eaten Lake Ontario fish or any freshwater fish, and only a few had eaten marine fishes (Bush 1983). For a 5-kg infant consuming 500 g milk daily, this amount would approximate a daily dietary intake of 0.01 µg mirex/kg body weight (Bush 1983), or about 1/10,000 of the lowest recorded dietary value causing delayed maturation in prairie voles (Shannon 1976). It is not known if a safety factor of 10,000 is sufficient to protect human health against delayed toxic effects of mirex, but it now appears reasonable to believe that it is.

21.8 MIREX IN OTHER GEOGRAPHIC AREAS

Mirex residues were determined in birds collected nationwide or from large geographic areas of the United States; however, aside from the Southeast and the Great Lakes, concentrations were low, considered nonhazardous, and occurred in a relatively small proportion of the samples collected (Cain and Bunck 1983; Wood et al. 1996). Among wings of mallards and American black ducks (*Anas rubripes*) collected from the four major flyways during 1976/77, mirex concentrations were highest and percent occurrence greatest in samples from the Atlantic Flyway: mallards, 50% occurrence, 0.14 mg/kg fresh weight; black ducks, 19% and 0.04 mg/kg (White 1979). Data for mallards collected from other flyways follow: Mississippi, 29% and 0.03 mg/kg; Central, 14% and 0.06 mg/kg; and Pacific 4% and 0.03 mg/kg (White 1979). Carcasses of several species of herons found dead or moribund nationwide from 1966 to 1980 were analyzed for a variety of common organochlorine pesticides by Ohlendorf et al. (1981). They detected mirex in less than 15% of the carcasses, a comparatively low frequency, and only in nonhazardous concentrations. However, about 20% of all herons found dead or moribund had lethal or hazardous concentrations of dieldrin or DDT. In bald eagles (*Haliaeetus leucocephalus*) found dead nationwide, elevated mirex levels were recorded in carcass lipids (24.0 mg/kg) and in fresh brain tissues (0.22 mg/kg) (Barbehenn and Reichel 1981). Among endangered species such as the bald eagle, it was determined that the most reliable indicator for assessing risk of organochlorine compounds was the ratio of carcass to brain residues on a lipid weight basis (Barbehenn and Reichel 1981). Wings from American woodcocks (*Philohela minor*) collected from 11 states in 1970/71 and 14 states in 1971/72 were analyzed for mirex and other compounds by McLane et al. (1978). Mirex residues in the 1971/72 wings showed the same geographical pattern of recovery as those observed in 1970/71: residues were highest in the southern states and New Jersey, and lowest in the northern and midwestern states. Mirex residues were significantly lower in 1971/72 than in 1970/71. As judged by the analysis of wings of immature woodcocks in Louisiana, mirex residues were significantly lower in immatures than in adults: 2.48 mg/kg lipid weight vs. 6.20 mg/kg, respectively (McLane et al. 1978).

Mirex concentrations in bald eagle eggs collected nationwide between 1969 and 1979 ranged from 0.03 to 2.0 mg/kg FW, and were highest in Florida and the Chesapeake Bay region (Wiemeyer et al. 1984). Up to 87% of bald eagle eggs from Florida and the Chesapeake Bay had detectable mirex residues, whereas this value was as low as 17% in Alaska. Wiemeyer et al. (1984) note that eggs from successful bald eagle nests had 0.03 mg mirex/kg FW and lower, but eggs from unsuccessful nests had 0.05 mg/kg FW and higher. Eggs of Cooper's hawk, *Accipiter cooperi*, collected in 1980 from various locations, all contained more than 0.05 mg mirex/kg FW. Concentrations were highest in Pennsylvania (with 0.84 mg/kg FW) and Wisconsin (with 1.6 mg/kg FW) (Pattee et al. 1985). Eggs of the loggerhead shrike (*Lanius ludovicianus*) from the Shenandoah Valley region of Virginia in 1985/86 contained an average of 0.04 mg mirex/kg FW, with a 63% frequency of occurrence; loggerhead shrike populations in that region are declining but the cause of the decline is not known with certainty (Blumton et al. 1990). Eggs of the ring-necked grebe (*Podiceps grisigena*) from Manitoba, Canada, in 1980/81, had as much as 28.6 mg mirex/kg lipid weight, and this may account, in part, for the high nesting loss of 79% observed in grebes at that time (De Smet 1987). Mirex and other organochlorine compounds in eggs of anhingas (*Anhinga anhinga*) and 17 species of waders (including herons, egrets, bitterns, ibises, and storks) were measured in various locations throughout the eastern United States during 1972 and 1973 (Ohlendorf et al. 1979). The highest mean concentration of 0.74 mg mirex/kg, range 0.19 to 2.5 mg/kg, was found in eggs of the green heron (*Butorides striatus*) from the Savannah National Wildlife Refuge in South Carolina; a single egg of the cattle egret (*Bubulcus ibis*) analyzed from there contained 2.9 mg mirex/kg. However, the overall frequency of mirex occurrence was higher in eggs collected from the Great Lakes region (24%) than in those from the South Atlantic coast (15.6%),

inland areas (10.7%), Gulf Coast (4.4%), or North Atlantic region (3.2%). Measurable mirex residues were detected in migratory birds collected from a variety of locations, including areas far from known sources or applications of mirex. For example, 22% of all eggs from 19 species of Alaskan seabirds collected in 1973 to 1976 contained mirex. The highest concentration was 0.044 mg/kg in eggs of a fork-tailed storm petrel (*Oceanodroma furcata*) from the Barren Islands. Mirex residues were low compared with those of other organochlorine compounds (Ohlendorf et al. 1982). Eggs from the clapper rail (*Rallus longirostris*) collected in New Jersey from 1972 to 1974 contained 0.16 to 0.45 mg mirex/kg (Klaas et al. 1980). Eggs from the greater black-backed gull (*Larus marinus*) collected from Appledore Island, Maine, in 1977 contained up to 0.26 mg/kg, but no mirex was detected in eggs of common eider (*Somateria mollissima*) or herring gull from the same area (Szaro et al. 1977). The greater black-backed gull is an active carnivore; 36 to 52% of its diet consists of small birds and mammals, whereas these items compose less than 1% in eider and herring gull diets. The higher mirex levels in black-backed gulls are attributed to its predatory feeding habits (Szaro et al. 1979). In New England, eggs of the black-crowned night-heron (*Nycticorax nycticorax*) contained between 0.28 and 0.66 mg mirex/kg wet weight in 1973; in 1979, this range was 0.11 to 0.37 mg/kg (Custer et al. 1983). Falcon eggs contained detectable mirex; levels were highest in the pigeon hawk (*Falco columbarius*) (0.25 mg/kg) and in the peregrine falcon (*Falco peregrinus*) (0.43 mg/kg), two species that feed on migratory birds or migrate to mirex-impacted areas (Kaiser 1978). Active mirex was also found in eggs of a cormorant (*Phalacrocorax* sp.) from the Bay of Fundy on the Atlantic coast; the suspected source of contamination was the southern wintering range (Kaiser 1978).

Mirex residues in 20 great horned owls (*Bubo virginianus*) found dead or dying in New York state in 1980 to 1982 contained concentrations of mirex and PCBs higher than those reported for great horned owls elsewhere (Stone and Okoniewski 1983). Owls in "poor flesh" contained higher residues than those in "good flesh"; these values were 6.3 mg/kg FW vs. 0.07 mg/kg FW for brain, and 5.6 mg/kg FW vs. 0.1 mg/kg FW for liver (Stone and Okoniewski 1983). Waterfowl collected from upstate New York between 1979 and 1982 had about 0.07 mg mirex/kg FW breast muscle and 0.28 mg/kg FW subcutaneous fat (Kim et al. 1984, 1985).

Mink (*Mustela vison*) collected from the Northwest Territories of Canada between 1991 and 1995 had liver mirex concentrations between 0.08 and 0.39 µg/kg FW. These extremely low mirex concentrations were, nevertheless, higher than liver mirex concentrations in prey species (snowshoe hare, *Lepus americanus*, 0.08 to 0.13 µg/kg FW; northern red-backed vole, *Clethrionomys rutilus*, 0.32 µg/kg FW), suggesting that mirex biomagnification in mammalian wildlife food chains is possible (Poole et al. 1998).

21.9 RECOMMENDATIONS

Mirex is classified as a Group 2B carcinogen, indicating that it is a possible human carcinogen (USPHS 1995). For the protection of human health, oral intake should not exceed 0.0002 mg/kg BW daily, equivalent to 0.014 mg daily for a 70-kg person (USPHS 1995). At present, the recommended concentration of mirex in water should not exceed 0.001 µg/L in order to protect human health, freshwater and marine life, irrigated crops, and watered livestock (USPHS 1995). Fish in the human diet should not contain more than 0.1 mg mirex/kg fresh weight. Average acceptable ambient air concentrations recommended for the protection of human health range between 0.03 µg/m³ in New York to 0.88 µg/m³ in Pennsylvania. In Kentucky, air emission levels of mirex products should not exceed 232 µg per hour (USPHS 1995).

Before the banning of mirex for all uses in 1978, the tolerance limits in food for human consumption were 0.1 mg/kg for eggs, milk, and fat of meat from cattle, goats, hogs, horses, poultry, and sheep, and 0.01 mg/kg for all other raw agricultural commodities (Waters et al. 1977; Buckler

et al. 1981); higher limits of 0.3 mg mirex/kg in fish and shellfish and 0.4 mg/kg in crabs were tolerated (NAS 1978). The maximum recommended allowable concentration of mirex in edible portions of domestic fish for human consumption was 0.1 mg/kg FW at that time (Scrudato and McDowell 1989). Avoidance of larger and older fish to minimize ingestion of fat-soluble contaminants, including mirex, was recommended. Trimming the fatty tissues from muscle of salmon and trout from Lake Ontario prior to consumption resulted in a mirex reduction of at least 44% in the trimmed fillet — reflecting loss of fat content — and a product considered safe (i.e., <0.1 mg mirex/kg FW) by the U.S. Food and Drug Administration (Insalaco et al. 1982; Voiland et al. 1991). However, mirex concentrations as low as 0.1 mg/kg in diets of adult prairie voles were associated with delayed maturation of pups, and with significant delays in the attainment of various early development behaviors such as bar-holding ability, hind-limb placing, and negative geotaxis (Shannon 1976). It is not known whether or not prairie voles can serve as a model for protection of health of humans or various wildlife species. In the absence of supporting data, however, it seems prudent now to establish a dietary threshold of mirex at some level lower than 0.1 mg/kg. A maximum concentration of 0.01 mg/kg total dietary mirex, which is a recommended level for most raw agricultural commodities, appears reasonable and conservative for the protection of fish, wildlife, and human health. This value could be modified as new data become available.

Although mirex is extremely persistent in the environment, research findings suggest that some degradation occurs and that some of the degradation products, such as photomirex, are biologically active. Accordingly, additional research is warranted on the fate and effects of mirex degradation products, with special emphasis on biomagnification through aquatic and terrestrial food chains.

Alternate means of controlling imported fire ants are under consideration. One approach has been to reduce the concentrations of active mirex in bait formulations from 0.3% to some lower, but effective, level. Paton and Miller (1980) demonstrated that mirex baits containing 0.07% mirex were effective in controlling Australian termites, reporting a 90% kill in 9 days. Baits containing as little as 0.01% mirex were also reported effective, although termite mortality was delayed considerably. Waters et al. (1977) indicated that alternate chemical control agents, such as chlordpyrifos, diazinon, dimethoate, or methyl bromide may be suitable and that nonbiocidal chemicals, such as various pheromones and hormones, which are capable of disrupting reproductive behavior of fire ants, are also under active consideration. Another proposal was to chemically modify mirex to a more water-soluble and rapidly degradable product (Waters et al. 1977). The formulation Ferriamicide, which consisted of 0.05% mirex, ferrous chloride, and a small amount of long-chain alkyl amines, was formulated in baits during 1978/79 for ant control (Lowe 1982). Ferriamicide degraded within a few days after initial application; however, approval was revoked in 1980 when it was learned that the toxicity of various degradation products to mammals, especially that of photomirex, exceeded that of 4X bait formulations (Lowe 1982).

Mirex replacements should not manifest the properties that led to the discontinuance of mirex for all uses, namely:

- Delayed mortality in aquatic and terrestrial fauna
- Numerous birth defects
- Tumor formation
- Histopathology
- Adverse effects on reproduction, early growth, and development
- High biomagnification and persistence
- Disrupted energy metabolism
- Degradation into toxic metabolites
- Population alterations
- Movement through aquatic and terrestrial environmental compartments.

It is emphasized that mirex replacement compounds must be thoroughly tested before widespread application in the environment; if testing is incomplete, it is almost certain that the nation's fish

and wildlife resources will be adversely affected. In 1980, the use of Amdro (tetrahydro-5,5-dimethyl-2) (Lh)-pyrimidine) was conditionally approved by the U.S. Environmental Protection Agency (Lowe 1982). Amdro reportedly has good ant control properties, degrades rapidly in sunlight, has a biological half life of less than 24 h, is nonmutagenic, and is relatively nontoxic to other than targeted species, except fish. Amdro was more acutely toxic than mirex to fish.

21.10 SUMMARY

Mirex (dodecachlorooctahydro-1,3,4-metheno-2H-cyclobuta [*c,d*] pentalene) has been used extensively in pesticidal formulations to control the red imported fire ant (*Solenopsis invicta*), and as a flame retardant in electronic components, plastics, and fabrics. One environmental consequence of mirex was the severe damage recorded to fish and wildlife in nine southeastern states and the Great Lakes, especially Lake Ontario. In 1978, the U.S. Environmental Protection Agency banned all further use of mirex, partly because of the hazards it imposed on nontarget biota. These included:

- Delayed mortality and numerous birth defects in aquatic and terrestrial fauna
- Tumor formation
- Histopathology
- Wildlife population alterations
- Adverse effects on reproduction, early growth, and development
- High biomagnification and persistence
- Degradation into toxic metabolites
- Movement through aquatic and terrestrial environmental compartments
- Disrupted mammalian energy metabolism
- Detection of residues in human milk and adipose tissues

Among susceptible species of aquatic organisms, significant damage effects were recorded when concentrations of mirex in water ranged from 2 to 3 µg/L. The recommended concentration of 0.001 µg mirex/L affords an unusual degree of protection. Evidence suggests that sensitive species of wildlife are adversely affected at 0.1 mg/kg of dietary mirex. For comparison, tolerance limits for mirex in food for human consumption range from 0.01 mg/kg for raw agricultural commodities to 0.1 mg/kg for eggs, milk, animal fat, and various seafood products. Additional research is needed on the fate of mirex degradation products and their effects on natural resources. Further, it is strongly recommended that environmental use of all mirex replacement compounds be preceded by intensive ecological and toxicological evaluation.
