CHAPTER 22

Paraquat

22.1 INTRODUCTION

Paraquat (1,1'-dimethyl-4,4'-bipyridinium) is one of the most widely used herbicidal chemicals in the world and is now available in more than 130 countries (Kimbrough 1974; Calderbank 1975; Dasta 1978; Haley 1979; Hughes 1988; Smith 1988b; Eisler 1990). Its chemical structure was first described in 1882, its oxidizing and reducing properties in 1933, and its herbicidal properties in 1955. Paraquat was marketed commercially in the United Kingdom in 1962 and registered for use in the United States in 1964. As the dichloride salt, it has found wide use as a nonselective contact herbicide at application rates of 1.12 kg/ha (1 pound/acre) and lower. Paraquat kills plants by affecting the green parts, not the woody stems, and is usually completely and rapidly inactivated by contact with clay in the soil. In its bound form, paraquat is biologically inert and innocuous to plants and animals (Fletcher 1974). In 1977, the discovery by narcotics authorities that some marijuana imported from Mexico had been treated with paraquat as a control agent generated much interest in the media (Dasta 1978; Haley 1979). Up to 70% of the paraquat in paraquat-treated marijuana, on smoking, is converted to bipyridine, a respiratory irritant. Frequent consumption of heavily contaminated cigarettes may result in cyanosis and possibly death. The use of paraquat for this purpose has been largely discontinued.

Numerous human injuries and deaths have resulted from intentional ingestion of the concentrated commercial product (Fletcher 1974; Dasta 1978; Haley 1979; Crome 1986; Smith 1988a, 1988b). For example, in the first 10 years following paraquat commercial use, 232 human deaths from paraquat poisoning were reported, about half suicidal, and almost all were due to the drinking of concentrated material. Most poisonings resulted from the ingestion of the 21% cation concentrate, which had been decanted and stored in empty beer, soft drink, or lemonade bottles; paraquat is a reddish-brown liquid that resembles root beer or cola drinks. One individual sprinkled paraquat on French fried potatoes, thinking that it was vinegar. He died 25 days later. Another died after applying the concentrated solution to his beard and scalp to treat a lice infestation. In Japan, more than 1000 persons each year are reportedly poisoned by paraquat. Initially, paraquat may produce multiorgan toxicity of kidneys, liver, heart, central nervous system, adrenal glands, skeletal muscle, and spleen, but the ultimate target organ is the lung, in which progressive irreversible pulmonary fibrosis develops. This effect has been described in man, rats, mice, guinea pigs, and dogs (Kimbrough 1974; Giri et al. 1979; Hampson and Pond 1988; O'Sullivan 1989). At present, there is no specific antidote for paraquat poisoning. In normal use as a spray, minor reversible injuries are reported to abraded skin, eyes, nose, and fingernails; it is not absorbed through intact skin (Kimbrough 1974; Smith 1988a). Paraquat is fetotoxic as judged by deliberate ingestion of concentrated solutions by nine pregnant Taiwanese women. Paraquat crosses the placenta and concentrates there to levels 4 to 6 times that of maternal blood. All fetuses died whether or not an emergency cesarean operation was performed (Talbot and Fu 1988). Research has focused on the tendency of paraquat to accumulate

in neuromelanin of mammals and amphibians and to cause lesions in the pigmented nerve cells, leading to effects very similar to those of Parkinson's disease (De Gori et al. 1988; Lindquist et al. 1988). Reviews on ecological and toxicological aspects of paraquat include those by Kimbrough (1974), Smith and Heath (1976), Autor (1977), Dasta (1978), Haley (1979), Summers (1980), Bauer (1983), Onyeama and Oehme (1984), Smith (1985, 1988a, 1988b), and Eisler (1990).

22.2 USES

Paraquat is a broad-spectrum contact weed killer and herbage desiccant that is used widely in agriculture and horticulture. Paraquat was originally formulated in 1882, but its herbicidal properties were not discovered until 1955. Since its introduction in the early 1960s, paraquat has been used extensively in about 130 countries, including the United Kingdom, Canada, and the United States, on a wide variety of agricultural crops (Fletcher 1974; Haley 1979; Kelly et al. 1979; Anonymous 1988).

Primary uses of paraquat include: weed control in orchards, plantation crops, and forests; weed control before sowing or before crop emergence; pasture renovation; preharvest desiccation; and aquatic weed control, although use as an aquatic herbicide in the United States is not permitted (Anonymous 1963, 1974; Summers 1980; Dial and Bauer 1984). In New Zealand, use of paraquat for aquatic weed control (2 mg/L for 30 min) in 1966/67 on the Waimakariri River severely reduced amphipod populations; paraquat is no longer used for this purpose in that country (Burnet 1972). Paraquat is registered domestically for preplant or preemergence use for cotton, barley, corn, lettuce, melons, peppers, safflower, soybeans, sorghum, sugar beets, tomatoes, potatoes, and wheat. It is also registered for use on noncrop areas, such as roadsides, highway margins, rights-of-way, around commercial buildings, power plants, storage yards, fence lines, and parkways (Anonymous 1963, 1974). In Switzerland, it is used to control voles (*Arvicola terrestris*) in fruit orchards (Summers 1980). Paraquat application to corn using a manual knapsack sprayer is considered unsafe to the human operators if lances are less than 1.0 m. Lances >1.0 m in length are recommended, as well as additional protective garments for legs, feet, and hands and switching the paraquat spraying operation to the back of the worker's body (Machado-Neto et al. 1998).

Paraquat is available as the dichloride or dimethylsulfate salt; both compounds are extremely soluble in water (Kimbrough 1974). In the United States, paraquat dichloride is available as a 29% liquid concentrate containing 240 g/L (2 pounds/gallon) of paraquat cation, or as a 42% liquid concentrate. Elsewhere, it is sold as Gramoxone liquid containing 20 to 24% paraquat dichloride (Fletcher 1974; Bauer 1983; Dial and Dial 1987a). Paraquat dichloride concentrates usually contain various wetting agents (condensation products of ethylene oxide and alkyl phenols), spreaders, humectants to promote moisture retention (calcium chloride, glycerol, polyethylene glycol), plant adhesion materials (carboxymethylcellulose, polymethacrylates), and antifoaming agents (Summers 1980).

The recommended field application rates for terrestrial weed control usually range between 0.28 and 1.12 kg paraquat cation/ha (0.25 and 1.0 pounds/acre), between 0.56 and 2.24 kg paraquat dichloride/ha (0.5 and 2.0 pounds/acre) — both applied as an aerosol — and between 0.1 and 2.0 mg/L for aquatic weed control, although sensitive aquatic plants may be affected between 0.019 and 0.372 mg/L (Ross et al. 1979; Summers 1980; Bauer 1983; Dial and Bauer 1984). Paraquat is frequently used in combination with other herbicides (Fletcher 1974; Summers 1980). Water solutions of the dichloride salt, which usually contain 240 g/L, have been successfully mixed with 2,4-D, substituted ureas, dalapon, amitrol, and various triazines (Anonymous 1963, 1974).

22.3 CONCENTRATIONS IN FIELD COLLECTIONS

Data are scarce on ecosystems treated with paraquat. It is clear, however, that both terrestrial and aquatic plants accumulate paraquat, and that the compound disappears rapidly from the water column and tends to concentrate in surface muds (Table 22.1).

Table 22.1 Paraquat Concentrations in Field Collections of Selected Organisms and Nonbiological Materials

Sample and Other Variables	Concentration (mg/kg dry weight)	Reference ^a
TREATED FIELDS		
Alfalfa, <i>Medicago sativa</i>	Up to 30	1
Graminaceae, various species	Up to 60	1
MUD, SURFACE		
From British lake treated with 0.5 mg paraquat/L		
Days after treatment		
1	1.2	2
2	2.4	2
8	6.7	2
32	11.2	2
197	17.7	2
364	8.0	2

Mud	16	3
<i>Chara</i> sp.	540	3
<i>Spirogyra</i> sp.	13	3

^a 1, Bauer 1983; 2, Way et al. 1971; 3, Earnest 1971.

Water from irrigation channels, rivers, and lagoons from Spanish marshes in 1996 bordering the Mediterranean Sea contained an average of 0.01 µg paraquat/L, with a maximum recorded value of 3.95 µg/L (Fernandez et al. 1998). Paraquat values were highest in the summer owing to high application rates, low rainfall, and high evaporation rates. At these comparatively low concentrations, paraquat is not easily degraded chemically or biologically and persists in river waters with more than 80% remaining after 56 days of incubation (Fernandez et al. 1998).

22.4 ENVIRONMENTAL CHEMISTRY

22.4.1 General

Paraquat is a nonvolatile, ionic compound that is almost completely soluble in organic solvents, which is typical of the bipyridyl group of chemicals. As discussed later, the biochemical mechanism of paraquat toxicity is due to the cyclic oxidation and reduction that occurs in various tissues, especially lung, leading to production of superoxide anion and other free radicals. These chemical species react with polyunsaturated free radicals, eventually forming the highly destructive hydrogen peroxide. Excretion of paraquat is rapid in living organisms, but delayed toxic effects, including

death, are not unusual. No treatment or chemical has proven completely successful in protecting against paraquat-induced lung toxicity.

Paraquat is strongly adsorbed to soils and sediments and is biologically unavailable in that form; however, it is not degraded significantly for many years, except in surface soils. In surface soils, paraquat loss through photodecomposition approaches 50% in 3 weeks. In freshwater ecosystems, loss from water column is rapid: about 50% in 36 h and 100% in 4 weeks. In marine ecosystems, 50 to 70% loss of paraquat from seawater was usually recorded within 24 h.

22.4.2 Chemical Properties

Paraquat is a nonvolatile, ionic compound that is almost completely insoluble in fat, and therefore not likely to be accumulated in food chains (Calderbank 1975). The compound belongs to the bipyridyl group of chemicals and is typical of the many hundreds that have been synthesized, variation usually being the result of introducing different quaternizing groups on the nitrogen atoms, which also shift (Fletcher 1974) (Table 22.2). Paraquat dichloride is produced from pyridine in the presence of sodium in anhydrous ammonia, then quaternizing the 4,4'-dipyridyl with methyl chloride (Haley 1979). The common paraquat salts are all fully ionized, and experiments have shown that the anions (e.g., chloride, sulfate, methyl sulfate) do not affect the toxicity of paraquat (Fletcher 1974). Chemical and other properties of paraquat are briefly summarized in Figure 22.1 and Table 22.2.

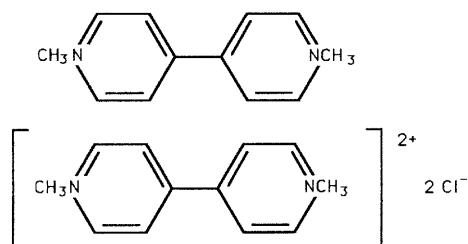

Figure 22.1 Structural formulas of paraquat cation (upper) and paraquat dichloride salt (lower).

22.4.3 Mode of Action

Paraquat is absorbed systematically in mammals, following different routes of exposure; absorption is greatest for the pulmonary route, followed by intragastric and dermal routes (Chui et al. 1988). Administration of paraquat by every route of entry tested frequently results in irreversible changes in lung (Boudreau and Nadeau 1987). In the intestinal tract, where some microbial degradation occurs, most paraquat (95 to 100%) is usually excreted unchanged in feces and urine within 2 days (Summers 1980). Absorption in the gastrointestinal tract ranges from 0.26% in cow, to 5% in man, 8% in guinea pig, 16% in cat, and up to 20% in rat. The half-time persistence (T_b 1/2) of paraquat in certain tissues ranges between 20 and 30 min, but up to 4 days in muscle and 2 days in plasma (Bauer 1983). Delayed toxic effects of paraquat occurring after the excretion of virtually all of the material have caused it to be classified as a “hit and run” compound, that is, a compound causing immediate damage, the consequences of which are not readily apparent (Conning et al. 1969).

Most authorities agree that free radical pathology is the most likely mechanism by which paraquat is cytotoxic (Bus et al. 1976; Frank et al. 1982; Patterson and Rhodes 1982; Combs and Peterson 1983; Onyeama and Oehme 1984; Gabryelak and Klekot 1985; Smith 1985; Wong and Stevens 1986; Seto and Shinohara 1987; Suleiman and Stevens 1987; Darr et al. 1988; Dunbar et al. 1988a; Wegener et al. 1988; Wenning et al. 1988; Arias et al. 1991; Babich et al. 1993). The biochemical mechanism of paraquat toxicity is related to the cyclic oxidation and reduction of paraquat that occurs in lung cells, which leads to continued production of high levels of superoxide

Table 22.2 Chemical and Other Properties of Paraquat

Variable	Datum
Chemical name	
Paraquat (cation)	1,1'-dimethyl-4,4'-bipyridinium
Paraquat dichloride (salt)	1,1'-dimethyl-4,4'-bipyridinium dichloride
Molecular weight	186.2 (cation), 257.2 (salt)
CAS Number	4685-14-17 (cation), 1910-42-5 (salt)
Empirical formula	C ₁₂ H ₁₄ N ₂ (cation), C ₁₂ H ₁₄ Cl ₂ N ₂ (salt)
Alternate names	Cekuquat, Crisquat, Dextrone, Dextrone X, Dexuron, Dual Paraquat, Esgram, Gramonol, Gramoxone, Gramuron, Herbaxon, Herboxone, Methyl Viologen, Ortho Paraquat, Orvar, Paracol, Paraquat CL, Pathclear, Pillarquat, Pillarxone, Preeglove, PP 148, PP 910, Sweep, Tenaklene, Totacol, Toxer Total, Weedol
Solubility at 20°C	
Water	561 g/L
Methanol	144 g/L
Ethanol	1.7 g/L
Acetone	200 mg/L
Most organic solvents	Insoluble or sparingly soluble
Physical state	White (pure), yellow (technical) solid
Main uses	Herbicide, desiccant
Specific gravity	1.24–1.26
Melting point	175–180°C, decomposes at 345°C
Stability	Stable on exposure to hot acids, unstable in alkalis at pH > 10
Flash point	Nonexplosive, nonflammable
Volatility	Nonvolatile

Data from Anonymous 1963, 1974, 1988; Haley 1979; Kelly et al. 1979; Johnson and Finley 1980; Hudson et al. 1984; Hill and Camardese 1986; Mayer 1987.

anion (O₂⁻) and other cytotoxic oxygen free radicals. Superoxide anion and other oxygen free radicals initiate the peroxidation of membrane lipids, causing tissue damage and death. Paraquat oxidation is coupled with the reduction of molecular oxygen, forming superoxide anion, singlet oxygen, and hydroxyl radicals. These molecular species react with polyunsaturated fatty acid free radicals and, on further oxidation, with lipid hydroperoxide radicals. The hydroperoxide radicals then maintain the formation of new fatty acid radicals while being converted to lipid peroxides in a chain reaction. Various enzymes in the cells catabolize the superoxide radical and reduce the lipid hydroperoxides to less-toxic lipid alcohols. The superoxide anions are converted to hydrogen peroxide and oxygen; hydrogen peroxide is further inactivated to water and oxygen by catalases and peroxidases. In the presence of reduced nicotinamide adenine dinucleotide phosphate (NADPH), paraquat is reduced by microsomal NADPH-cytochrome reductase. The reduction of lipid peroxides by glutathione peroxidase requires reduced glutathione. Because the reduction of oxidized glutathione is coupled with NADPH oxidation via glutathione reductase, it seems that the availability of NADPH is essential for paraquat detoxification, and that the critical depletion of NADPH may render the cell more susceptible to lipid peroxidation.

The lung is the organ most severely affected in paraquat poisoning (Campbell 1968; Conning et al. 1969; Haley 1979; Aldrich et al. 1983; Bauer 1983; Combs and Peterson 1983; Christian et al. 1985; Smith 1985; Wong and Stevens 1986; Boudreau and Nadeau 1987; Baud et al. 1988; Dunbar et al. 1988a; Wegener et al. 1988). Pulmonary injury is due largely to the preferential accumulation of paraquat in lung — mediated by an energy-dependent system for uptake of endogenous polyamines — and to the continuous exposure of lung to atmospheric oxygen. Characteristic signs of poisoning include severe anoxia, marked and widespread fibroblastic proliferation in the alveolar walls around the terminal bronchi and blood vessels, and frequently death. The specific toxicity to the lung can be explained by the accumulation of paraquat in the alveolar Type II cells. These cells are responsible for the synthesis of pulmonary surfactant, the surface-active material lining the alveolar epithelium. The pulmonary surfactant is secreted after storage in

cytoplasmic organelles known as lamellar bodies. Thus, any damage to the alveolar epithelium could alter synthesis and secretion of the pulmonary surfactant. The pulmonary effects of paraquat are probably related to the conversion of paraquat to a free radical, followed by conversion to a long-lived dihydroderivative, which causes transformation of normal alveolar epithelial cells to fibroblasts. The increase in toxicity of paraquat by oxygen supports the hydroperoxide theory, in which the reversible action of the free radical's oxidation-reduction gives rise to hydrogen peroxide. Paraquat also depletes NADPH in the isolated lung to the extent of mixed function oxidation impairment. Depletion of NADPH would impair fatty acid and lipoprotein synthesis and inhibit various detoxification and biosynthetic functions.

Other organs and systems affected by paraquat include the kidney (pathology of proximal tubules), liver (hepatocellular necrosis), spleen and thymus (pathology), circulatory system (irregular and feeble heart beat, myocardial congestion, increase in erythrocytes and leucocytes, external pericarditis, myocardium edema), brain (neuronal depletion, myelin destruction), gastrointestinal tract (esophagitis; ulceration of buccal cavity, pharynx, gastric mucosa; mucosal erosion), skin (erythema, hyperkeratosis), reproductive system (degeneration), nervous system (hyperexcitability, irritability, incoordination, convulsions), various enzyme systems, and the eye (Giri et al. 1979, 1982, 1983; Summers 1980; Bauer 1983; Seto and Shinohara 1987, 1988; Hughes 1988; Takegoshi et al. 1988).

Several early indicators of paraquat-induced stress have been proposed, including alkaline phosphatase activity, fibronectin levels, and intracellular calcium uptake. Alkaline phosphatase activity is associated with the lamellar body, and changes in this variable are suggested as indicative of toxicity to Type II alveolar epithelium cells (Boudreau and Nadeau 1987). Levels of fibronectin, an extracellular matrix glycoprotein, were elevated in patients with fibrotic lung diseases and in monkeys given multiple injections of paraquat (Dubaybo et al. 1987). Lung intracellular calcium uptake was significantly disrupted, even at doses that normally produce significant increases in lung water content (Agarwal and Coleman 1988). These subjects seem to merit additional research, as does the role of polyamines in mediating fibrotic changes in the lung (Dunbar et al. 1988b); paraquat-altered synthesis of proteins, DNA, collagen, and pentose phosphate metabolism (Simon et al. 1983); and hyperoxia, that is, increased oxygen-free radical generation (Frank et al. 1982).

Certain treatments or chemicals provide varying degrees of protection against paraquat-induced lung toxicity and lethality, although no treatment or chemical has proven completely successful. Present treatment of paraquat-poisoned animals and humans is directed to elimination of the material from the body using repeated doses of adsorbents such as Fuller's earth or bentonite, cathartics to reduce paraquat absorption, and hemodialysis, forced diuresis, and hemofiltration to enhance excretion (Fletcher 1974; Autor 1977; Haley 1979; Pond et al. 1987; Kitakouji et al. 1989). The use of 100% oxygen is contraindicated, as mortality is greatly increased (Fletcher 1974; Autor 1977; Wong and Stevens 1986). Toxicity mediated by free radicals can be moderated by several cellular defense mechanisms, including superoxide dismutase, catalase, glutathione peroxidase, Vitamin E, and reduced glutathione (Gabryelak and Klekot 1985; Wenning et al. 1988). A low-molecular-weight superoxide dismutase mimic, based on manganese, was found to protect mammalian cells against the cytotoxic effects of the superoxide radical produced by paraquat (Darr et al. 1988). Certain chemicals reportedly provide limited protection to small laboratory animals under carefully controlled conditions of administration: nicotinic acid (Shibata and Iwai 1988); niacin (Heitkamp and Brown 1982); cysteine (Szabo et al. 1986); *N*-acetylcysteine (Wegener et al. 1988); metallothionein — a metal-binding, low-molecular-weight, protein rich in cysteine (Sato et al. 1989); d-penicillamine (Szabo et al. 1986); clofibrate (Frank et al. 1982); lipid-soluble anti-oxidants (Kohen and Chevion 1988; Wegener et al. 1988); various amino acids (Heitkamp and Brown 1982); phenobarbital (Bus et al. 1976; Summers 1980); methyl prednisolone (Kitazawa et al. 1988); and certain anti-inflammatory drugs (Autor 1977). In bluegills, 1,10-phenanthroline, a chelator of ionic iron, reduced the toxicity of paraquat through the prevention of hydroxyl radical formation (Babich et al. 1993). In tilapia, the paraquat-induced increase in gill carbonic anhydrase activity was not observed when ionic lead was present at 47 mg/L (Arias et al. 1991). In plants,

the pea (*Pisum sativum*) is protected by cerium chloride, in part, through counteracting peroxide formation (Vaughn and Duke 1983).

Paraquat toxicity is increased and its effects otherwise exacerbated in organisms fed diets deficient in selenium or Vitamin E, although high levels of these substances in diets did not provide protection (Autor 1977; Haley 1979; Summers 1980); by methyl prostaglandins (Williams et al. 1988) or diethyl maleate (Summers 1980); and by increased iron and copper (Kohen and Chevion 1988; Ogino and Awai 1988). Dietary changes that do not result in nutrient deficiency or toxicity may affect the biocidal properties of paraquat and other compounds. In studies with rodents subjected to paraquat insult, survival was higher in those fed cereal-based diets vs. purified diets, and higher in egg-white (protein) purified diet vs. a casein diet (Tanaka et al. 1981; Evers et al. 1982), suggesting a need to use strictly defined diets in the study of paraquat toxicity to control for any paraquat-diet interactions.

Paraquat causes tissue damage and increased stress in the common carp (*Cyprinus carpio*), as judged by the increased enzyme activities of lactic dehydrogenase, glutamic oxaloacetic transaminase, and glutamate dehydrogenase, and by the elevated blood sugar levels. Paraquat and copper sulfate when administered together to carp were synergistic in terms of tissue damage and stress effects, especially liver damage (Asztalos et al. 1990).

Paraquat adhering to the plant surface is usually degraded photochemically (Haley 1979; Summers 1980). Paraquat is phytotoxic through inhibition of processes involving photosynthesis and respiration (Haley 1979; Christian et al. 1985; Anonymous 1988). Its mode of action in plants is similar to that in animals; that is, lipid peroxidation of membranes due to formation of the superoxide radical and related species (Summers 1980). Photosynthetic tissues reduce paraquat to stable free radicals that, upon reoxidation, produce hydrogen peroxide. Unsaturated lipids in the cells are oxidized by the peroxide, and damage is dependent largely on production of hydrogen peroxide (Haley 1979; Vaughn and Duke 1983). The reaction is light and oxygen dependent (Conning et al. 1969; Kelly et al. 1979).

In bacteria (*Escherichia coli*), paraquat is concentrated, reduced to the monocation radical, and combines with molecular oxygen to produce the superoxide radical within the cell. Copper and iron are essential mediators in bactericidal effects. The cytoplasmic membrane is the target organelle in paraquat toxicity to *E. coli*, and extent of damage correlates positively with levels of these metals (Kohen and Chevion 1988).

22.4.4 Fate in Soils and Water

In contact with soil, paraquat is rapidly adsorbed — usually in the clay mineral lattice sheets — and inactivated by base exchange. The process is facilitated by the flat and highly polarizable nature of the paraquat ion (Anonymous 1963; Conning et al. 1969; Calderbank 1975; Summers 1980; Kearney et al. 1985). The strong binding of paraquat to soil constituents reduces the mobility of the herbicide due to leaching, although paraquat is displaced from binding sites by low concentrations of ions of ammonium, potassium, sodium, and calcium (Smith and Mayfield 1978). Paraquat adsorption is not significantly affected by soil pH, but is modified by soil porosity, moisture content, residence time, and adsorption capacity (Smith and Mayfield 1978; Summers 1980). Paraquat applied to a sandy loam soil at field application rates between 0.56 and 2.24 kg/ha was adsorbed by organic matter and clays, usually in the top centimeter of soil (Smith and Mayfield 1978). Typical soils contain about 300 mg paraquat/kg after treatment at recommended applications; however, adsorption capacity varies among soils. Clay minerals, such as kaolinite, can adsorb 2500 to 3500 mg/kg, whereas others, such as montmorillonite, adsorb up to 85,000 mg/kg after paraquat treatment (Summers 1980).

Paraquat is not degraded significantly in soil during incubation periods up to 16 months at 25°C by chemical or microbiological vectors (Smith and Mayfield 1978). For example, paraquat dichloride applied once annually at 4.48 kg/ha, or 4 times annually at 1.12 kg/ha, remained essentially undegraded in the soil for 6 years (Fryer et al. 1975; Moyer and Lindwall 1985). Massive applications

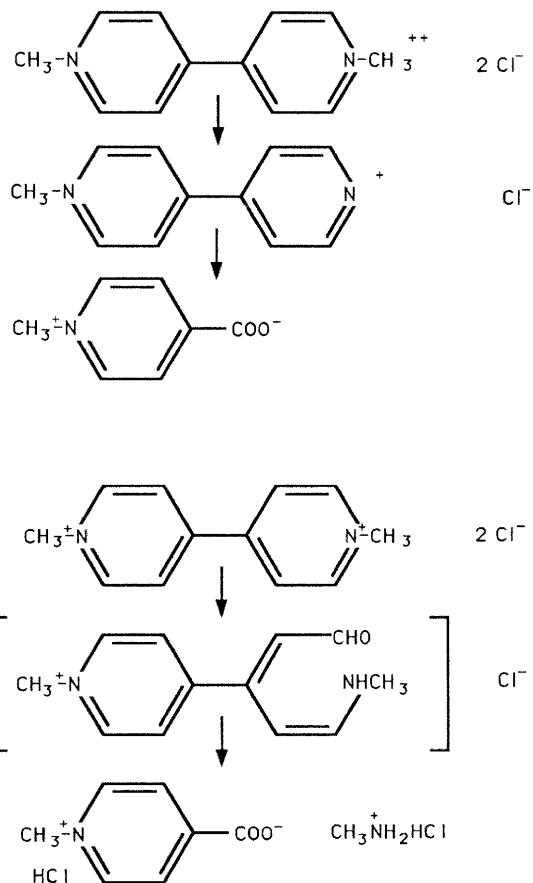

Figure 22.2 Proposed pathway of paraquat degradation by a bacterial isolate (*upper*) and by ultraviolet irradiation (*lower*). (Modified from Funderburk, H.H., Jr. and G.A. Bozarth. 1967. Review of the metabolism and decomposition of diquat and paraquat. *Jour. Agric. Food Chem.* 15:563-567.

to soils of 3000 kg/ha can persist for at least 6 months without significant degradation (Moyer and Lindwall 1985). Bacterial degradation — which occurs only slowly in soils — consists of demethylation, followed by ring cleavage to eventually form the carboxylated 1-methylpyridinium ion (Figure 22.2). Photochemical decomposition of paraquat is the predominant mechanism of paraquat degradation in soils (Smith and Mayfield 1978). In surface soils, paraquat loss through photodecomposition was 20 to 50% in 3 weeks (Christian et al. 1985). Photochemical degradation products of paraquat include 4-carboxy-1-methylpyridinium ion and methylamine hydrochloride (Figure 22.2). Laboratory studies have demonstrated that paraquat in soils slated for disposal can be degraded by ultraviolet (UV) irradiation in the presence of oxygen or ozone. Reaction products identified were 4-carboxy-1-methylpyridinium ion, 4-picolinic acid, hydroxy-4-picolinic acid, succinic acid, *N*-formylglycine, malic acid and oxalic acid (as trimethylsilicon derivatives), and 4,4'-bipyridyl (Kearney et al. 1985).

Paraquat is used to control aquatic weeds. It also passes into aquatic environments through rain, where it is rapidly accumulated by aquatic organisms, especially fish (Gabryelak and Klekot 1985). Paraquat applied to control aquatic weeds is accumulated by aquatic macrophytes and algae, and it is adsorbed to sediments and suspended materials. Initial applications of 1 to 5 mg/L in the water column are usually not detectable under field conditions after 8 to 27 days (Summers 1980). The half-time persistence of paraquat in water column at normal doses for weed control (i.e., 0.5 to 1.0 mg/L) was 36 h; less than 0.01 mg/L was detectable in 2 weeks (Calderbank 1975). In solution, paraquat was subject to photodecomposition and microbial metabolism, degrading to methylamine

and 4-carboxy-1-methylpyridium ion (Kearney et al. 1985). In freshwater, without sediment or plants, 100% of the initial concentration of 0.5 mg paraquat/L was degraded in 35 weeks. When sediments were present, 100% loss from the water column occurred in 6 to 8 weeks; and when both sediment and aquatic plants were present, paraquat was not detectable in the water column in 3 to 4 weeks (Summers 1980). Mud cores taken from a paraquat-treated lake had elevated paraquat residues, but showed no phytotoxic effects on barley seedlings germinated on them (Calderbank 1975).

Paraquat loss from seawater in 24 h was 70% at an initial concentration of 1 mg/L, 68% at 5 mg/L, and 76% at 10 mg/L; most of the loss occurred within the first 60 min (Fytizas 1980).

22.5 LETHAL AND SUBLETHAL EFFECTS

22.5.1 General

Adverse effects of paraquat in sensitive species of terrestrial plants and soil microflora have been documented at application rates of 0.28 to 0.6 kg/ha (death, inhibited germination of seeds, reduced growth), at soil concentrations of 10 to 25 mg/kg (growth inhibition), and at soil-water concentrations as low as 1.6 mg/L (reduced growth, inhibited synthesis of protein and RNA). Among terrestrial invertebrates, certain species of mites were sensitive to paraquat at recommended rates of application, and the sensitive honey bee died when its diet contained 100 mg/kg. However, paraquat in soils was not accumulated by earthworms and other species of soil invertebrates after applications up to 112 kg/ha. These points, and others listed in this section, are discussed in greater detail later.

Freshwater algae and macrophytes usually die at paraquat concentrations between 0.25 and 0.5 mg/L. Marine algae, however, are relatively resistant and usually require 5 mg/L or higher for significant inhibition in growth to occur in 10 days. Aquatic invertebrates, especially crustaceans, seem to be the most sensitive group, with effects most pronounced at elevated temperatures in early developmental stages. Adverse effects were noted in crab larvae at nominal water concentrations between 0.9 and 5.0 µg/L, although 1000 µg/L and higher were needed to produce similar effects in other species of aquatic invertebrates. Amphibians and fishes were usually unaffected at concentrations below 3000 µg/L, although sensitive species, such as frog tadpoles and northern carp (*Cyprinus carpio*), were impacted at 500 µg/L. There was little accumulation of paraquat from the medium by aquatic fauna.

Paraquat is embryotoxic to sensitive species of birds. Concentrations equivalent to 0.056 kg/ha applied in oil solution to the surface of eggs of the mallard (*Anas platyrhynchos*) inhibited development; when applied in aqueous solution, paraquat was toxic at a dose equivalent to 0.56 kg/ha. In each case, adverse effects occurred below the recommended field application rate of about 1.0 kg/ha. The lowest doses of paraquat that produced harmful effects in sensitive birds were 10 mg/kg body weight (BW) in nestlings of the American kestrel (*Falco sparverius*), 20 mg/kg in the diet of northern bobwhite (*Colinus virginianus*), 40 mg/L in the drinking water of domestic chickens (*Gallus* sp.), and 199 mg/kg BW in mallards (acute oral LD50).

Sensitivity of mammals to paraquat was variable, owing to inherent differences in interspecies resistance. Representative mammals were measurably affected at aerosol concentrations of 0.4 to 6.0 µg/L, acute oral doses of 22 to 35 mg/kg BW, dietary concentrations of 85 to 100 mg/kg ration, and drinking water levels of 100 mg/L.

22.5.2 Terrestrial Plants and Invertebrates

In terrestrial plants, paraquat's action is at the point of local absorption (Anonymous 1963). Characteristic damage signs to susceptible species include wilting and general collapse in herbaceous plants. Regrowth may occur in some perennial plants, but in resistant species temporary scorch may be the most marked effect (Anonymous 1963). In sugarcane (*Saccharum officinarum*), paraquat

application severely desiccated the plant within 72 h, and disrupted activity of leaf amylase and sucrose (Haley 1979). Paraquat, once absorbed in plants, is likely to persist (Bauer 1983). The addition of cationic or nonionic surface active agents increases the phytocidal effectiveness of paraquat (Anonymous 1963), but in combination with various herbicides paraquat was markedly less phytotoxic to certain cereal grains (O'Donovan and O'Sullivan 1986).

Paraquat adsorbed to soils is usually unavailable to crops. In the case of wheat (*Triticum aestivum*), effects from contaminated soils were negligible until soil residues surpassed 600 to 1000 kg/ha, causing growth reduction of 10%, or 1650 kg/ha, causing elevated residues in leaves but not in grain (Moyer and Lindwall 1985).

Three species of grains (barley, *Hordeum vulgare*; wheat; oat, *Avena sativa*) died (>95% kill) following application of 0.28 kg paraquat/ha (O'Donovan and O'Sullivan 1986). At 0.6 kg/ha, paraquat inhibited germination and growth in seeds of six species of grasses (Kentucky bluegrass, *Poa pratensis*; perennial ryegrass, *Lolium perenne*; bentgrass, *Agrostis tenuis*; tall fescue, *Festuca arundinacea*; red fescue, *Festuca rubra*; orchard grass, *Dactylis glomerata*), but two species of legumes (alfalfa, *Medicago sativa*; red clover, *Trifolium pratense*) were comparatively resistant (Salazar and Appleby 1982). Paraquat was phytotoxic to several species of terrestrial plants (rape, *Brassica rapa*; ryegrass; white clover, *Trifolium repens*) for several days following application of 1.1 to 2.2 kg/ha (Summers 1980). Transpiration rate of soybean (*Glycine max*) was lowered at 1 mg/kg (Haley 1979). Paraquat is not considered to be carcinogenic or teratogenic, but is weakly mutagenic to some plants (e.g., 4.1% chromosomal aberrations in seeds of wheat at 9.3 mg/kg; Haley 1979). Spray solutions containing 0.6 g paraquat/L applied to crowns of eastern red cedar (*Juniperus virginiana*) killed up to 90% of small trees and up to 30% of large trees; at 0.3 g/L, up to 60% of small trees were affected (Engle et al. 1988). Seedlings of corn (*Zea mays*) sprayed with 0.2% paraquat ion solution for 6 h had decreased rates of total protein synthesis and some polysome dissociation (Wu et al. 1988), suggesting that additional research is needed on mutagenicity of paraquat in plants.

Paraquat resistance has been documented in several genera of weeds. For example, paraquat-resistant strains of barley grass (*Hordeum glaucum*) were first noted in 1982 in Australia; resistant strains (based on chromosome counts and resistance to paraquat) were confined to a small number of lucerne fields where paraquat had been used consistently for at least 10 years. However, the potential exists for this biotype to be transferred and established in other areas by the movement of livestock, machinery, hay, and seeds (Islam and Powles 1988; Tucker and Powles 1988). Paraquat-resistant strains of weeds have been reported in England, Japan, Egypt, and Australia (Polos et al. 1988). Paraquat-resistant strains of bacteria, ferns, and other species of flora have been documented (Carroll et al. 1988). Paraquat-tolerant ferns (*Ceratopteris richardii*) were 10 to 20 times more resistant than sensitive wild-type strains (Carroll et al. 1988). Paraquat-resistant strains of perennial rye were up to 10 times more resistant than normal susceptible strains (Faulkner and Harvey 1981). In the case of barley grass, survival was reduced 50% at 0.025 kg/ha in normal susceptible biotypes; but in resistant biotypes, 3.2 kg/ha were required (Islam and Powles 1988; Tucker and Powles 1988). Paraquat-tolerant plants may enjoy certain advantages over nonresistant plants, including resistance to various air pollutants. For example, paraquat-tolerant tobacco plants (*Nicotiana tabacum*), which had higher superoxide dismutase activity than controls, were tolerant to aerosol sprays of 2 mg SO₂/L, while controls experienced severe damage (Tanaka et al. 1988).

In every case of resistance, paraquat had been applied 2 or 3 times annually during the preceding 5 to 11 years. In some cases, a cross-resistance to atrazine was also reported (Polos et al. 1988). Paraquat-resistance mechanisms in plants include increased epicuticular wax (preventing penetration), binding of paraquat to cell walls, restricted movement into chloroplasts, and altered redox potential (Polos et al. 1988). For example, sequestration of paraquat within the apoplast of the leaf seems to be inheritable and controlled by a single nuclear gene with incomplete dominance (Islam and Powles 1988). Studies with paraquat-tolerant strains of various plants, including perennial rye and tobacco, suggest that tolerance is related to their general ability to rapidly detoxify the generated

oxygen species through increased levels of superoxide dismutase, glutathione reductase, and other antioxidants (Shaaltiel et al. 1988).

At recommended field concentrations, paraquat had negligible effect on soil microflora or soil fertility, although it did cause a temporary suspension of soil nitrification (Haley 1979). A concentration as low as 1.0 mg/L completely inhibited ammonium and nitrite oxidation for 40 days in a mixed culture of nitrifying bacteria isolated from soil (Gadkari 1988). Paraquat at 1.6 mg/L adversely affected *Escherichia coli* in 6 h, as judged by diminished growth rate and inhibited synthesis of RNA and protein; at a higher concentration of 18.6 mg/L, interference with metabolism of glucose and DNA synthesis was observed (Davison and Papirmeister 1971). Four species of soil bacteria had 50% growth inhibition at paraquat concentrations between 93 and 18,600 mg/kg soil; moreover, the mode of action in some species of microorganisms may differ from the generally accepted mechanisms for paraquat toxicity in mammals (Carr et al. 1986). Sensitive species of soil fungi experienced marked growth inhibition between 10 and 25 mg paraquat/kg soil (Summers 1980). In various genera of soil fungi (*Rhizopus*, *Ophiobolus*, *Helminthosporium*, *Fusarium*, *Eurotium*), paraquat concentrations up to 100 mg/L could be tolerated. At higher concentrations, spore germination was suppressed, mycelial growth was inhibited, and spore development was abnormal (Haley 1979).

Terrestrial invertebrates show varying degrees of sensitivity to paraquat. In honey bees (*Apis mellifera*), 100 mg paraquat/kg syrup (diet) produced toxic signs, 4.4 kg/ha applied as a spray killed 90% in 3 days, and 1000 mg/L in drinking water killed most in a few days and 100% within 5 weeks (Summers 1980). In soils, adsorbed paraquat may be ingested by soil invertebrates, such as earthworms, but it was not absorbed from the gut into tissues and was rapidly lost when the earthworms were transferred to clean soil (Calderbank 1975). For example, earthworms (*Lumbricus terrestris*) fed soil treated with 112 kg paraquat/ha had 111 mg paraquat/kg in gut contents, but <0.3 mg/kg in the carcass without gut (Summers 1980). Two species of collembolid insects (*Folsomia candida*, *Tullbergia granulata*) fed diets containing 600 mg paraquat/kg for 22 weeks survived without measurable adverse effects, but higher dietary levels of 1000 and 5000 mg/kg were associated with decreased survival, lengthier instar development, decreased egg production, and decreased egg viability (Subagja and Snider 1981). Adults and larvae of the German cockroach (*Blattella germanica*) died after consuming diets containing 1000 mg paraquat/kg (Summers 1980). Also, paraquat was lethal to two species of mites (*Tetranychus urticae*, *Typhlodromus* sp.) at concentrations below recommended field application rates (Summers 1980).

22.5.3 Aquatic Organisms

In general, paraquat is more toxic to aquatic fauna in soft water than in hard water, more toxic to early developmental stages than to juveniles or adults, and more toxic in formulations containing wetting agents than in formulations without these agents (Summers 1980; Arunlertarce and Kawatsu 1992). In water, paraquat is taken up rapidly by plants or adsorbed to particulate matter in the water column; however, paraquat is not bioconcentrated by aquatic fauna (Calderbank 1975; Summers 1980). Paraquat effects on aquatic biota are summarized in [Table 22.3](#), and these data suggest several trends. Early developmental stages of certain species of crustaceans are extremely sensitive, and significant adverse effects occur in the range of 0.9 to 100 µg/L, although most species of crustaceans and all other species of invertebrates tested were relatively unaffected at concentrations below 1000 µg/L. Freshwater algae and macrophytes are eliminated after treatment with 250 to 500 µg/L, but marine algae are relatively resistant and require 5000 µg/L or higher to produce significant growth inhibition. Aquatic vertebrates usually are not adversely affected and show little accumulation at 1000 µg/L or lower; but at 500 µg/L, frog tadpoles have low survival and a high frequency of developmental abnormalities, and carp experience biochemical upset.

Paraquat controlled *Typha* and *Phragmites* weeds in Egyptian irrigation canals, drains, and marshes without apparent harm to fishes (Haley 1979). Paraquat residues in decomposed plants

become available for adsorption to sediments and bottom muds and are not readily available for microbial degradation (Summers 1980). Indirect fish kills may occur from anoxia due, in part, to consumption of dissolved oxygen by decaying weeds (Bauer 1983). Paradoxically, it has been suggested that paraquat may be helpful in improving the oxygen status of aquatic environments at a concentration of 1 mg/L by restricting nitrate production due to inhibition of bacterial nitrification (Chan and Leung 1986; Gadkari 1988). At effective herbicidal concentrations, paraquat was also toxic to eggs, but not adults, of three species of gastropod vectors of bilharzia (*Bulinus truncatas*, *Biomphalaria alexandrina*, *Lymnaea calliaudi*); newly hatched snails were the most sensitive (Haley 1979).

Changes in fauna of a reservoir following use of paraquat for weed control are likely to be indirect effects caused by decomposition of angiosperms (Brooker and Edwards 1974). Planktonic invertebrates closely associated with aquatic macrophytes were either eliminated by paraquat or survived at lower densities for at least a year posttreatment; analysis of fish stomachs showed dietary changes following weed control and reflected availability of many invertebrate species associated with aquatic plants (Brooker and Edwards 1974).

Paraquat can induce activities of antioxidant enzymes such as superoxide dismutase, glutathione peroxidase, and catalase in many species of plants, invertebrates, and vertebrates. Results of studies with ribbed mussels (*Geukensia demissa*) support the hypothesis that these bivalve molluscs can activate redox cycling compounds and demonstrate responses typical of oxidative stress observed in other species (Wenning et al. 1988). Paraquat also disrupts glucose metabolism and acetylcholinesterase activity and accumulates in melanin. Disrupted glucose metabolism in paraquat-stressed carp was attributed to a high level of circulating epinephrine (Simon et al. 1983). Paraquat-induced acetylcholinesterase inhibition in erythrocytes and electric organs of the electric eel (*Electrophorus electricus*) was reversible (Seto and Shinohara 1987, 1988). Paraquat tended to concentrate in melanin, as judged by accumulation in neuromelanin of frogs (*Rana temporaria*) after intraperitoneal injection (Lindquist et al. 1988), with important implications for research on Parkinson's disease. It seems that paraquat has a structural similarity to a metabolite of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), which may induce a Parkinson-like condition. MPTP and its metabolites, like paraquat, have melanin affinity (Lindquist et al. 1988).

Table 22.3 Effects of Paraquat on Selected Species of Aquatic Plants and Animals (Concentrations are in mg of paraquat cation per liter of medium.)

Taxonomic Group, Organism, and Other Variables	Concentration (mg/L) and Effect	Reference ^a
ALGAE AND MACROPHYTES		
Lesser duckweed, <i>Lemna minor</i>	0.00074; lethal	1
Submerged weeds		
4 species	0.25–0.5; lethal	2
3 species	0.5–2.5; lethal	2
<i>Chara</i> sp., <i>Polygonum</i> sp.	0.5; no adverse effects in 32 days	3
Freshwater algae		
3 species	0.25–1.0; lethal	2
2 species	>5.0; lethal	2
Rooted emergents		
2 species	0.25–0.5; lethal	2
2 species	2.0–3.0; lethal	2
1 species	>5.0; lethal	2
Floating weeds		
Water weed, <i>Elodea canadensis</i>	0.5; eradicated from British lakes in 32 days for at least 2 years	3
4 species	0.5; herbicidal	2
Pondweed, <i>Potamogeton pusillus</i>	0.5; residues of 36 mg/kg dry weight (DW) in 14 days	4, 5

Table 22.3 (continued) Effects of Paraquat on Selected Species of Aquatic Plants and Animals
 (Concentrations are in mg of paraquat cation per liter of medium.)

Taxonomic Group, Organism, and Other Variables	Concentration (mg/L) and Effect	Reference ^a
Eurasian watermilfoil, <i>Myriophyllum spicatum</i>	1.0; residues up to 112 mg/kg DW in 14 days	4, 5
Cattail, <i>Typha latifolia</i>	0.5; shoreline colonies severely affected after exposure for 32 days	3
Duckweed, <i>Spirodella oligorrhiza</i>	0.5; inhibits chlorosis in 48 h	3
Marine algae		
<i>Isochrysis galbana</i>	5; 50% growth inhibition in 10 days	6
<i>Phaeodactylum tricornutum</i>	10; 50% growth inhibition in 10 days	6
<i>Dunaliella tertiolecta</i>	20; 50% growth inhibition in 10 days	6
<i>Chlorococcum</i> sp.	50; 50% growth inhibition in 10 days	6
4 species	2500–>5000; respiration reduced 50% in 2 h	6
INVERTEBRATES		
Mud crab		
<i>Rithropanopeus harrisii</i> , larvae	0.00086; LC50 (19 days)	4
<i>R. harrisii</i> , larvae	0.001–0.005; 50% mortality prior to zoeal stage	4
Isopod, <i>Asellus meridianus</i>		
15°C	0.1; LC50 (14 days)	7
15°C	0.58; LC50 (8 days)	7
5°C	0.62; LC50 (14 days)	7
5°C	6.3; LC50 (8 days)	7
Freshwater invertebrates, 3 species (<i>Asellus</i> , <i>Lymnaea</i> , <i>Sialis</i>)	0.5; no deaths in 4 days following spray application to British lake	3
Gastropod		
<i>Murex brandaris</i>	1; LC50 (18 days)	8
<i>M. brandaris</i>	10; LC50 (24 h)	8
<i>M. brandaris</i>	1–10; residues, in mg/kg fresh weight (FW) soft parts, after exposure for 3 days ranged between 1.5 and 2.8, and were dose dependent	8
Hermit crab		
<i>Pagurus</i> sp.	1; LC50 (10 days)	8
<i>Pagurus</i> sp.	10; LC50 (36 h)	8
<i>Pagurus</i> sp.	1–5; residues, in mg/kg whole-body FW, after exposure for 3 days ranged between 3.2 and 15, and were dose dependent	8
Brown shrimp, <i>Penaeus aztecus</i>	>1.0; 50% immobilization in 48 h	6
American oyster, <i>Crassostrea virginica</i>	>1.0; 50% growth reduction in 96 h	6
Louisiana red crayfish, <i>Procambarus clarkii</i>		
Juvenile	1.4; LC50 (96 h)	9
Juvenile	2.4; LC50 (72 h)	9
Adult	17; LC50 (72 h)	9
All stages	Sublethal; Dose-dependent increase in hyperactivity and oxygen consumption	9
Daphnid		
<i>Daphnia hyalina</i>	2.5; LC50 (14 days)	7
<i>Daphnia pulex</i>	2.7; 50% immobilization in 48 h	10
<i>D. pulex</i>	4.0; LC50 (48 h)	11
Cladoceran		
<i>Simocephalus serrulatus</i>	2.8; 50% immobilization in 48 h	10
<i>S. serrulatus</i>	3.7; LC50 (48 h)	11
Liver fluke, <i>Fasciola hepatica</i>		
Egg through miracidium	5; LC50 (20 days); effects counteracted by dinoseb	12
Egg	6; delayed embryonic development; delayed hatch of miracidia	12
Egg	8; 26% hatch	12

Table 22.3 (continued) Effects of Paraquat on Selected Species of Aquatic Plants and Animals
 (Concentrations are in mg of paraquat cation per liter of medium.)

Taxonomic Group, Organism, and Other Variables	Concentration (mg/L) and Effect	Reference ^a
Egg	10; 9% hatch	12
Egg	15; no hatch	12
Freshwater copepods, 2 species (<i>Eucyclops</i> , <i>Diaptomus</i>)	5; LC50 (48 h)	13
Freshwater copepods, 2 species	10; LC50 (24 h); effects counteracted by metribuzin, another herbicide	13
Aquatic insects, nymphs		
Coreiid, <i>Sigara</i> sp.	5; LC50 (14 days)	7
Baetid, <i>Cloeon dipterum</i>	29; LC50 (14 days)	7
Daphnid		
<i>Daphnia magna</i>	6; 24% immobilized in 26 h; all mobile daphnids transferred to paraquat-free medium died within 48 h	14
<i>D. magna</i>	11; 50% immobilized in 26 h	14
<i>D. magna</i>	14; 70% immobilized in 26 h; all mobile daphnids transferred to paraquat-free medium died within 24 h	14
Amphipod, <i>Gammarus fasciatus</i>	11; LC50 (96 h)	10, 11
Ribbed mussel, <i>Geukensia demissa</i>		
<i>G. demissa</i>	93; elevated catalase activity, lipid peroxidation rate, and total superoxide dismutase levels in 12–36 h	15
<i>G. demissa</i>	744; no deaths in 7 days	15
<i>G. demissa</i>	1190; LC100 (7 days)	15
Chironomid, 4th instar larvae, <i>Psectrocladius</i> sp.	>100; LC50 (14 days)	7
Stonefly, <i>Pteronarcys californica</i>	>100; LC50 (96 h)	10, 11
Mosquito larvae, 2 species	275–>1000; LC50	4
FISHES		
Characid, <i>Bryconamericus iheringii</i>	20.2; LC50 (96 h)	29
Common carp <i>Cyprinus carpio</i>	0.5; after 6 days, 300% increase in phosphorylase and 200% increase in glucose-6-phosphatase activities in liver; increase in sugar level and serum lactic dehydrogenase activity	18
<i>C. carpio</i>	5; increase in activities of various liver enzymes, and in blood sugar levels during exposure for 6 days; effects enhanced by the herbicide methidation	19
<i>C. carpio</i>	5; initial reduction by 50% of serum cholinesterase activity which gradually increased to 130% of control values during exposure for 2 weeks, suggesting that paraquat may influence resynthesis of acetylcholinesterase	28
<i>C. carpio</i>	10; during exposure for 96 h, significant alterations were recorded in lipid peroxidation rate, hemoglobin concentration, and erythrocyte antioxidant enzymes, that is, catalase, superoxide dismutase, and glutathione peroxidase activities	20
<i>C. carpio</i>	10; after 8 h, increased superoxide dismutase in gill, liver, and brain; effects exacerbated under conditions of hypoxia	32
<i>C. carpio</i>	11.3–33.3; LC50 (96 h) values for early and late embryo developmental stages, respectively	31
<i>C. carpio</i>	13–214; acetylcholinesterase activity reduced 50% after exposure for 2 h in serum (13 mg/L), heart (39 mg/L), muscle (102 mg/L), and brain (214 mg/L)	21

Table 22.3 (continued) Effects of Paraquat on Selected Species of Aquatic Plants and Animals
 (Concentrations are in mg of paraquat cation per liter of medium.)

Taxonomic Group, Organism, and Other Variables	Concentration (mg/L) and Effect	Reference ^a
<i>C. carpio</i>	67.5–134.1; LC50 (96 h) values for fry and fingerlings, respectively	31
Plecostomid catfish		
<i>Plecostomus commersonii</i> , fry	0.6; decrease in cardiac contraction rate after exposure for 36–60 h	27
<i>P. commersonii</i> , fry	1.3; decrease in opercular ventilation rate after exposure for 60 h	27
<i>P. commersonii</i> , fry	2.5; decrease in cardiac contraction rate after exposure for 12 h	27
<i>P. commersonii</i> , fry	5.2 (3.9–6.4); LC50 (60 h)	27
<i>P. commersonii</i> , fry	10.0; all dead within 60 h	27
Freshwater fish		
4 species	1.0; maximum residues, in mg/kg whole-body FW, during exposure for 16 days ranged between 0.6 in green sunfish (<i>Lepomis cyanellus</i>) and 1.6 in bluegill (<i>Lepomis macrochirus</i>); intermediate values were recorded for rainbow trout (<i>Oncorhynchus mykiss</i>) and channel catfish (<i>Ictalurus punctatus</i>)	22
3 species	10; in exposures lasting up to 96 h, paraquat caused an exposure-dependent increase in lipid peroxidation rate and in activity enhancement of peroxide metabolism enzymes in erythrocytes	23
3 species	250; lesions in skin and gills of survivors and increasing susceptibility to secondary invaders	30
Smallmouth bass, <i>Micropterus dolomieu</i>	1.0; adverse sublethal effects	22
Striped mullet		
<i>Mugil cephalus</i>	1.0; LC50 (16 days); survivors had pronounced gill histopathology and residues, in mg/kg FW, of 0.2 in muscle, 0.2 in ovary, 4.7 in skin, and 6.1 in digestive tract	8
<i>M. cephalus</i>	10.0; LC50 (60 min)	8
Thai silverbarb		
<i>Puntius gonionotus</i>	1.0; no tissue histopathology after exposure for 12 days	24
<i>P. gonionotus</i>	4.0; gill histopathology evident after exposure for 12 days; gills normal during exposure for only 5 days	24
Longnose killifish, <i>Fundulus similis</i>	>1.0; LC50 (48 h)	6
Mosquitofish		
<i>Gambusia affinis</i>	3; adverse effects	22
<i>G. affinis</i>	604; LC50 (96 h)	5
Zebra danio, <i>Brachydanio rerio</i>	7.5–48.5; LC50 (96 h)	4
Poeciliid fish, <i>Cnesterodon decemmaculatus</i> ; fry	9.4 (6.8–11.8); LC50 (96 h)	26
Shortfin molly, <i>Poecilia mexicana</i>	12; LC50 (24 h)	5
Medaka, <i>Oryzias latipes</i>		
Egg	12; normal development	5
Egg	23; abnormal development	5
Embryo	>50; 100% lethal	5
Bluegill, <i>Lepomis macrochirus</i>	13; LC50 (96 h)	10, 11
Guppy, <i>Poecilia reticulata</i>	15–22; LC50 (96 h)	4
Rainbow trout		
<i>Oncorhynchus mykiss</i>	15–32; LC50 (96 h)	5, 10, 11
<i>O. mykiss</i>	>100; LC50 (24 h)	10
Brown trout, <i>Salmo trutta</i>	25; LC50 (96 h)	5
Tilapia, <i>Oreochromis hornorum</i>	31.5; LC50 (96 h)	25
Channel catfish, <i>Ictalurus punctatus</i>	>100; LC50 (96 h)	5, 10, 11

Table 22.3 (continued) Effects of Paraquat on Selected Species of Aquatic Plants and Animals
 (Concentrations are in mg of paraquat cation per liter of medium.)

Taxonomic Group, Organism, and Other Variables	Concentration (mg/L) and Effect	Reference ^a
AMPHIBIANS		
Leopard frog, <i>Rana pipiens</i>		
Early gastrula stage	0.1; normal growth, survival, development, and swimming behavior after 7 days of exposure	16
Early gastrula stage	0.5; high mortality, high number of tail abnormalities, reduced growth rate in survivors, and abnormal swimming behavior after exposure for 7 days (3 days posthatch) to 0.5 mg/L and higher	16
15-day-old tadpoles	0.5; 33% dead after exposure for 16 days	17
15-day-old tadpoles	2.0; 95% dead after exposure for 16 days; increase in growth retardation and in developmental abnormalities such as tail malformations and cranial defects	17
Fowler's toad		
<i>Bufo woodhousei fowleri</i> , tadpole	15; LC50 (96 h)	10
<i>B. w. fowleri</i>	56; LC50 (24 h)	10
Water frog		
<i>Scinax nasica</i> , tadpoles	6.5–18; dose-dependent increase in gill histopathology in 96 h	33
<i>S. nasica</i> , tadpoles	10.8; no deaths in 96 h	33
<i>S. nasica</i> , tadpoles	18; LC15 (96 h)	33
<i>S. nasica</i> , tadpoles	22; LC50 (96 h)	33
Western chorus frog		
<i>Pseudacris triseriata</i> , tadpole	28; LC50 (96 h)	10
<i>P. triseriata</i>	43; LC50 (24 h)	10
Frog, <i>Limnodynastes peroni</i> , adult	100; LC50 (96 h)	5
Frog, <i>Adelotus brevis</i> , adult	262; LC50 (96 h)	5

22.5.4 Birds

Signs of oral paraquat intoxication in birds include excessive drinking and regurgitation, usually within 10 min of exposure. Other signs appeared after 3 h: diarrhea, ruffled feathers, muscular incoordination, imbalance, wing drop, hyporeactivity, slowness, weakness, running and falling, constriction of the pupil, and terminal convulsions. Additional signs reported after dermal exposure include blistering and cracking of skin, lacrimation, wing spread, and wing shivers. Deaths usually occurred between 3 and 20 h postexposure; remission took up to 12 days (Smalley 1973; Haley 1979; Summers 1980; Hudson et al. 1984). The blood chemistry pattern of paraquat-intoxicated Japanese quail (*Coturnix japonica*) suggested adrenal gland impairment, although recovery from hematologic effects was rapid (Clark et al. 1988). Paraquat causes pseudofeminization of male chicken and quail embryos; testes showed intersexual phenomena and Mullerian duct abnormalities; and both sexes had a reduction in gonocyte number (Haley 1979; Bauer 1983).

The lowest doses of paraquat causing measurable adverse effects in sensitive species of birds (Table 22.4) were:

- 0.2 mg/kg BW administered by single intravenous injection to Japanese quail, causing anemia
- 0.25 mg/kg applied in oil solution to the surface of eggs of the mallard, producing reduced survival, reduced growth, and increased frequency of developmental abnormalities
- 10 mg/kg BW administered orally for 10 days to nestlings of the American kestrel, causing reduced growth
- 20 mg/kg in diet of the northern bobwhite, producing a reduction in egg deposition
- 40 mg/L in drinking water of the domestic chicken, causing elevated tissue residues and an increase in the number of abnormal eggs produced
- 199 mg/kg BW in mallards, producing an acute oral LD₅₀

Paraquat is highly toxic to avian embryos but is less toxic to adult birds (Bunck et al. 1986). It is toxic by several routes of administration, including injection and topical application (Hoffman et al. 1985). Paraquat was the most toxic to eggs of the mallard of 42 herbicides and insecticides tested. Paraquat applied to eggshell surfaces in nontoxic oil vehicles was significantly more embryo-toxic than were aqueous paraquat solutions, presumably owing to greater penetration of oil past the shell and membranes (Hoffman and Eastin 1982; Hoffman and Albers 1984) (Table 22.4). The LC₅₀ values for paraquat and mallard eggs were 1.68 kg/ha (1.5 pounds/acre) in aqueous emulsion and 0.11 kg/ha (0.1 pound/acre) in an oil vehicle (Hoffman and Eastin 1982). The computed LC₅₀ aqueous value was about 1.5 times higher than the recommended field application rate of about 1.0 kg/ha; however, paraquat in aqueous solution caused some deaths at only half the field level of application, and survivors showed impaired growth and some developmental abnormalities (Hoffman and Eastin 1982) (Table 22.4).

Nestlings of altricial species, such as the American kestrel, were more sensitive to paraquat exposure than were young or adults of precocial species (Hoffman et al. 1985). There are several food items of kestrels (e.g., grasshoppers, small rodents, passerine birds) that are readily contaminated by paraquat through direct contact during agricultural spraying or by ingestion of contaminated vegetation (Hoffman et al. 1985). From a comparative viewpoint, however, lungs of nestling kestrels were less sensitive to paraquat than were mammalian lungs (Hoffman et al. 1987).

Northern bobwhite hens immediately exposed to simulated field application rates of paraquat took longer to lay a clutch of eggs once laying had commenced; the completed clutch appeared 10 days later in the season than birds free from paraquat exposure. It is uncertain whether the paraquat-induced delay in sexual maturation produced experimentally will also be reflected in nonlaboratory situations (Bauer 1983, 1985). Turkeys (*Meleagris gallopavo*), for example, held in field plots sprayed 24 h earlier with paraquat at 100 times the recommended agricultural application rate (i.e., up to 200 ounces cation/acre or 14 kg/ha) showed no signs of toxicity for 30 days after spraying (Smalley 1973).

Acute toxicity of paraquat in the domestic chicken was highly responsive to nutritional selenium status and not to Vitamin E status. As little as 0.01 mg Se/kg ration protected 8-day-old chicks against acute paraquat poisoning (Combs and Peterson 1983). Paraquat administered to chickens by way of diet was less toxic than the same amount administered in drinking water (Fletcher 1967).

Table 22.4 Paraquat Effects on Selected Species of Birds

Species, Dose, and Other Variables	Effects and Reference
MALLARD, <i>Anas platyrhynchos</i>	
Fertilized eggs exposed on day 3 of incubation for 0.5 min at room temperature	
Oil solutions	
0.25 mg/kg egg, equivalent to 0.056 kg/ha or 0.05 pounds/ acre	17% dead, reduced growth, 16% abnormal development (Hoffman and Eastin 1982)
0.5 mg/kg egg	50% dead, some abnormal survivors (Hoffman and Albers 1984)
2.5 mg/kg egg	83% dead, 60% abnormal (Hoffman and Eastin 1982)

Table 22.4 (continued) Paraquat Effects on Selected Species of Birds

Species, Dose, and Other Variables	Effects and Reference
Aqueous solutions 2.8 mg/kg egg, equivalent to 0.56 kg/ha or 0.5 pounds/ acre 8.3 mg/kg egg	23% dead, survivors stunted, 9% abnormal (Hoffman and Eastin 1982) 50% dead. The computed LC50 concentration was about 1.5 times the recommended field application rate. At 1.5–3.0 times the field level, paraquat produced abnormal development, including edema, stunting, and brain malformations (Hoffman and Albers 1984) 73% dead, 63% of survivors abnormal (Hoffman and Eastin 1982)
27.7 mg/kg egg Adults and juveniles 199 mg/kg body weight (BW)	Acute oral LD50; deaths usually occurred between 3 and 20 h after treatment. Remission took up to 12 days (Hudson et al. 1984)
600 mg/kg BW	Percutaneous LD50 for 10- to 11-month-old drakes after a 24-h dermal foot exposure. Deaths occurred between 6 and 22 h after treatment; remission took up to 5 days (Hudson et al. 1984)
4048 mg/kg diet	Fatal to 50% after 5 days on treated diet plus 3 days on untreated ration (Heath et al. 1972)
NORTHERN BOBWHITE, <i>Colinus virginianus</i>	
Parent generation (P_1) fed diets containing 20, 60, 180, or 360 mg /kg ration for 6 weeks; in next generation (F_1), none was administered	360-mg/kg P_1 group had reduced fertility and hatchability, significant body weight loss, and reduction in ovary and oviduct weight; there was no increase in chick abnormalities or histopathology; the 180-mg/kg P_1 group laid significantly fewer eggs during treatment; all F_1 hens from the 20-, 60-, and 180-mg/kg groups started laying 1 week later than controls and produced fewer eggs; F_1 males experienced a delay in maturation; F_1 chicks from the 20-mg/kg group were significantly heavier than all other groups (Bauer 1983, 1985)
Fed diets containing 25 or 100 mg paraquat/kg food for 60 days	No signs of toxicity or impaired learning (Bunck et al. 1986)
981 mg/kg diet, 2- to 3-week-old birds	Fatal to 50% after 5 days on treated diet plus 3 days on untreated diet (Heath et al. 1972; Anonymous 1974)
JAPANESE QUAIL, <i>Coturnix japonica</i>	
Juveniles received a single intravenous injection of 0.2, 2, or 20 mg/kg BW	Some deaths in 20 mg/kg group. All survivors from all groups showed hemolytic anemia within 24 h postinjection, recovery beginning within 72 h; the 0.2-mg/kg birds also showed reductions in erythrocyte number, hematocrit, and hemoglobin within 24 h (Clark et al. 1988)
14-day-old chicks fed treated diets for 5 days followed by 3 days of untreated food	
500 mg/kg diet	Fatal to 20% (Hill and Camardese 1986)
948–970 mg/kg diet	Dietary LD50 (Heath et al. 1972; Hill and Camardese 1986)
1516 mg/kg diet	Fatal to 90% (Hill and Camardese 1986)
Eggs dusted with 0.4–0.8% paraquat powder	Hatching rate ranged between 58 and 79% (Bauer 1983)
100 mg/L in drinking water	Lethal within 7 days (Summers 1980)
AMERICAN KESTREL, <i>Falco sparverius</i>, nestlings	
Daily oral doses, for 10 days, of 10, 25, or 60 mg paraquat/kg BW	All groups exhibited reduced growth rate and elevated total sulphydryl and protein-bound sulphydryl levels in lung, when compared to controls. The 25-mg/kg group had reduced skeletal growth of humerus and femur. In the 60-mg/kg group, 44% died in 4 days; survivors showed abnormal blood chemistry, liver histopathology, kidney damage, and reduced skeletal growth of humerus, femur, radius-ulna, and tibiotarsus (Hoffman et al. 1985, 1987).
DOMESTIC CHICKEN, <i>Gallus</i> sp.	
Egg >0.1 mg/kg 0.5 mg	Hatching rate reduced after injection (Fletcher 1967; Bauer 1983) Injected eggs did not hatch (Haley 1979)

Table 22.4 (continued) Paraquat Effects on Selected Species of Birds

Species, Dose, and Other Variables	Effects and Reference
0.4–0.8% paraquat powder	Hatching rate of eggs dusted with powder ranged between 46 and 77% (Bauer 1983)
Adult	
Single intravenous injection of 25 mg paraquat dichloride/kg BW	60% reduction in urine flow within 50 min (Prashad et al. 1981)
40 mg/L in drinking water for 14 days followed by 14 days of paraquat-free water	No effect on egg production or hatchability, but 7% increase in number of abnormal eggs produced. Paraquat residues in eggs rose to about 0.1 mg/kg, but declined to below detection limits 6 days after treatment was halted. No effect on food and water consumption of hens or on number and type of abnormalities in chicks (Fletcher 1967)
131 mg/kg BW	Acute oral LD50, diet deficient in Vitamin E and selenium (Combs and Peterson 1983)
148 mg/kg BW	Acute oral LD50, diet deficient in selenium (Combs and Peterson 1983)
419 mg/kg BW	Acute oral LD50, diet deficient in Vitamin E (Combs and Peterson 1983)
Chicks, 8-days old, 200–380 mg/kg BW	Acute oral LD50 (Haley 1979; Summers 1980; Bauer 1983)
TURKEY, <i>Meleagris gallopavo</i>	
20 mg/kg BW	Lethal dose, intravenous injection route (Smalley 1973)
100 mg/kg BW	Lethal dose, intraperitoneal injection route (Smalley 1973)
290 mg/kg BW	Lethal dose, oral administration route (Smalley 1973)
500 mg/kg BW	Lethal dose, dermal route (Smalley 1973)
RING-NECKED PHEASANT, <i>Phasianus colchicus</i>	
1468 mg/kg diet	Fatal to 50% after 5 days on treated diet plus 3 days on untreated diet (Heath et al. 1972)

22.5.5 Mammals

Resistance to paraquat among mammals varied substantially owing to inherent differences in sensitivity between species, to route of administration, and to reproductive state (Table 22.5). The lowest recorded doses of paraquat causing measurable adverse effects on growth, survival, or reproduction were (Table 22.5):

- Aerosol concentrations of 0.4 to 6.0 µg/L (rat, guinea pig)
- 0.05 mg administered directly in lung (rat)
- Intravenous injection of 1 to 12 mg/kg BW (sheep, dog, rat)
- Subcutaneous injection of 2.4 to 28 mg/kg BW (rat, mouse, monkey)
- Intraperitoneal injection of 3 to 10 mg/kg BW (mouse, guinea pig, goat)
- Acute oral dose of 22 to 35 mg/kg BW (dog, cat, hare, guinea pig)
- Dermal application of 70 to 90 mg/kg BW (rat)
- Dietary levels of 85 to 100 mg/kg ration (dog, mouse, rat)
- Drinking water concentration of 100 mg/L (mouse)

In microtine rodents, feed aversion and toxicant avoidance were the most significant behaviors elicited by feed tainted with paraquat (Linder and Richmond 1990).

In general, intraperitoneal and intravenous injections were the most sensitive administration routes (Bauer 1983). LD50 dermal values, however, are often not true percutaneous values because of oral contamination from normal grooming (Summers 1980). Aerosol exposure to paraquat produced a concentration-dependent rapid, shallow breathing pattern in guinea pigs (*Cavia* sp.)

18 h after exposure (Burleigh-Flayer and Alarie 1988). Aerosol LC50 values in paraquat toxicity tests with mammals were directly related to the duration of exposure, paraquat concentration in spray, and particle size; particles of 3 µm diameter seemed most effective (Haley 1979).

Paraquat produces rapidly progressive, fatal, interstitial inflammation and fibrosis of the lung in humans following accidental ingestion, and this has been produced experimentally in several species of laboratory animals (Butler and Kleinerman 1971; Murray and Gibson 1972). Initial symptoms of paraquat poisoning include burning of the mouth and throat, followed by nausea and vomiting. After a latent period of up to several days, increasing respiratory distress develops; death is usually the result of a progressive fibrosis and epithelial proliferation that occurs in the lungs (Kimbrough 1974). Paraquat poisoning in humans has a mortality of 30 to 70%, depending largely on the dose ingested. It causes multiorgan failure, including the heart, lungs, kidney, liver, and brain. Although recovery may follow mild involvement of any of these organs, many patients die from progressive untreatable pulmonary fibrosis. This illness usually succeeds renal failure and relates in part to active pulmonary uptake of paraquat (Webb 1983). In one case, a 15-year-old boy accidentally ingested a mouthful of paraquat and developed severe respiratory distress, necessitating transplantation of one lung; paraquat-induced rejection of the graft resulted in death 2 weeks after the operation (Matthew et al. 1968). Paraquat cannot be absorbed significantly through intact human skin; but in the event of broken or abraded skin brief exposure to a concentration of 5 g paraquat/L may result in death (Smith 1988a).

Paraquat tends to rapidly localize in selected tissues of injected mice, including melanin, alveolar type cells of the lung, choroid plexus, muscle, proximal tubules of the kidney, liver, gallbladder, and intestinal contents (Waddell and Marlowe 1980). Half-time persistence of paraquat in rat tissues ranged from 20 to 30 min in plasma to about 5 days in muscle (Sharp et al. 1972).

Acute effects of paraquat poisoning in livestock and small laboratory animals are similar to those in humans (Conning et al. 1969; Murray and Gibson 1972; Rose et al. 1976; Smith and Heath 1976; Haley 1979; Kelly et al. 1979; Manzo et al. 1979; Summers 1980) (Table 22.5). Signs of acute paraquat toxicosis included hyperexcitability leading to convulsions or incoordination, inflammation of the mouth and throat, vomiting, reluctance to eat or drink, diarrhea, tachycardia, eye irritation of the conjunctiva, corneal lesions, skin reddening, skin ulceration, skin necrosis, histopathology of liver and kidney, and respiratory failure. Paraquat was selectively accumulated in lung of canines, primates, and rodents, regardless of route of administration. Lung pathology included congestion, hemorrhage, edema, and collapse. This was associated with degeneration of alveolar and bronchial cells. Death may occur within 10 days of acute exposure.

Chronic administration of small doses or repeated injections usually produce no clinical signs for several weeks. Signs develop suddenly, in general, and include weight loss, anorexia, and death — usually within 10 days of onset of signs (Smith and Heath 1976). Decreased food consumption and consequent loss of body weight are common in paraquat-poisoned rats and dogs. The area postrema of the hindbrain is an important neural site for detection of blood-borne chemicals and is speculated to control paraquat-induced taste aversion formation and weight loss (Dey et al. 1987).

Rabbits are comparatively resistant to paraquat-induced lung damage, regardless of the route of administration (Summers 1980; Dikshith et al. 1979; Bauer 1983), but the closely related hare (*Lepus europaeus*) is comparatively sensitive to paraquat. Hares placed on alfalfa plots within a few hours after the fields were treated with 0.6 kg paraquat/ha experienced 50% mortality in 120 h; survivors that were killed 2 weeks later showed lung damage and ulceration of the lingual mucous membrane. Plant residues were about 30 mg/kg fresh weight for alfalfa and 60 mg/kg for weeds; residues were negligible in tissues of the hare (Lavaur et al. 1973). In a similar incident in Italy, Stracciari et al. (1980) found that only 1 of 56 hares found dead had lung damage, although all had elevated urine paraquat levels of 0.5 mg/L. It was concluded that paraquat alone was not the causative agent of death, and that paraquat interactions with other chemicals applied at the same time on other crops in the same area may be responsible.

Paraquat applications to spruce plantations for grass control had no effect on the movement or density of field mice (*Microtus arvalis*) and voles (*Microtus agrestis*), but shrews (*Sorex* sp.) migrated from treated areas to untreated ones (Summers 1980).

Paraquat is poorly absorbed from the gut and readily excreted. Typical gut absorption rates (%) and peak concentrations in blood (mg/L) were 15 to 20% and 3 to 4 mg/L in rat, 5 to 10% and 1 mg/L in guinea pig, 16% and 13 mg/L in cat, 0.26% in cow, and 1 to 5% in humans (Conning et al. 1969). Paraquat is actively secreted by a renal mechanism that is vulnerable to paraquat toxicity; poisoning of the secretory component removed a large part of the excretory capacity for paraquat (Webb 1983). In rats, a single oral LD₅₀ dose produced a reduction in renal function within 24 h. This effect is probably secondary to a decrease in plasma volume with a consequent reduction in renal blood flow (Lock 1979). Paraquat caused mild renal tubular damage in the rat; within 24 h of injection of 20 mg/kg BW, there was marked diuresis, sugar and albumin in the urine, and increased plasma urea concentrations (Lock and Ishmael 1979). Paraquat-poisoned mice showed a decreased ability to excrete organic acids and bases, probably reflecting interference with proximal tubule function because no change in glomerular filtration rate was observed (Ecker et al. 1975).

Paraquat was not mutagenic, as judged by noninterference with DNA metabolism, and had no reverse mutation-inducing capability (Anonymous 1988). Paraquat had little or no teratogenicity to mammals (Bus et al. 1975). No teratogenic effects were observed in rats fed diets containing 400 mg paraquat/kg for three generations (Anonymous 1988). The most common malformations in paraquat-stressed rats were those involving costal cartilage (Bauer 1983). Studies demonstrated transplacental transfer of paraquat in pregnant rats and guinea pigs. High concentrations of radio-labeled paraquat were found in the placenta and throughout the fetuses within 30 min of intravenous administration. Concentrations in placenta, maternal blood, and fetal blood were in the ratio of 16 to 4 to 1 (Ingebrigtsen et al. 1984), suggesting that additional research is needed on paraquat embryotoxicity.

Table 22.5 Paraquat Effects on Selected Species of Mammals

Species, Dose, and Other Variables	Effects and Reference
COW, CATTLE, <i>Bos</i> sp.	
Calves administered 5 mg/kg BW, iv injection	No effect on pulmonary function or blood gases after 7 days (Kiorpis et al. 1982)
20 mg/L drinking water, 1 month	No measurable effect (Calderbank 1975)
35–75 mg/kg BW	Acute oral LD ₅₀ (Fletcher 1974; Haley 1979; Summers 1980; Heitkamp and Brown 1982)
200–400 mg/kg diet for 30 days	No observable effect; no measurable residues in meat or milk (Calderbank 1975)
DOG, <i>Canis familiaris</i>	
25 µg/L air, 60 min exposure	No ill effects (Haley 1979)
Fed diets containing 7, 34, 85, or 170 mg paraquat/kg ration for 27 months	No significant abnormalities at 7 or 34 mg/kg; toxic effects noted at 85 and 170 mg/kg diet (Anonymous 1974)
12 mg/kg BW, single iv injection	Extensive lung damage after 7 days (Hampson and Pond 1988)
25 mg/kg BW, single iv injection	All dead within 36 h. Prior to death, plasma levels of glucose, cortisol, and catecholamines increased and glucose levels decreased. Increases in activity of plasma lactic dehydrogenase, creatinine phosphokinase, glutamic oxaloacetic transaminase, creatinine, and rennin. Residues in dead dogs, in µg/kg fresh weight (FW), were highest in bile (41), kidney (8), lung (5), liver (5), spleen (4), heart (3), adrenal (3), pancreas (1), thymus (1), and muscle (1) (Giri et al. 1982, 1983)
25–50 mg/kg BW	Acute oral LD ₅₀ (Heitkamp and Brown 1982; Anonymous 1988)
36 mg/kg diet for 2 years	No measurable effect (Haley 1979)

Table 22.5 (continued) Paraquat Effects on Selected Species of Mammals

Species, Dose, and Other Variables	Effects and Reference
GOAT, <i>Capra</i> sp.	
10 mg/kg BW, ip injection	Mild paraquat-related lung tissue changes, but toxicosis was not clinically significant after 10 days (Kiorpis et al. 1982)
GUINEA PIG, <i>Cavia</i> sp.	
Aerosol exposure, in mg/m ³	
0.1, 0.4, or 0.8, 6 h daily, 5 days weekly, 3-week exposure	Rapid shallow dose-dependent breathing pattern, with return to control values during first 7 days of exposure, suggesting adaptation (Burleigh-Flayer and Alarie 1988)
0.7, 4-h exposure, 2-week observation	Decrease in lung volume and increase in respiratory frequency; maximum effects measured several days postexposure with return to control values (Burleigh-Flayer and Alarie 1988).
0.83–2.07, 4-h exposure, flow rate 21 L/min, particles usually <0.65 µ diameter	Concentration-related decrease in lung volume and 2-fold increase in respiratory frequency 18 days postexposure (Burleigh-Flayer and Alarie 1987)
3 mg/kg BW	Acute intraperitoneal LD50 (Haley 1979; Manzo et al. 1979)
22–80 mg/kg BW	Acute oral LD50 in 7 days (Murray and Gibson 1972; Haley 1979; Summers 1980; Heitkamp and Brown 1982; Bauer 1983)
CHINESE HAMSTER, <i>Cricetus</i> spp.	
Cultured cells subjected to 0.8 mg/L for 3 h, recovery for 21 days	50% frequency of chromosomal aberrations; higher frequency by pretreatment with diethyldithiocarbamate (an inhibitor of superoxide dismutase), or dimethyl maleate (a glutathione scavenger), or at high oxygen concentrations (Sofuni and Ishidate 1988)
CAT, <i>Felis domesticus</i>	
26–50 mg/kg BW	Acute oral LD50 (Fletcher 1974; Haley 1979; Summers 1980; Heitkamp and Brown 1982; Bauer 1983)
26–50 mg/kg BW	Peak concentration in blood of 13 mg/L (Conning et al. 1969)
HUMAN, <i>Homo sapiens</i>	
Child, 6-year-old, accidentally swallowed unknown amount of Gramoxone W (contains paraquat)	Residue in urine 6 days after exposure was 3.6 mg paraquat/L; death 7 days after onset of symptoms. Autopsy showed ulceration of buccal mucosa, emphysema, severe lung damage, jaundice, and renal failure (Campbell 1968)
Adult male. Died 30 h after swallowing paraquat solution	Histopathology of lung and adrenal gland. Residues, in mg/kg fresh weight, were highest in kidney (17), followed by lung (6), muscle (4.4), liver (3.8), blood (1.4), skin (0.9), and brain (0.4) (Spector et al. 1978)
Ingestion — but not necessarily swallowing — of about 15 mL ("mouthful") of a 20% solution	Fatal dose (Kimbrough 1974)
4–>40 mg/kg BW	Acute oral LD50 (Manzo et al. 1979; Summers 1980)
Ingestion of 30 mg/kg BW	Associated with hepatic, cardiac, or renal failure, and sometimes death (Dasta 1978)
Total ingested dose of 3–6 g	Fatal dose (Haley 1979)
HARE, <i>Lepus</i> sp.	
35 mg/kg BW	Acute oral LD50 (Fletcher 1974)
JAPANESE MONKEY, <i>Macaca fuscata</i>	
Adults, >3.5 year of age, 2 mg/kg BW every 2 days for 8 or 10 days, sc injection	After 4 injections (8 days), 63% died; after 5 injections, 75% died; all deaths occurred between days 11 and 35. At day 66, survivors had elevated lung collagen and increased ceruloplasmin (Masaoka et al. 1987)

Table 22.5 (continued) Paraquat Effects on Selected Species of Mammals

Species, Dose, and Other Variables	Effects and Reference
MONKEY, <i>Macaca</i> sp.	
50–75 mg/kg BW	Acute oral LD50 in 7 days (Fletcher 1974; Smith and Heath 1976; Heitkamp and Brown 1982; Bauer 1983).
>63 mg/kg BW, oral route	All dead within 2 days; death preceded by convulsions (Murray and Gibson 1972)
PRAIRIE VOLE, <i>Microtus ochrogaster</i>	
56 mg/kg BW; single oral dose	50% dead in 10 days (Linder and Richmond 1990)
60 mg/kg ration	Feed aversion and reduced dietary intake (Linder and Richmond 1990)
MOUSE, <i>Mus musculus</i>	
Fed diets containing 45, 90, or 125 mg/kg ration for two generations	At 45 mg/kg and 90 mg/kg, there was no significant difference from controls in reproductive organ development, fertility, mating behavior, embryotoxicity, or developmental abnormalities; at 125 mg/kg diet, survival was significantly lower, fewer pairs reproduced, and females matured later; second generation mice were more resistant than the first generation (Dial and Dial 1987a)
DOMESTIC MOUSE, <i>Mus</i> spp.	
1.65 or 3.35 mg/kg BW ip injection, or 20 mg/kg BW orally, daily on days 8–16 of gestation	No significant teratogenic effects; low accumulations in embryos (Bus et al. 1975)
Fed diets containing 2, 10, 30, or 100 mg/kg ration for 2 years	Maximum no-effect level was 30 mg/kg diet, equivalent to 3.92 mg/kg BW daily for males and 3.82 mg/kg BW daily for females (Anonymous 1988)
Single ip injection of 8 mg/kg BW on day 9 of pregnancy, or 2 mg/kg BW on day 9, 10, 11, or 12 of pregnancy	No measurable effect on survival, reproduction, birth weight, or chromosomal aberrations; no evidence of mutagenicity to mice liver cells (Selypes et al. 1980)
16–30 mg ion/kg BW	LD50, intraperitoneal injection (Manzo et al. 1979; Selypes et al. 1980; Anonymous 1988)
28 mg ion/kg BW	LD50, subcutaneous injection (Anonymous 1988)
38–120 mg/kg BW	Acute oral LD50 (Fletcher 1974; Haley 1979)
50 or 100 mg/L in drinking water	Low dose had no effect on growth or survival; high-dose group showed increased postnatal mortality after 2 generations (Bauer 1983)
RABBIT, <i>Oryctolagus</i> sp.	
Single iv injection of 0.05 mg/kg BW	Plasma paraquat concentrations, in mg/L, were 0.6 within 2 h, 0.01 at 8 h, and <0.002 at 24 h; estimated half-life (T _b 1/2) of 24.5 h (Yonemitsu 1986)
Single iv injection of 5 mg/kg BW	Plasma paraquat concentrations, in mg/L, were about 30 in 2 h, 1 in 8 h, 0.1 in 24 h, and <0.01 in 48 h; estimated T _b 1/2 of 12.8 h; kidney histopathology evident 7 days after injection but lung damage negligible (Yonemitsu 1986)
Oral administration of 11 mg/kg BW daily for 30 days	No significant toxic signs (Dikshith et al. 1979)
5 ip injected doses totaling 2–100 mg/kg BW	At doses of 25 mg/kg BW and higher, rabbits usually died within 4 days after treatment. No delayed pulmonary changes in rabbit typical of those induced in man and other animals observed in survivors up to 1 month after treatment (Butler and Kleinerman 1971)
20 mg/kg BW, iv injection	Paraquat tended to concentrate in lung; lung histopathology and biochemical upset (Ilett et al. 1974)
24 mg/kg BW, 20 dermal applications	No effect (Anonymous 1974)
49–150 mg/kg BW	Acute oral LD50 (Fletcher 1974; Haley 1979)
Total aerosol dose of 250 mg delivered in 60 min	Significantly increased levels in serum of phospholipids, cholesterol, and triglycerides; reduced growth rate; no evidence of liver or lung damage (Seidenfeld et al. 1984)
346–480 mg/kg BW	Acute dermal LD50 (Anonymous 1974; Haley 1979)

Table 22.5 (continued) Paraquat Effects on Selected Species of Mammals

Species, Dose, and Other Variables	Effects and Reference
SHEEP, <i>Ovis aries</i>	
Single iv injection of 1, 2, 4, or 8 mg/kg BW	Paraquat was nephrotoxic, producing glomerular and tubular defects in a dose-dependent manner, including inhibited glomerular filtration rates and inhibited paraquat secretion. LD50 (6 weeks) about 1 mg/kg BW. Serum levels 60 min postexposure, in mg paraquat/L, were 0.07 for the 1-mg/kg group, 0.25 for the 2-mg/kg group, 1.23 for the 4-mg/kg group, and 2.05 for the 8-mg/kg group (Webb 1983, 1983a)
50–75 mg/kg BW	Acute oral LD50 (Fletcher 1974; Summers 1980; Heitkamp and Brown 1982)
RAT, <i>Rattus sp.</i>	
0.000116 or 0.000232 µg/kg BW hourly for 7 days, iv infusion, equivalent to a total dose of 0.0465 mg (low dose) or 0.093 mg (high dose)	No adverse effects evident at low dose. At high dose, survivors showed weight loss, histopathology, increased lung glutathione and glucose-6-phosphate dehydrogenase activity — reflecting paraquat-induced oxidant stress and an increased demand on lung NADPH (Dunbar et al. 1988a).
0.0001 or 0.0004 mg/L air, 6-h exposure daily for 3 weeks	No effect at 0.0001 mg/L; pulmonary irritation at 0.0004 mg/L (Haley 1979)
0.001–1.0 mg/kg BW, entire dose in right lung	Dose-dependent lung injury and fibrosis; tissue fibronectin levels remained elevated for at least 14 days after administration (Dubaybo et al. 1987)
0.006 mg/L air for 60 min	LC50; 3-µm particle size most effective (Haley 1979)
0.01 or 0.05 mg, brain injection	Intense pattern of behavioral stimulation, including increased locomotor activity, especially circling, and convulsions; abnormal brain wave patterns (De Gori et al. 1988)
0.0116 mg/kg BW, single dose, various routes	Dose administered by intravenous and intragastric routes cleared rapidly; urine and feces were major excretion routes; Tb 1/2 in blood about 68 min. Dose administered by dermal and pulmonary routes tended to remain at site of injection (Chui et al. 1988)
0.05 mg/kg BW, entire dose in lung	Pulmonary lesions, lung congestion and collapse, edema, hemorrhage, degenerate changes, proliferative fibrosis in lung tissue (Kimbrough and Gaines 1970; Summers 1980).
0.09–9 mg/kg BW, single sc injection	At doses >0.5 mg/kg BW, paraquat produced a dose-dependent avoidance of foods; the ED50 for conditioned taste aversion was 2.4 mg/kg BW (minimum effective dose was 0.78 mg/kg BW); none of these doses produced overt clinical or histological signs of toxicity (Dey et al. 1987)
0.125 or 0.25 mg/kg BW hourly, continuous iv infusion	After 7 days, lungs of high-dose group had elevated putrescine, spermidine, and ornithine decarboxylase activity, reflecting changes in polyamine metabolism; no measurable effects in low-dose group (Dunbar et al. 1988b)
Pregnant dams given 1.5, 4.5, or 13.5 mg/kg BW daily from day 7 to day 17 of gestation	No fetal toxicity or teratogenicity in any group, although maternal survival was low in the 13.5-mg/kg group (Anonymous 1988)
6 mg/kg BW, iv injection	Lung fibrosis (Summers 1980)
Fed diets containing 10, 30, 100, or 300 mg/kg for 2 years	No adverse effects in males at 30 mg/kg diet (1.06 mg/kg BW daily) and lower, or in females at 100 mg/kg diet (4.3 mg/kg BW daily) and lower. Lung histopathology observed in males at 100 mg/kg diet, and in both sexes at 300 mg/kg. At 300 mg/kg diet, clinical signs included reduced growth, reduced food and water intake, abnormal blood chemistry, and increased frequency of cataracts. No conclusive evidence of carcinogenicity (Anonymous 1988)
10 or 30 mg/kg BW, ip injection	At both doses, there was a decrease in calcium uptake by lung microsomes for 3–4 days after injection, followed by recovery during the next 4 days (Agarwal and Coleman 1988)
14–34 mg/kg BW	LD50, ip injection (Haley 1979; Manzo et al. 1979; Anonymous 1988)
16–18 mg/kg BW	LD50, iv injection (Sharp et al. 1972)

Table 22.5 (continued) Paraquat Effects on Selected Species of Mammals

Species, Dose, and Other Variables	Effects and Reference
18 mg/kg BW, single ip injection	Significant increases in enzymes and compounds responsible for protecting against lipid peroxidation, including catalase, glucose-6 phosphate dehydrogenase, and nonprotein sulfhydryl (Omaye and Reddy 1980)
19–26 mg/kg BW	LD50, sc injection (Haley 1979; Lock 1979; Anonymous 1988)
20 mg/kg BW, iv injection	
Time, after injection	
5 min	Residues were 90 mg/kg in kidney, 30 in plasma, and 10–20 in lung, liver, and muscle (Summers 1980)
4 h	Residues (in mg/kg) were 8 in lung, 6 in kidney, 2 in liver, 0.8 in muscle, and 0.3 in plasma (Summers 1980)
3 days	Lung contained 3 mg/kg, kidney 0.7, muscle 0.5, liver 0.3, and plasma 0.04 (Summers 1980)
10 days	In survivors, muscle contained 0.25 mg/kg, lung 0.1, kidney 0.06, liver 0.03, and plasma 0.01 (Summers 1980)
Fed diets containing 20, 100, or 200 mg/kg ration for 2 generations	Maternal and fetal toxicity in the 200 mg/kg diet group (Anonymous 1988)
21 mg/kg BW	90-dose oral LD50 in females (Kimbrough and Gaines 1970)
27 mg/kg BW, single iv injection	Within 24 h, lung surfactant decreased 32%, suggesting a loss in alveolar stability (Haley 1979)
Adult males	
30 mg/kg BW, single ip injection	No deaths in 72 h; marked reduction of acid and alkaline phosphatase activity in alveolar epithelium of lung (Boudreau and Nadeau 1987)
45 mg/kg BW, ip injection	After 48 h, marked increase in blood glucose, depressed plasma insulin level, marked depletion of liver glycogen, significant increase in plasma creatinine phosphokinase and glutamic oxaloacetic transaminase activity (Giri et al. 1979)
Fed diets containing 50, 120, or 250 mg/kg ration for 8 weeks	No progressive accumulations in tissues. No pulmonary lesions at 50 or 120 mg/kg diet; however, 100% of the 250 mg/kg group had pulmonary lesions (Summers 1980)
Fed 2-year diet containing 70 mg/kg ration	No significant toxicity (Anonymous 1974)
70–90 mg/kg BW	LD50, dermal exposure (Kimbrough and Gaines 1970; Kimbrough 1974; Haley 1979; Anonymous 1988)
95–174 mg/kg BW	Acute oral LD50 (Kimbrough and Gaines 1970; Murray and Gibson 1972; Anonymous 1974, 1988; Kimbrough 1974; Manzo et al. 1979; Heitkamp and Brown 1982; Bauer 1983)
125 mg/kg BW, oral dose	Survivors had decreased kidney glomerular filtration rate within 24 h (Lock 1979)
170 mg/kg diet for 2 years	No measurable adverse effect (Haley 1979)

22.6 RECOMMENDATIONS

Criteria have not yet been promulgated by regulatory agencies for the protection of sensitive species of fish and wildlife against paraquat.

The degradation rate of paraquat in certain soils can be slow, and the compound can persist for years — reportedly in a form that is biologically unavailable. But data are missing or incomplete on flux rates of paraquat from soil into food webs and on interaction dynamics of paraquat with other herbicides frequently applied at the same time. It seems prudent at this time to keep under close surveillance the residues of paraquat in soils in situations where repeated applications have been made over long periods of time (Summers 1980).

In Argentina, paraquat concentrations used to control aquatic weeds is set at 0.1 to 0.2 mg/L, with no more than four applications each year (Tortorelli et al. 1990). However, some aquatic

invertebrates, especially early developmental stages of crustaceans, are unusually sensitive to paraquat. Adverse effects to aquatic invertebrates are documented in the range of 1.0 to 100 µg/L ([Table 22.6](#)). For this reason, paraquat should be used with caution in estuarine and marshy areas (Summers 1980). Fish seem to be “safe” against aquatic weed control concentrations of <1.0 mg paraquat/L (Summers 1980). But aquatic plants tend to accumulate paraquat from the medium; accordingly, more research is needed on the effects of ingestion of contaminated plants and plant detritus by amphibians, reptiles, and other aquatic fauna (Dial and Dial 1987).

Eggs of migratory waterfowl seem to be especially sensitive to paraquat at recommended application rates in an oil vehicle, but were significantly more resistant to the same dose applied in water ([Table 22.6](#)). Application of paraquat in oil solution appears contraindicated in areas containing nesting waterfowl.

Among mammals, one of the most sensitive species is man, and permissible residues in his diet are low when compared to no-observed-effect levels in other warm-blooded species ([Table 22.6](#)). An air concentration of 0.4 mg/m³ may exceed a safe level for certain mammals, particularly if the size of the aerosol particle is submicroscopic and capable of penetrating the lung (Burleigh-Flayer and Alarie 1988). Accordingly, the proposed paraquat aerosol standard — set at 0.5 mg/m³ — may have to be modified downward. Misuse of paraquat has raised the question of cancellation of its registration, cancellation of its use in homes and recreational areas, or changing its packaging to prevent individuals from drinking it (Haley 1979). In almost all cases of fatal human poisonings, death was due to the ingestion of a concentrated (20%) solution. More dilute formulations (5% paraquat) are usually not fatal if swallowed accidentally, suggesting that a dilute form of paraquat should be the only formulation permitted commercially (Kimbrough 1974).

22.7 SUMMARY

Paraquat (1,1'-dimethyl-4,4'-bipyridinium) and its dichloride salt (1,1'-dimethyl-4,4'-bipyridinium dichloride) are broad-spectrum contact plant killers and herbage desiccants that were introduced commercially during the past 35 years. Today, they rank among the most widely used herbicides globally and are frequently used in combination with other herbicides. The recommended field application rates for terrestrial weed control usually range between 0.28 and 1.12 kg paraquat/ha (0.25 and 1.0 pounds/acre); for aquatic weed control, it is 0.1 to 2.0 mg/L. Target plant species are unable to metabolize paraquat and tend to contain elevated residues; paraquat-resistant

strains of terrestrial flora, whose numbers are increasing, require greater concentrations for control and may contain proportionately greater residues. Paraquat from decayed flora is usually adsorbed to soils and sediments. Paraquat in surface soils generally photodecomposes in several weeks, but paraquat in subsurface soils and sediments may remain bound, and biologically unavailable, for many years without significant degradation.

Paraquat is not significantly accumulated by earthworms and other species of soil invertebrates, and is usually excreted rapidly by higher animals. However, delayed toxic effects — including death of birds and mammals — are common. At concentrations below the recommended application rate, paraquat is embryotoxic to developing eggs of migratory waterfowl (0.056 kg/ha), and adversely affects sensitive species of freshwater algae and macrophytes (250 µg/L), larvae of crustaceans (0.9 to 5.0 µg/L), and frog tadpoles and carp (500 µg/L). Sensitive species of birds are negatively affected at dose rates of 10 mg paraquat/kg body weight daily, or when fed diets containing 20 mg/kg ration, or drinking water containing 40 mg/L. Adverse effects in sensitive mammals were observed at dietary levels of 85 to 100 mg/kg ration and higher, or 100 mg/L in drinking water. Acute oral LD₅₀ values for sensitive species of birds were near 200 mg/kg body weight, and for mammals 22 to 35 mg/kg body weight. Man is one of the more sensitive species, and numerous human poisonings have resulted from accidental or intentional ingestion of a concentrated paraquat formulation.

The biochemical mechanism of paraquat toxicity is due to the cyclic oxidation and reduction in tissues, leading to production of superoxide anion and other free radicals, and eventually the highly destructive hydrogen peroxide. The lung is the organ most severely affected in paraquat poisoning, due largely to the preferential accumulation of paraquat in lung alveolar cells. Although many organs are affected by paraquat, death is usually due to progressive pulmonary fibrosis. At present, there is no completely successful treatment for paraquat-induced lung toxicity.

More information is needed in several areas in order to establish effective criteria for the protection of sensitive species of fish and wildlife against paraquat. These include:

- Flux rates of paraquat from soil into terrestrial food chains
- Biomagnification potential of paraquat in aquatic food chains, with special reference to plants, plant detritus, amphibians, and reptiles
- Toxicokinetics of mixtures of paraquat and other herbicides applied concomitantly
- The implications of the high sensitivities of crustacean larvae and waterfowl embryos to paraquat

CHAPTER 23

Pentachlorophenol

23.1 INTRODUCTION

Pentachlorophenol (PCP) and its water-soluble salt, sodium pentachlorophenate, are commercially produced organochlorine compounds used primarily as preservatives of wood and wood products, and secondarily as herbicides, insecticides, fungicides, molluscicides, and bactericides (U.S. Environmental Protection Agency [USEPA] 1980; Prescott et al. 1982; U.S. Public Health Service [USPHS] 1994). Both compounds have been sold for these purposes since 1936 under a variety of trade names (Knudson et al. 1974). Because of its widespread use, animals and humans are exposed to significant amounts of PCP. Detectable PCP levels are found in most people living in industrialized societies, probably as a result of food chain exposure to PCP-treated wood products (Dougherty 1978; McConnell et al. 1980; Prescott et al. 1982). In Japan, PCP has been widely used as an herbicide in rice fields; but owing to its high toxicity to fishes, its use was limited (beginning in 1971) to upland fields (Nishimura 1984; Mikesell and Boyd 1986). The use of PCP in Japan has resulted in the contamination of all surface water in that country to concentrations of 0.01 to 0.1 µg/L (Lu et al. 1978). The chemical and its degradation products bioconcentrate in fish and are among the phenolic compounds known to taint fish flesh (Boyle et al. 1980). It has been detected in the atmosphere over industrial as well as remote areas, lake sediments, aquatic biota, drinking water, and human blood and urine (Schimmel et al. 1978; Klemmer et al. 1980; Trujillo et al. 1982; Larsson et al. 1993). All samples of human milk from nursing mothers tested in Bavaria from 1979 to 1981 contained PCP (Gebefugi and Korte 1983). In the United States between 1976 and 1980, PCP was present in the urine of 71.6% of the general population, suggesting that almost 112 million individuals age 12 to 74 years had been exposed to PCP (Kutz et al. 1992).

In humans, illnesses and deaths have been reported after exposure to PCP through diet or by direct contact with PCP-treated products (Prescott et al. 1982). For example, 20 of 80 infants who wore, for 8 days, diapers rinsed in an antimicrobial laundry neutralizer containing sodium pentachlorophenate developed enlarged livers and spleens, had high fevers, and sweated profusely. Although most recovered spontaneously, seven died (Knudsen et al. 1974; USEPA 1980). At least 24 industrial PCP fatalities have been reported. The first deaths occurred at a wood preservative plant in France in 1952. Others were recorded at a chemical factory in Japan in 1953, during herbicide spraying in Australia in 1956, at a sawmill in Indonesia in 1958, in South Africa in 1961, and in Canada and the United States in 1965 (Wood et al. 1983). The acute toxic action of PCP in humans and experimental animals is caused by the uncoupling of oxidative phosphorylation mechanisms, resulting in marked increases in metabolism (Murphy 1986).

Data are scarce on PCP effects on wildlife, although it is speculated that no wildlife losses should occur under normal PCP application conditions and that chronic toxicity would not be serious because PCP is rapidly excreted (Bevenue and Beckman 1967). However, mortality was

heavy in two species of bats that came into contact with PCP-treated timbers up to 14 months after treatment (Leeuwangh and Voute 1985; Racey and Swift 1986). Wood preservatives, including PCP, are implicated in the decline of the bat population in the United Kingdom (Chadwick and Reston 1993). Furthermore, evidence accumulating on the harmful effects of PCP to domestic animals suggests that the chemical may have considerable adverse effects on other species of wildlife. In the poultry industry, for example, PCP has been implicated in the cause of musty taint in chicken meat and eggs and in increased morbidity in chickens housed on PCP-contaminated wood shavings or given PCP-contaminated food (Prescott et al. 1982).

Pentachlorophenol is repellent to animals. Diets containing PCP have been rejected by rats, cats, and cattle (Bevenue and Beckman 1967). In farm animals, PCP intoxication has increased as a result of confinement in buildings recently treated with a PCP wood preservative, and through dermal contact with PCP-treated fences and feed bunks (Osweiler et al. 1984). Dairy cattle contaminated by PCP produced less milk, grew poorly, and developed skin lesions (Firestone et al. 1979; Greichus et al. 1979; Parker et al. 1980). The issue is confounded by the presence of various amounts of toxic impurities — primarily dioxins and dibenzofurans — in technical and commercial preparations of PCP. These contaminants are mainly responsible for its observed toxicity in rabbits, rats, pigs, cattle, and chickens (Dougherty 1978; McConnell et al. 1980; Prescott et al. 1982). In one example in 1957, millions of chickens died in the southeastern United States after eating poultry feeds containing fat from hides preserved with PCP. Nine dioxins were detected in the toxic animal fat, including the potent 1,2,3,7,8,9-hexachlorodibenzo-*p*-dioxin isomer (Parker et al. 1980; Stedman et al. 1980; Prescott et al. 1982).

Useful reviews on the ecological and toxicological aspects of PCP have been published by Bevenue and Beckman (1967), Cote (1972), Rao (1978), USEPA (1980, 1986), Williams (1982), Choudhury et al. (1986), World Health Organization [WHO] (1987), Eisler (1989), and USPHS (1992, 1994).

23.2 ENVIRONMENTAL CHEMISTRY

23.2.1 General

Pentachlorophenol and its water-soluble salt, sodium pentachlorophenate, are used extensively in agriculture and industry. Most — about 80% — of the 50 million kg PCP manufactured each year is used in the protection and preservation of wood products. Commercial samples of technical-grade PCP are heavily contaminated with many compounds, including chlorophenols, dioxins, dibenzofurans, hexachlorobenzene, and phenoxyphenols. The relative toxicities and accumulation potentials of some of these contaminants may exceed those of PCP by several orders of magnitude. Pentachlorophenol interferes with the production of high-energy phosphate compounds essential for cell respiration. In general, it readily degrades in the environment by photochemical, chemical, and microbiological processes.

23.2.2 Sources and Uses

In the United States, PCP is one of the most heavily used compounds and is found in all environmental media as a result of its past widespread use. In addition, a number of other chemicals are known to be metabolized to PCP, including hexachlorobenzene, pentachlorobenzene, and benzenehexachloride isomers (Rugman and Cosstick 1990; van Raaij et al. 1991b; USPHS 1994). Although PCP was first synthesized in 1841, it was not produced commercially until 1936 (Wood et al. 1983; Menzer and Nelson 1986). It has since been registered for use as an insecticide, fungicide, herbicide, algicide, and disinfectant, and as an ingredient in antifouling paint; at least

578 products contain PCP (Cote 1972; Cirelli 1978; Choudhury et al. 1986; Murphy 1986). By 1967, PCP and its sodium salt, sodium pentachlorophenate (Na-PCP), were used extensively in industry and agriculture, due in large part to the solubility of PCP in organic solvents and of Na-PCP in water (Bevenue and Beckman 1967; Cirelli 1978). The major commercial application of technical-grade preparations of PCP is in wood preservation formulations, where its fungicidal and bactericidal actions inhibit the growth of wood-destroying organisms (Kinzell et al. 1981; USPHS 1994).

In the United States, about 80% of the 23 million kg of technical PCP produced annually — or about 46% of worldwide production — is used mainly for wood preservation, especially utility poles (Pignatello et al. 1983; Kinzell et al. 1985; Zischke et al. 1985; Choudhury et al. 1986; Mikesell and Boyd 1986; USPHS 1994). It is the third most heavily used pesticide, preceded only by the herbicides atrazine and alachlor (Kinzell et al. 1981). Pentachlorophenol is a restricted-use pesticide and is no longer available for home use (USPHS 1994). Before it became a restricted-use pesticide, annual environmental releases of PCP from production and use were 0.6 million kg to the atmosphere from wood preservation plants and cooling towers, 0.9 million kg to land from wood preservation use, and 17,000 kg to aquatic ecosystems in runoff waters of wood treatment plants (USPHS 1994). There are about 470 wood preservative facilities in the United States, scattered among 45 states. They are concentrated in the South, Southeast, and Northwest — presumably due to the availability of preferred timber species in those regions (Cirelli 1978). Livestock facilities are often constructed of wood treated with technical PCP; about 50% of all dairy farms in Michigan used PCP-treated wood in the construction of various components of livestock facilities (Kinzell et al. 1985). The chemical is usually applied to wood products after dilution to 5% with solvents such as mineral spirits, No. 2 fuel oil, or kerosene. More than 98% of all wood processed is treated with preservative under pressure; about 0.23 kg of PCP is needed to preserve 1 cubic foot of wood (Cirelli 1978). Lumber treated with PCP retains its natural appearance, has little or no odor, and can be painted as readily as natural wood (Wood et al. 1983).

In addition to its extensive use by the construction and lumber industries to control damage by mold, termites, powder post beetles, and wood-boring insects (Bevenue and Beckman 1967), PCP has been used as a bactericide and fungicide to protect many products, such as adhesives, paper and paperboard, cable coverings, leather, paints, textiles, rope, ink, rubber, and petroleum drilling muds (Bevenue and Beckman 1967; Firestone et al. 1979; Williams 1982). It has been used to control algae and fungi in cooling towers at electric plants (Williams 1982). It has also been added to fabrics for moth-proofing, although derivatives such as pentachlorophenol laurate are more widely used for this purpose because their resistance to dry cleaning and washing exceeds that of PCP, and their toxicity to mammals is lower (Bevenue and Beckman 1967). It has been applied in agriculture and around industrial sites as an herbicide and preharvest desiccant, on pastureland, and in pineapple, rice, and sugarcane fields (Bevenue and Beckman 1967). A Japanese manufacturer added PCP to soy sauce — in violation of the law — as a preservative (Bevenue and Beckman 1967). It has also been used as a bird repellent: PCP discourages woodpeckers when it is mixed as a pellet and plugged into holes drilled by the bird (Cirelli 1978).

In Canada, the main use of PCP is in the protection and preservation of wood, and secondarily as an herbicide and insecticide for agricultural purposes. A total of 50 wood preserving plants — mostly in British Columbia, Alberta, and Ontario — used about 2.7 million kg PCP in 1978 (Hoos 1978). Treatment with PCP significantly increased the life of timbers, construction lumber, telephone poles, and railway ties. For example, jackpine poles treated with PCP lasted at least 35 years, compared to 7 years for untreated poles (Hoos 1978). Sodium pentachlorophenate has been used to control schistosomiasis by eliminating snails that are intermediate hosts of human schistosomes (Bevenue and Beckman 1967). It is also used as a fungicide, bactericide, and algicide in construction materials, emulsion polymers, paints, textiles, and finished paper products; as a preservative for ammonium alginate; and at concentrations of 15 to 40 mg/L, to control microbial growth in secondary oil recovery (Bevenue and Beckman 1967; Cirelli 1978).

23.2.3 Properties

Pentachlorophenol is readily soluble in most organic solvents, oils, and highly aromatic and olefinic petroleum hydrocarbons — a property that makes it compatible for inclusion in many pesticide formulations (Table 23.1; Figure 23.1). Purified PCP, however, is practically insoluble in water; therefore, the readily water-soluble sodium pentachlorophenate salt is substituted in many industrial applications (Table 23.1) (Beveneu and Beckman 1967; USPHS 1994).

The solubility of sodium and potassium pentachlorophenolate in water is pH dependent; it increases from 79 mg/L at pH 5.0 to >4 g/L at pH 8.0 (Beveneu and Beckman 1967). But the differential toxicity of PCP in solution is primarily attributable to variations in uptake as a function

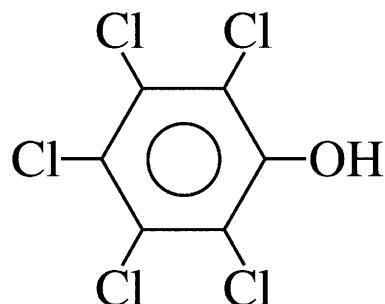

Figure 23.1 Structural formula of pentachlorophenol.

Table 23.1 Chemical and Other Properties of Pentachlorophenol

Variable	Datum
Chemical name	Pentachlorophenol
CAS Number	87-86-5
Alternate names	Chem-Penta, Chemtrol, Chlorophen, Dow Pentachlorophenol, Dowicide 7, Dowicide EC-7, Dowicide G, DP-2, Durotox, Lauxtol A, Ontrack WE-1, PCP, Penchlorol, Penta, 2,3,4,5,6-pentachlorophenol, Penta General Weed Killer, Petacon, Penta-kil, Pentanol, Pentasol, Penwar, Permacide, Permaguard, Permasem, Permatox, Prilox, Santobrite, Santophen, Sinituho, Term-I-trol, Weed-Beads, Weedone
Primary uses	Wood preservative, preharvest defoliant, herbicide, molluscicide, insecticide, fungicide
Producers	Dow Chemical Company, Monsanto Company, Reichold Chemical Company, Vulcan Materials Company
Empirical formula	C_6Cl_5OH
Physical state	White solid with needle-like crystals. Produced by chlorination of molten phenol. Technical-grade material is dark gray to brown
Molecular weight	266.35
Melting point	190–191°C
Boiling point	309–310°C (decomposes)
Specific gravity	1.978 g/mL at 22°C
Vapor pressure	
25°C	0.0016 mmHg
100°C	0.02 mmHg
211°C	40.0 mmHg
Solubility	
Water	
0°C	5 mg/L
20°C	14 mg/L
30°C	20 mg/L
50°C	35 mg/L
Carbon tetrachloride	20–30 g/L
Benzene	110–140 g/L
Ethanol	470–520 g/L
Methanol	570–650 g/L
Solubility of sodium salt (sodium pentachlorophenate, CAS 131–52-2) in water at 25°C	330 g/L
Log K_{ow} (octanol/water partition coefficient)	5.01–5.12

Data from Beveneu and Beckman 1967; Cote 1972; Cirelli 1978; USEPA 1980; Williams 1982; Hudson et al. 1984; Choudhury et al. 1986; Hill and Camardese 1986; Mayer 1987; USPHS 1994.

of pH (Jayaweera et al. 1982; Kaiser and Valdmanis 1982; Fisher and Wadleigh 1986; Smith et al. 1987), and not to water solubility. At pH 4.0, for example, PCP is fully protonated and therefore highly lipophilic, and has its greatest accumulation potential. Conversely, PCP is completely ionized at pH 9.0; lipophilicity is markedly reduced, as is its toxicity to the alga *Selenastrum capricornutum* (Jayaweera et al. 1982; Smith et al. 1987) and the midge *Chironomus riparius* (Fisher and Wadleigh 1986).

In recent years, it has become clear that many commercial samples of technical-grade PCP are heavily contaminated with a large number of potentially toxic compounds and materials (Figure 23.2) (Table 23.2). These contaminants include, in part, various isomers of chlorophenols, dibenzofurans, dioxins, hexachlorobenzene, and phenoxyphenols (Table 23.2), as well as various chlorinated diphenyl ethers, dihydroxybiphenyls, anisoles, catechols, guaiacols, and other chlorinated dibenzodioxin and dibenzofuran isomers (Kaufman 1978; Nilsson et al. 1978; Firestone et al. 1979; USEPA 1980; Singh et al. 1985; Menzer and Nelson 1986; Mikesell and Boyd 1986; Murphy 1986; Holsapple et al. 1987). In relative toxicity and accumulation potential, some contaminants in technical-grade PCP may exceed the parent compound by several orders of magnitude (Huckins and Petty 1981). For example, some isomers of hexachlorodibenzodioxin, which are present in technical-grade PCP at concentrations of 1000 to 17,300 µg/kg (Table 23.2), produce LD₅₀ values in guinea pigs of 60 to 100 µg/kg body weight — thus ranking them as extremely toxic chemicals (Eisler 1986; Murphy 1986).

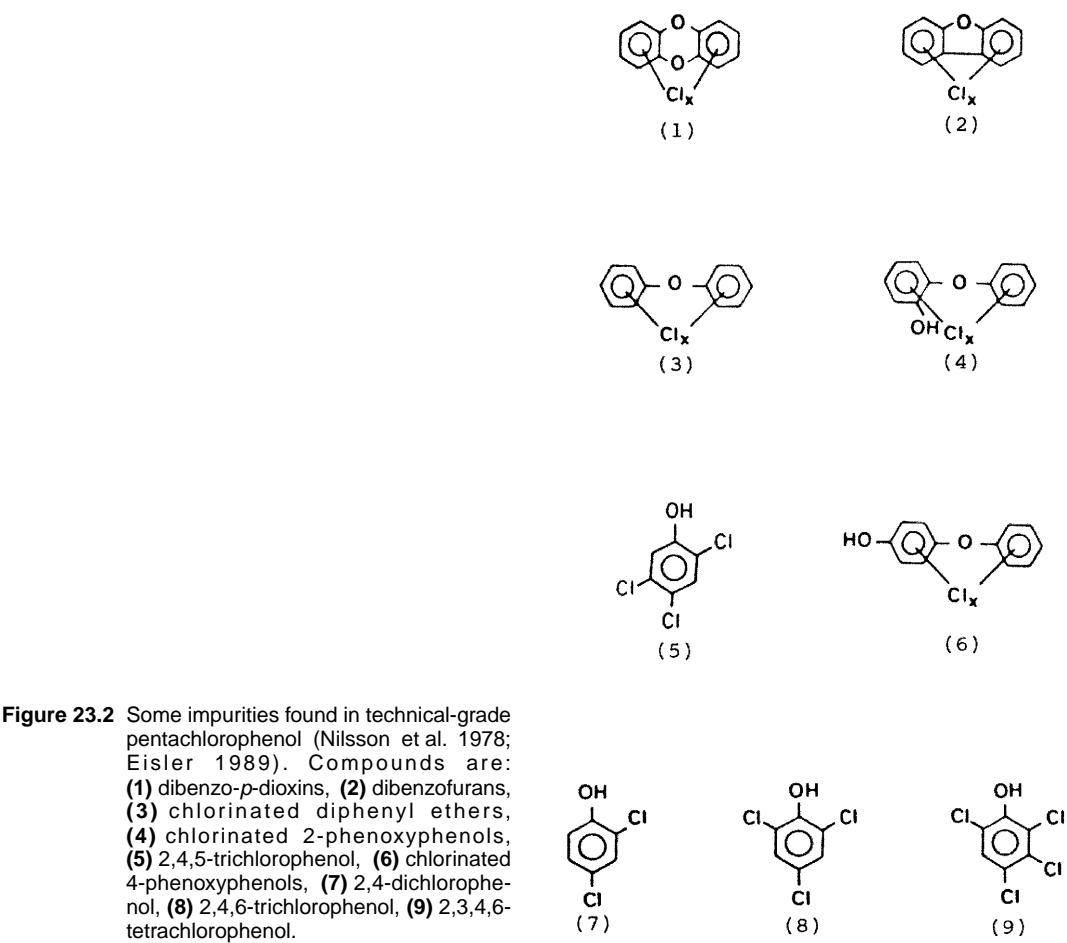

Table 23.2 Partial List of Contaminants Detected in Technical-Grade and Purified Pentachlorophenol (All values are in mg contaminant/kg product [ppm].)

Contaminant	Grade and Concentration (% PCP)			Reference

23.2.4 Fate

Pentachlorophenol can be absorbed into the body through inhalation, diet, or skin contact (Bevenue and Beckman 1967; Williams 1982; Gray et al. 1985). PCP residues in blood serum, adipose tissue, and urine are useful biomarkers of PCP exposure (USPHS 1994). Its acute toxicity results from its ability to interfere with the production of high-energy phosphate compounds essential for cell respiration. This interference, or uncoupling, causes stimulation of the cell's metabolism to the toxic stage, which is accompanied by fever and other signs of stress (Bevenue and Beckman 1967; Hodson and Blunt 1981; Williams 1982; USPHS 1994). The metabolic consequences resemble those of vigorous exercise in some species (Hodson and Blunt 1981). In addition to the proven uncoupling effects on oxidative phosphorylation, the overall inhibitory effects on a variety of enzymes, metabolism of lipids and carbohydrates, ion transport, and protein synthesis may account for the broad-spectrum biocidal effects of PCP and its salts (Rao et al. 1979; Gray et al. 1985; Smith et al. 1987; Renner and Hopfer 1991).

Pentachlorophenol is fetotoxic and teratogenic during early gestation; however, evidence of its mutagenic or carcinogenic properties is incomplete (Williams 1982). PCP is not mutagenic in bacteria or *Drosophila*, but positive mutagenicity was reported in yeast and in mice, indicating a need for additional research (USPHS 1994). Tetrachlorohydroquinone (TCHQ), a major metabolite of PCP, can induce mutations in Chinese hamster cells through formation of reactive oxygen species (Jansson and Jansson 1991). PCP was carcinogenic in the B6C3F1 mouse strain (Reigner et al. 1992b). Purified PCP fed to mice in chronic dietary studies was carcinogenic (USPHS 1994). Human case histories suggest a possible association with occupational exposure to technical PCP and cancer — including Hodgkin's disease, soft tissue sarcoma, acute leukemia — but no convincing epidemiological evidence exists to indicate that inhalation of PCP in any form produces cancer in humans. Nevertheless, the International Agency for Research on Cancer has assigned pentachlorophenol a Group 2B classification, indicating that PCP is possibly carcinogenic in humans (USPHS 1994).

Pentachlorophenol readily degrades in the environment by chemical, microbiological, and photochemical processes (Kaufman 1978; Choudhury et al. 1986; Seech et al. 1991; Rutgers et al. 1998). Its suggested metabolic fates include oxidation and dechlorination to tri- and tetrachloro-*p*-hydroquinones, and glucuronide conjugation to PCP- and tetrachloro-*p*-hydroquinone conjugates (Williams 1982; Stehly and Hayton 1988; Renner and Hopfer 1990; Reigner et al. 1991, 1992a). In soils, reductive dehalogenation appears to be the most significant PCP degradation pathway, producing mono-, di-, tri-, and tetrachlorophenols, as well as various tetrachlorocatechols and tetrachlorohydroquinones. Further degradation results in ring cleavage, liberation of chloride, and carbon dioxide evolution; degradation is more rapid in flooded or anaerobic soils than in aerobic moist soils (Kaufman 1978). Irradiation of PCP solutions with sunlight or ultraviolet light produces photodegradation products that include chlorinated phenols, tetrachlorodihydroxyl benzenes, and nonaromatic fragments such as dichloromaleic acid (Wong and Crosby 1978; USEPA 1980). Subsequent irradiation of the tetrachlorodiols produces hydroxylated trichlorobenzoquinones, trichlorodiols, dichloromaleic acid, and nonaromatic fragments (Wong and Crosby 1978; Boyle et al. 1980). Prolonged irradiation of PCP or its degradation products yielded colorless solutions containing no ether-extractable volatile materials; evaporation of the aqueous layer left no observable polymeric residue (Wong and Crosby 1978). Photolytic condensation of PCP to form octachlorodioxins was observed on a wood substrate. Octachlorodioxin residues ranged from 4 mg/kg for purified PCP, to about 1500 mg/kg for technical-grade PCP (Lamparski et al. 1980).

Pentachlorophenol can be degraded by microbial flora, both aerobically and anaerobically. Degradation is more rapid under aerobic conditions but slows significantly at temperatures <19°C (Pignatello et al. 1985, 1986). Several strains of aerobic bacteria can metabolize and degrade PCP: *Flavobacterium* sp., a pseudomonad, a coryneform bacterium, and a strain of *Arthrobacter* (Pignatello et al. 1983; Mikesell and Boyd 1986; Steiert and Crawford 1986; Steiert et al. 1987; Seech et al. 1991; Rutgers et al. 1998). Microbial degradation under aerobic or anaerobic conditions was the major process by which PCP was degraded in estuarine sediments; tidal transport and photodegradation played minor roles (DeLaune et al. 1983). The biotic process requires a moderately long adaptive response by the aquatic microflora, but eventually becomes the predominant mechanism of PCP removal (Pignatello et al. 1983, 1985). Several significant observations were recorded when the degradation and transformation of PCP were documented in freshwater streams continuously dosed with PCP for 16 weeks (Pignatello et al. 1983):

- Photolysis accounted for a 5 to 28% decline in initial PCP concentrations and was most rapid at the water surface under conditions of bright sunlight
- Adsorption to sediments and uptake by biota accounted for less than 5% loss in acclimated waters and probably less than 15% in unacclimatized waters
- Microbial degradation of PCP became significant about 3 weeks after dosing and eventually became the primary mechanism of PCP removal, accounting for up to a 46% decline in initial PCP.

A Gram-negative bacterium, *Pseudomonas* sp. strain SR3, can degrade PCP from 39 to 40 mg PCP/L (a concentration lethal to many species of aquatic organisms) to a nonlethal 0.0006 mg PCP/L within 5 days (Middaugh et al. 1993). However, biodegraded PCP may still be environmentally hazardous. Bioassays with embryonic inland silversides (*Menidia beryllina*) showed that the bio-degraded PCP samples were embryotoxic or teratogenic, suggesting that toxic intermediate metabolites were present (Middaugh et al. 1993).

The half-life (T_b 1/2) of PCP in water ranged from 0.15 to 1.5 days; degradation was most rapid under conditions of high incident radiation, high dissolved oxygen, and elevated pH (Bevene and Beckman 1967; Wong and Crosby 1978; Boyle et al. 1980; Niimi and Cho 1983; Crossland and Wolff 1985; Smith et al. 1987). The T_b 1/2 in the water column controlled by microbial degradation alone is usually 5 to 12 h (Pignatello et al. 1986). Pentachlorophenol solutions in water at the appropriate pH and dissolved oxygen content decompose in sunlight, and this makes a strong case for the likelihood of essentially total PCP destruction in aquatic environments (Wong and Crosby 1978). The short residence time of PCP in an aquatic system before degradation further suggests that biological effects would be most pronounced in localized areas that continuously receive PCP from a point source (Niimi and Cho 1983). Technical-grade PCP was initially degraded at the same rate as reagent-grade PCP by anaerobic microorganisms in municipal sewage sludge, but was later degraded more slowly. Dechlorination and mineralization (to carbon dioxide and methane) of the reagent-grade PCP was complete in 7 to 9 days, but only half the technical-grade PCP had been transformed in 6 to 10 days (Mikesell and Boyd 1986). At nontoxic concentrations, PCP was readily biodegradable in activated sludge after an adaptation period of 10 to 20 days. Preexposure of activated sludge to PCP drastically eliminated the acclimatization period and increased the tolerance of the sludge to PCP toxicity (Ingerslev et al. 1998).

In soils, PCP persisted for 15 to more than 60 days, depending on soil conditions and application rate. At initial concentrations of 100 mg PCP/kg soil, the T_b 1/2 was 10 to 40 days at 30°C under flooded conditions. However, in aerobic soils there was virtually no degradation after 2 months (Kaufman 1978). In rice paddy soils, initial concentrations of 4 mg PCP/kg fell to 2 mg/kg in 7 days (Bevene and Beckman 1967). Pentachlorophenol was still measurable after 12 months in warm, moist soils (Cote 1972; USEPA 1980). In estuarine sediments, degradation was most rapid under conditions of increased oxygen and a pH of 8.0 (DeLaune et al. 1983).

A variety of analytical techniques are used to measure PCP, including gas chromatography–mass spectrometry (GC–MS), which has a detection limit of 7.6 µg/kg honey (Muino and Luzano 1991), liquid chromatography with fluorescence detection (de Ruiter et al. 1990), and liquid chromatography–electrochemistry (LC–ED) procedures (Butler and Pont 1992). At present, GC–MS is the most accurate, but LC–ED is used most frequently (Butler and Pont 1992).

23.3 CONCENTRATIONS IN FIELD COLLECTIONS

23.3.1 General

Measurable PCP concentrations in field collections of living and nonliving materials over widespread geographic areas are almost certainly due to anthropogenic activities, especially to the use of the chemical as a wood preservative.

23.3.2 Biological and Nonbiological Samples

Pentachlorophenol-contaminated air, rain, snow, surface waters, drinking waters, groundwaters, and aquatic biota are common in the United States (Table 23.3) (Pignatello et al. 1983; Choudhury et al. 1986). Residues of PCP in food, water, and mammalian tissues may result from the direct use of PCP as a wood preservative and pesticide, or as a result of the use of other chemicals that

form PCP as degradation products (i.e., hexachlorobenzene and lindane) (USEPA 1980; Choudhury et al. 1986). To confound matters, PCP was judged to be the source of dioxin and dibenzofuran contamination in chickens in Canada (Ryan et al. 1985). More than 50% of all chickens sampled contained hexachlorinated dibenzo-*p*-dioxins (hexa-CDDs) at concentrations of 27 ng/kg fat and higher; 62% contained hepta-CDDs at more than 52 ng/kg, and 46% contained octa-CDDs at more than 90 ng/kg; concentrations of hexa- and heptachlorinated dibenzofurans were similar.

Pentachlorophenol was found at high concentrations in all samples of sediments, waters, and biota collected near industrial facilities that used PCP as a wood preservative (Niimi and Cho 1983; Oikari and Kukkonen 1988) (Table 23.3). Fish can bioconcentrate PCP from water up to 10,000 times (Fox and Joshi 1984). However, similar concentrations were measured in blue mussel, *Mytilus edulis* (Folke and Birklund 1986), and softshell clam, *Mya arenaria* (Butte et al. 1985), from the vicinity of PCP-contaminated wastewater discharges as well as from more distant collection sites. Thus, PCP bioaccumulation in marine bivalve molluscs does not appear to be dose related.

Pentachlorophenol in terrestrial ecosystems clears rapidly (Haque et al. 1988). In one case, a terrestrial ecosystem was given a single surface application of radiolabeled PCP equivalent to 5 kg sodium pentachlorophenate/ha. PCP residues on foliage decreased rapidly, with 50% metabolized within 15 days. After 131 days (autumn), most of the remaining PCP was in the topsoil and plant litter. After 222 days (winter), 39% of the radiocarbon remained. There was little bioconcentration in the resident fauna, due to rapid metabolism and excretion (Haque et al. 1988).

There are differences between the United States, Germany, and the United Kingdom in human intake and absorption of PCP. In the United Kingdom, the typical nonoccupationally exposed individual has a total daily intake of 5.7 µg PCP, of which 4.5 µg is absorbed (Wild and Jones 1992). Most of the PCP (92%) comes from the diet, 1% via inhalation, and the rest from drinking water. Occupationally-exposed individuals in the U.K. absorb 21.2 µg daily from an intake of 39 µg daily; most of the PCP (78.8%) in this group is via inhalation and only 19.6% from the diet (Wild and Jones 1992). In Germany, the main route of PCP uptake by nonoccupationally exposed humans is by ingestion of contaminated food, including drinking water, fish, sugar, pork, chicken, and other foodstuffs (Geyer et al. 1987). The chickens and pigs were contaminated by PCP because they were reared on PCP-treated wooden floors. The average German diet contains 13.9 (2.7 to 27.6) µg PCP/kg ration. The total amount of PCP in an average nonoccupationally exposed German citizen (weight 65 kg, age 45 years) is about 532 µg: 204 µg in body fat, 143 µg in liver, 103 µg in blood, 63 µg in brain, 14 µg in kidneys, 4 µg in spleen, and about 1.6 µg in urine in bladder (Geyer et al. 1987). In the United States, it was estimated that the long-term average daily intake of PCP by humans is 16 µg (Hattemer-Frey and Travis 1989), and this is in good agreement with the value of Geyer (1987). However, the source of PCP in that study was attributed almost exclusively (99.9%) to fruits, vegetables, grains, and other crops grown in PCP-contaminated soils. PCP concentrations in U.S. citizens were usually higher in adipose tissues than in nonfatty tissues, and between the ages of 22 and 75 will increase by a factor of at least 2 (Wagner et al. 1991).

23.4 EFFECTS

23.4.1 General

The toxicity of commercial or technical grades of PCP significantly exceeds that of analytical or purified PCP. Some of this added toxicity is attributed to impurities such as dioxins, dibenzofurans, chlorophenols, and hexachlorobenzene. Pentachlorophenol is rapidly accumulated and rapidly excreted, and has little tendency to persist in living organisms. It acts by uncoupling oxidative

phosphorylation. Terrestrial plants and soil invertebrates were adversely affected at 0.3 mg PCP/L (root growth), and at 1 to 5 g PCP/m² soil (reduction in soil biota populations).

Pentachlorophenol was most toxic and most rapidly metabolized in aquatic environments at elevated temperatures and reduced pH. Adverse effects on growth, survival, and reproduction of representative sensitive species of aquatic organisms occurred at PCP concentrations of about 8 to 80 µg/L for algae and macrophytes, about 3 to 100 µg/L for invertebrates (especially molluscs), and <1 to 68 µg/L for fishes, especially salmonids. Fatal PCP doses for birds were 380 to 504 mg/kg BW (acute oral), >3850 mg/kg in diets, and >285 mg/kg in nesting materials. Adverse sublethal effects were noted at dietary levels as low as 1.0 mg/kg ration. Residues (mg/kg fresh weight) in birds found dead from PCP poisoning were >11 in brain, >20 in kidney, >46 in liver, and 50 to 100 in egg.

Data are scarce on the toxicity of PCP to mammalian wildlife, but studies with livestock and small laboratory animals show that the chemical is rapidly excreted. However, there is great variability between species in their ability to depurate PCP, as well as in their overall sensitivity. Acute oral LD₅₀ values in laboratory animals were 27 to 300 mg/kg BW. Tissue residues were elevated at dietary levels as low as 0.05 mg/kg feed and at air levels >0.1 mg/m³. Histopathology, reproductive impairment, and retarded growth were evident at doses of 0.2 to 1.25 mg/kg BW, and when the diets fed contained >30 mg PCP/kg.

23.4.2 Terrestrial Plants and Invertebrates

Pentachlorophenol is toxic to plant mitochondria; the mode of action is similar to that in other organisms (i.e., uncoupling of oxidative phosphorylation). At 267 µg PCP/L, 50% uncoupling was noted in isolated mitochondria of potato, *Solanum tuberosum*, and mung bean, *Phaseolus aureus* (Ravanel and Tissut 1986). Both PCP and its metabolite tetrachlorohydroquinone adversely affect cell growth and synthesis of RNA and ribosome in yeast, *Saccharomyces* sp., in a dose-related manner (Ehrlich et al. 1987). Uptake of PCP by rice (*Oryza sativa*) grown over a 2-year period under flooded conditions was studied after a single application of radiolabeled PCP was applied to the soil at 23 kg/ha (Weiss et al. 1982). During the first year, PCP uptake was 12.9% of the application. Roots contained about 5 mg PCP/kg, distributed as follows (mg/kg): 3.95 as unextractable residues, 0.48 as polar nonhydrolyzable substances, 0.43 as free and conjugated lower chlorinated phenols, 0.14 as free PCP, 0.07 as anisoles, 0.06 as conjugated PCP, 0.03 as hydroxymonomethoxytetrachlorobenzenes, and 0.01 as dimethoxytetrachlorobenzenes. In the second year, PCP uptake was reduced to 2.5%, and soil residues corresponded to 8.4 kg/ha; the amounts of unextractable residues in plants increased, and lower chlorinated conjugated phenols were identified (Weiss et al. 1982). Root growth in rice seedlings was inhibited 50% at 0.3 mg PCP/L (Nagasawa et al. 1981).

Laboratory studies with adult earthworms (*Lumbricus terrestris*) exposed for 96 h to filter paper containing 5 to 50 µg PCP/cm² were conducted by Giggelman et al. (1998). The LC₅₀ (96 h) concentration was 25 µg PCP/cm² filter paper; the LD₅₀ (96 h) value was 878 mg PCP/kg DW whole worm. At 10 µg PCP/cm², all worms survived for 96 h with an average whole-body concentration of 501 mg PCP/kg DW. At 20 µg PCP/cm², 20% died and survivors had 804 mg/kg DW. At 35 µg PCP/cm², none survived 96 h; dead worms had approximately 1060 mg PCP/kg DW.

Pentachlorophenol applied to beech forest soils every 2 months for 2 years at the rate of 1.0 g/m² markedly reduced populations of soil organisms. At 5.0 g/m², it drastically reduced most of the soil animal species and also the microflora (Zietz et al. 1987). Reduction of the soil metabolism by PCP retards decomposition and affects the overall nutrient balance of forest ecosystems (Zietz et al. 1987). Pentachlorophenol is more toxic to earthworms in soils with comparatively low levels of organic materials. The LC₅₀ (14-day) value for *Lumbricus rubellus* was 1094 mg PCP/kg DW soils with 6.1% organic matter, and 883 mg/kg DW soils with 3.7% organic matter (Van Gestel and Ma 1988). The earthworm *Eisenia fetida andrei* is more sensitive than *Lumbricus rubellus*;

the LC50 (14-day) values were 143 mg/kg DW for soils containing 6.1% organic matter, and 94 mg/kg DW for soils of 3.7% organic matter. Both species accumulated similar concentrations of PCP (Van Gestel and Ma 1988). Other studies with earthworms (*Allolobophora caliginosa*, *Lumbricus terrestris*) demonstrated differences between species in sensitivity to PCP, differences in PCP accumulation rates, and rapid metabolism of sodium-PCP when compared to PCP (Haque and Ebing 1988).

23.4.3 Aquatic Biota

In general, the most sensitive stages are embryo and larval stages of invertebrates and the late larval premetamorphosis stage of fish; fish are more sensitive to PCP than invertebrates (USEPA 1986). Pentachlorophenol affects energy metabolism by partly uncoupling oxidative phosphorylation and increasing oxygen consumption, by altering the activities of several glycolytic enzymes and the citric acid cycle enzymes, and by increasing the consumption rate of stored lipid (Johansen et al. 1985; Brown et al. 1987; McKim et al. 1987). Collectively, these events could reduce the availability of energy for maintenance and growth and thereby reduce the survival of larval fish and the ability of prey to escape from a predator (Brown et al. 1985, 1987; Hodson et al. 1991; Samis et al. 1993, 1994). Pentachlorophenol has a dose-dependent inhibitory effect on chemiluminescence activity of isolated phagocyte cells of the Japanese medaka (*Oryzias latipes*) (Anderson and Brubacher 1992), and the mummichog (*Fundulus heteroclitus*) (Roszell and Anderson 1993). Since chemiluminescence is due to the production of reactive oxygen intermediates (ROIs), such as superoxide anion (O_2^-) and H_2O_2 , suppression of ROI may adversely affect the teleost immune system (Roszell and Anderson 1993).

The accumulation of PCP in fishes is rapid, and primarily by direct uptake from water rather than through the food chain or diet (Niimi and Cho 1983). Signs of PCP intoxication in fish include rapid swimming at the surface and increased opercular movements, followed by loss of balance, settling to the bottom, and death (Holmberg et al. 1972; Gupta 1983). PCP is rapidly excreted by fishes after conjugates of PCP-glucuronide and PCP-sulfate are formed; half-lives in tissues are less than 24 h (USEPA 1980; Makela et al. 1991; Cravedi et al. 1995). Major roles were played by gall bladder and bile in PCP-glucuronide depuration kinetics, and by gill in PCP-sulfate depuration (Kobayashi 1978; Lech et al. 1978; McKim et al. 1986). It has been suggested that the efficient elimination of PCP should allow vertebrates to tolerate periodic low doses of PCP without toxic effects (McKim et al. 1986).

Many species of aquatic organisms were found dead in rice fields of Surinam, South America, after they were sprayed with PCP to control populations of snails (Vermeer et al. 1974). Residues of PCP in dead organisms (mg PCP/kg fresh body weight) were 8.1 in frogs (*Pseudis paradoxa*); 36.8 in snails (*Pomacea* spp.); and, in three species of fish, 31.2 in krobia (*Cichlasoma bimaculatum*), 41.6 in kwi kwi (*Hoplosternum littorale*), and 59.4 in srieba (*Astyanax bimaculatus*). Pentachlorophenol was also implicated in fish kills in Europe and North America, all of which were associated with the pulpwood industry (Schimmel et al. 1978). In December 1974, near Hattiesburg, Mississippi, water containing PCP in fuel oil that overflowed the banks of a holding pond of a wood-treatment wastewater facility killed all fish in a 24-ha lake. Concentrations of PCP in water and fish returned to background concentrations 10 months after the spill. However, the chemical persisted in leaf litter and sediments for at least 17 months after the spill (Pierce and Victor 1978). In December 1976, another fish kill was observed near the same facility. Residues of PCP in surviving fish — including bluegills (*Lepomis macrochirus*), largemouth bass (*Micropterus salmoides*), and channel catfish (*Ictalurus punctatus*) — were greatly elevated 1 month later: 8 to 19 mg PCP/kg fresh weight in muscle, 42 to 48 mg/kg in gill, and 130 to 221 mg/kg in liver (Pierce and Victor 1978). Pentachlorophenol persisted in fish for 6 to 10 months before reaching background concentrations.

Studies with experimental ecosystems have indicated that the effects of PCP on community structure and activity are profound. These included a reduction in the number of individuals and species of estuarine macrobenthos after exposure to 55 to 76 µg PCP/L for 5 to 9 weeks (Tagatz et al. 1977, 1983) or 15.8 µg/L for 13 weeks (Tagatz et al. 1978); a decrease in periphyton biomass, fish growth, and larval drift, and a suppression of community metabolism at 48 µg PCP/L after 3-months' exposure (Hedtke and Arthur 1985; Zischke et al. 1985; Yount and Richter 1986); elevated levels of PCP in postlarval shrimp, *Penaeus vannamei*, after chronic exposure to 10 µg PCP/L (Seidler et al. 1986); and bioconcentration factors after exposure to radiolabeled PCP of 5 for an alga (*Oedogonium cardiacum*), 21 for a snail (*Physa* sp.), 26 for a mosquito larva (*Culex pipiens quinquefasciatus*), 132 for mosquitofish (*Gambusia affinis*), and 205 for *Daphnia magna* (Lu et al. 1978). In laboratory studies, increased accumulation and adverse effects on growth, survival, and reproduction were seen in sensitive species of aquatic organisms: in algae and macrophytes at water concentrations (µg PCP/L) of 7.5 to 80; in a wide variety of invertebrates, especially molluscs, at 2.5 to 100; and in fishes, especially salmonids, at less than 1.0 to 68 (Table 23.4).

Biocidal properties of PCP were significantly modified by water pH, dissolved oxygen, salinity, and temperature, and by the purity of PCP compounds tested. In general, PCP was most toxic and was metabolized most rapidly at elevated water temperatures (USEPA 1980, 1986; Hodson and Blunt 1981; Niimi and Palazzo 1985; Fisher 1986), reduced pH (Bevenue and Beckman 1967; USEPA 1980, 1986; Dave 1984; Choudhury et al. 1986; Fisher 1986; Seidler et al. 1986; Larsson et al. 1993), and decreased dissolved oxygen (USEPA 1986). Increasing the pH of the water column decreases the hazard of PCP to aquatic biota: at pH values above 4.8, for example, hydroxyl proton is dissociated and penetration in aquatic organisms is reduced (Fisher 1986; Rutgers et al. 1998). In studies with goldfish (*Carassius auratus*) exposed to 5 µg PCP/L for 96 h, a pH increase from 7 to 9 resulted in lesser amounts of PCP in the fish, fewer metabolites formed, and a decreased ability to deplete the PCP from the exposure water; the uptake of PCP at pH 7, 8, and 9 seemed to be controlled by its K_{ow} at these pH values (Stehly and Hayton 1990). Water salinity affects PCP accumulations in euryhaline teleosts. In the Japanese medaka (*Oryzias latipes*), for example, increasing salinity was associated with decreased PCP uptake rates and increased clearance rates; the greater excretion of PCP-glucuronide by seawater-adapted medakas may be responsible for the rapid elimination of PCP (Tachikawa et al. 1991; Tachikawa and Sawamura 1994). All authorities agree that commercial or technical grades of PCP are significantly more toxic to aquatic organisms than is purified PCP (USEPA 1980; Cleveland et al. 1982; Huckins and Petty 1983; Dominguez and Chapman 1984; Stuart and Robinson 1985; Hamilton et al. 1986; Nagler et al. 1986). The sublethal effects of low concentrations of commercial PCP to aquatic biota are due primarily to impurities, composed mostly of octa- and nonachlorophenoxyphenols (Hamilton et al. 1986), and also to relatively large quantities of hexachlorobenzene, dioxins, and dibenzofurans (Cleveland et al. 1982).

Salicylamide and PCP dose are important. Salicylamide is an inhibitor of PCP metabolism in fry of rainbow trout, producing elevated BCF values. Fry exposed to 5 µg PCP/L for 96 h in the presence of 25 mg salicylamide/L had higher concentrations of PCP than did fry exposed without salicylamide (Stehly and Hayton 1989). Bluegills exposed to PCP at continuous low-level sublethal concentrations were at greater risk for decreased growth than were bluegills exposed to a more concentrated short-term pulse of PCP resulting in some deaths (Samis et al. 1991). Fat content of diets of juvenile rainbow trout, however, were relatively unimportant in PCP acute toxicity bioassays. Rainbow trout juveniles fed high-fat (21%) or low-fat (13%) diets for 11 weeks had similar LC50 (144 h) values (109 µg/L vs. 108 µg/L), although the high-fat group had 3% more body lipids than the low-fat group (van den Heuvel et al. 1991).

Table 23.4 Lethal and Sublethal Effects of Pentachlorophenol on Selected Species of Aquatic Organisms

Species and Other Variables	Concentration (g PCP/L medium)	Effect	Reference ^a
ALGAE AND MACROPHYTES			
Alga			
<i>Chlorella pyrenoidosa</i>	7.5	Total chlorosis inhibition in 72 h	1
<i>Skeletonema costatum</i>	17–20	50% reduction in cell numbers at 96 h	1
Filamentous algae (<i>Chara</i> sp., <i>Enteromorpha</i> sp.)	50–100	Lethal in 30 days in outdoor ponds; decay was responsible for depression of dissolved oxygen and later fish deaths	2
Alga, <i>Scenedesmus costatum</i>	80	50% growth inhibition in 96 h	2
<i>Selenastrum capricornutum</i>	110–150	50% growth reduction in 96 h in soft water	3
<i>S. capricornutum</i>	290	50% growth inhibition in 96 h	2
<i>S. capricornutum</i>	760	50% growth reduction in 96 h in hard water	3
<i>Dunaliella tertiolecta</i>	170–206	50% reduction in cell numbers in 96 h	1
<i>Thalassiosira pseudonana</i>	179–189	50% reduction in cell numbers in 96 h	1
Giant kelp, <i>Macrocystis pyrifera</i>	277	50% inhibition of photosynthetic activity in 4 days	70
Duckweed			
<i>Lemna minor</i>	800	50% inhibition of chlorosis in 48 h	1
<i>L. minor</i>	1000	Inhibition of photosynthetic oxygen production	5
<i>L. minor</i>	1400	No measurable effect after exposure for 21 days	4
INVERTEBRATES			
Duck mussel			
<i>Anodonta anatina</i>	0.5–1.0	Bioconcentration factor (ratio PCP in mg/kg FW soft tissues: PCP medium in mg/L) during 3-h exposure ranged between 81 and 162 and was independent of water temperature or PCP concentration	59
<i>A. anatina</i>	0.6–5.2	BCF values after 8 days at 13°C ranged between 263 and 461	59
American oyster			
<i>Crassostrea virginica</i>	2.5	Bioconcentration factor (BCF) of 78 in 28 days; 100% depuration within 4 days postexposure	6
<i>C. virginica</i>	25	BCF of 41 between days 4 and 28 of exposure; 100% depuration within 4 days postexposure	6
<i>C. virginica</i>	34	50% reduction in shell deposition in 8 days	1
<i>C. virginica</i>	40	50% abnormal development of larvae in 48 h	7
<i>C. virginica</i>	77	LC50 (96 h)	1
Cladoceran			
<i>Ceriodaphnia reticulata</i>	4.1	Reduction in number of young/female in lifetime exposure	4
<i>C. reticulata</i>	164	LC50 (48 h)	8
Polychaete worm			
<i>Ophryotrocha diadema</i>	10–13	No effect on reproduction in 41 days	8
<i>O. diadema</i>	23–75	50% inhibition in reproduction in 41 days	8
Clam, <i>Mulinia lateralis</i>	15.8	Populations reduced after 7 days	9
Razor clam, <i>Ensis minor</i>	15.8	Populations reduced after 7 days	9
Hydra, <i>Hydra littoralis</i>	19	Threshold for reproduction inhibition	8

Table 23.4 (continued) Lethal and Sublethal Effects of Pentachlorophenol on Selected Species of Aquatic Organisms

Species and Other Variables	Concentration (g PCP/L medium)	Effect	Reference ^a
Snail			
<i>Physa gyrina</i>	26	Reduction in number of egg masses produced and in egg survival during lifetime exposure	4, 10, 70
<i>P. gyrina</i>	220	LC50 (96 h) at 24°C	4
<i>P. gyrina</i>	730	LC50 (96 h) at 8.6°C	11
<i>P. gyrina</i>	1380	LC50 (96 h) at 3.2°C	4
Pacific oyster, <i>Crassostrea gigas</i>	55	62% of exposed embryos developed abnormally in 48 h	1
Midge			
<i>Chironomus riparius</i> , 4th instar	84	LC50 (24 h) at pH 4	12
<i>C. riparius</i>	465	LC50 (24 h) at pH 6	12
<i>C. riparius</i>	631	50% locomotion inhibition at 35°C	13
<i>C. riparius</i>	1176	50% locomotion inhibition at 15°C	13
<i>C. riparius</i>	1948	LC50 (24 h) at pH 9	12
Snail			
<i>Lymnaea acuminata</i>	100	LC16 (96 h)	14
<i>L. acuminata</i>	160	LC50 (96 h)	14
<i>L. acuminata</i>	210	LC84 (96 h)	14
Snail, <i>Australorbis glabratus</i>	100	Reduction in egg production and viability after exposure for 7–8 days	2
Sea urchin			
<i>Paracentrotus lividus</i> , embryos	100	Reductions in various amino acid activity levels during exposure for 40 h	15
<i>P. lividus</i>	200	Number and size of swimming blastulae, gastrulae, and plutei reduced in 40-h exposure	15
Short-necked clam, <i>Tapes philippinarum</i>	100	Lethal in 120 h	16
Snail, <i>Lymnaea luteola</i>	112	LC50 (96 h)	17
Flatworm, <i>Dugesia lugubris</i>	130	LC50 (48 h)	8
Snail, <i>Lymnaea stagnalis</i>	180	LC50 (16 days)	2
Cladoceran			
<i>Daphnia magna</i>	180	No observable effect level in lifetime exposure	1
<i>D. magna</i>	320	Some adverse effects observed in lifetime exposure	1
<i>D. magna</i>	370–440	50% immobilization in 48 h	18
<i>D. magna</i>	475	LC50 (96 h)	1
Cladoceran			
<i>Simocephalus vetulus</i>	204	LC50 (96 h) at 24°C	4
<i>S. vetulus</i>	670	LC50 (96 h) at 18°C	11
Tubificid worm			
<i>Tubifex tubifex</i>	286	LC50 (24 h) at pH 7.5	1
<i>T. tubifex</i>	619	LC50 (24 h) at pH 8.5	1
<i>T. tubifex</i>	1294	LC50 (24 h) at pH 9.5	1
Snail			
<i>Gillia altilis</i>	300	LC50 (96 h) in flow-through test	19
<i>G. altilis</i>	810	LC50 (96 h) in static test	19
Mysid, <i>Mysidopsis bahia</i>	320	LC50 (96 h)	20
Grass shrimp			
<i>Paleomonetes pugio</i>	400–440	LC50 (96 h) during molting	20, 21
<i>P. pugio</i>	473–637	Adversely affects initiation and progress of limb regeneration without altering duration of molt cycle	22

Table 23.4 (continued) Lethal and Sublethal Effects of Pentachlorophenol on Selected Species of Aquatic Organisms

Species and Other Variables	Concentration (g PCP/L medium)	Effect	Reference ^a
<i>P. pugio</i>	649–1200	LC50 (96 h)	1, 7
<i>P. pugio</i>	1000	Histopathology of gill, hepatopancreas, and midgut epithelial cells after exposure for 12 days in shrimp that molted; normal tissues in shrimp that had not yet molted	21
<i>P. pugio</i>	2500	LC50 (96 h) during intermolt	20, 21
Polychaete worm, <i>Neanthes arenaceodentata</i>	435	LC50 (96 h)	1
Amphipod			
<i>Gammarus pseudolimnaeus</i>	770	Significant decreases in free amino acids after 5 days; in whole-body glycogen, protein, and caloric content after 15 days; and in lipid content after 30 days	23
<i>G. pseudolimnaeus</i>	860	LC50 (30 days)	23
<i>G. pseudolimnaeus</i>	1150	LC50 (96 h)	24
<i>G. pseudolimnaeus</i>	1680	At 48 h, significant decrease in total free amino acid levels	24
Pond snail, <i>Viviparus bengalensis</i>	840	LC50 (96 h)	25
Caddisfly, <i>Philarctus quaeris</i>	1200	LC50 (96 h)	11
Mayfly, <i>Callibaetis skokianus</i>	1700	LC50 (96 h)	11
Amphipod, <i>Crangonyx pseudogracilis</i>	1900	LC50 (96 h)	11
Isopod			
<i>Asellus racovitzai</i>	2300	LC50 (96 h) at 8.6°C	11
<i>A. racovitzai</i>	4320	LC50 (96 h) at 4.2°C	4
<i>A. racovitzai</i>	>7770	LC50 (96 h) at 3.2°C	4
Crayfish			
<i>Astacus fluviatilis</i>	9000	LC50 (8 days) at pH 6.5	26
<i>A. fluviatilis</i>	53,000	LC50 (8 days) at pH 7.5	26
VERTEBRATES			
Rainbow trout			
<i>Oncorhynchus mykiss</i>	0.035	After 115 days, whole fish BCF of 286–572; half eliminated in 7 days	8, 57
<i>O. mykiss</i>	0.7	After 115 days, BCF of 160 in whole fish; Tb 1/2 elimination time of 7 days	8, 57
<i>O. mykiss</i>	1.0	Whole-body BCF of 221 in 18 h and 466 in 11.7 days; Tb 1/2 of 65 h and 95% depuration in 12 days. Highest PCP tissue residues were bile > liver > blood > kidney > spleen > skin-bone-gill-gonad > muscle	27
<i>O. mykiss</i>	7.4	27% inhibition of growth in 28 days	1
<i>O. mykiss</i>	10–20	Some deaths during exposure from fertilization to yolk-sac absorption; 100% dead at 5 mg dissolved oxygen (DO)/L and 20 µg PCP/L; 100% dead at 3 mg DO/L and 10 µg PCP/L	28
<i>O. mykiss</i>	11	No adverse effects observed during exposure from fertilization through day 72	29, 70

Table 23.4 (continued) Lethal and Sublethal Effects of Pentachlorophenol on Selected Species of Aquatic Organisms

Species and Other Variables	Concentration (g PCP/L medium)	Effect	Reference ^a
<i>O. mykiss</i>	19	Embryo mortality negligible during exposure from fertilization through day 72 but alevin mortality was 3 times that of controls. Growth in length and weight reduced. Fin erosion, mild cranial malformations, and lethargy reported	29
<i>O. mykiss</i>	22	48% reduction in viable oocytes after exposure for 18 days	30
<i>O. mykiss</i>	25	After 24 h, BCF of 40 in muscle, 240 in fat, 260 in blood, and 640 in liver. Tb 1/2 values ranged from 7 h in muscle to 23 h in fat	31, 58
<i>O. mykiss</i>	28	11–19% inhibition in growth in 20–38 days	1
<i>O. mykiss</i>	34–121	LC50 (96 h)	1, 29, 32–34
<i>O. mykiss</i>	40	100% mortality during exposure from fertilization to yolk-sac absorption (72 days)	28
<i>O. mykiss</i>	46	LC100 (41 days)	1
<i>O. mykiss</i>	49	81% reduction in oocytes available to complete oogenesis after exposure for 18 days	30
<i>O. mykiss</i>	60	Eye abnormalities noted in developing embryos after exposure for 17 days; all dead at day 72 of exposure	29
<i>O. mykiss</i>	122	LC50 (17 h)	68
<i>O. mykiss</i>	271	LC50 (5 h)	68
<i>O. mykiss</i>	10,000	LC50 (3.5 h)	35
Sockeye salmon			
<i>Oncorhynchus nerka</i>	3.2	10% growth inhibition in 6 weeks	1
<i>O. nerka</i>	46–120	LC50 (96 h)	1, 56, 70
American flagfish, <i>Jordanella floridae</i>	5	BCF after 28 days was 216 for whole fish on fresh-weight basis and 1633 on lipid-weight basis; 90% steady state attained in 54 h; 50% cleared in 16.3 h in uncontaminated media	63
Common carp			
<i>Cyprinus carpio</i>	9.5	LC50 (96 h), larvae	8
<i>C. carpio</i>	266	Reduction in liver glucose and glycogen release after 3 days; high accumulations in liver	36
<i>C. carpio</i>	1500	LC50 (3 h)	37
Largemouth bass			
<i>Micropterus salmoides</i>	10	Food conversion efficiency reduced in a concentration-dependent fashion at concentrations >10 µg/L	38
<i>M. salmoides</i>	25.2	Growth reduction after exposure for 52 days	38
<i>M. salmoides</i>	45	Decline in feeding activity after 8 weeks	38
<i>M. salmoides</i>	50	After 14 days, food conversion efficiency reduced 30%, reduction in ability to capture prey and in food consumed	39
<i>M. salmoides</i>	54	LC50 (120 days)	38

Table 23.4 (continued) Lethal and Sublethal Effects of Pentachlorophenol on Selected Species of Aquatic Organisms

Species and Other Variables	Concentration (g PCP/L medium)	Effect	Reference ^a
<i>M. salmoides</i>	67	Exposure for 8 weeks produced hyperactivity and reductions in feeding rate and in prey capture	40
<i>M. salmoides</i>	136–287	LC50 (96 h)	38, 39, 41
Rasbora			
<i>Rasbora daniconius neilgeriensis</i>	10	LC0 (96 h)	42
<i>R.d. neilgeriensis</i>	67	LC16 (96 h)	42
<i>R.d. neilgeriensis</i>	148	LC50 (96 h)	42
<i>R.d. neilgeriensis</i>	330	LC84 (96 h)	42
Fathead minnow			
<i>Pimephales promelas</i>	16.5–34.6	No adverse effect-adverse effect values in lifetime exposure at pH 6.5	70
<i>P. promelas</i>	27.6–58.2	As above at pH 7.5	70
<i>P. promelas</i>	32–75	As above at pH 8.0	70
<i>P. promelas</i>	64–125	As above at pH 8.5	70
<i>P. promelas</i>	45	No-observable-effect level in lifetime exposure	1, 54
<i>P. promelas</i>	48	Growth and larval drift reduced after exposure for 12 weeks	10
<i>P. promelas</i>	50	Whole-body BCF of 174 after 14 days; nondetectable residues after 14 days in clean water	45
<i>P. promelas</i>	73	Some adverse effects in lifetime exposure	1, 54
<i>P. promelas</i>	85	Growth reduction after 90 days exposure	46
<i>P. promelas</i>	120	LC50 (96 h) at 16.6°C	4
<i>P. promelas</i>	170	LC50 (96 h) at 10.1°C	4
<i>P. promelas</i>	200–350	LC50 (96 h)	2, 11, 35
<i>P. promelas</i>	300	LC50 (96 h) at 3.4°C	4
Japanese medaka			
<i>Oryzias latipes</i>	20–100	Freshwater-adapted fish had BCF of 1680 (vs. 370 for saltwater-adapted group) after 10 days	66
<i>O. latipes</i>	60–200	Time for 50% depuration was 71–108 h for freshwater medakas (vs. 31 h for marine group)	66
Pinfish, <i>Lagodon rhomboides</i>	31–53	LC50 (96 h)	1, 7, 20
Coho salmon, <i>Oncorhynchus kisutch</i>	32–60	LC50 (96 h), juveniles	70
Bluegill			
<i>Lepomis macrochirus</i>	32–215	LC50 (96 h)	1, 11, 32, 33
<i>L. macrochirus</i>	48	Food intake normal but growth rate declined 26%; food conversion normal after 22 days in untreated water	61, 62, 69
<i>L. macrochirus</i>	100	After exposure for 8 days, BCF 13 in muscle, 60 in gill, 210 in gastrointestinal tract, and 350 in liver. Rapid elimination, but some residues in muscle and liver were detectable 16 days postapplication	43
<i>L. macrochirus</i>	100	Liver histopathology after 32 days; degenerative changes detectable after 2 days	44

Table 23.4 (continued) Lethal and Sublethal Effects of Pentachlorophenol on Selected Species of Aquatic Organisms

Species and Other Variables	Concentration (g PCP/L medium)	Effect	Reference ^a
<i>L. macrochirus</i>	173	No deaths. Food intake declined 29% and growth rate declined 75%	61, 62, 69
<i>L. macrochirus</i>	240	22% dead in 3 days; survivors had normal food conversion efficiency	69
<i>L. macrochirus</i>	240	LC50 (96 h)	69
<i>L. macrochirus</i>	432	LC100 (8 days)	10
Freshwater fishes, Scandinavia, 5 species	38–66	LC50 (96 h) range for newly hatched larvae and juveniles	60
Atlantic salmon			
<i>Salmo salar</i>	46	Altered temperature preference in 24 h	1
<i>S. salar</i>	59–140	LC50 (96 h), juveniles	64
<i>S. salar</i>	500	LC50 (96 h)	35
<i>S. salar</i>	2000	LC50 (10.5 h)	35
<i>S. salar</i>	10,000	LC50 (2.7 h)	35
Sheepshead minnow			
<i>Cyprinodon variegatus</i>	47	No-observable-effect level in lifetime exposure	1
<i>C. variegatus</i>	88	12% mortality in lifetime exposure	47
<i>C. variegatus</i>	195	Life cycle exposure resulted in reduced hatch and survival of second-generation fish	47
<i>C. variegatus</i>	223–392	LC50 (96 h) for fry age 1 day to 6 weeks	7
<i>C. variegatus</i>	389	LC100 (60 days)	47
<i>C. variegatus</i>	442	LC50 (96 h)	1, 47
Plaice (flounder)			
<i>Pleuronectes platessa</i>	50	LC50 (8 weeks), eggs	8
<i>P. platessa</i>	60–140	LC50 (96 h), larvae	8
<i>P. platessa</i>	100–130	LC50 (96 h), juveniles	8
Channel catfish, <i>Ictalurus punctatus</i>	54–68	LC50 (96 h)	8, 32, 33
Coho salmon, <i>Oncorhynchus kisutch</i>	55	LC50 (96 h)	1
White crappie, <i>Pomoxis annularis</i>	56–75	LC50 (96 h)	35
Longnose killifish, <i>Fundulus similis</i>	57–610	Whole-body BCF of 53 after 168 h; Tb 1/2 of 4.7 days. Whole-body residues up to 33 mg/kg FW	48
Chinook salmon, <i>Oncorhynchus tshawytscha</i>	68–78	LC50 (96 h)	1, 32, 55
White sucker, <i>Catostomus commersoni</i>	85	LC50 (96 h)	4
Eel, <i>Anguilla anguilla</i>	100	Seawater-exposed eels, after exposure for 8 days, had 33 mg PCP/kg FW in liver, 9 in muscle, and 4 in blood; after depuration for 8 days, values were 12 in liver, 4 in muscle, and 2 in blood. Eels exposed in freshwater for 4 days had 2–9 mg PCP/kg tissue, and <1.2 mg/kg 38 days postexposure	49
Goldfish			
<i>Carassius auratus</i>	100	BCF of 1000 after 12 h. Residues in dead fish were 82–116 mg PCP/kg BW; no surviving fish contained more than 114 mg/kg	16, 48
<i>C. auratus</i>	200	Whole-body residue of 116 mg/kg after exposure for 120 h	48

Table 23.4 (continued) Lethal and Sublethal Effects of Pentachlorophenol on Selected Species of Aquatic Organisms

Species and Other Variables	Concentration (g PCP/L medium)	Effect	Reference ^a
Tilapia, <i>Tilapia nilotica</i>	100	In 24-h tests, fish acclimatized to seawater were twice as resistant as freshwater-acclimatized fish to biocidal PCP properties, and contained lower residues	50
Mullet			
<i>Rhinomugil corsula</i>	100	Metabolic rate elevated after 3 h	37
<i>R. corsula</i>	1000	LC50 (3 h)	37
Striped mullet, <i>Mugil cephalus</i>	112	LC50 (96 h), whole-body BCF of 38	1, 6
Brook trout, <i>Salvelinus fontinalis</i>	128	LC50 (96 h)	1
Salamander			
<i>Ambystoma mexicanus</i>	130	LC0 (48 h)	8
<i>A. mexicanus</i>	300	LC50 (48 h)	8
Common shiner			
<i>Notropis cornutus</i>	180	25% growth reduction after exposure for 7 days	51
<i>N. cornutus</i>	320	LC100 (7 days)	51
Fish, 19 species	200–600	LC50 (96 h)	35
Frog			
<i>Xenopus laevis</i>	210	LC0 (48 h)	8
<i>X. laevis</i>	260	LC50 (48 h)	8
Arctic charr, <i>Salvelinus alpinus</i>	500	LC50 (96 h), larvae	65
Guppy			
<i>Poecilia reticulata</i>	500–700	Reduction in ability to escape from piscine predators	52
<i>P. reticulata</i>	700	LC21 (30 days)	52
<i>P. reticulata</i>	1000	LC0 (12 days); possible acclimatization	53
<i>P. reticulata</i>	1020	LC50 (96 h)	52
Sea lamprey, <i>Petromyzon marinus</i>	924	LC100 (4 h)	1
Mummichog, <i>Fundulus heteroclitus</i>	1000–20,000	Dose-dependent inhibition of peak chemiluminescence in phagocytes after incubation for 20 h	67

23.4.4 Birds

Signs of PCP intoxication in birds include excessive drinking and regurgitation, rapid breathing, wing shivers or twitching, jerkiness, shakiness, ataxia, tremors, and spasms (Hudson et al. 1984). Signs

sometimes appear within 10 min. Mallards usually die 2 to 24 h posttreatment, and ring-necked pheasants 3 to 5 days posttreatment; remission in pheasants requires up to 2 weeks (Hudson et al. 1984).

Pentachlorophenol killed various species of birds at single oral doses of 380 to 504 mg/kg BW, at dietary concentrations of 3850 mg/kg ration fed over a 5-day period, and when nesting materials contained >285 mg/kg. Residues (mg/kg fresh weight tissue) in birds found dead from PCP poisoning were 11 in brain, 20 in kidney, 46 in liver, and 50 to 100 in egg (Table 23.5). Sublethal effects, including liver histopathology and diarrhea, were reported in domestic chickens at dietary levels as low as 1 mg PCP/kg feed over an 8-week period; significant accumulations in tissues were measured after consumption for 14 days of diets containing 10 mg PCP/kg (Table 23.5). Residues in chickens fed PCP-containing diets for 8 weeks were dose related and highest in kidney and liver and lower in other tissues; the high residues may reflect the principal routes of metabolism and excretion (Stedman et al. 1980). The loss of body fat in chickens, accomplished by feeding bile acid-binding resins, hastens PCP excretion (Table 23.5) (Polin et al. 1986).

Spraying of PCP to control populations of water snails in rice fields of Surinam resulted in the death of fish and birds, including snail kites (*Rostrhamus sociabilis*), certain egrets and herons, and wattled jacanas (*Jacana jacana*). Levels of PCP in these birds and their food items suggested that PCP-contaminated food probably caused the deaths (Vermeer et al. 1974) (Table 23.5).

Pentachlorophenol is widely used as a wood preservative, which often results in residues in wood shavings used as poultry litter. A moldy smell and taste in chicken tissue has been traced to the presence of chloroanisoles formed from PCP and tetrachlorophenol in the bedding. Several dioxins, diphenyl ethers, dibenzofurans, and 2-phenoxyphenols have also been identified (Newsome et al. 1984). For example, PCP-contaminated (134 mg/kg) commercial wood shavings used as chicken litter contained detectable levels of heptachlorinated diphenyl ethers (18 µg/kg), octachlorinated diphenyl ethers (12 µg/kg) nonachlorinated diphenyl ethers (6 µg/kg), octachlorinated 2-phenoxyphenols (299 µg/kg), nonachlorinated 2-phenoxyphenols (50 µg/kg), heptachlorinated dibenzodioxins (19 µg/kg), and octachlorinated dibenzodioxins (143 µg/kg). After 9 weeks, PCP was detectable in liver, fat, and muscle; chlorinated diphenyl ethers were detectable in fat, but not in muscle or liver; octa- and nonachlorinated 2-phenoxyphenols were found in all three tissues; and dioxins only in liver and fat (Newsome et al. 1984). Exposure of domestic chickens to litter contaminated with PCP enhanced susceptibility to common poultry pathogens, perhaps due to immunosuppression by the chemical (Prescott et al. 1982).

Table 23.5 Effects of Pentachlorophenol on Selected Species of Birds

Species and Other Variables	Effect and Reference
MALLARD, <i>Anas Platyrhynchos</i>	Acute oral LD50 of 380 mg/kg body weight (BW); 95% confidence interval 205–704 mg/kg BW (Hudson et al. 1984)
JAPANESE QUAIL, <i>Coturnix japonica</i>, Birds age 14 days were fed treated diets for 5 days, then untreated feed for 3 days	No deaths at 3100 mg/kg diet, 35% dead at 3850, 50% at 5139 (4149–6365), and 69% dead at 6000 mg PCP/kg diet (Hill and Camardese 1986)
DOMESTIC CHICKEN, <i>Gallus gallus</i> Fed diets containing 1, 10, 100, or 1000 mg PCP/kg for 8 weeks	Liver histopathology and diarrhea recorded in all treated groups vs. none in controls. The 1000 mg/kg diet was the only ration to adversely affect the weight of all organs analyzed. After 5 weeks on PCP-free diet, residues were still measurable in adipose tissues of all treated birds (Stedman et al. 1980) No deaths in any group. Residues (mg/kg fresh weight) in 600 mg/kg group at 8 weeks were 2 in muscle, 10 in fat, 25 in liver and 80 in kidney vs. <0.02 in controls; no significant difference from controls in growth, blood chemistry, histopathology, or immune response. In the 1200- and 2400-mg/kg groups body weight decreased and liver weight increased; tissue residues were dose related (Prescott et al. 1982)
Fed dietary levels of 600, 1200, or 2400 mg/kg for 8 weeks	The PCP residues (mg/kg FW) were 3.7 in liver, 0.4 in muscle, and 0.3 in fat, vs. <0.08 in controls (Newsome et al. 1984)
Raised over wood shavings containing 134 mg PCP/kg for 9 weeks	

Table 23.5 (continued) Effects of Pentachlorophenol on Selected Species of Birds

Species and Other Variables	Effect and Reference
Fed diets containing 10 mg PCP/kg for 14 days, then 21 days on PCP-free diets containing either no additives, 5% mineral oil, or 5% colestipol hydrochloride Eggs received single injected dose	Body burden at 14 days was 362 µg/bird or 1.1 µg/kg BW. After 21 days, body burdens were 255 µg/bird in no-additive diet and nondetectable levels of <0.7 µg/bird in mineral oil and colestipol additive diets (Polin et al. 1986)
RING-NECKED PHEASANT, <i>Phasianus colchicus</i>	Hatching reduced 50% at a dose of 50 mg PCP/kg egg and 100% at 100 mg/kg (none hatched) (Stedman et al. 1980)
SNAIL KITE, <i>Rostrhamus sociabilis</i>. Found dead in rice fields after spraying to control snails (<i>Pomacea glauca</i> , <i>P. lineata</i>) — the exclusive food of snail kites. Residues in soft parts of snails found dead after spraying were about 37 mg PCP/kg fresh weight	Acute oral LD ₅₀ of 504 mg/kg BW; 95% confidence interval of 343–743 mg/kg BW (Hudson et al. 1984)
CANARY, <i>Serinus canarius</i>. Nesting on straw containing 285 mg PCP/kg	Residues in dead snail kites, in mg PCP/kg FW, were 46 in liver, 20 in kidney, and 11 in brain vs. <0.2 in controls, and 2–17 in birds surviving exposure (Vermeer et al. 1974)
	Reduced hatch, high mortality of young during the first week posthatch, and none surviving to age 3 months. Prior to death, young showed inhibited growth and feather development. Adult birds appeared normal (Dorrestein and Zella 1979)

23.4.5 Mammals

Data are scarce on the biological effects of PCP on mammalian wildlife, although evidence continues to accumulate on this subject for humans, livestock, and small laboratory animals (Table 23.6). Available data on PCP and domestic mammals are briefly summarized, but it is not clear if these findings are applicable to representative species of sensitive mammalian wildlife. PCP tends to accumulate in mammalian tissues unless it is efficiently conjugated into a readily excreted form (Kinzell et al. 1985). The ability to conjugate PCP varies widely among species (Braun and Sauerhoff 1976; USEPA 1980). For example, both laboratory rats (*Rattus* sp.) and humans eliminate about 75% of all PCP in the urine in an unconjugated form, but rhesus monkeys (*Macaca mulatta*) are unable to excrete PCP efficiently, whereas mice were the most efficient. As one result, Tb 1/2 values were low (about 24 h) for mice, high (up to 360 h) for rhesus monkeys, and intermediate for rats and humans (USEPA 1980; van Raaij et al. 1991a). In humans, however, the observed elimination half-life indicates that steady-state body burdens are 10 to 20 times higher than values extrapolated from animal pharmacokinetic data (Uhl et al. 1986).

Biotransformation of PCP in mammals occurs via conjugation, reductive dechlorination, hydrolytic dechlorination, and oxidation. In the process, a number of metabolites are formed, some of which are demonstrably toxic (Renner and Hopfer 1990; Jansson and Jansson 1991; Reigner et al. 1991). Metabolites of PCP found in rat urine and identified (acute oral LD₅₀ to mice, in mg/kg BW) include (Renner and Hopfer 1990):

- PCP (74)
- 2,3,5,6-Tetrachlorophenol (109)
- 2,3,4,6-Tetrachlorophenol (131)
- Tetrachlorocatechol (325–612)
- Trichlorohydroquinone and tetrachlorohydroquinone (376–500)
- 2,3,4,5-tetrachlorophenol (400)
- Tetrachlororesorcinol (752)
- Traces of trichloro-1,4-benzoquinone and tetrachloro-1,4-benzoquinone

Pentachlorophenol is not a carcinogen, and the evidence for mutagenicity is mixed. No carcinomas were produced in rodents, regardless of the composition of the PCP solution tested or route of exposure (USEPA 1980; Choudhury et al. 1986). Some studies suggested that PCP may be

mutagenic in the bacterium *Bacillus subtilis*, the yeast *Saccharomyces cerevisiae*, and in laboratory mice (*Mus* sp.), but not in two other species of bacteria tested — *Salmonella typhimurium* and *Escherichia coli* (Choudhury et al. 1986). The PCP metabolite tetrachlorohydroquinone — found in urine of occupationally exposed humans and experimentally dosed rodents — is twice as toxic to cultured Chinese hamster ovary cells as PCP (based on growth), and induced significant dose-related increases in micronuclei and DNA single-strand breaks (Ehrlich 1990; Jansson and Jansson 1992). But tetrachlorohydroquinone was 5 times less toxic than PCP to mice *in vivo*, with no evidence of mutagenicity (Ehrlich 1990).

The primary sources of PCP in humans include direct intake by way of diet, air, or water and through contact with PCP-contaminated materials (Uhl et al. 1986). It is now established that PCP is taken up by female rhesus monkeys via the skin from PCP-contaminated soils. Monkeys accumulated up to 24% of the PCP in contaminated California soils over a 24-h period (Wester et al. 1993). In humans, the chief routes of exposure in an industrial setting are by way of inhalation and skin contact. Percutaneous absorption is significantly enhanced when PCP is dissolved in organic solvents, such as fuel oil, or when PCP comes in contact with open cuts and scratches (Wood et al. 1983). PCP has resulted in death of humans through suicide and occupational and accidental exposures (USEPA 1980; Rozman et al. 1982; Lambert et al. 1986). Cases of PCP intoxication in humans, including fatalities, have been described in farmers, handlers of preserved wood, and industrial workers. Symptoms always included high fever, renal insufficiency, profuse perspiration, rapid heart beat and breathing, abdominal pain, dizziness, nausea, spasms, and sometimes death 3 to 25 h after onset of symptoms (Knudsen et al. 1974; Haley 1977; USEPA 1980; Wood et al. 1983). Postmortem examination showed kidney degeneration, inflamed gastric mucosa, edematous lungs, and centrilobular degeneration of liver (USEPA 1980; St. Omer and Gadusek 1987). Symptoms of nonfatal PCP intoxication in man include conjunctivitis, chronic sinusitis, nasal irritation, upper respiratory complaints, sneezing, coughing, recurring headache, neurological complaints, weakness, several types of skin lesions (Knudsen et al. 1974; USEPA 1980; Rozman et al. 1982), chloracne (O'Malley et al. 1990), aplastic anemia, leukemia, and other hematologic disorders (Roberts 1990). All symptoms were related to proximity to PCP-treated wood, and sometimes to elevated PCP residues in serum and urine (Lambert et al. 1986). Chloracne and hematologic disorders may be associated with various contaminants in the PCP, including various chlorophenols, phenoxy acids, dioxins, and dibenzofurans (O'Malley et al. 1990; Roberts 1990). At the cellular level, PCP — like other halogenated phenols — uncouples oxidative phosphorylation. A possible antidote to PCP poisoning is the administration of cholestyramine, a compound that interferes with the enterohepatic cycle of PCP, and also increases its elimination directly across the intestinal wall (Rozman et al. 1982). Cholestyramine is known to bind phenols and to enhance fecal elimination of PCP in rats, humans, and rhesus monkeys (USPHS 1994). Phenobarbital increases the biotransformation of PCP, and its action is enhanced in combination with cholestyramine. Substances to be avoided in suspected cases of PCP poisoning include atropine and salicylates, such as aspirin, because they exacerbate the toxicity of phenolic substances (USPHS 1994).

The exposure of livestock to PCP can result from ingestion of feeds stored or fed in PCP-treated wooden structures, licking of treated wood, cutaneous absorption by direct contact with treated wood, and inhalation of air containing preservative chemicals — particularly volatile chlorophenols (Forsell et al. 1981). Acute signs of PCP intoxication in various domestic and laboratory animals include elevated blood sugar, vomiting, elevated blood pressure, increased respiration rate, tachycardia, motor weakness, weakened eye reflex, frequent defecation, high fever, collapse, asphyxial convulsions, and death followed by rapid rigor mortis (Knudsen et al. 1974; Nishimura 1984; St. Omer and Gadusek 1987). In domestic cattle (*Bos* sp.), PCP has also been associated with decreased milk production, skin lesions, increased mastitis, persistent infections, reduced survival (Forsell et al. 1981), and in sheep, disrupted reproductive and metabolic hormones, and oviductal cysts (Rawlings et al. 1998).

Among sensitive species of mammals tested against PCP (Table 23.6), acute oral LD₅₀ values ranged from 27 to 300 mg/kg BW, but most values were between 55 and 150 mg/kg BW. Sublethal effects were noted at much lower concentrations than those causing death. They included elevated tissue residues at dietary intake equivalent to 0.05 mg/kg BW, or atmospheric concentrations >0.1 mg/m³; organ damage at 0.2 to 2.0 mg/kg BW; reproductive impairment at >1.25 mg/kg BW; and retarded growth and reproduction in animals fed rations containing >30 mg/kg (Table 23.6). PCP was responsible for the deaths of pipistrelle bats (*Pipistrellus pipistrellus*) roosting on PCP-treated wooden surfaces; PCP concentrations on the roosting structures were similar to those applied in remedial timber treatment (Shore et al. 1991).

Many commercial lots of technical PCP are known to contain small — but possibly biologically significant — amounts of highly toxic dioxins, dibenzofurans, and hexachlorobenzene. These contaminants may be responsible for most of the toxicity of technical PCP preparations (McConnell et al. 1980; Parker et al. 1980; Wollesen et al. 1986; Holsapple et al. 1987). However, both technical- and analytical-grade PCP can induce hepatic mixed-function oxidases in intoxicated rats and cattle. In cattle, this effect was observed in both calves and adults, and in hepatic as well as pulmonary microsomes, and seemed to be dose related (Shull et al. 1986).

Table 23.6 Effects of Pentachlorophenol on Selected Mammals

Organism, Dose, and Other Variables	Effects and Reference
DOMESTIC CATTLE, <i>Bos taurus</i>	
Oral dose of 0.05 or 0.5 mg/kg BW	Maximal plasma values of 1.5 and 9.6 mg/L, respectively. Calves fed grain and hay from a PCP-treated feeder for 10 days contained plasma PCP levels of 1.1 mg/L, but levels returned to normal after access to feeder was denied (Osweiler et al. 1984)
Fed equivalent of 0.2 mg/kg BW daily for 75–84 days, then 2.0 mg/kg BW daily for 50 to 62 days	No effect on milk production, feed intake, body weight, lymphocyte function, or histopathology of spleen, thymus, or lymph nodes. Postmortem examination showed enlarged liver, lungs, kidneys, and adrenals; significant loss of renal function (Forsell et al. 1981; Kinzell et al. 1981)
Fed 0.2 mg/kg BW daily for 95 days, then given single oral dose of uniformly ring-labeled C ¹⁴ -PCP; analyzed 4 days postadministration	Highest residues were in liver, kidney, and lungs; in milk, fat fraction contained the greatest amount. Tb 1/2 for absorption was 4.3 h, and for elimination 43 h. Most excretion was by way of urine (76%), then milk and feces (5% each). In urine, PCP was present in the conjugated form (Kinzell et al. 1985)
Fed 20 mg technical-grade PCP/kg BW daily for 10 days, then 10 mg/kg BW for an additional 60 days	No clinical effects noted during the 70-day treatment or during a 165-day posttreatment period. Contaminants in PCP — including several dioxins and hexachlorobenzene — were found in milk, fat, and blood. PCP residues in whole milk rose to 4 mg/kg, but declined to <0.1 mg/kg within a few days after PCP cessation (Firestone et al. 1979)
Female yearling Holsteins fed technical- or analytical-grade PCP in diets at 20 mg/kg BW daily for 42 days (647 mg/kg diet), then 15 mg/kg BW daily for 118 days (491 mg/kg diet) 140 mg/kg BW	Technical-grade PCP was related to decreased body weight and feed conversion efficiency, anemia, enlarged liver and lungs, decreased thymus weight, and lesions in urinary bladder mucosa. Holsteins exposed to analytical grade PCP were comparable to controls. The toxicity of PCP in cattle seems to be due to its contamination with toxic impurities, especially dioxins (McConnell et al. 1980; Parker et al. 1980) Acute oral LD ₅₀ (Knudsen et al. 1974)
DOMESTIC DOG, <i>Canis familiaris</i>	
150–200 mg/kg BW	Acute oral LD ₅₀ (Knudsen et al. 1974)
GUINEA PIG, <i>Cavia porcellus</i>	
100 mg/kg BW	Acute oral LD ₅₀ (Choudhury et al. 1986)
HAMSTER, <i>Cricetus spp.</i>	
1.25–20 mg/kg BW	Fetal deaths and resorption (USEPA 1980)

Table 23.6 (continued) Effects of Pentachlorophenol on Selected Mammals

Organism, Dose, and Other Variables	Effects and Reference
DOMESTIC CAT, <i>Felis domesticus</i>	
Pine wood shavings used as litter, containing 470 mg PCP/kg	Of 14 cats in contact with litter, 3 died and 8 became ill but recovered. Maximum PCP residues (mg/kg) in the dead cats were 20 in liver, 24 in kidney, and 10 in stomach contents (Peet et al. 1977)
HUMAN, <i>Homo sapiens</i>	
Humans exposed occupationally for 6.5 (0.3–26.3) years vs. reference population	No adverse health effects, although daily urinary PCP levels were increased in occupationally exposed population: 174 µg/L vs. 35 µg/L (USPHS 1994)
Average concentrations of 0.0012–0.18 mg/m ³ air for 3–34 years among occupationally exposed workers	PCP concentrations in blood of 20 workers ranged between 0.023 and 0.775 mg/L and were below the "biological tolerance value" of 1.0 mg/L; no effect on sister chromatid exchange or chromosomal aberrations (Ziemsen et al. 1987)
<0.02–>0.1 mg/L urine in occupationally exposed woodworkers	During a 16-day vacation and plant shutdown, urinary excretion accounted for 90% elimination in those with high initial PCP levels (i.e., >0.1 mg/L) to 67% elimination in those with initial urinary levels of 0.02–0.1 mg PCP/L, and to 34% reduction in workers with <0.02 mg/L; Tb 1/2 was estimated at 33 h in urine and 30 h in plasma (Kalmann and Horstman 1983)
Single oral dose of 0.1 mg/kg BW	In urine of four subjects, 74% was eliminated unchanged and 12% as PCP-glucuronide; 4% was eliminated in feces as PCP and PCP-glucuronide. A peak blood level of 0.25 µg/L was reached 4 h after dosing (USEPA 1980; USPHS 1994)
>1.0 mg/m ³ air	Painful irritation in upper respiratory tract, sneezing, and coughing in persons newly exposed to PCP; up to 2.4 mg/m ³ can be tolerated by conditioned individuals (USEPA 1980)
Total dose of 3.9–18.0 mg	Steady state attained in about 3 months; Tb 1/2 values of 20 days in whole body and about 17 days in urine and blood (Uhl et al. 1986)
Blood concentrations of chronically exposed workers	
>25 µg PCP/L	Increased frequency of female reproductive disorders (USPHS 1994)
>42 µg PCP/L	Increased frequency of menstrual dysfunction (USPHS 1994)
>73 µg PCP/L	Increased frequency of female infertility (USPHS 1994)
8–1130 mg/kg fresh weight tissue	Residues in tissues of 33-year-old male who died after working in chemical plant for 3 weeks; job involved breaking up large blocks of PCP with jackhammer. Before death, high body temperature and coma. After death, rigor mortis was profound and immediate. Postmortem examination showed cerebral edema, fatty degeneration of viscera, and PCP levels (mg/kg) of 8 in stomach contents, 29 in urine, 52 in liver, 116 in lung, 162 in blood, 639 in kidney, and 1130 in bile (Wood et al. 1983; Gray et al. 1985)
28–225 mg/kg fresh weight tissue	Residues associated with acute toxicosis and death were 28–123 in kidney, 50–176 in blood, and 62–225 in liver (USEPA 1980)
75–225 mg/kg fresh	Residues in tissues of PCP suicide victim were 75 in urine, 116 weight tissue in kidney, 173 in blood, and 225 in liver (USEPA 1980)
4000 mg/L solution	Immersion of hands for 10 min produced skin irritation (USEPA 1980)
RHESUS MONKEY, <i>Macaca mulatta</i>	
Radiolabeled [¹⁴ C]PCP given intravenously or dermally	Half-time persistence of 4.5 days regardless of route (Wester et al. 1993)
10 mg/kg BW, single oral dose	Residues highest in liver and GI tract; all other tissues contributed <4% of total body burden (USEPA 1980)
10 mg/kg BW, single oral dose	Tb 1/2 values in blood and urine were 41–72 h in males and 84–92 h in females (Braun and Sauerhoff 1976)
50 mg/kg BW, repeated 4 weeks later	During the first day after each dose, 20% was excreted into urine, 0.5% into feces, and 20% into bile. The addition of 4% cholestyramine to diets for 6 days resulted in increased fecal excretion by a factor of 18 and increased total body burden excretion by 1.4 times (Rozman et al. 1982)

Table 23.6 (continued) Effects of Pentachlorophenol on Selected Mammals

Organism, Dose, and Other Variables	Effects and Reference
DOMESTIC MOUSE, <i>Mus</i> sp.	
Fed diet equivalent to 0.5 mg/kg BW daily for 6 weeks	Decreased antibody response (USPHS 1994)
Fed diets equivalent to 3 mg/kg BW daily for 24 months	No measurable effect in females, based on clinical chemistry, hematology, routine histopathology, and organ weight changes (USEPA 1980)
Fed diet equivalent to 6.5 mg/kg BW daily for 12 weeks	Hepatocellular swelling; enhanced susceptibility to tumor growth (USPHS 1994)
Fed diets equivalent to 10 mg/kg BW daily for 22 months	No measurable effect in males, based on clinical chemistry, hematology, routine histopathology, and organ weight changes (USEPA 1980)
15–37 mg/kg BW through ip or sc route	T _b 1/2 of about 24 h through urinary excretion (USEPA 1980)
Fed diet equivalent to 17.5 mg/kg BW daily for 2 years	Increased frequency of hepatocellular carcinoma (USPHS 1994)
Single oral dose of 15 mg/kg BW by iv injection or orally	Peak PCP concentration of 28 mg/L was measured in plasma 1.5 h after administration; half-time persistence of PCP was 5.2 h for iv injection and 5.8 h for oral route. PCP was primarily recovered in urine as conjugates, including the mutagen tetrahydroquinone (5%) and its conjugates (15%); sulfates accounted for >90% of the total conjugates (glucuronides and sulfates); only 8% of the PCP administered was excreted unchanged (Reigner et al. 1992b)
Fed diets containing 50 mg pure (99%) PCP/kg or technical grade (86%) for 10–12 weeks	Mice exposed to technical-grade PCP had enhanced tumor susceptibility (1.9 times) from transplanted tumors; mortality increased 2.4 times over controls after sarcoma virus inoculation. Mice exposed to pure PCP showed no enhanced growth of reduced tumors, but developed splenic tumors; 22% vs. none in controls (Kerkvliet et al. 1982)
Single ip injection of 59 mg/kg BW	LD50 (Reigner et al. 1992b)
Single dose of 65–252 mg/kg BW	Acute oral LD50; females more sensitive than males (Knudsen et al. 1974; Borzelleca et al. 1985; Choudhury et al. 1986; USPHS 1994)
Single oral dose of 15 mg/kg BW	Peak plasma concentration of 28 mg/L reached 1.5–2 h after administration (USPHS 1994)
WHITE RABBIT, <i>Oryctolagus cuniculus</i>	
1–3 mg/kg BW daily for 90 days administered orally	No signs of intoxication (USEPA 1980)
39 mg/kg BW	Lethal cutaneous dose administered in pine oil (Cote 1972)
60–200 mg/kg BW	Acute dermal lethal dose (USEPA 1980)
100–130 mg/kg BW	Acute oral LD50 (Knudsen et al. 1974; Choudhury et al. 1986)
350 mg/kg BW	Lethal cutaneous dose administered in olive oil (Cote 1972)
DOMESTIC SHEEP, <i>Ovis aries</i>	
Ewes given 2 mg/kg BW twice weekly for 43 days via oral route	By day 36, serum had significantly less thyroxine than controls and more insulin; significant increase in severity of oviductal epithelial cysts (Rawlings et al. 1998)
120 mg/kg BW	Acute oral LD50 (Knudsen et al. 1974)
PIPISTRELLE BAT, <i>Pipistrellus pipistrellus</i>	
Females roosting in contact with timbers treated with 5% PCP solutions	All bats introduced 6 weeks postapplication died in 3–7 days; those introduced 8 weeks postapplication died in 1–2 days; bats in contact with timbers 14 months postapplication died in 5–23 days (Racey and Swift 1986)
Adult females and weaned juveniles of both sexes held in outdoor flight enclosures; roost boxes treated with 69,300 mg PCP/kg and wood shavings contained 65,000 mg/kg FW	All dead within 24 h (90% survival in controls after 32 days). Carcasses of dead bats had 13.1 mg PCP/kg FW. Total PCP burden, in µg, ranged from 17–152 in whole body and 29–181 in fur. Maximum tissue concentrations, in µg/kg FW, were 99 in fat, 65 in liver, 25 in kidney, and 30 in remainder (Shore et al. 1991)

Table 23.6 (continued) Effects of Pentachlorophenol on Selected Mammals

Organism, Dose, and Other Variables	Effects and Reference
LABORATORY WHITE RAT, <i>Rattus</i> sp.	
Dietary levels of 20, 100, and 500 mg/kg feed equivalent to 1.2, 6, and 30 mg/kg BW daily, respectively	No effect after exposure for 8 months to pure-grade PCP at doses of 20 and 100 mg/kg. Technical-grade PCP produced disruptions in liver enzyme activity in females at 20 and 100 mg/kg. At 500 mg/kg, body weight gain was reduced in both sexes and by both grades of PCP (USEPA 1980)
Diets containing 25, 50, or 200 mg PCP/kg, equivalent to 1.5, 3, and 12 mg/kg BW daily, respectively	After 12 weeks, no observable effect at 25 mg/kg diet; dose-related adverse effects on liver, kidney calcium deposits, and chemistry at higher dietary levels (Knudsen et al. 1974)
Single dose of 2.5 mg PCP/kg BW given orally or by iv injection	PCP clearance was essentially metabolic, with only 5.3% unchanged by the kidney. About 60% of the dose was recovered in urine mainly as conjugated PCP and conjugated tetrachlorohydroquinone. For both routes of administration, about 10% of the dose was recovered in feces as PCP and its metabolites, which indicates that biliary excretion contributes to total elimination (Reigner et al. 1991)
Dietary level of 50 mg/kg, equivalent to about 3 mg/kg BW daily	After 62 days, no observable effect on reproduction, neonatal growth, survival, or development. After 12 weeks, males had decreased hemoglobin and erythrocytes. After 2 years, no significant adverse effects on growth, survival, reproduction, or development (Schwetz et al. 1978; USEPA 1980; McConnell et al. 1980)
Single oral dose of 2.5 mg PCP/kg BW	Peak plasma concentration of 7.3 mg/L reached 1.5–2 h after administration (USPHS 1994)
5.0–5.8 mg/kg BW on days 6 to 15 of gestation	Delayed ossification of skull (USEPA 1980)
10 mg/kg BW	
10 or 100 mg/kg BW	After a single oral dose, 0.44% remained after 9 days; 82% of total residue was in kidney and liver, and lowest residues were in brain, spleen, and fat. A maximum residue of 45 mg/L was attained in blood plasma; the Tb 1/2 in plasma was 13–121 h (USEPA 1980)
Pregnant females given 75 mg PCP/kg BW daily by gavage on days 7–18 of gestation	After a single dose, elimination occurred by way of several routes: catabolism to tetrachlorohydroquinone; excretion of unchanged PCP and its glucuronide conjugate in urine; excretion of PCP or its metabolites into bile. More than 90% was eliminated during the rapid phase, the Tb 1/2 being 13–17 h (Braun et al. 1977)
Dietary levels of 200 mg/kg, equivalent to about 13 mg/kg BW daily	Decrease in mean fetal weight (USPHS 1994)
14 mg/m ³ air for 45 min	
15 mg/kg BW daily of purified PCP on days 6–15 of gestation	After 181 days, reduction in crown-rump length and increase in fetal skeletal variations (Welsh et al. 1987)
27–300 mg/kg BW	LC50 for sodium pentachlorophenate aerosols (USPHS 1994) No measurable effect on development (USEPA 1980)
Dietary levels equivalent to 25 mg/kg BW daily for 2 generations	Acute oral LD50 range. Lower values in tests when PCP dissolved in fuel oil, in weanling rats, and in adult rats; higher values in tests with juveniles and when immersion vehicle is peanut oil (Knudsen et al. 1974; McConnell et al. 1980; Borzelleca et al. 1985; Choudhury et al. 1986; St. Omer and Gadusek 1987; USPHS 1994)
Dietary levels equivalent to 30 mg/kg BW daily	Decrease in size of litter (USPHS 1994)
Dietary levels equivalent to 43 mg PCP/kg BW daily for 181 days	
50 mg/kg BW on days 6 to 15 of gestation	Decrease in neonatal survival and growth after 62 days. After 2 years, no evidence of carcinogenicity, but adverse effects on adult growth and serum enzyme activity levels (Schwetz et al. 1978)
60 mg/kg BW	Embryo deaths (USPHS 1994) 100% fetal resorption (USEPA 1980) Single dose on day 9 or 10 of gestation produced reduction in fetal weight; no effect when given on days 11, 12, or 13 (USEPA 1980)

Table 23.6 (continued) Effects of Pentachlorophenol on Selected Mammals

Organism, Dose, and Other Variables	Effects and Reference
120 mg/kg BW	Single dose results in early hepatic glycogen depletion and elevation in blood glucose (Nishimura 1984)
DOMESTIC PIG, <i>Sus</i> spp.	
5, 10, or 15 mg purified PCP/kg BW daily for 30 days	No effect on weight gain, food consumption, or kidney weight. Significantly enlarged liver in 10- and 15-mg/kg groups. Elevated PCP residues in all groups. Residues in 5-mg/kg group vs. controls, in mg/kg fresh weight, were: 78.1 vs. 0.7 for blood, 6.7 vs. 0.2 for muscle, 22.0 vs. 0.2 for kidney, and 28.9 vs. 0.5 for liver (Grechus et al. 1979)
27–55 mg/kg BW	Fatal chronic dose (Schipper 1961)
30 mg/kg BW daily for 7 days	Acute toxicosis (Grechus et al. 1979)
Pregnant swine in direct contact with lumber freshly treated with PCP	Extensive mortality in newborn swine (Schipper 1961)
EASTERN CHIPMUNK, <i>Tamias striatus</i>	
138 mg/kg BW	Acute oral LD50 (Ege 1985)
200 mg/kg BW	Acute oral LD100 (Ege 1985)
Fed diets containing 250 or 500 mg PCP/kg for 2 weeks	No increase in metabolic activity. Some weight loss due to food avoidance; enlarged livers (Ege 1985)

23.5 RECOMMENDATIONS

Commercial PCP preparations often contain variable amounts of chlorophenols, hexachlorobenzene, phenoxyphenols, dioxins, dibenzofurans, chlorinated diphenyl ethers, dihydroxybiphenyls, anisoles, catechols, and other chlorinated dibenzodioxin and dibenzofuran isomers. These contaminants contribute to the toxicity of PCP — sometimes significantly — although the full extent of their interactions with PCP and with each other in PCP formulations are unknown. Unless these contaminants are removed or sharply reduced in existing technical- and commercial-grade PCP formulations, efforts to establish sound PCP criteria for protection of natural resources may be hindered.

Proposed PCP ambient water quality criteria to protect freshwater and marine life range from 48 to 55 µg/L for acute effects, 3.2 to 34 µg/L for chronic effects, and daily mean concentrations of 6.2 µg/L, not to exceed 140 µg/L (Table 23.7). Available data, however, suggest that significant adverse effects occur at much lower PCP concentrations (i.e., between 0.035 and 19 µg/L). In rainbow trout (*Oncorhynchus mykiss*), for example, concentrations of 0.035 to 1.0 µg/L produced elevated tissue residues (Choudhury et al. 1986; McKim et al. 1986); 7.4 µg/L caused growth inhibition in 28 days (USEPA 1980), and 10 to 19 µg/L produced adverse effects and some deaths (Chapman and Shumway 1978; Dominguez and Chapman 1984). Other sensitive fish species include sockeye salmon (*Oncorhynchus nerka*), showing growth inhibition after prolonged exposure to 1.8 µg PCP/L (USEPA 1980; Choudhury et al. 1986); larvae of common carp (*Cyprinus carpio*), having an 96-h LC50 of 9.5 µg/L (Choudhury et al. 1986); and largemouth bass (*Micropterus salmoides*), exhibiting reduced food conversion efficiency at 10 µg/L (Johansen et al. 1987). Among sensitive species of plants and invertebrates, American oysters (*Crassostrea virginica*) have elevated tissue residues after exposure for 28 days to 2.5 µg/L (Schimmel et al. 1978); cladocerans have impaired reproduction at 4.1 µg/L (Hedtke et al. 1986); alga show chlorosis inhibition in 72 h at 7.5 µg/L (USEPA 1980); and estuarine macrobenthos populations decreased in abundance and species after exposure for 13 weeks to 15.8 µg/L (Tagatz et al. 1981). Also, an air concentration of 0.2 mg/m³ — a tolerable level to humans (Table 23.7) — interfered with photosynthesis in

duckweed, *Lemna minor* (Huber et al. 1982). As judged by these studies, it seems appropriate to suggest modification of certain aquatic PCP criteria. A maximum PCP concentration of 3.2 µg/L is indicated, and this level would probably protect most aquatic species, although it would not prevent accumulations and growth inhibition in salmonids or accumulations in oysters. Some downward modifications have been proposed (see [Table 23.7](#)). However, additional research is needed to establish sound water quality criteria for PCP, and also to interpret the significance of its residues and their metabolites in tissues of representative species.

Microorganisms and other bioremediation processes followed by hyperfiltration may be useful in removing PCP from groundwater and yielding a final effluent acceptable for discharge into the environment or into a municipal sewage treatment facility (Wall and Stratton 1991; Middaugh et al. 1994a). At present, diluted PCP-contaminated groundwater may be discharged into the sewerage collection system of Escambia County, Florida, provided that 1% solutions were not teratogenic or embryotoxic to embryos of the inland silverside (*Menidia beryllina*) or lethal to the daphnid (*Ceriodaphnia dubia*) (Middaugh et al. 1994b). More research is encouraged on the use of sentinel organisms to assess PCP water quality (Middaugh et al. 1994b).

Dietary concentrations of 1.0 mg/kg and higher produced diarrhea and liver histopathology in chickens (*Gallus* spp.) after 8 weeks (Stedman et al. 1980), and deaths occurred at relatively high dietary concentrations (i.e., 3850 mg/kg, in Japanese quail [*Coturnix japonica*] after 5 days) (Hill and Camardese 1986). Wood shavings contaminated with PCP produced elevated residues when used as litter for domestic chickens (Newsome et al. 1984), and death in canaries (*Serinus canarius*), when used as nesting materials (Dorresteijn and Zelle 1979). Tissue residues >2 mg/kg fresh weight are considered to be indicative of significant environmental PCP contamination, and those >11 mg/kg fresh weight were associated with birds that died or were recovering from PCP exposure ([Table 23.7](#)) (Vermeer et al. 1974). No data are currently available on avian wildlife and PCP contamination in their diets, residues in their tissues, or frequency of use of PCP-contaminated wood shavings for nesting materials and other purposes.

As judged by studies with domestic and small laboratory mammals, no observable adverse effects have been noted at dietary levels equivalent to 3 to 10 mg PCP/kg BW ([Table 23.7](#)). Variability is great among species, however, and adverse effects have been documented in some species ([Table 23.7](#)) at doses as low as 0.05 to 0.2 mg/kg BW (elevated tissue residues), 0.2 to 2.0 mg/kg BW or 50 mg/kg diet (histopathology, reproductive impairment, increased tumor frequency), and 55 to 60 mg/kg BW (death). Based on guidelines for carcinogen risk assessment and inadequate evidence for animal carcinogenicity or absence of human cancer data, PCP is classified as group D, meaning that it is *not* classified as a human carcinogen (Choudhury et al. 1986). More research is recommended on the genotoxic and carcinogenic potential of PCP and its metabolites, with special reference to tetrachlorohydroquinone (WHO 1987; Jansson and Jansson 1992; USPHS 1994).

Data for humans show that adverse effects occur at concentrations in air >1.0 mg PCP/m³ and in tissues at more than 8 mg/kg fresh weight ([Table 23.7](#)). No adverse effects were noted at daily intakes of 2.1 mg per 70-kg adult or 30 µg/kg BW, up to 1.01 mg/L in drinking water, <0.5 mg/m³ in air, <0.5 mg/L in blood plasma, and <1.0 mg/L in blood ([Table 23.7](#)). It is noteworthy that the recommended PCP air concentration of 0.5 mg/m³ results in a daily intake of 2.5 to 3.8 mg (based on 15 to 23 m³ of air inhaled daily, 8-h exposure), equivalent to 42 to 63 µg/kg BW for a 60-kg female. These levels are higher than the currently recommended no-adverse-effect level of 30 µg/kg BW daily ([Table 23.7](#)), and overlap or exceed the 58 to 74 µg/kg BW daily range — a level recommended by Williams (1982). Air concentrations >1.0 mg PCP/m³ can produce respiratory irritation in unacclimatized individuals, but concentrations as high as 2.4 mg/m³ can be tolerated by conditioned individuals (USEPA 1980). The biological tolerance value of <1000 µg PCP/L in blood, recommended by Ziems et al. (1987), is based on occupational air exposure studies: exposure to maximum average air concentrations of 0.18 mg PCP/m³ for up to 34 years produced blood PCP residues of 23 to 775 µg/L, with no measurable adverse effects. The authors concluded

that PCP and its impurities in occupationally relevant concentrations below the maximum concentration in the workplace and below the biological tolerance value do not produce genotoxic damage that can be detected on the chromosomal level, either *in vivo* or *in vitro*.

The human taste threshold for PCP in drinking water is about 30 µg/L (USEPA 1980), a level far below the upper safe limit of 1.01 mg/L and near the no-observable-effect level of 21 µg/L (Table 23.7). Odor detection is not as sensitive as taste: the odor threshold for PCP ranges from about 857 µg/L at 30°C, to 1600 µg/L at 20 to 22°C, to 12,000 µg/L at 60°C (USEPA 1980). It is not clear whether the determined organoleptic threshold values made the water undesirable or unfit for consumption (USEPA 1980). If fish and wildlife species of concern have PCP organoleptic thresholds that are similar to those of humans, or lower, will they too avoid contaminated habitats or diets?

Data for PCP and terrestrial wildlife are incomplete and — in view of the large interspecies variations in sensitivity — need to be collected. Research is needed on reproductive effects in animals following inhalation exposure to PCP; additional acute and intermediate toxicity testing; chronic duration exposure studies on cancer induction, genotoxicity, and immunotoxicity; and the development of alternate biomarkers of PCP exposure and antidotes (WHO 1987; USPHS 1994). Until the results of these studies become available, it seems reasonable to apply to wildlife the same levels recommended for human health protection.

Table 23.7 Proposed Pentachlorophenol Criteria for the Protection of Natural Resources and Human Health

Resource and Criterion	Concentration or Dose	Reference ^a
AQUATIC BIOTA		
Freshwater life		
Acute (former)	48 to <55 µg/L	1–3
Chronic (former)	<3.2 µg/L	1
24-h mean (former)	<6.2 µg/L	2
Current		
pH 6.5	4-day mean concentration not to exceed 3.5 µg/L more than once every 3 years and 1-h mean concentration does not exceed 5.5 µg/L ^e	28
pH 7.8	4-day mean concentration not to exceed 13.0 µg/L more than once every 3 years and 1-h mean concentration does not exceed 20 µg/L ^e	28
pH 9.0	4-day mean concentration not to exceed 43.0 µg/L more than once every 3 years and 1-h mean concentration does not exceed 68 µg/L	28
Maximum concentration		
Fish	<140 µg/L	2
Warmwater species	10 to <15 µg/L	4
Coldwater species	20 to <40 µg/L	4
Saltwater life		
Acute (former)	<53 µg/L	1
Chronic (former)	<34 µg/L	1, 5
Current	4-day mean concentration not to exceed 7.9 µg PCP/L more than once every 3 years, and 1-h concentration does not exceed 13.0 µg/L more than once every 3 years	28

^e At pH 6.6, a water concentration of 1.74 µg PCP/L caused a 50% reduction in growth of yearling sockeye salmon in an 8-week test (USEPA 1986).

23.6 SUMMARY

Pentachlorophenol (PCP) is a synthetic organochlorine compound that was first manufactured commercially in 1936 and is now used primarily as a wood preservative and secondarily as an herbicide, insecticide, fungicide, molluscicide, and bactericide. Current global production of PCP is estimated to be 50 million kg annually. Widespread use of PCP has resulted in the detection of residues in air, rain, snow, groundwater, surface water, drinking water, fish, and aquatic invertebrates, as well as in human urine, blood, and milk. Pentachlorophenol may be incorporated into animal tissues through inhalation, diet, or contact; its toxic action results from its ability to interfere with the production of high-energy phosphate compounds essential for cell respiration. Pentachlorophenol has caused numerous occupational illnesses and deaths, and has had significant adverse effects on domestic animals. It is fetotoxic and teratogenic, but evidence for mutagenicity and carcinogenicity is incomplete or negative. Commercial PCP preparations often contain variable amounts of toxic impurities — including chlorophenols, hexachlorobenzene, phenoxyphenols, dioxins, and dibenzofurans — that contribute to its toxicity. Pentachlorophenol is rapidly accumulated and rapidly excreted, and has little tendency to persist in living organisms; it is readily degraded in the environment by chemical, microbiological, and photochemical processes.

In sensitive aquatic species, PCP adversely affected growth, survival, and reproduction at media concentrations of 8 to 80 µg PCP/L in algae and higher plants, at 3 to 100 µg/L in invertebrates,

and <1 to 68 µg/L in fish. In birds, PCP was fatal at 380 to 580 mg/kg body weight (BW) in oral doses, >3580 mg/kg in the diet, and >285 mg/kg in contaminated nesting materials (i.e., wood shavings). Residues >11 mg PCP/kg fresh weight in bird tissues were associated with acute toxicosis. Adverse sublethal effects in birds were noted at dietary levels as low as 1 mg/kg ration. In small laboratory mammals and domestic livestock, acute oral LD₅₀ values ranged from 27 to 300 mg/kg BW. Tissue residues in mammals were elevated at PCP doses as low as 0.05 mg/kg BW, and at air levels >0.1 mg/m³. Histopathology, reproductive impairment, growth retardation, and other effects were evident in sensitive mammals at PCP concentrations of 0.2 to 1.25 mg/kg BW, and at dietary levels >30 mg/kg ration.

Pentachlorophenol is an undesirable pollutant whose use patterns should be carefully regulated to avoid contamination of soil, water, and food. Recommendations for protection of sensitive fishery and wildlife resources follow; however, it is emphasized that some of these recommendations are markedly lower than those proposed by regulatory agencies. For protection of aquatic life, it is recommended that the PCP water concentration not exceed 3.2 µg/L; but even at this level, certain species of fishes and oysters accumulate enough of the toxicant to retard their growth. In birds, dietary concentrations greater than 1.0 mg/kg feed and tissue residues greater than 2.0 mg/kg fresh weight should be viewed as presumptive evidence of significant environmental PCP contamination. Data are scarce for PCP and mammalian wildlife; until more data are collected, PCP levels recommended for human health protection (i.e., “no adverse effects” levels) are suggested as reasonable substitutes. In humans, no adverse effects were noted at daily PCP intakes equivalent to 39 µg/kg BW in food, or at concentrations of 21 µg/L in drinking water, 0.5 mg/m³ in air, 0.5 mg/L in blood plasma, and 1.0 mg/L in blood.

CHAPTER 24

Polychlorinated Biphenyls

24.1 INTRODUCTION

Polychlorinated biphenyls (PCBs), a group of 209 synthetic halogenated aromatic hydrocarbons, are used extensively in the electricity generating industry as insulating or cooling agents in transformers and capacitors. Because of human activities and the chemical characteristics of the products, PCBs are now distributed worldwide, and measurable concentrations occur in aquatic organisms and wildlife from North America, Europe, the United Kingdom, and the Atlantic and Pacific Oceans. PCBs elicit a variety of effects, including death, birth defects, reproductive failure, liver damage, tumors, and a wasting syndrome. They bioaccumulate and biomagnify in the food chain. Legislation has prohibited virtually all uses of PCBs and their manufacture in the United States since 1979; the ban has been accompanied by declines in PCB residues in fishes and wildlife. But the current environmental burden of PCBs in water, sediments, disposal sites, deployed transformers, and other PCB containers — now estimated at more than 374 million kg, much of it localized — continues to represent a potential hazard to associated natural resources (Pal et al. 1980; Eisler 1986; Hansen 1987; Parkinson and Safe 1987; Safe 1987a, 1990, 1994; Huckins et al. 1988; Tanabe 1988; Skaare et al. 1991; U.S. Public Health Service [USPHS] 1995; Eisler and Belisle 1996; Hoffman et al. 1996a; Niimi 1996).

24.2 SOURCES AND USES

The Monsanto Industrial Chemical Company, the principal domestic manufacturer of PCBs, began PCB production in 1929; commercial mixtures of PCBs were also produced in Western Europe and Japan. PCBs have been used in dielectric fluids; in waxes for metal castings; as heat transfer agents; as plasticizers in paints, coatings, and carbonless copy paper; in cutting oils; in sealants and caulking compounds; and as pesticide extenders (Eisler 1986). The use of PCBs was curtailed in the United States in 1971, and sales were limited to manufacturers of capacitors and transformers; all new uses were banned in 1976 (U.S. National Oceanic and Atmospheric Administration [NOAA] 1991). In 1977, all production of PCBs was halted, and no shipments were made after October. Direct and indirect sources of PCB contamination may include aerial transport of combustion products, vaporization from continental and marine areas, current and historic industrial and municipal waste discharges, precipitation, land runoff, concealed dumping, transformer fires, and accidental spills (NOAA 1991; U.S. Environmental Protection Agency [USEPA] 1992a).

The ubiquity of PCBs is indicated by their presence in environmental samples from the polar regions of air, snow, ice, water, and in living organisms (Norstrom et al. 1988; Hargrave et al. 1989; Larsson et al. 1992; Tanabe et al. 1993). The presence of PCBs in such remote areas suggests the importance of atmospheric transport. The Committee on the Assessment of Polychlorinated Biphenyls

in the Environment estimated that 50 to 80% of the PCBs derived from the United States were now in sediments and waters of the north Atlantic Ocean (National Academy of Sciences [NAS] 1979). Of the estimated total world PCB production of 1.2 million tons to date, about 374,000 tons are now in various portions of the terrestrial, coastal, and open ocean ecospheres (Table 24.1). Another 783,000 tons are still in use in electrical equipment and other products or deposited in landfills and dumps (Tanabe 1988) and represent a potential source of environmental contamination. An additional 43,000 tons have been degraded or incinerated (Tanabe 1988). Long-range atmospheric and oceanic transport seem to be the primary mechanisms of global PCB dispersal (Kannan et al. 1989).

Table 24.1 Estimated PCB Loads in the Global Environment

Ecosystem	PCB Loads (metric tons)
TERRESTRIAL AND COASTAL	
Air	500
River and lakewater	3500
Seawater	2400
Soil	2400
Sediment	130,000
Biota	4300
OPEN OCEAN	
Air	790
Seawater	230,000
Sediment	110
Biota	270
TOTAL	374,000

Data from Tanabe, S. 1988. PCB problems in the future: foresight from current knowledge. *Environ. Pollut.* 50:5-28.

24.3 CHEMICAL AND BIOCHEMICAL PROPERTIES

24.3.1 General

Polychlorinated biphenyls, a highly lipophilic group of global pollutants, consist of 209 congeners (Figure 24.1) with widely different toxicity and other biological effects (Kannan et al. 1989). In vertebrates, toxicological effects of PCBs have been related to their ability to induce the cytochrome P-450-dependent monooxygenase system (P-450). This varies with the degree of chlorination and the arrangement of chlorine atoms on the biphenyl molecule (Skaare et al. 1991). Transformation of PCBs to hydroxylated metabolites by the cytochrome P-450 system is the major pathway of PCB metabolism (Sipes and Schnellmann 1987) and occurs mainly in the liver. The rate of cytochrome P-450-catalyzed hydroxylation of PCBs decreases as the number of chlorine atoms increases and as the number of unsubstituted adjacent carbon atoms decreases. Some animals metabolize PCBs at different rates, and this is related in part to differences in the basal level of particular isozymes of cytochrome P-450 present in liver. For example, the dog eliminates PCBs more rapidly than other species because it has higher levels of a constitutive isozyme of cytochrome P-450 with activity toward the slowly metabolized, bioaccumulated 2,2',4,4',5,4'-hexachlorobi-

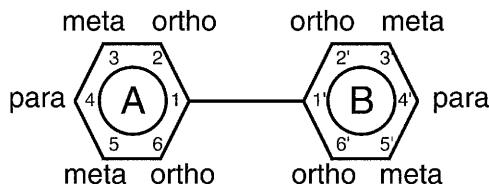

Figure 24.1 Structure of biphenyl. (Modified from National Academy of Sciences 1979; USEPA 1980; Safe 1984, 1994; Eisler 1986.) Polychlorinated biphenyls (PCBs) are commercially produced by chlorination of a biphenyl with anhydrous chlorine in the presence of iron filings or ferric chloride as the catalyst. Depending on the conditions under which chlorination occurred, the purified product is a complex mixture of chlorobiphenyls containing 18 to 79% chlorine. Ten possible degrees of chlorination of the biphenyl group produce 10 PCB congener groups: mono-, di-, tri-, tetra-, penta-, hexa-, hepta-, octa-, nona-, and decachlorobiphenyl. Within any congener group, a number of positional isomers are possible. For example, the tetrachlorobiphenyl group consists of 30 possible isomers, and the pentachlorobiphenyl congener group contains 46 possible isomers. Not all of the 209 possible isomers are likely to be formed during the manufacturing process. In general, the most common PCB isomers formed have either an equal number of chlorine atoms on both rings, or a difference of one chlorine atom between rings. Chlorine substitution is favored at the *ortho*- and *para*-positions; however, commercial products are complex mixtures of isomers and congeners with no apparent positional preference for halogen substitution.

phenyl (Hansen 1987; Sipes and Schnellmann 1987). The reactive arene oxides formed during biotransformation can bind covalently to tissue macromolecules or conjugate with glutathione. Derivatives of glutathione conjugates and glucuronides of the hydroxylated products are major PCB metabolites. Biotransformation of xenobiotics by cytochrome P-450 is not always beneficial to the organism because metabolites can be more toxic or biologically active than the parent compound (Parkinson and Safe 1987). The carcinogenic effect of certain xenobiotics depends on the conversion by cytochrome P-450 to a reactive carcinogenic metabolite (Parkinson and Safe 1987). In general, PCB metabolites are less toxic than their parent compounds, although hydroxylated metabolites of 3,3',4,4'-tetrachlorobiphenyl can disrupt thyroxine levels and serum transport of Vitamin A in rodents (Klasson-Wehler et al. 1998). Hydroxylated metabolites and methylsulfonyl metabolites of PCBs were found in plasma and liver of the Laysan albatross (*Diomedea immutabilis*) and the black-footed albatross (*Diomedea nigripes*). Total concentrations of hydroxylated metabolites accounted for 20 to 100% of the total PCBs, but methylsulfonyl metabolites accounted for only 0.004% of the total PCBs (Klasson-Wehler et al. 1998). Metabolites and possible degradation pathways of selected PCBs in mammals are presented in detail by Sipes and Schnellmann (1987).

Sedimentation and volatilization are the dominant processes that determine the fate of PCBs in lakes. Both processes remove PCBs from the water, but the relative importance of the transferred amount is influenced by particulate dissolved-phase partitioning that determines the relative size of the particulate pool for sedimentation and the soluble pool for volatilization of PCBs (Millard et al. 1993). PCB-contaminated sediments from the St. Lawrence River (300 mg total PCBs/kg DW sediment) dechlorinated rapidly (36% loss during the first 4 months) under laboratory incubations over a 39-month period, and more slowly afterwards (Sokol et al. 1998). High productivity of algae increased the proportion of added PCBs that is absorbed to particulate matter and sedimented. In general, PCB volatilization losses increase under conditions of high mixing and low productivity (Millard et al. 1993). Volatilization of mono-, di-, and trichlorobiphenyls from Aroclor 1248-contaminated sediments occurs at ambient environmental conditions with volatilization enhanced by microbial reductive dechlorination (Bushart et al. 1998). Aroclor 1242 and 1254 were anaerobically dechlorinated by microorganisms eluted from PCB-contaminated sediments. Dechlorination occurred mainly from the *meta*-position and suggests that dioxin-like toxicities of PCB mixtures are markedly reduced by microbial reductive dechlorination (Quensen et al. 1998).

24.3.2 Physical Properties

Mullin et al. (1984) synthesized and determined the retention times and response factors relative to a reference standard (octachloronaphthalene) of all 209 congeners (Table 24.2) by using temperature-programmed, high-resolution gas chromatography, and electron-capture detection methods (HRGC/ECD). The relative retention times (the ratio of congener retention time/reference standard retention time) of 187 of the 209 congeners differed and permitted HRGC column identification contingent on full or partial separation. Eleven congener pairs had the same retention times and coeluted: 60/56, 70/76, 94/61, 95/80, 133/122, 140/139, 144/135, 145/81, 163/160, 202/171, and 203/196. Of the 209 congeners, 20 can assume a planar configuration (Creaser and Al-Haddad 1989) because of the absence of chlorine substitution in the *ortho*-positions (Hong et al. 1992) (Figure 24.1). Approximately 1% of the non-*ortho*-substituted biphenyl molecules adopt the planar configuration (Safe 1987a). Among the isomers of each homolog, the planar PCBs had the longest retention times. The presence of *ortho*-chloro-substituents reduces planarity of the rings. However, congeners with 1 or 2 *ortho*-chlorines can also assume a planar ring position (Safe 1990). Although peak resolution is greatly improved by substitution of high-resolution capillary columns for packed columns, more than one candidate congener may occur at many GC peaks. Using a narrow bore column, Duinker et al. (1988a) found only 17 PCB congeners that were fully separated without potential interference from coeluting congeners.

The transport and fate of PCBs in aquatic systems and their partitioning between sediment, water, and organisms depends largely on sorption reactions. In soils, the sorption and retention of PCB congeners is influenced by the number of chlorine atoms in the molecule, and the more highly chlorinated PCBs tend to be more strongly bound. Relative sorption capacity and other properties of congeners also depend on PCB configuration. The soil sorption capacities of PCB congeners and their bioconcentration factors were related to octanol/water partition coefficients (Connor 1984) as follows:

$$K_{ow} = C_{ow}/C_{wo}$$

where K_{ow} is the octanol/water partition coefficient, C_{ow} the concentration of the solute in octanol saturated with water, and C_{wo} the concentration of the solute in water saturated with octanol.

K_{ow} values are used to estimate bioconcentration factors (bioaccumulation after uptake from water), soil and sediment organic carbon/water partition coefficients, toxicities, and aqueous solubilities (Woodburn et al. 1987; Hawker and Connell 1988). Techniques for measuring the K_{ow} values include the shake-flask method (Shiu and Mackay 1986), the reverse-phase thin-layer chromatography (Bruggeman et al. 1982), reverse-phase high-performance liquid chromatography (Rapaport and Eisenreich 1984), and the generator column technique (Woodburn et al. 1987; Hawker and Connell 1988), or it can be calculated by an estimation technique based on correlation with properties of compounds with known K_{ow} values. From a strong linear relation calculated between known log K_{ow} values and calculated total surface areas (TSA; correlation coefficient of 0.951 for 30 congeners), Hawker and Connell (1988) estimated K_{ow} values of individual congeners from the calculated TSA. Estimated K_{ow} values (Table 24.2) were previously unavailable for many PCB congeners, including toxic non-*ortho*-substituted congeners found only in relatively small amounts in commercial Aroclors. Reported K_{ow} values of some congeners vary in the literature and may not be comparable when different measuring techniques are used. Reverse-phase thin-layer chromatography (RP-TLC) and high-performance liquid chromatography (RP-HPLC) require empirical correction factors. Discrepancies in K_{ow} values between the generator column and RP-HPLC techniques for *ortho*-PCBs relative to the other PCBs were resolved with an *ortho*-correction factor (Woodburn et al. 1987). Nonplanarity of the *ortho*-substituted PCBs may reduce the ability of the solute to interact with the stationary phase in RP-TLC (Bruggeman et al. 1982). Despite these uncertainties, the K_{ow} is routinely used in hazard evaluation and risk assessment of most organic chemicals.

24.3.3 Toxic Equivalency Factors

A significant part of the toxicity associated with commercial PCB mixtures is related to the presence of the small number of planar congeners. These compounds induce several similar toxic effects in mammals and birds, such as hepatotoxicity, immunotoxicity, and reproductive toxicity (Janz and Metcalfe 1991b; Brunstrom et al. 1995). Planar halogenated aromatic compounds act, in part, by a common mechanism initiated by binding to a cytosolic aryl hydrocarbon receptor. The relative toxicities of planar halogenated hydrocarbons are calculated by expressing their toxicity in relation to 2,3,7,8-TCDD, the most potent compound in this class of chemicals. Toxic equivalency factors (TEFs) are fractional potencies that relate a compound's potency to that of 2,3,7,8-TCDD. The 2,3,7,8-TCDD TEF has been used to estimate the relative toxic potencies of individual planar halogenated hydrocarbons (Safe 1987b; 1990, 1994; Janz and Metcalfe 1991b; Johansen et al. 1993). According to Safe (1990), TEF values should be derived from data on the following effects in descending order of priority:

1. Long-term carcinogenicity studies
2. Reproductive studies
3. Subchronic studies that measure Ah receptor-mediated responses, such as thymic atrophy, loss in body weight, and immunotoxicity
4. Acute toxicity studies
5. *In vivo* or *in vitro* biochemical responses such as enzyme induction and receptor binding.

Relative toxic potencies are modified by many variables, including age, sex, species, and strain of the animal; the efficiency of the chemical to induce cytochrome P-450 and associated monooxygenase enzyme activities, glucuronosyl and glutathione transferases, and other drug-metabolizing enzymes; and the efficiency of the organism to modulate steroid-metabolizing enzymes, induce delta-aminolevulinic acid synthetase, inhibit porphyrinogen decarboxylase, decrease Ah receptor binding activity, and alter Vitamin A and thyroid hormone levels (Safe 1990, 1994).

The *in vitro* induction of the cytochrome P-450c-dependent monooxygenases, AHH, or EROD by 2,3,7,8-TCDD and related halogenated aryl hydrocarbons in rat liver cells was developed as a short-term quantitative bioassay for these chemicals. Aromatics that do not fit this correlation are considered as congeners that are readily metabolized *in vivo* (Safe 1987b). Induction of either AHH or EROD activity in the H4IE rat hepatoma cell line by PCB, PCDF, and PCDD congeners, either singly or in combination, correlates well with the *in vivo* toxicity of these compounds to rats (as quoted in Ankley et al. 1991). The proposed mean TEF values range from 0.01 to 0.1 in non-*ortho*-substituted planar PCBs, to 0.001 in mono-*ortho*-substituted planar PCBs, to 0.00002 in di-*ortho*-substituted planar PCBs (Table 24.3). Although the concentration of non- and mono-*ortho*-substituted PCBs in animal tissues ranges from about 0.01 µg/kg to several micrograms per kg (about 1000 to 100,000 times lower than the sum of total PCBs), it is significantly higher than the concentration of the highly toxic 2,3,7,8-TCDD and 2,3,4,7,8-pentachlorodibenzofuran. Accordingly, the non- and mono-*ortho*-PCBs — despite their lower toxic potency — often contribute as much or more to the 2,3,7,8-TCDD-like activity than either dioxins or furans (Johansen et al. 1993). However, the overall importance of mono-*ortho*-PCBs to the TEF is questioned by Ahlborg et al. (1994), and this must be considered in future risk assessment evaluations.

Table 24.3 Proposed Toxicity Equivalency Values (TEF) Relative to 2,3,7,8-TCDD of non-*ortho*, mono-*ortho*, and di-*ortho* Planar PCBs

PCB congener	TEF
NON-<i>ORTHO</i> PLANAR PCBs	
PCB 77	0.0005
PCB 126	0.1
PCB 169	0.01
MONO-<i>ORTHO</i> PLANAR PCBs	
PCB 105	0.0001
PCB 114	0.0005
PCB 118	0.0001
PCB 123	0.0001
PCB 156	0.0005
PCB 157	0.0005
PCB 167	0.00001
PCB 189	0.0001
DI-<i>ORTHO</i> PLANAR PCBs	
PCB 170	0.0001
PCB 180	0.00001

Data from Safe 1990, 1994; Ahlborg et al. 1994.

Mammal-derived TEFs underestimate the potency of planar PCB mixtures in fish (Newsted et al. 1995). TEF values of non-*ortho*-PCB congeners based on mortality of rainbow trout in early life stages are as much as 1000 times lower than TEFs proposed for human risk assessment (Walker

and Peterson 1991, 1994). Clemons et al. (1996) compared TEFs for PCBs using cytochrome P-4501A1 induction measured as EROD activity in a rainbow trout liver cell line and in a rat hepatoma cell line. EROD activity in trout liver cells was induced only by PCBs 77, 81, 118, and 126 under normal growth conditions, and in some cultures with PCBs 105, 156, and 169. The trout TEFs were 0.023 for PCB 126, 0.064 for PCB 81, 0.0034 for PCB 77, 0.00016 for PCB 169, and 0.000017 for PCB 118; TEFs for PCBs 105 and 156 were <0.00003. In rat cells, however, all seven PCBs clearly induced EROD activity. Clemons et al. (1996) concluded that the toxic impact of PCBs on rainbow trout is overestimated by risk assessment TEFs based on rat cells and assessed more appropriately with TEFs derived from rainbow trout cells.

24.3.4 Structure—Function Relations

Safe (1984, 1990) described three classes of PCB congeners on the basis of their ability to induce benzo[*a*]pyrene hydroxylase (also known as aryl hydrocarbon hydroxylase or AHH) and ethoxyresorufin *O*-deethylase (EROD) activities:

1. Planar PCBs
2. Mono-*ortho*-analogs of the planar PCBs
3. Di-*ortho*-analogs of the planar PCBs

Among the 20 possible planar PCB congeners and their analogs (Figure 24.2), the most toxic in rats were PCBs 77, 126, and 169; these three congeners are approximate isostereomers of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (2,3,7,8-TCDD) and have similar toxic effects, including induction of 3-methylcholanthrene-type drug-metabolizing enzymes, body weight loss, thymic atrophy, dermal disorders, hepatic damage, high binding affinity to hepatic cytosolic receptor proteins, immunotoxicity, reproductive impairment, and teratogenicity (Massee et al. 1986; Parkinson and Safe 1987; Tanabe et al. 1987; Gooch et al. 1989; Kannan et al. 1989; Janz et al. 1992; Himberg 1993; Giesy et al. 1994a). PCBs 77, 126, and 169 have been detected in eggs of terns from Lake Michigan, in marine mammals and humans, and in fish from the Hudson and Ohio Rivers (Huckins et al. 1988). However, they are difficult to detect without proper methods (Tanabe 1988; Schwartz et al. 1993).

The structural characteristics of individual PCB congeners influence their induction of various P-450 activities. In mammals, PCB congeners have been characterized as 3-methylcholanthrene-type inducers, phenobarbital-type inducers, or mixed-type inducers of both. AHH and EROD activities (which are preferentially catalyzed by the P-4501A gene subfamily) have been induced by planar PCBs in fish and mammals and by some mono- and di-*ortho*-analogs of planar PCBs in mammals (Skaare et al. 1991). The mechanism of toxic action of planar and mono-*ortho* planar PCBs is linked to an interaction with the 2,3,7,8-TCDD (or Ah) receptor protein. But this mechanism does not account for all observed PCB toxicities (Hansen 1987; Safe 1994). Toxic responses unrelated to Ah receptor effects have been reported of PCBs 4, 28, 31, 49, 52, 84, 95, 110, 136, and 153. For example, PCB 153 is less cytotoxic than PCB 169 but is a more effective inhibitor of intercellular communication. PCB 52 caused moderate chick embryotoxicity; however, PCBs 18 and 153 were inactive, and PCBs 84 and 118 were severely toxic but by different mechanisms (Hansen 1987). The induction of cytochrome P-4501A activity in the presence of both an inducer (PCB 126) and low concentrations of an inhibitor (tributyltin = TBT) indicates that TBT does not interfere with the Ah receptor binding (Kannan et al. 1998). Potentiation of EROD activity and cytotoxicity as a result of coexposure to PCB 126 and TBT is significant because they both accumulate in a variety of marine organisms (Kannan et al. 1998).

Group I planar PCBs are 10 times more toxic and 100 times more effective as inducers of cytochrome P-450c-dependent monooxygenase and 70 times more effective in competitively displacing 2,3,7,8-TCDD from a rat cytosol receptor protein than Group II planar PCBs (Table 24.4;

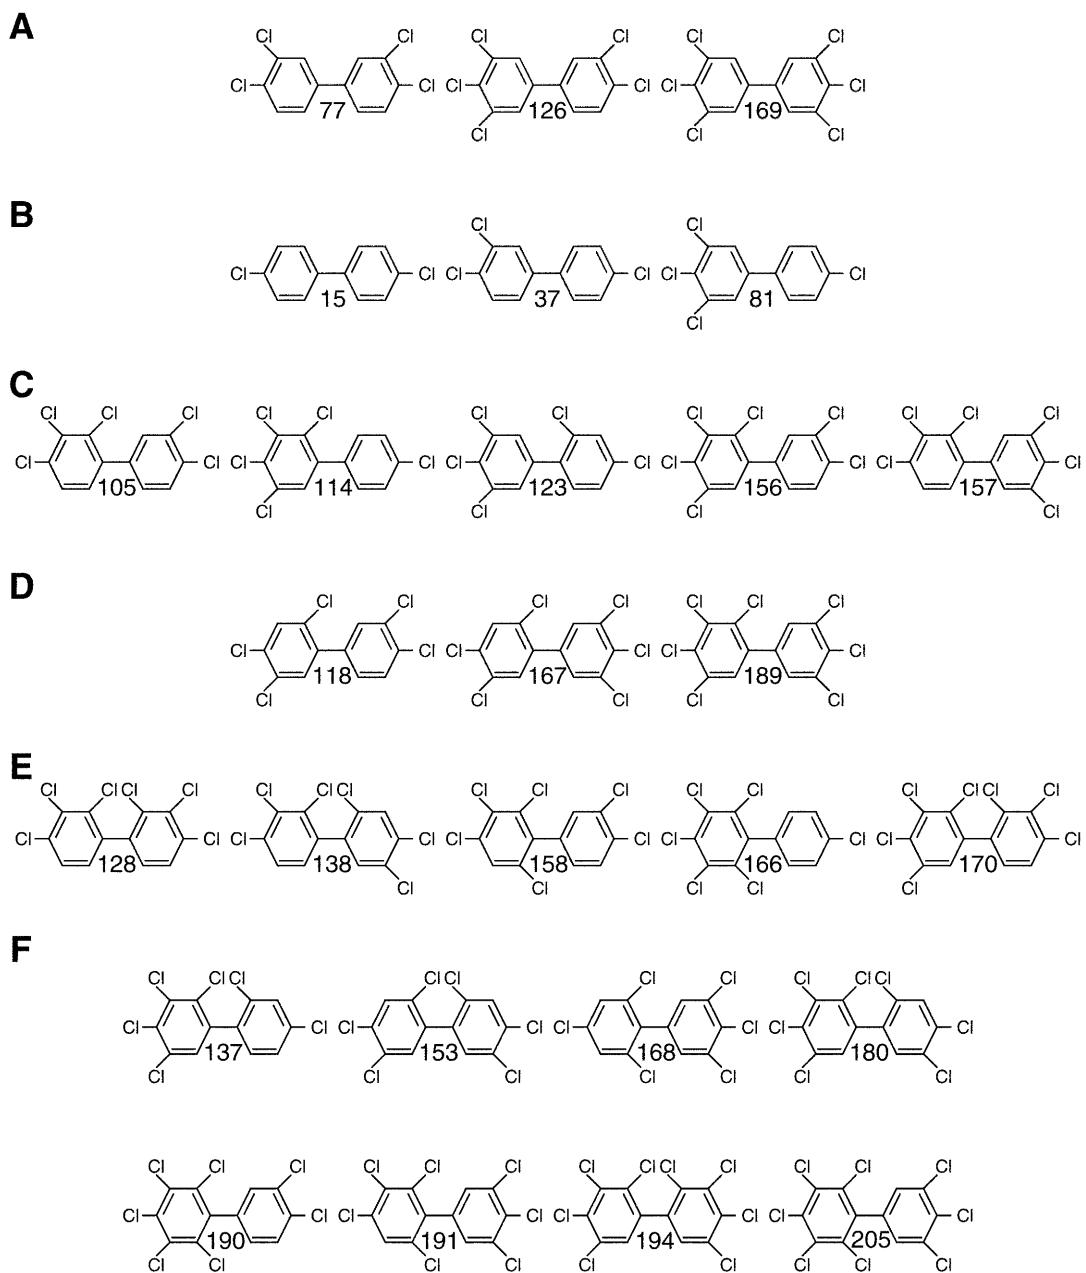

Figure 24.2 (See caption on facing page.)

Safe 1990; [Figure 24.2](#)). Mono-*ortho*-analogs of the planar PCBs have one substituent in the *ortho* (2 or 2') position; these compounds possess diminished yet significant EROD- or AHH-inducing capacity and also induce P-450 forms that are induced by the phenobarbital class of compounds (Gooch et al. 1989). Mono-*ortho*-derivatives (PCBs 105, 118, 156, and 189) may be more important in terms of 2,3,7,8-TCDD-like activity and in occurrence (Hansen 1987). Di-*ortho*-analogs of the planar PCBs, that is, those with *ortho*-, *meta*-, and *para*-substituents, possess still weaker but significant AHH-inducing activity (Gooch et al. 1989). Certain di-*ortho*-derivatives of the 3,3',4,4' pattern (PCBs 128, 138, 153, 170, 180) are significant components of PCB residues; however, PCBs 128, 138, and 170 have reduced 2,3,7,8-TCDD-like effects (Hansen 1987). In rats, several

Table 24.4 Interactive Effects of PCBs on the Induction of Rat (*Rattus* sp.) Liver Microsomal Cytochrome P-450c

Data from Parkinson, A. and S. Safe. 1987. Mammalian biologic and toxic effects of PCBs. Pages 49-75 in S. Safe (ed.). *Polychlorinated Biphenyls (PCBs): Mammalian and Environmental Toxicology*. Environ. Toxin Ser. 1. Springer-Verlag, New York.

PCBs (105, 114, 118, 123, 126, 156, 157, 169) produced a linear correlation between the EC50 response (*in vitro*) of AHH induction against the ED50 (*in vivo*) of body weight loss, thymic atrophy, hepatic AHH, and EROD induction (Safe 1987b). The planar mono- and di-*ortho*-derivatives (PCBs 105, 118, 156, 189, 128, 138, 153, 170, 180) are referred to as mixed inducers because they elicit effects similar to coadministration of phenobarbital plus methylcholanthrene (Hansen 1987).

PCB 156, a mixed inducer of microsomal enzymes, significantly increases the incidences of cleft palates by 2,3,7,8-TCDD in rodents (Birnbaum et al. 1985). Interactions among polychlorinated congeners may range from antagonism to additivity to synergism (Safe 1990), and the toxicity of individual PCBs can be raised by interaction with other PCBs (Table 24.5).

Figure 24.2 Planar polychlorinated biphenyls and their derivatives. (Data from Hansen 1987; Parkinson and Safe 1987; Safe 1987b, 1994; Tanabe et al. 1987; Kannan et al. 1989; de Voogt et al. 1990; Ankley et al. 1991; Sonzogni et al. 1991; Hong et al. 1992; Johansen et al. 1993.) The general order of biological activity is: Group I non-*ortho* planar PCBs > Group II non-*ortho* planar PCBs > mono-*ortho* planar PCBs > di-*ortho* planar PCBs. **A.** Group I: potent non-*ortho* planar PCBs. This group contains no *ortho*-, 2 *para*-, and at least 2 *meta*-chlorines (PCBs 77, 126, and 169), and are approximate stereoisomers of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (2,3,7,8-TCDD). They are less potent than 2,3,7,8-TCDD but elicit similar biological responses, including induction of cytochrome P-450 and aryl hydrocarbon hydroxylase (AHH). This group is the most biologically active of all planar PCBs and their derivatives. **B.** Group II: less-potent non-*ortho* planar PCBs (PCBs 15, 37, and 81). Group II non-*ortho* planar PCBs, when compared to Group I, were only 0.1 times as toxic, 0.01 times as effective in inducing cytochrome P-450c-dependent monooxygenase, and about 0.015 times as effective in competitively displacing 2,3,7,8-TCDD from a cytosol-receptor protein in rat liver. **C.** Potent mono-*ortho* planar PCBs. The addition of a single *ortho*-chlorine substituent to non-*ortho* planar PCBs 77, 81, 126, and 169 yields eight derivatives, of which five (PCBs 105, 114, 123, 156, 157) were more potent when the *ortho*-chlorine was adjacent to a *meta*-hydrogen. **D.** Less-potent mono-*ortho* planar PCBs. The toxicity of non-*ortho* planar PCBs is reduced by the introduction of an *ortho*-chloro substituent, especially when it is adjacent to a *meta*-chlorine (PCBs 118, 167, 189). **E.** Potent di-*ortho* planar PCBs. The di-*ortho* planar PCBs are less toxic than the mono-*ortho* planar PCBs. At least five di-*ortho* derivatives (PCBs 128, 138, 158, 166, 170) compete with 2,3,7,8-TCDD for receptor binding sites in rat liver cytosol to induce cytochrome P-450c. **F.** Less-potent di-*ortho* planar PCBs. These eight di-*ortho* derivatives (PCBs 137, 153, 168, 180, 190, 191, 194, 205) are less potent than those figured in E.

Table 24.5 Summary of PCB Structure—Function Relations in Rats (*Rattus* sp.)

PCB Structure	Cytochrome P-450 Induction (% of controls)		Relative Activity (% of controls)		Receptor Binding
	P-450c + P-450d	P-450b + P-450e	In vivo	In vitro	
Planar PCBs: Group I	1800–4100	None	+++	1–100	35–100
Planar PCBs: Group II	1100–1500	600–1400	++	0.03	0.5
Mono-ortho planars	750–2400	2600–4700	++	0.00002–0.3	1.5–6
Di-ortho planars	250–900	1000–6300	+	Inactive	<0.3
PCB 153	None	7300	Inactive	Inactive	<0.3
2,3,7,8-TCDD	3500	None	+++++	400	2500

Data from Parkinson, A. and S. Safe. 1987. Mammalian biologic and toxic effects of PCBs. Pages 49–75 in S. Safe (ed.). *Polychlorinated Biphenyls (PCBs): Mammalian and Environmental Toxicology*. Environ. Toxin Ser. 1. Springer-Verlag, New York.

24.3.5 Quantitation

PCBs are chemically inert, nonpolar compounds and relatively stable during collection and storage. However, PCB concentrations in environmental samples vary with different measurement techniques (Kratochvil et al. 1984; Huckins et al. 1990b; Lebo et al. 1992; Prest et al. 1992; Bidleman et al. 1993; Litten et al. 1993), with types of Aroclor standards used for calibration (Table 24.6), and with oven-drying techniques (Table 24.7). Reports of interlaboratory comparison studies for PCB analysis show wide variations and strongly indicate a need for more rigorous quality control and assurance. In one multilaboratory study (Alford-Stevens 1988) — wherein PCBs were determined in water, soil, and sediments — percent recoveries from analysis of fortified waters averaged 60% in the high concentration sample containing 148 µg/L total PCBs and 55% in the low concentration sample of 37 µg/L. No single combination of extraction and cleanup was best for all solid samples. An analytical intercomparison exercise (International Council for the Exploration of the Sea [ICES] 1992) was conducted on solutions containing 10 PCB congeners. Of the 61 evaluated laboratories, a group of 47 laboratories produced between-group standard deviations of 1.10 to 1.13 by all PCB congeners except PCB 52; a group of 11 laboratories was identified as an outlier group. Only three laboratories were able to quantify PCBs 110 and 77, which coelute in most GC columns. Peak height measurements gave better reproducibility than peak area methods. In another intercomparison study, the analysis by 11 laboratories of a solution containing 12 pure congeners resulted in a variation of as much as 20% for analysis of a single congener. For the analysis of the same congeners in a fish oil, the coefficient of variation ranged from 17.4 to 132% (66.2% without outliers) and had a median of 47.1% (ICES 1992).

PCBs in biological samples are usually extracted by a Soxhlet column and with a nonpolar solvent such as hexane. The sample is first mixed with sodium sulfate to remove moisture. The extraction of PCBs from sediments was tested with sonication, with two sonications interspersed at a 24-h quiescent interval, with steam distillation, or with Soxhlet extraction (Dunnivant and Elzerman 1988). Comparison of the recoveries of various PCB mixtures from dry and wet sediments by the four techniques and the extraction efficiency of four solvents showed that the best overall recoveries were obtained by Soxhlet extraction and the two sonication procedures. In comparisons of solvent systems of acetone, acetonitrile, acetone–hexane (1+1), and water–acetone–isoctane (5+1.5+1), recoveries of lower chlorinated congeners (dichloro- to tetrachloro-) were usually higher with acetonitrile and recoveries of higher chlorinated congeners (tetrachloro- to heptachloro-) extracted with acetone were superior (Dunnivant and Elzerman 1988). The completeness of extraction from a sample matrix does not seem to discriminate against specific isomers; however, discrimination in the cleanup and fractionation process may occur and must be tested (Duinker et al. 1988b).

With most analytical techniques for the quantification of PCB residue levels, chromatographic separations were used, most frequently electron-capture gas chromatography (GC/ECD). With early methods, selected peaks were used to estimate total PCBs. Low-resolution separations were satisfactory when packed columns that produced a pattern of peaks with measured areas were used. The patterns were compared with known amounts of Aroclor mixtures. If the Aroclor peaks in a sample closely resembled a particular Aroclor reference mixture of known weight, the total area or peak height of the sample PCBs was compared to those of the reference mixture and the weight of calculated sample PCBs (Kaiser et al. 1980). Other investigators used selected peaks to report Aroclor equivalents (Draper et al. 1991; Turle et al. 1991), but these methods are not useful when samples and Aroclor standards are dissimilar. For another procedure, response factors were used for individual Aroclor peaks as determined by GC and GC-MS procedures (Webb and McCall 1973). The sample peaks were compared with peaks from common Aroclors obtained on packed columns; retention time windows for the early-, middle-, and late-eluting peaks were assigned to three Aroclors (1242, 1254, 1260), based on the presence or absence of specific peaks. The weight of PCB in the sample peak was calculated by multiplying its peak area by the appropriate response factor; all peaks were added to obtain a total weight of PCB. However, packed columns failed to separate and to identify many congeners because several congeners usually eluted under a single peak of identical retention time. These methods do not account for changes in composition from interfering compounds; congener changes from hydrolysis, photodegradation, and biodegradation; selective evaporation and adsorption of certain isomers; or solubility differences resulting in different partitioning ratios among the various environmental compartments. Some researchers, who used capillary columns, estimated PCB residues on the basis of a relatively simple cleanup and analysis by high-resolution GC/ECD (Duinker et al. 1988b; Maack and Sonzogni 1988; Sericano et al. 1990; Draper et al. 1991) or by HRGC-MS (Porte et al. 1988; Niimi and Oliver 1989; Harrad et al. 1992). Others emphasized total PCBs, homologue subgroups, or individual congeners present in substantial amounts in the sample or in commercial mixtures (Maack and Sonzogni 1988; Niimi and Oliver 1989). And still others used total PCBs derived from the sum of homologue subgroup concentrations (Gebhart et al. 1985; Sericano et al. 1990), concentrations of individual subgroups (Gebhart et al. 1985), or the contribution of all congeners in each subgroup (Niimi and Oliver 1989).

Gas chromatography/mass spectrometry in the electron ionization mode (GC-MS/EI) has been used to a more limited extent for routine analysis of PCBs (Alford-Stevens et al. 1985; Kuehl et al. 1991). Some interference with quantification ions can occur with EI when compounds such as PCBs 77 and 110 coelute. GC-MS has also been operated in the negative chemical ionization mode (NCI) for PCB determinations (Guevremont et al. 1987; Swackhammer et al. 1987; Erhardt-Zwabik et al. 1990). Increased selectivity is observed in the NCI mode, although interference from other compounds that readily form stable negative ions may be observed. Improvements have also been made in capillary column separations. However, the application of single long, narrow bore capillary columns does not enable investigators to attain full separation of PCB congeners (Ballschmiter and Zell 1980; Bush et al. 1983; Mullin et al. 1984; Duinker et al. 1988b). Multidimensional GC (MDGC) analysis of PCBs drastically improved congener separations and the analysis of all sample constituents. Schomburg et al. (1985) connected two capillary columns of different polarities in a double-oven instrument. The first column was temperature programmed, the second was operated isothermally. Congeners of Clophen A 50 were separated by valveless flow switching. Using MDGC techniques, Duinker et al. (1988a, 1988b) analyzed PCBs 28, 52, 101, 138, 153, and 180, and positively identified PCBs 52, 101, and 180 as well as coeluting peaks of PCBs 24, 26, 29, 44, 49, 81, 84, 114, 128, 151, 169, 177, 183, 187, 189 and 194. In a following paper, Schultz et al. (1989) used the same MDGC technique to fully resolve all congeners in commercial PCB mixtures of Clophen A30, A40, A50, A60 and in Aroclors 1221, 1016, 1242, 1254, and 1260. A column of SE-54 with ECD was used to monitor the eluate, and a second, more polar column (usually OV-210) with ECD was used to obtain fully resolved single peaks. The procedure required exact timing of cuts based on retention time but fully separated the PCB congeners by gas chromatography for the

first time. A total of 132 congeners at concentrations above 0.05% (w/w) were eluted as fully resolved single peaks and measured (Schultz et al. 1989).

Pattern recognition techniques that incorporate statistical methods have been used to determine spatial and temporal patterns in PCB residue data. Stalling et al. (1980, 1987), for example, characterized sample PCB profiles from 105 individual congeners, measured parameters of similarity between sample and standard mixtures, and determined whether the sample residue pattern corresponded to an Aroclor mixture. Modeling environmental samples with the individual congener concentrations provided more accurate estimations of Aroclor profiles than homologue concentrations. Intact commercial Aroclors have been characterized by automated mass spectrometric determination of weight percent distribution by homologue groups (Alford-Stevens 1986). One isomer from each level of chlorination was normally used to calibrate the MS response to all measurable isomers in that group. In another example, Macdonald et al. (1992) applied pattern recognition techniques to assess biomagnification and to characterize source patterns of multicomponent pollutants such as PCBs, PCDDs, and PCDFs in eggs of the herring gull (*Larus argentatus*) from the Great Lakes between 1983 and 1990. Turle et al. (1991) fitted a linear regression to PCB concentrations in herring gull eggs from the Great Lakes during 1970 to 1985 and from more recent measurements. Aroclor equivalents in eggs were determined with PCB 138 as a single peak estimate for the older data and more recent PCB data as the sum of 41 congeners. The earlier choice of PCB 138 for quantitation seemed fortunate; uptake of heptachloro isomers maintained a stable percentage of total PCB egg residues over time, whereas less chlorinated congeners generally declined and more chlorinated congeners increased over time (Turle et al. 1991).

Data from Bush, B., L.A. Shane, and M. Wahlen. 1987. Sedimentation of 74 PCB congeners in the upper Hudson River. *Chemosphere* 16:733-744.

Methods were developed for routine analysis of AHH-inducing and other PCB congeners in fish using a comparatively simple gel permeation chromatography (GPC) cleanup and GC-MS/NCI (Schmidt and Hesselberg 1992). Methane was used as the reagent gas for NCI, source temperature and pressure were optimized (1100°C and 0.9 Torr), and fragmentation of the major ions was reduced as much as 10%. A peak area correction factor for interfering ion fragmentation was obtained by instrument calibration with standards and manually applied to coeluting ions as needed (Schmidt and Hesselberg 1992). Additional methods were developed for the analysis of planar congeners. Using a carbon foam adsorbent, Huckins et al. (1978, 1980, 1988) devised procedures for the analysis of toxic non-*ortho*-chloro-substituted PCB congeners and trace planar impurities in Aroclors. With carbon-foam chromatography (carbon particles suspended on a polyurethane substrate), concentrations of planar PCB congeners in Aroclors 1016, 1242, 1248, 1254, and 1260 were detected by high-resolution electron capture gas chromatography (HRGC/ECD). With current chemical methods for analysis of non-*ortho*-chloro-substituted planar PCBs, extraction and a preliminary cleanup, carbon chromatography, and HRGC/ECD or HRGC-MS are generally used (Feltz et al. 1995). The brands of carbon available for isolating planar PCBs include Amoco AX-21 (PX-21), Alltech SK-4, Serva SP-1, and Wako active carbon (Storr-Hansen and Cederberg 1992). All methods shared at least three characteristics:

1. They require some form of adsorption chromatography (usually with carbon) to isolate planar compounds.
2. They include several cleanup steps.
3. They are complicated.

A semipermeable membrane device (SPMD) with a nonpolar, low-density polymeric film is used to separate PCBs from large amounts (20 to >50 g) of lipids by dialysis in an organic solvent prior to chemical analysis (Huckins et al. 1990a; Meadows et al. 1993). Liquid–liquid phase partitioning of extracts in organic solvent with sulfuric acid has been used to convert fats and pigments into water-soluble compounds that can be separated and removed from the target analytes with water rinses. Fats may be removed by refluxing or partitioning extracts with alcoholic potassium hydroxide to form water-soluble hydrolysis products. For example, Tanabe et al. (1987) and Kannan et al. (1987b) combined alkali digestion, active carbon column chromatography, fuming sulfuric acid cleanup, HRGC/ECD, and HRGC-MS confirmation for the analysis of PCBs 77, 126, and 169 in porpoise blubber. Measurement of these three highly toxic PCBs in Aroclor and Kanechlor mixtures is reported by Kannan et al. 1987a). Creaser and Al-Haddad (1989) separated five non-*ortho*-substituted PCBs from a synthetic mixture containing Aroclors, organochlorine and organophosphorus pesticides, dioxins, and dibenzofurans on an HPLC column packing of porous graphite carbon (PGC). Soil samples required prior cleanup to remove coextracted organics, and elution from a multilayered column containing acid, base, and silica was followed by elution from Florisil. Procedures are available for separating mono- and non-*ortho*-chloro PCBs. Hong and Bush (1990) used sulfuric acid cleanup, low-pressure liquid chromatography with activated carbon/silica gel, and HRGC/ECD to analyze four non-*ortho*- and eight mono-*ortho*-substituted PCBs. Haglund et al. (1990) used a non-carbon HPLC column of 2-(1-pyrenyl)ethylidimethylsilylated silica (PYE) column to isolate mono- and non-*ortho*-chloro PCBs from tissue samples. Isolation with this column required almost complete prior removal of lipids by sulfuric acid partitioning and subsequent gel permeation chromatography (GPC) with Bio-Beads S-X3 to remove remaining lipids. Ford et al. (1993) adapted an automated dioxin analysis system with programmable pump and valve setup for the sequential processing of non-*ortho*-substituted PCBs in five blubber samples. The procedure included ball/mill tissue extraction, preliminary GPC separation and cleanup, silica gel chromatography, and automated separation of non-*ortho*-substituted PCBs on AX21 activated carbon/glass fiber with three solvent systems and was followed by GC/ECD and GC-MS/EI analysis with selected ion monitoring (SIM). The application of high-resolution capillary column techniques combined

with the development of carbon adsorbents for the separation of planar aromatics has become a powerful tool for the identification and measurement of single congeners in complex PCB mixtures and has facilitated the resolution and more accurate quantification of individual congeners and the correction of the presence of non-PCB interferences. But the introduction of such methods in long-term monitoring programs, where one, several, or all peaks in Aroclor standard mixtures were used to estimate total PCBs, raises the problem of comparing results among the data sets. For such purposes, a value for total Aroclor can also be reported (Porte et al. 1988; Turle et al. 1991).

24.4 CONCENTRATIONS IN FIELD COLLECTIONS

24.4.1 General

An increasing number of reports indicate the widespread presence of toxic planar PCB congeners such as the non-*ortho*-substituted planar PCBs 77, 126, and 169. These PCB congeners were detectable in all Finnish food commodities of animal origin sold in Helsinki (Himberg 1993); in all samples of salmon muscle, cod liver, and seal blubber from the Baltic Sea and environs in the 1980s (Koistinen 1990); and at concentrations between 0.03 and 30 µg/kg fat fresh weight (FW) in a wide variety of vertebrates, including fish, marine mammals, dogs, cats, and humans (Tanabe et al. 1987). These and other planar congeners contribute the majority of the toxic potency to PCB mixtures, as judged by their ability to induce AHH and EROD (Kannan et al. 1989; Ankley et al. 1991; Sonzogni et al. 1991). Detection of these toxic residues in field collections from remote areas suggests that planar PCBs are now as widely distributed as other PCB isomers (Tanabe et al. 1987). The clear positive correlation between concentrations of total PCBs and PCBs 77, 126, and 169 in all analyzed mammals suggests that the sources of planar PCB contamination to the environment are mainly commercial PCB formulations (Tanabe et al. 1987).

24.4.2 Nonbiological Materials

Relatively little contamination from PCBs was found in sediments from riverine and pothole wetlands at national wildlife refuges and waterfowl production areas (WPA) in the north central United States in 1980 to 1982. PCBs were above detection levels (20 µg/kg) in less than 4% of the sediments; a similar case was recorded in fish from WPAs (Martin and Hartman 1985). Maximum total PCB concentrations in field collections of nonbiological materials were 0.000028 µg/kg in ice, 0.000125 µg/kg in snow, 12.3 µg/m³ in air, 233 µg/L in seawater, 3860 µg/L in sediment interstitial waters, and 1800 mg/kg in sediments. Concentrations were comparatively elevated in urban areas, near anthropogenic activities, and at known sites of PCB contamination (Table 24.8).

Atmospheric transport is a major route in PCB distribution (Swackhamer et al. 1988). Deposition and evaporation studies of 17 PCB congeners in Siskiwit Lake on Isle Royale, Michigan, showed that PCB input fluxes to the lake from rain, snow, and aerosol equalled output fluxes from sedimentation and evaporation. The magnitude of the net vapor flux, calculated by difference and with the assumption that inputs equal outputs, was large and positive for almost all 17 congeners (Swackhamer et al. 1988). Low but measurable PCB concentrations (measured as Aroclor 1254) were found in air, snow, ice, seawater, and sediment in the Arctic Ocean north of Axel Heiberg Island off Canada's northern outer coast (Hargrave et al. 1989). PCB residues were relatively high in melted snow (8 to 125 pg/L), indicating efficient scavenging from air. The ice island area from which surface seawater samples were collected was well removed from any direct influence of river drainage, and PCB concentrations probably reflect those over much of the Arctic Ocean (Hargrave et al. 1989). PCBs were also monitored in the atmosphere of Ross Island, Antarctica, from March 1988 to January 1990 (Larsson et al. 1992). The geometric mean of total PCBs in air during this

period was 15.2 pg/m³, and the maximum concentration was 12,300 pg/m³. The geometric mean during the Antarctic summers of 1988/89 and 1989/90 was 21 pg/m³. During one sampling period (December 16 to 28, 1988), PCB levels were about 100 times higher than during any other period, suggesting either irregular, long-range transport of atmospheric pollutants or volatilization of PCBs from a local dumpsite at McMurdo Base on Ross Island. PCB levels did not correlate with seasonal temperature changes, although changes in atmospheric levels were recorded. The absence of seasonal differences may be due to the cold climate and the low vapor pressure of PCBs (Bidleman et al. 1983).

PCB concentrations in sediment cores from Lake Ontario were similar to production and sales data of PCBs in the United States (Eisenreich et al. 1989). Annual PCB accumulation rates in the sediments rose from about 2 ng/cm² in 1950 to about 40 ng/cm² in the 1966 to 1969 peak years and declined in 1980 to 10 to 20 ng/cm²; about 50% of the 1966 to 1969 load was attributed to the upward mixing by oligochaete worms (Eisenreich et al. 1989). Each of several PCB congeners in Lake Ontario sediments contributed 5.7 to 7.9% of the total PCBs (PCBs 66, 110, and 56/60) and others (including PCBs 44, 52, 70/76, 101, and 153) contributed 4.0 to 4.7% (Oliver and Niimi 1988; Oliver et al. 1989). Surficial sediments of Lake Ontario in 1981 to 1986 contained elevated concentrations of organochlorine compounds, including mirex, chlorobenzenes, octachlorostyrenes, DDT, 2,3,7,8-TCDD, fluorinated aromatic compounds, and PCBs (Oliver et al. 1989). Among the identified congeners, PCBs 60 (5.7%) and 118 (2.6%) are AHH-active (Smith et al. 1990). The frequency of isomers of low chlorination decreased with core depth in sediments, remained fairly stable of hexa-isomers, and increased with core depth of the more highly chlorinated congeners. This pattern with depth reflects the change in use pattern over time to less highly chlorinated PCBs such as Aroclor 1016. The more highly chlorinated congeners that are disproportionately present in deeper sediments may be due to stronger partitioning to sediment and higher hydrophobicity than those of less chlorinated congeners and to the positive correlation with their high octanol/water partition coefficients (Karickhoff 1981). Anaerobic dechlorination was not evident in these sediments. This contradicts the findings of others who maintain that relatively high levels of less chlorinated PCBs in the bottom (anaerobic) core sections of Hudson River sediments were due to anaerobic dechlorination (Brown et al. 1985). Oliver et al. (1989) concluded that the total mass of PCBs in Lake Ontario sediments was about 50 tons and sufficient to impact Lake Ontario for many years. Lake Michigan sediments, analyzed for 18 planar AHH-active PCBs, total PCBs, 2,3,7,8-TCDD, and 2,3,7,8-tetrachloro-*p*-dibenzofuran (2,3,7,8-TCDF), had elevated levels of PCBs 77, 126, and 169 (Smith et al. 1990). Results suggest that the contribution of toxic equivalents — that is, the sums of congeners after the raw congener concentrations were normalized by the TEF — was greater from PCBs 77, 126, and 169 than from 2,3,7,8-TCDD and 2,3,7,8-TCDF, even in environments with significant concentrations of dioxins and dibenzofurans (Smith et al. 1990). Sediments from the Waukegan Harbor, Illinois, in 1978 contained weathered mixtures of Aroclors 1242, 1248, and 1254. Total PCB concentrations were variable between stations and ranged from 10.6 mg/kg to 13,360 mg/kg DW; 3,3',4,4'-TCB residues ranged from 5 to 27,500 µg/kg DW, or about 0.16% of the total PCBs; concentrations were higher of 2,3,3',4,4'-TCB (102 to 131,000 µg/kg DW, or 0.66%) (Huckins et al. 1988).

PCB homologues and total PCBs in water, sediments, and biota were measured in Hamilton Harbour on Lake Ontario and Wheatley Harbour on Lake Erie. Hamilton Harbour receives inputs from steel mills and an incinerator plant; Wheatley Harbour receives fish-processing plant wastes. Total PCBs in sediments ranged from 608 to 14,185 µg/kg DW in Hamilton Harbour and from 166 to 1177 µg/kg DW in Wheatley Harbour (Mudroch et al. 1989). The high PCB value in Hamilton Harbour is similar to values reported earlier in Lake Erie sediments (Frank et al. 1977). Concentrations of lower chlorinated homologues were greater in water than in sediment in both harbors (Mudroch et al. 1989). Homologue patterns in biota (oligochaetes, snails, isopods, and fish) reflected patterns in sediments but not in water. Concentrations of penta- and hexachlorobiphenyls were dominant in the oligochaetes and sediment samples from Wheatley Harbour; concentrations

of these homologues also predominated in Hamilton Harbour, but the differences were less pronounced. Particle size distribution of 82 to 98% silt and clay (63 µm) was similar in both harbors. The concentrations of several metals (Zn, Pb, Cu, and Cr) were much higher in Hamilton Harbour, but their effect on PCB bioaccumulation is unknown (Mudroch et al. 1989).

Contaminated sediments are a major source of PCBs in aquatic environments (Dillon and Burton 1992). PCB discharges prior to 1977 from capacitor-manufacturing plants on the Hudson River at Ft. Edward and Harbor Falls, New York (14 kg PCBs daily for 30 years, mostly Aroclors 1242 and 1016), contaminated 306 km of riverbed between Hudson Falls and New York Harbor. By 1978, an estimated 63,500 kg PCBs were in the riverbank deposits, 134,000 kg in the upper river, and 91,000 kg in the lower river (Brown et al. 1985; Eisler 1986; Bush et al. 1987; Kennish 1992). PCB concentrations in biota and the water column are largely controlled by PCB concentrations in surficial sediments. Declines in PCB levels in Hudson River sediments corresponded to decreased use of PCBs at local capacitor-manufacturing plants (Brown et al. 1985; Kennish 1992). The stabilization of highly contaminated upper stream banks and reduced PCB releases from bed sediments contributed to lower concentrations in the water column. A model of the fate and accumulation of seven PCB homologues in the Hudson River estuary showed that 66% of the 270,454 kg total PCBs discharged into the estuary between 1947 and 1987 had volatilized, 6% was stored in sediments, and the rest was either dredged or lost by boundary transport to the New York Bight and Long Island Sound (Thomann et al. 1991). Total PCBs peaked in the mid-1970s and upstream loading now has a relatively small effect. The upstream PCB load above Troy, New York, accounts for about 20% of the PCB concentrations in striped bass. A steady decline of Aroclors 1016 and 1254 in upstream contribution was projected to the year 2005 and suggests that 95% of 3- to 6-year-old striped bass in the lower Hudson would have residues below the USFDA action level of 2 mg/kg FW by the year 2004 (Thomann et al. 1991). PCB congener patterns in Hudson River sediments differed from the Aroclors discharged into the river. Sediments had comparatively enriched concentrations of certain lower-chlorinated congeners, especially *ortho*-substituted congeners, and some congeners not usually detected in commercial Aroclor mixtures. Changes in PCB composition of sediments were greater in lower portions of sediment cores than in surficial sediments (Brown et al. 1987). Two dechlorination mechanisms seemed to be operating: *meta*-, *para*-dechlorinations with stepwise, selective dechlorination at the *meta*- and *para*-positions of certain *ortho*-substituted di- through tetra-*ortho*-chlorinated biphenyls; and *ortho*-, *meta*-, *para*-dechlorinations, in which the dechlorinations occur at *ortho*-, *meta*-, or *para*-positions and reactivity is favored by increasing electron affinity and relatively positive reduction potential. Both mechanisms preferentially removed toxic congeners (Brown et al. 1987). Residues of individual PCB congeners in the upstream water were similar to residues in caddisfly larvae from that system (Bush et al. 1985), although residues in the larvae were enriched with lower-chlorinated congeners. Because of their relatively high water solubility and low affinity for sediment, higher concentrations of lower-chlorine homologues were expected to preferentially dissolve in water. But PCB profiles of dissolved residues transported downstream in the water samples during low-flow season were dominated by only three low-chlorinated PCBs; more than half of the residues consisted of 2-chlorobiphenyl and 2,2'- and 2,6'-dichlorobiphenyl congeners (Bush et al. 1985).

Anoxic Hudson River sediments contaminated with PCBs and dredged sediments in clay encapsulation were treated to induce or raise anaerobic biodegradation of PCBs (Rhee et al. 1989). Variations in sediment type, bacterial flora, and treatment influenced dechlorination. The addition of biphenyl under anoxic nitrogen was the most effective treatment for raising biodegradation. Unlike the findings of Brown et al. (1987), no evidence was found of accumulation of less-chlorinated PCBs from biodegradation of more highly chlorinated congeners, although a faster degradation rate of less-chlorinated congeners than the more highly substituted PCBs would have allowed this phenomena to occur unobserved. Hudson River sediments incubated at room temperature (25°C) under a nitrogen atmosphere or incubated with biphenyl enrichment under nitrogen for 7 months decreased significantly in chlorobiphenyl compounds of 33 to 65%. In general, mono- and

dichlorobiphenyl congeners from Hudson River sediments were not significantly degraded by the biphenyl, but biphenyl addition significantly decreased the higher chlorinated congeners (Rhee et al. 1989). In earlier studies with the same mixed bacterial culture without biphenyl addition, significant reductions were evident in Hudson River sediments of PCB congeners with as many as three chlorines (Chen et al. 1988).

Sediments in oceans, estuaries, rivers, and lakes concentrate PCBs. Organisms accumulate PCBs by way of the water column, from interstitial sediment waters, and from consumption of contaminated prey by predator species. Coastal sediments with the highest total PCB concentrations between 1984 and 1989 are usually within 20 km of population centers of more than 100,000 people (NOAA 1991) and directly correlate with sediment content of total organic carbon (Karickhoff 1981). Variability in PCB content of sediments is great, and large differences between adjacent stations is not uncommon (NOAA 1988). The approximate percent PCB distribution in sediments by level of chlorination was di- 3.9%, tri- 11%, tetra- 20%, penta- 24%, hexa- 21%, hepta- 12%, octa- 3.9%, and nona- 1.3%. The mean PCB concentration in sediments at 233 sites was 39 µg/kg, and concentrations greater than 200,000 µg/kg were considered elevated (NOAA 1988) ([Table 24.8](#)). In most regions of New Jersey, for example, PCB contamination of sediments and water column was negligible (Kennish 1992). But PCBs in estuarine and coastal locations of New Jersey showed elevated sediment contamination in the northeastern region — an area that included the Hudson–Raritan estuary and adjacent ocean waters of the New York Bight — where direct discharges from capacitor-manufacturing plants on the upper Hudson River, dredged material, and sewage-sludge dumping were the principal sources of PCB contamination. PCB levels in teleosts from the northeastern region in 1986/87 exceeded the USFDA action level of 2000 µg/kg and were consistent with data from previous years. Action levels were also exceeded in fishes from Camden and from the northern coastal regions (Kennish 1992). PCB sediment residues in Raritan Bay in the 1970s averaged 100 µg/kg DW in a range of 3.4 to 2035 µg/kg (Stainken and Rollwagen 1979). Water column concentrations were usually not detectable but approached 0.04 µg/L in parts of the New York Bight after sewage sludge and dredged material were deposited in the 1970s and early 1980s (Boehm 1981). Sediments near dumpsites in the New York Bight contained as many as 15,000 µg/kg PCBs (MacLeod et al. 1981), and bottom sediments in the upper Hudson River had localized contaminated areas containing more than 50,000 µg/kg (Brown et al. 1985). Nationwide, PCB loadings in surficial sediments and mussels (*Mytilus edulis*) in the Long Island Sound were greater than in other sites (Robertson et al. 1991).

Surficial stream sediments in the San Francisco estuarine system during 1972 had high residues (350 to 1400 µg/kg DW) at several locations (Phillips and Spies 1988). However, residues were highly variable between sites (Law and Goerlitz 1974). In 1984, low to intermediate concentrations of PCBs (9 to 60 µg/kg DW) were measured at four locations in the San Francisco Bay. Overall, congener profiles resembled Aroclor 1254 and were dominated by pentachlorobiphenyl isomers (NOAA 1987). The patterns of the 11 reported congeners were variable between areas, indicating many sources of different PCB mixtures.

Lake Hartwell in South Carolina received Aroclor 1016 and 1254 discharges for 21 years from a capacitor-manufacturing plant (Elzerman et al. 1991). Analysis of sediment cores collected between 1984 and 1987 showed that samples nearest the source were relatively high in lower-chlorinated PCB congeners, and downstream samples were enriched with the higher congeners; in all samples, total PCB concentrations decreased with increasing distance from the point source. The estimated total remaining PCBs was 41,000 kg (Elzerman et al. 1991). The highest PCB concentrations were in subsurface sediments, although PCB levels in surficial sediments were also elevated (Dunnivant et al. 1989). A survey of total PCBs in sediments and invertebrates in major estuaries of South Carolina showed no significant contamination. PCBs were found only in sediments (622 µg/kg) and in oysters (87 µg/kg) from the Wando River near a large ship repair and retrofitting facility; PCB residues in crabs, when present, ranged from 95 to 375 µg/kg (Marcus and Renfrow 1990).

24.4.3 Marine Mammals

Marine mammals are the most vulnerable to and most probable target organisms of PCBs (Tanabe 1988). The metabolic potential to degrade organochlorine contaminants and therefore accumulate relatively high concentrations of persistent PCBs is lower in marine mammals, particularly in cetaceans, than in terrestrial mammals (Tanabe et al. 1987; Kannan et al. 1989, 1993). Dead harbor porpoises (*Phocoena phocoena*) along the Dutch coast contained 51,350 to 139,790 µg total PCBs/kg blubber; 35 to 50% of the total PCBs were PCBs 138 and 153 (Duinker et al. 1988a). A similar pattern was noted in harbor porpoises from Scandinavia in 1987 to 1991 (Kleivane et al. 1995), and harbor seals from the northern hemisphere in 1988 to 1995 (Vetter et al. 1996). The intrinsic toxicity of PCBs mainly resulted from the planar PCB congeners that imposed a greater toxic threat to marine mammals than chlorinated dioxins and furans (Tanabe 1988; Tanabe et al. 1989; Daelemans et al. 1993; Falandysz et al. 1994b). The toxic threat of planar PCBs to higher aquatic predators was primarily assessed by 2,3,7,8-tetracholoridibenzo-*p*-dioxin toxic equivalent analysis, which is based on the induction of arylhydrocarbon hydroxylase (AHH) and ethoxyresorufin *O*-deethylase (EROD) (Kannan et al. 1989). The concentrations of planar PCBs in marine mammals were higher (in the order of di-*ortho* > mono-*ortho* > non-*ortho* congeners) and significantly higher than the levels of toxic dioxins and furans (Tanabe 1988; Tanabe et al. 1989; Kannan et al. 1989). In particular, the accumulation of PCBs 105 and 126 in carnivorous aquatic mammals is cause for considerable concern (Tanabe et al. 1987, 1989; Kannan et al. 1989; Daelamans et al. 1993; Storr-Hansen and Spliid 1993). TCDD-like toxicity is relatively serious in Baikal seals (*Phoca sibirica*) because of the enrichment of toxic PCB congeners in tissues (Nakata et al. 1997).

Declines in total PCB levels in blubber of marine mammals between the late 1960s and 1990 to 1992 have been noted worldwide (Muir et al. 1988; Lake et al. 1995a), possibly because of the PCB ban in the mid-1970s. PCB levels in animal tissues will probably not decline in the near future because of the greater quantities of PCBs still in use than the quantity that already escaped into the open environment (Tanabe 1988). Temporal changes of PCBs in remote marine waters are slow and could be attributable to the large PCB load in the marine environment (Loganathan et al. 1990). The geographical distribution of planar PCBs with reference to total PCBs did not vary in terrestrial, coastal, and open ocean mammals, whereas those of dioxins and furans decreased from land to ocean (Tanabe et al. 1989). PCB concentrations — including planar PCBs — in blubber of striped

dolphins (*Stenella coeruleoalba*) from the Mediterranean Sea in 1990 to 1992 are among the highest reported in the literature (Table 24.9) (Kannan et al. 1993; Borrell et al. 1996). Striped dolphins affected by the western Mediterranean morbillivirus epizootic also contained extremely high concentrations of PCBs (including non- and mono-*ortho* planar congeners) and low immune suppression, suggesting that PCBs were a major factor in this epizootic; however, this needs verification. Planar PCBs in blubber of striped dolphins accounted for about 53% of total PCBs and for virtually all of the potential toxicity. Di-*ortho* planar PCBs accounted for 93.7% of all planar PCB residues (especially PCB 170) in striped dolphins and for 21% of the potential toxicity, mono-*ortho* planars for 6.3% of the residues and 70.8% of the potential toxicity, and non-*ortho* planars (especially PCB 126) for 0.03% of the residues and 8.2% of the potential toxicity (Kannan et al. 1993; Borrell et al. 1996). Concentrations of PCBs in tissues of adult male striped dolphins of the same age from the Pacific coast of Japan did not change between 1979 and 1986 (Loganathan et al. 1990). However, PCB concentrations in blubber of male striped dolphins were about twofold higher than in females, and this is attributed to PCB transfer to offspring by females (Borrell et al. 1996).

Beluga whales (*Delphinapterus leucas*) of the St. Lawrence River estuary were severely contaminated by DDT metabolites and PCBs; the highest residues were in blubber (Masse et al. 1986). High concentrations of PCBs and other organochlorines may impair the immune function in these animals (De Guise et al. 1998). Several PCB congeners known to be AHH inducers — including PCBs 138 and 153 — were among the major PCB congeners detected in tissues of beluga whales (Masse et al. 1986). Because these compounds are not metabolized and persist indefinitely in tissues of the beluga whale, the integrated total exposure to these AAH inducers may be significant. Considerable variations by sex, age, and lipid content of the tissues in PCB concentrations were observed in beluga whales. Qualitative and quantitative differences in the PCB profiles of beluga whales were not solely related to the respective lipid content of the tissues, but also to the specific nature of the lipids, which varied from one tissue to the other. The major PCB components in various tissues of beluga whales were PCBs 52, 99, 129, 137, 141, 153, 165, 180, and 185. Organ-specific retention of some PCB congeners occurs in beluga whales. PCBs 165 and 179, which were minor in blubber, were more abundant in kidney, liver, and lung. PCB 129 was more abundant in kidney and liver than in lung. Atlantic cod (*Gadus morhua*) composed a minor part of the beluga whale diet. However, PCB patterns in cod positively correlated with those in beluga whale tissues, suggesting a common source of intake. PCB congeners 52, 91, 99, 108, 118, 128, 138, 144, 149, 153, 163, and 180 were among the most abundant chlorinated biphenyls in cod liver oil and in the beluga whale blubber, liver, lung, kidney, and milk (Masse et al. 1986). Beluga whales from the St. Lawrence River estuary had elevated levels of PCBs in blubber in 1987 to 1990 due to elevated levels in diet, as judged by bioaccumulation ratios. PCB 126 was the most prominent planar PCB in blubber; other biologically active congeners found were PCBs 105 and 118 (Muir et al. 1996a). Significant declines in concentrations of Aroclor PCBs were measured in blubber of male — but not female — beluga whales from the St. Lawrence estuary between the 1982 to 1985 and 1993/94 collection periods; these declines were also evident in eels, harp seals, and seabirds (Muir et al. 1996b).

When compared to other cetaceans, PCB residues in blubber of harbor porpoises (*Phocoena phocoena*) from the Black Sea showed a measurable sexual difference. PCB concentrations were lower in older female porpoises possibly due to lactational transfer to their calves, while in males the PCB concentrations were positively correlated with increasing age (Tanabe et al. 1997). In stellar sea lions (*Eumetopias jubatus*), the transfer rate of PCBs through lactation was estimated at 80% of the total body PCB burden of adult females (Lee et al. 1996). PCB concentrations in liver of the stellar sea lion from the Bering Sea increased with increasing age and correlated positively with those of blubber (Lee et al. 1996). In ringed seals (*Phoca hispida*) from the Russian Arctic, lactational transfer of PCBs was estimated at 25% of whole-body burden in the mature female (Nakata et al. 1998), or about one third that of stellar sea lions. In grey seals (*Halichoerus*

grypus), PCBs were transferred from blubber to milk by way of the circulatory system. Of the total concentration of PCBs in various tissues of maternal grey seals, PCB 153 accounted for about 30% in blubber, 20% in serum, and 30% in milk; PCB 180 accounted for 20% in blubber, 20% in serum, and 10% in milk; and PCB 77 accounted for 20% in serum (Addison and Brodie 1987). Most of the toxicity in grey seal milk was attributed to PCB 126; the mono-*ortho*-chlorinated PCBs 105, 118, 156 and *ortho*-chlorinated PCBs 170 and 180 — especially PCB 170 — were responsible for 47% of the toxicity (Green et al. 1996). In whales (*Ziphius* sp.), the dominant PCB congeners in blubber had 5 to 8 chlorines; PCBs 138, 153, 149, 180, and 201 accounted for about 70% of the total PCBs (Duinker et al. 1988b). In the Canadian Arctic food chain of Arctic cod (*Boreogadus saida*) to ringed seal (*Phoca hispida*) to polar bear (*Ursus maritimus*), the total PCB concentrations, in µg/kg FW, ranged from 4 in cod muscle to 680 in seal blubber to 4500 in bear fat. The hexachlorobiphenyl PCB 153 accounted for 42% of the total PCBs in bear fat and for only 20% in seal blubber and 7% in cod muscle. Tri- and tetrachlorobiphenyl homologues predominated in cod, penta- and hexachlorobiphenyl congeners predominated in seal blubber, and hexa- and heptachlorobiphenyl congeners in fat of polar bears (Muir et al. 1988).

PCB 180	0.8 DW vs. 0.6 FW	34

Table 24.9 (continued) PCB Concentrations in Field Collections of Selected Aquatic Organisms
 (Concentrations are in micrograms PCBs per kilogram [ppb] fresh weight [FW], dry weight [DW], or lipid weight [LW].)

Taxonomic Group, Organism, PCB Congener, and Other Variables	Concentration ^a (g/kg)	Reference ^b
Burrowing mayfly, <i>Hexagenia</i> sp., adults; summer 1987; contaminated sites on Detroit and St. Clair Rivers		
PCB 18	Max. 7.6 DW	35
PCB 31	Max. 2.8 DW	35
PCB 52	Max. 10.9 DW	35
PCB 66	Max. 4.6 DW	35
PCB 87	Max. 6.5 DW	35
PCB 97	Max. 3.5 DW	35
PCB 101	Max. 16.6 DW	35
PCB 110	Max. 6.0 DW	35
PCB 118	Max. 13.6 DW	35
PCB 138	Max. 18.1 DW	35
PCB 141	Max. 6.1 DW	35
PCB 153	Max. 23.2 DW	35
PCB 170	Max. 4.8 DW	35
PCB 180	Max. 10.4 DW	35
PCB 182	Max. 7.3 DW	35
PCB 194	Max. 4.7 DW	35
Squid, <i>Ilex illecebrosus argentinus</i> ; near Falkland Islands, March 1988; muscle		
PCBs 28, 31, 44, 47 49, 52, 66, 87, 97, 101, 105, 110, 118, 128, 138, 141, 149, 151, 153, 170, 180, 184, 187, 206	ND	3
Common mussel, <i>Mytilus edulis</i>		
German Bight, 6 locations; 1993; extractable organic matter; spring vs. autumn		
PCB 77	33–50 DW vs. 4–8 DW	49
PCB 81	5–7 DW vs. 2–4 DW	49
PCB 105	45–60 DW vs. 37–130 DW	49
PCB 114	Max. 1.1 DW vs. Max. 0.5 DW	49
PCB 118	75–97 DW vs. 65–520 DW	49
PCB 123	9–150 DW vs. 0.2–4 DW	49
PCB 126	4–15 DW vs. 6–12 DW	49
PCB 138	280–420 DW vs. 83–210 DW	49
PCB 156	Max. 3.9 DW vs. Max. 1.4 DW	49
PCB 169	0.0–2.1 DW vs. 0.4–4.1 DW	49
PCB 170	0.0–7.9 DW vs. 2.2–4.1 DW	49
PCB 180	18–43 DW vs. 9–23 DW	49
PCB 189	0.5–1.7 DW vs. 0.1–0.4 DW	49
Long Island Sound, New York vs. freshwater mussels (species unknown) from a contaminated site near Troy, New York; soft parts		
Total PCBs	247 DW vs. 2734 DW	4
Total planar PCBs	11.9 DW vs. 112.9 DW	4
PCB 77	0.4 DW vs. 6.9 DW	4
PCB 81	ND vs. 0.9 DW	4
PCB 105	3.3 DW vs. 27.0 DW	4
PCB 114	ND vs. 4.0 DW	4
PCB 118	8 DW vs. 53 DW	4
PCB 123	ND vs. ND	4
PCB 126	ND vs. 0.6 DW	4
PCB 156	ND vs. 1.8 DW	4
PCB 157	ND vs. 0.6 DW	4
PCB 167	0.2 DW vs. 18.6 DW	4
PCB 169	ND vs. 0.1 DW	4
PCB 189	ND vs. 0.1 DW	4

Table 24.9 (continued) PCB Concentrations in Field Collections of Selected Aquatic Organisms
 (Concentrations are in micrograms PCBs per kilogram [ppb] fresh weight [FW], dry weight [DW], or lipid weight [LW].)

Taxonomic Group, Organism, PCB Congener, and Other Variables	Concentration ^a (g/kg)	Reference ^b
FISHES		
Bloater, <i>Coregonus hoyi</i> ; Lake Michigan		
Whole; total PCBs		
1972 vs. 1975	5700 FW vs. 4500 FW	5
1978 vs. 1982	3100 FW vs. 2100 FW	5
1986	1600 FW	5
Diet; invertebrate prey		
1970	350–650 FW	59
1975	170–250 FW	59
1980	120–210 FW	59
1990	50–100 FW	59
Margined flyingfish, <i>Cypselurus cyanopterus</i> ; near Falkland Islands, March 1988; muscle		
PCBs 28, 31, 44, 47, 49, 52, 66, 87, 97, 101, 105, 110, 128, 141, 151, 170, 194, 206	0.01–0.1 FW	3
PCBs 118, 138, 180, 187	0.14–0.31 FW	3
PCB 153	0.45 FW	3
Fish liver oil; various species; Finland		
PCB 77	2.7 LW	6
PCB 105	30.0 LW	6
PCB 126	0.62 LW	6
PCB 169	0.13 LW	6
Fish muscle; various species sold for human consumption; Finland		
PCB 77	0.006–0.153 FW	6
PCB 105	0.113–2.7 FW	6
PCB 126	0.002–0.035 FW	6
PCB 169	ND–0.012 FW	6
Fish, 14 species, muscle; Wisconsin, 1986–87; total PCBs	1300 (700–7000) FW	7
Freshwater fishes; U.S.; nationwide; whole; adults; total PCBs measured as Aroclors 1248, 1254, and 1260; noncontaminated sites		
1976–77	Max. 70.6 FW	48
1978–79	Max. 92.8 FW	48
1980–81	Max. 11.3 FW	48
1984	Max. 6.7 FW	48
Freshwater fishes; U.S.; nationwide; whole; 1986–87; mostly contaminated sites		
Median	209 FW	52
Mean	1890 FW	52
Maximum	124,000 FW	52
Atlantic cod, <i>Gadus morhua</i>		
Liver; Norway, 1988		
PCB 28	19 (0.5–64) FW	8
PCB 52	31 (0.5–144) FW	8
PCB 101	78 (0.5–533) FW	8
PCB 118	170 (1.1–653) FW	8
PCB 138	283 (1.4–918) FW	8
PCB 153	363 (1.3–1175) FW	8
PCB 170	28 (0.4–163) FW	8
PCB 180	68 (1.1–391) FW	8
PCB 209	7 (0.3–35) FW	8

Table 24.9 (continued) PCB Concentrations in Field Collections of Selected Aquatic Organisms
 (Concentrations are in micrograms PCBs per kilogram [ppb] fresh weight [FW], dry weight [DW], or lipid weight [LW].)

Taxonomic Group, Organism, PCB Congener, and Other Variables	Concentration ^a (g/kg)	Reference ^b
Liver; Norway 1989		
PCB 77	Max. 4.8 LW	9
PCB 105	Max. 39.0 LW	9
PCB 126	Max. 1.0 LW	9
PCB 169	Max. 0.3 LW	9
Muscle; Baltic Sea, 1988		
PCB 77	Max. 4.2 LW	9
PCB 105	Max. 36.0 LW	9
PCBs 126, 169	ND	9
Ictalurids, 4 species (blue catfish, <i>Ictalurus furcatus</i> ; black bullhead, <i>Ameiurus melas</i> ; channel catfish, <i>Ictalurus punctatus</i> ; flathead catfish, <i>Pylodictis olivaris</i>); whole; 1944-km stretch of Mississippi River; July–August 1987		
Total PCBs	Max. 138 FW; Max. 2910 LW	10
Tetrachlorobiphenyls	Max. 21 FW; Max. 671 LW	10
Pentachlorobiphenyls	Max. 56 FW; Max. 1230 LW	10
Hexachlorobiphenyls	Max. 67 FW; Max. 870 LW	10
Heptachlorobiphenyls	Max. 12 FW; Max. 140 LW	10
Dab, <i>Limanda limanda</i>		
German Bight; December 1988–May 1989; total of 35 PCB congeners		
Females		
Liver (mostly PCBs 77, 138, and 153)	1200–16,200 LW	36
Ovaries (mostly PCBs 77, 138, and 153)	2600–4300 LW	36
Males		
Liver	900–24,400 LW	36
Testes (mostly PCBs 15, 13, 52)	1900–11,800	36
North Sea; January–March 1987; total PCBs		
Liver, Females	1450 FW	11
Liver, Males	2000 FW	11
Ovaries	2600 FW	11
Tilefish, <i>Lopholatilus chamaeleonticeps</i> ; 1981–1982; New Jersey vs. Georges Bank		
Total PCBs		
Gonad	3373 DW vs. 1004 DW	12
Liver	4693 DW vs. 1002 DW	12
Muscle	435 DW vs. 190 DW	12
Dichlorobiphenyls		
Gonad	196 DW vs. 15 DW	12
Liver	258 DW vs. 42 DW	12
Muscle	9 DW vs. 5 DW	12
Trichlorobiphenyls		
Gonad	164 DW vs. 11 DW	12
Liver	278 DW vs. 35 DW	12
Muscle	11 DW vs. 7 DW	12
Tetrachlorobiphenyls		
Gonad	1176 DW vs. 192 DW	12
Liver	789 DW vs. 151 DW	12
Muscle	62 DW vs. 25 DW	12
Pentachlorobiphenyls		
Gonad	806 DW vs. 463 DW	12
Liver	1273 DW vs. 358 DW	12

Table 24.9 (continued) PCB Concentrations in Field Collections of Selected Aquatic Organisms
 (Concentrations are in micrograms PCBs per kilogram [ppb] fresh weight [FW], dry weight [DW], or lipid weight [LW].)

Taxonomic Group, Organism, PCB Congener, and Other Variables	Concentration ^a (g/kg)	Reference ^b
Hexachlorobiphenyls		
Gonad	664 DW vs. 191 DW	12
Liver	1290 DW vs. 221 DW	12
Muscle	112 DW vs. 46 DW	12
Heptachlorobiphenyls		
Gonad	158 DW vs. 27 DW	12
Liver	109 DW vs. 27 DW	12
Muscle	14 DW vs. 3 DW	12
Nonochlorobiphenyls		
Gonad	62 DW vs. 6 DW	12
Liver	22 DW vs. 13 DW	12
Muscle	3 DW vs. 0.5 DW	12
Decachlorobiphenyl		
Gonad	45 DW vs. 6 DW	12
Liver	24 DW vs. 16 DW	12
Muscle	2 DW vs. 0.7 DW	12
PCB 77		
Gonad	48 DW vs. 19 DW	12
Liver	86 DW vs. 45 DW	12
Muscle	62 DW vs. ND	12
PCB 126		
Gonad	ND vs. 27 DW	12
Liver	214 DW vs. 33 DW	12
Muscle	19 DW vs. 4 DW	12
Argentinian hake, <i>Merluccius merluccius hubbsi</i> ; near Falkland Islands, March 1988; muscle		
PCBs 28, 31, 44, 47, 49, 87, 97, 105, 128, 141, 151, 194, 206	0.01–0.04 FW	3
PCBs 52, 66, 101, 110, 170	0.05–0.1 FW	3
PCBs 118, 138, 149, 153, 180, 187	0.11–0.28 FW	3
Striped bass, <i>Morone saxatilis</i> ; muscle		
New York, Long Island Sound, 1985		
Total PCBs	5500 FW; Max. 15,000 FW	13
PCBs 48, 52, 82, 101, 118, 138, 153	Contributed at least 28% of total PCB concentration	13
New York, various locations		
Total PCBs	1100–24,100 FW	4
Total planar PCBs	100–2020 FW	4
PCB 77	Max. 37 FW	4
PCB 81	Max. 5 FW	4
PCB 105	Max. 562 FW	4
PCB 114	Max. 112 FW	4
PCB 118	Max. 779 FW	4
PCB 126	Max. 8 FW	4
PCB 156	Max. 202 FW	4
PCB 157	Max. 68 FW	4
PCB 167	Max. 232 FW	4
PCB 169	Max. <0.1 FW	4
PCB 189	Max. 19 FW	4
Striped mullet, <i>Mugil cephalus</i> ; Japan, May 1976; muscle		
Total PCBs	1200 (220–3200) FW	14
PCB 77	2.1 (0.6–4.8) FW	14
PCB 126	0.1 (0.03–0.23) FW	14
PCB 169	0.002 (0.001–0.004) FW	14

Table 24.9 (continued) PCB Concentrations in Field Collections of Selected Aquatic Organisms
 (Concentrations are in micrograms PCBs per kilogram [ppb] fresh weight [FW], dry weight [DW], or lipid weight [LW].)

Taxonomic Group, Organism, PCB Congener, and Other Variables	Concentration ^a (g/kg)	Reference ^b
Rainbow trout, <i>Oncorhynchus mykiss</i> ; Lake Ontario, 1989; liver vs. muscle		
PCB 77	2.9 FW, 78 LW vs. 3.3 FW, 85 LW	31
PCB 126	0.7 FW, 18 LW vs. 0.9 FW, 22 LW	31
PCB 169	0.3 FW, 8 LW vs. 0.3 FW, 9 LW	31
Red mullet, <i>Mullus barbatus</i> ; Spain, Mediterranean coast, summers 1989, 1990; muscle		
Sum of PCBs 28, 52, 101, 118, 138, 153, 180	21.2 (7.4–33.2) FW	33
Sum of PCBs 18, 31, 44, 97, 99, 105, 110, 128, 134, 146, 149, 151, 170, 174, 177, 183, 187, 194, 201	38.4 (15.5–61.4) FW	33
Chinook salmon, <i>Oncorhynchus tshawytscha</i> ; Lake Michigan, 1986; eggs		
Total PCBs	7020 FW	32
PCBs 77, 105, 118, 126	0.2–12 FW	32
Fathead minnow, <i>Pimephales promelas</i> ; upper Hudson River, 1985; caged juveniles exposed for 3–42 days during the year; whole fish	Regardless of exposure duration or season, the consistently most abundant congeners in caged fish were PCBs 37, 42, 44, 47, 48, 49, 52, 59, 61, 66, 70, 73, 75, 76, 93, 95, and 104	15
European flounder, <i>Platichthys flesus</i> ; Norway, 1988; liver		
PCB 28	7 (0.3–68) FW	8
PCB 52	21 (0.7–609) FW	8
PCB 101	44 (1.1–1452) FW	8
PCB 118	77 (3.2–1693) FW	8
PCB 138	90 (1.1–1960) FW	8
PCB 153	95 (5.7–2088) FW	8
PCB 170	7 (0.4–158) FW	8
PCB 180	16 (1.2–296) FW	8
PCB 209	4 (0.4–88) FW	8
Paddlefish, <i>Polyodon spathula</i> ; Ohio River, Kentucky; 1988–89; total PCBs; males vs. females		
Gonads	16,200 (5600–23,000) FW vs. 7300 (50–18,700) FW	16
Red muscle (females only)	4200 (2000–6300) FW	16
White muscle	700 (50–3300) FW vs. 400 (50–1000) FW	16
Winter flounder, <i>Pleuronectes americanus</i>		
Long Island Sound, New York, 1984–86; total PCBs		
Liver	420–2400 FW	17
Ovaries	30–730 FW	17
Testes	50–190 FW	17
New Bedford Harbor, Massachusetts vs. two control sites in Rhode Island; spring, 1988; liver		
Planar PCBs		
PCB 77	391 DW vs. 4.6 DW	38
PCB 126	49 DW vs. 1.8 DW	38
PCB 169	3.7 DW vs. 0.4 DW	38
Nonplanar PCBs		
PCB 47	2530 DW vs. 14 DW	38
PCB 52	1100 DW vs. 6.5 DW	38
PCB 101	2450 DW vs. 49 DW	38
PCB 105	2200 DW vs. 92 DW	38
PCB 118	12,800 DW vs. 239 DW	38
PCB 128	1370 DW vs. 47 DW	38
PCB 138	7070 DW vs. 286 DW	38

Table 24.9 (continued) PCB Concentrations in Field Collections of Selected Aquatic Organisms
 (Concentrations are in micrograms PCBs per kilogram [ppb] fresh weight [FW], dry weight [DW], or lipid weight [LW].)

Taxonomic Group, Organism, PCB Congener, and Other Variables	Concentration ^a (g/kg)	Reference ^b
PCB 151	422 DW vs. 19 DW	38
PCB 153	11,000 DW vs. 441 DW	38
PCB 180	1010 DW vs. 141 DW	38
PCB 194	79 DW vs. 23 DW	38
PCB 195	32 DW vs. 1.4 DW	38
PCB 206	33 DW vs. 33 DW	38
PCB 209	3.1 DW vs. 20.5 DW	38
Total PCBs		
Gravid females	333,000 DW vs. 3900 DW	38
Spent females	132,000 DW vs. 4000 DW	38
Ripe males	124,000 DW vs. 13,300 DW	38
Sediments	8000 DW vs. 500 DW	38
Atlantic salmon, <i>Salmo salar</i> , Baltic Sea and environs		
Eggs, 1988		
PCB 77	Max. 28 LW	9
PCB 105	Max. 90 LW	9
PCB 126	Max. 2.4 LW	9
PCB 169	Max. 0.6 LW	9
Muscle, 1985		
Total PCBs	Max. 332 FW	18
PCB 77	Max. 1.1 FW	18
PCBs 126, 169	ND	18
Muscle, 1988		
PCB 77	Max. 34 LW	9
PCB 105	Max. 170 LW	9
PCB 126	Max. 3.8 LW	9
PCB 169	Max. 0.8 LW	9
Brown trout, <i>Salmo trutta</i> ; Catalonia, Spain; isolated mountain lakes; summers 1989, 1990; muscle		
Sum of PCBs 28, 52, 101, 118, 138, 153, 180	2.5 (1.3–3.8) FW	33
Sum of PCBs 18, 31, 44, 97, 99, 105, 110, 128, 134, 146, 149, 151, 170, 174, 177, 183, 187, 194, 201	4.8 (2.7–7.5) FW	33
Lake trout, <i>Salvelinus namaycush</i>		
Lake Ontario; total PCBs; whole fish		
1977 vs. 1978	6800 FW vs. 8000 FW	19
1979 vs. 1980	3700 FW vs. 3900 FW	19
1981 vs. 1982	2900 FW vs. 5300 FW	19
1983 vs. 1984	4500 FW vs. 4800 FW	19
1985 vs. 1986	2500 FW vs. 3100 FW	19
1987 vs. 1988	3400 FW vs. 2500 FW	19
Lake Michigan		
Adult females; whole; total PCBs		
1985	4900–10,100 FW	47
1986	6100–6800 FW	47
1987	3500–13,900 FW	47
Adult females; 1987; whole fish vs. eggs		
PCB 77	9.7 FW vs. 2.1 FW	47
PCB 126	4.0 FW vs. 0.65 FW	47
PCB 169	<0.4 FW vs. <0.4 FW	47
Great Lakes; adults; liver; 1993		
PCB 77	0.07–92.9 FW	63
PCB 81	<0.00009–0.3 FW	63
PCB 126	0.01–0.58 FW	63
PCB 169	0.0001–0.26 FW	63

Table 24.9 (continued) PCB Concentrations in Field Collections of Selected Aquatic Organisms
 (Concentrations are in micrograms PCBs per kilogram [ppb] fresh weight [FW], dry weight [DW], or lipid weight [LW].)

Taxonomic Group, Organism, PCB Congener, and Other Variables	Concentration ^a (g/kg)	Reference ^b
MARINE MAMMALS		
Giant bottlenosed whale, <i>Berardius bairdii</i> ; blubber Japan, July 1985		
Total PCBs	2300 (1800–2800) FW	20, 21
Di-ortho planars		
PCB 128	54 (36–70) FW	20, 21
PCB 138	460 (260–810) FW	20, 21
Mono-ortho planars		
PCB 105	5 (2–8) FW	20, 21
PCB 118	47 (15–94) FW	20, 21
PCB 156	23 (6–50) FW	20, 21
Non-ortho planars		
PCB 77	1.3 (0.7–1.9) FW	20, 21
PCB 126	0.35 (0.1–0.57) FW	20, 21
PCB 169	0.24 (0.09–0.45) FW	20, 21
Northern north Pacific, July 1985		
Total PCBs	2600 (2400–2800) FW	14
PCB 77	1.6 (1.3–1.9) FW	14
PCB 126	0.48 (0.39–0.57) FW	14
PCB 169	0.31 (0.17–0.45) FW	14
Beluga whale, <i>Delphinapterus leucas</i>		
St. Lawrence estuary; found dead; 1987–90; blubber; females vs. males		
Total PCBs	29,600 (8820–83,300) LW vs. 78,900 (7930–451,000) LW	53
TrichloroBPs	30 LW vs. 37 LW	53
TetrachloroBPs	2470 LW vs. 10,200 LW	53
PentachloroBPs	6360 LW vs. 17,600 LW	53
HexachloroBPs	11,300 LW vs. 32,900 LW	53
HeptachloroBPs	6920 LW vs. 14,300 LW	53
Nonachloro and decachloroBPs	121 LW vs. 58 LW	53
St. Lawrence River estuary; found dead; 1993–94; blubber; females vs. males		
Total PCBs	61,100 (15,300–181,000) LW vs. 79,200 (49,300–135,000) LW	54
TrichloroBPs	188 LW vs. 305 LW	54
TetrachloroBPs	4900 LW vs. 7290 LW	54
PentachloroBPs	12,300 LW vs. 16,100 LW	54
HexachloroBPs	26,700 LW vs. 36,200 LW	54
HeptachloroBPs	13,800 LW vs. 15,500 LW	54
OctachloroBPs	2378 LW vs. 3030 LW	54
Nonachloro and decachloroBPs	172 LW vs. 230 LW	54
Canada, St. Lawrence estuary; 1983–84; beach-stranded whales; total PCBs		
Blubber	Max. 72,200 FW	22
Kidney	Max. 10,000 FW	22
Liver	Max. 2500 FW	22
Lung	Max. 560 FW	22
Milk	Max. 1720 FW	22
Dolphins and toothed whales; blubber; total PCBs		
Atlantic Ocean, 1980–88; 15 species	130–190,000 FW	23
Indian Ocean, 1980–91; 5 species	520–7900 FW	23
Pacific Ocean, 1980–86; 7 species	190–40,000 FW	23

Table 24.9 (continued) PCB Concentrations in Field Collections of Selected Aquatic Organisms
 (Concentrations are in micrograms PCBs per kilogram [ppb] fresh weight [FW], dry weight [DW], or lipid weight [LW].)

Taxonomic Group, Organism, PCB Congener, and Other Variables	Concentration ^a (g/kg)	Reference ^b
Stellar sea lion, <i>Eumetopias jubatus</i> ; Alaska and Russian portion of Bering Sea; blubber; 1976–81; males vs. females	17,000 (5700–41,000) LW vs. 5300 (600–16,000) LW	55
Gray seal, <i>Halichoerus grypus</i> Baltic Sea and environs; 1981–87; blubber		
PCB 77	Max. 10 LW	9
PCB 105	Max. 180 LW	9
PCB 126	Max. 3 LW	9
PCB 169	Max. 2 LW	9
Nova Scotia, 1984–85; total PCBs; mother vs. pups		
Blood	6080 LW vs. 6240 LW	24
Blubber	16,200–30,300 LW vs. 8800–10,400 LW	24
Milk (mother)	7480–10,120 LW	24
Serum	10,210 LW vs. 11,840 LW	24
Scotland; Isle of May; 1990–93; maternal milk		
PCB 77	20–66 LW	60
PCB 126	81–434 LW	60
PCB 169	11–352 LW	60
Pacific white-sided dolphin, <i>Lagenorhynchus obliquidens</i> ; Japan, 1981; blubber		
Total PCBs	53.00 (40,000–71,000) FW	14
PCB 77	27 (14–38) FW	14
PCB 126	3.8 (3.2–4.4) FW	14
PCB 169	1.2 (0.9–1.4) FW	14
Finless porpoise, <i>Neophocaena phocaenoides</i> ; Japan, July 1985; blubber		
Total PCBs	320,000 FW	20, 21
Di-ortho planars		
PCB 128	3500 FW	20, 21
PCB 138	35,000 FW	20, 21
Mono-ortho planars		
PCB 105	1200 FW	20, 21
PCB 118	11,000 FW	20, 21
PCB 156	160 FW	20, 21
Non-ortho planars		
PCB 77	14 FW	14, 20, 21
PCB 126	0.9 FW	14, 20, 21
PCB 169	0.6 FW	14, 20, 21
Killer whale, <i>Orcinus orca</i> ; blubber		
Died after 2 years in captivity		
Total PCBs	160,000 FW	14
PCB 77	42.0 FW	14
PCB 126	4.0 FW	14
PCB 169	3.6 FW	14
Pacific coast of Japan; July 1985		
Total PCBs	370,000 (350,000–410,000) FW	20, 21
Di-ortho planars		
PCB 128	8000 (3200–12,000) FW	20, 21
PCB 138	65,000 (24,000–85,000) FW	20, 21
Mono-ortho planars		
PCB 105	3000 (2300–3600) FW	20, 21
PCB 118	11,000 (6700–14,000) FW	20, 21
PCB 156	1900 (950–3100) FW	20, 21

Table 24.9 (continued) PCB Concentrations in Field Collections of Selected Aquatic Organisms
 (Concentrations are in micrograms PCBs per kilogram [ppb] fresh weight [FW], dry weight [DW], or lipid weight [LW].)

Taxonomic Group, Organism, PCB Congener, and Other Variables	Concentration ^a (g/kg)	Reference ^b
Non-ortho planars		
PCB 77	48 (39–55) FW	14, 20, 21
PCB 126	3.7 (2.4–4.4) FW	14, 20, 21
PCB 169	7.7 (2.3–12.0) FW	14, 20, 21
Ringed seal, <i>Phoca hispida</i> ; Kera Sea; Russian Arctic; 1995; blubber		
Total PCBs	7100 LW	62
Non-ortho congeners		
PCB 77	0.99 LW	62
PCB 126	0.57 LW	62
PCB 169	<0.003 LW	62
Mono-ortho congeners		
PCB 105	230 LW	62
PCB 118	450 LW	62
PCB 156	61 LW	62
Di-ortho congener		
PCB 180	270 LW	62
Baikal seal, <i>Phoca sibirica</i> ; Lake Baikal, Siberia; blubber; May–June 1992		
Males; immature vs. mature		
Total PCBs	5000 FW vs. 26,000 FW	56
PCB 77	6.3 FW vs. 23.0 FW	56
PCB 126	2.4 FW vs. 3.5 FW	56
PCB 169	0.2 FW vs. 0.4 FW	56
PCB 105	250 FW vs. 1200 FW	56
PCB 118	650 FW vs. 2800 FW	56
PCB 156	87 FW vs. 260 FW	56
PCB 137	180 FW vs. 1300 FW	56
PCB 138	650 FW vs. 3800 FW	56
PCB 153	990 FW vs. 6700 FW	56
PCB 180	250 FW vs. 1700 FW	56
Females; immature vs. mature		
Total PCBs	5000 FW vs. 10,000 FW	56
PCB 77	8.8 FW vs. 14.0 FW	56
PCB 126	2.5 FW vs. 3.4 FW	56
PCB 169	0.3 FW vs. 0.3 FW	56
PCB 105	260 FW vs. 360 FW	56
PCB 118	740 FW vs. 960 FW	56
PCB 156	74 FW vs. 150 FW	56
PCB 137	160 FW vs. 370 FW	56
PCB 138	650 FW vs. 1400 FW	56
PCB 153	990 FW vs. 2400 FW	56
PCB 180	190 FW vs. 710 FW	56
Harbor porpoise, <i>Phocoena phocoena</i>		
Black Sea, Turkey; 1993; blubber; accidentally drowned in sturgeon trammel nets; males vs. females; total PCBs	16,000 FW vs. 12,000 FW; Max. 39,000 FW	57
Dutch coast; 1990–93; found stranded		
Blubber		
PCB 77	0.3–3.2 FW	58
PCB 126	0.2–1.1 FW	58
PCB 169	0.2–1.2 FW	58
Maximum values		
PCBs 31, 50, 207, and 209	34–78 FW	58

Table 24.9 (continued) PCB Concentrations in Field Collections of Selected Aquatic Organisms
 (Concentrations are in micrograms PCBs per kilogram [ppb] fresh weight [FW], dry weight [DW], or lipid weight [LW].)

Taxonomic Group, Organism, PCB Congener, and Other Variables	Concentration ^a (g/kg)	Reference ^b
PCBs 18, 28, 44, 97, 156, 195, and 202	143–464 FW	58
PCBs 105, 143, 194	538–658 FW	58
PCBs 52, 101, 118, 151, 170, 183	1405–2899 FW	58
PCB 138	12,256 FW	58
PCB 149	6395 FW	58
PCB 153	15,676 FW	58
PCB 180	4065 FW	58
PCB 187	4089 FW	58
PCB 153 vs. total PCBs		
Blubber	600–19,200 FW vs. 1900–61,200 FW	58
Liver	30–2400 FW vs. 100–7300 FW	58
Kidney	300–1200 FW vs. 100–3600 FW	58
Ringed seal, <i>Pusa hispida</i> ; Norway, March–April, 1990		
Blubber		
PCBs 77, 126, 169	ND–0.19 LW	25
PCBs 66, 110, 149	20–22 LW	25
PCBs 52, 61, 105, 180	40–52 LW	25
PCBs 101, 118, 138	108–188 LW	25
PCBs 153	280 LW	25
Kidney		
PCBs 77, 126, 169	ND	25
PCBs 66, 110, 149 180	12–14 LW	25
PCBs 52, 61, 105	21–28 LW	25
PCBs 101, 118, 138	49–67 LW	25
PCB 153	95 LW	25
Liver		
PCBs 77, 126, 169	ND–0.78 LW	25
PCBs 61, 66, 105, 110, 149, 180	18–43 LW	25
PCBs 52, 101, 118	57–71 LW	25
PCBs 138, 153	115–188 LW	25
Harbor seal, <i>Phoca vitulina</i> ; northeast coast of U.S.; 1980–92		
Blubber; 1980 vs. 1990–92		
Total PCBs	12,000 (7300–24,300) FW vs. 6660 (2610–11,300) FW	51
PCB 8	ND vs. 0.9 FW	51
PCB 18	26 FW vs. 2 FW	51
PCB 28	99 FW vs. 16 FW	51
PCB 44	105 FW vs. 17 FW	51
PCB 52	661 FW vs. 213 FW	51
PCBs 66 + 95	192 FW vs. 29 FW	51
PCB 77	0.36 FW vs. 0.07 FW	51
PCB 101	897 FW vs. 500 FW	51
PCB 105	205 FW vs. 82 FW	51
PCBs 118 + 149	615 FW vs. 279 FW	51
PCB 126	1.45 FW vs. 0.53 FW	51
PCB 128	459 FW vs. 244 FW	51
PCB 138	2990 FW vs. 1650 FW	51
PCB 153	3040 FW vs. 1880 FW	51
PCB 169	0.019 FW vs. 0.013 FW	51
PCBs 170 + 190	458 FW vs. 266 FW	51
PCB 180	1210 FW vs. 713 FW	51
PCB 187	865 FW vs. 601 FW	51
PCB 195	67 FW vs. 56 FW	51

Table 24.9 (continued) PCB Concentrations in Field Collections of Selected Aquatic Organisms
 (Concentrations are in micrograms PCBs per kilogram [ppb] fresh weight [FW], dry weight [DW], or lipid weight [LW].)

Taxonomic Group, Organism, PCB Congener, and Other Variables	Concentration ^a (g/kg)	Reference ^b
PCB 206	72 FW vs. 79 FW	51
PCB 209	22 FW vs. 34 FW	51
Liver; 1980 vs. 1990–92		
Total PCBs	9860 (6290–16,000) FW vs. 6260 (528–25,300) FW	51
PCB 8	ND vs. 1.2 FW	51
PCB 18	8.2 FW vs. 0.5 FW	51
PCB 28	27 FW vs. 10 FW	51
PCB 44	42 FW vs. 8 FW	51
PCB 52	343 FW vs. 145 FW	51
PCBs 66 + 95	127 FW vs. 9 FW	51
PCB 101	523 FW vs. 371 FW	51
PCB 105	345 FW vs. 26 FW	51
PCBs 118 + 149	470 FW vs. 196 FW	51
PCB 128	385 FW vs. 232 FW	51
PCB 138	2250 FW vs. 1550 FW	51
PCB 153	2040 FW vs. 1690 FW	51
PCBs 170 + 190	476 FW vs. 253 FW	51
PCB 180	1160 FW vs. 696 FW	51
PCB 187	1450 FW vs. 904 FW	51
PCB 195	85 FW vs. 60 FW	51
PCB 206	97 FW vs. 80 FW	51
PCB 209	41 FW vs. 36 FW	51
Common porpoise, <i>Phocoena phocoena</i>		
Found dead along Dutch coast, 1971–81		
Blubber vs. liver		
PCB 44	530 FW vs. 1 FW	26
PCB 49	900 FW vs. 5 FW	26
PCB 52	10,000 FW vs. 80 FW	26
PCB 101	3200 FW vs. 20 FW	26
PCB 118	8200 FW vs. 35 FW	26
PCB 138	28,900 FW vs. 280 FW	26
PCB 149	16,700 FW vs. 140 FW	26
PCB 153	32,600 FW vs. 340 FW	26
PCB 172	530 FW vs. 5 FW	26
PCB 174	3700 FW vs. 40 FW	26
PCB 177	6200 FW vs. 60 FW	26
PCB 180	4000 FW vs. 80 FW	26
PCB 183	3700 FW vs. 50 FW	26
PCB 194	700 FW vs. 10 FW	26
PCB 201	1200 FW vs. 20 FW	26
PCB 206	360 FW vs. 7 FW	26
PCB 209	40 FW vs. 10 FW	26
Total PCBs (from above congeners)		
Blubber	51,350–139,790 FW	26
Heart	1410–4900 FW	26
Kidney	860–3970 FW	26
Liver	1190–17,400 FW	26
Muscle	960–3990 FW	26
Three females found dead in fishing nets; Baltic Sea, 1989–90		
Blubber, maximum concentrations		
PCB 77	3.6 FW	37
PCB 126	1.4 FW	37

Table 24.9 (continued) PCB Concentrations in Field Collections of Selected Aquatic Organisms
 (Concentrations are in micrograms PCBs per kilogram [ppb] fresh weight [FW], dry weight [DW], or lipid weight [LW].)

Taxonomic Group, Organism, PCB Congener, and Other Variables	Concentration ^a (g/kg)	Reference ^b
PCB 169	2.1 FW	37
PCB 60	15 FW	37
PCB 105	150 FW	37
PCB 118	1100 FW	37
PCB 156	ND	37
PCB 137	730 FW	37
PCB 138	7700 FW	37
PCB 153	9600 FW	37
PCB 170	380 FW	37
PCB 180	1500 FW	37
PCB 194	84 FW	37
Liver vs. muscle		
PCB 77	0.2 FW vs. ND	37
PCB 126	0.05 FW vs. ND	37
PCB 169	0.02 FW vs. ND	37
PCB 118	63 FW vs. 120 FW	37
PCB 138	250 FW vs. 350 FW	37
PCB 153	320 FW vs. 500 FW	37
PCB 170	33 FW vs. 64 FW	37
PCB 180	110 FW vs. 220 FW	37
Scandinavia; 1987–91; blubber; males; total of 47 detected PCB congeners	23,300 (3710–65,260) LW	50
Dall's porpoise, <i>Phocoenoides dalli dalli</i> ; northern North Pacific, 1980–85; blubber		
Total PCBs		
Females	1500 (1000–2000) FW	14
Males	12,000 (7100–18,000) FW	14
All samples	8600 (1000–18,000) FW	20, 21
Di-ortho planars		
PCB 128	480 (110–1100) FW	20, 21
PCB 138	970 (160–2000) FW	20, 21
Mono-ortho planars		
PCB 105	100 (30–200) FW	20, 21
PCB 118	280 (90–450) FW	20, 21
PCB 156	11 (5–15) FW	20, 21
Non-ortho planars		
PCB 77	2.3 (0.4–3.5) FW	14, 20, 21
PCB 126	0.16 (0.08–0.25) FW	14, 20, 21
PCB 169	0.11 (0.04–0.2) FW	14, 20, 21
Ringed seal, <i>Pusa hispida</i> ; Baltic Sea and environs, 1981–87; blubber		
PCB 77	Max. 9 LW	9
PCB 105	Max. 1100 LW	9
PCB 126	Max. 4 LW	9
PCB 169	Max. 0.3 LW	9
Striped dolphin, <i>Stenella coeruleoalba</i> ; blubber		
Japan; 1978–79 vs. 1986; adult males; total PCBs	29,000 (15,000–46,000) FW vs. 28,000 (17,000–38,000) FW	27
Mediterranean Sea; 1990–92; 30 dead animals killed by morbillivirus epizootic		
Total PCBs	855,000 LW	61
PCB 77	122 LW	61
PCB 105	8000 LW	61

Table 24.9 (continued) PCB Concentrations in Field Collections of Selected Aquatic Organisms
 (Concentrations are in micrograms PCBs per kilogram [ppb] fresh weight [FW], dry weight [DW], or lipid weight [LW].)

Taxonomic Group, Organism, PCB Congener, and Other Variables	Concentration ^a (g/kg)	Reference ^b
PCB 118	19,000 LW	61
PCB 126	43 LW	61
PCB 156	4000 LW	61
PCB 169	21 LW	61
PCB 179	47,000 LW	61
PCB 180	63,000 LW	61
Mediterranean Sea; 1990		
Total PCBs		
Alive vs. dead	480,000 FW vs. 340,000 FW	28
Males vs. females	430,000 FW vs. 94,000 FW	28
Matures vs. immatures	430,000 FW vs. 380,000 FW	28
Healthy vs. emaciated	480,000 FW vs. 340,000 FW	28
Di-ortho planars		
PCB 137	5500 FW	28
PCB 138	60,000 FW	28
PCB 153	73,000 FW	28
PCB 170	12,000 FW	28
PCB 180	39,000 FW	28
PCB 194	4000 FW	28
Mono-ortho planars		
PCB 60	160 FW	28
PCB 105	2000 FW	28
PCB 118	7900 FW	28
PCB 156	3000 FW	28
Non-ortho planars		
PCB 77	43 (16–85) FW	28
PCB 126	6.8 (2.4–13.0) FW	28
PCB 169	7.8 (1.9–15.0) FW	28
Goosebeaked whale, <i>Ziphius cavirostris</i> ; Bermuda, 1981; beached		
Blubber vs. liver		
PCB 44	5 FW vs. 0.4 FW	26
PCB 49	6 FW vs. 0.4 FW	26
PCB 52	36 FW vs. 4 FW	26
PCB 101	47 FW vs. 6 FW	26
PCB 118	74 FW vs. 13 FW	26
PCB 138	153 FW vs. 19 FW	26
PCB 149	73 FW vs. 15 FW	26
PCB 153	186 FW vs. 21 FW	26
PCB 172	14 FW vs. 2 FW	26
PCB 174	32 FW vs. 6 FW	26
PCB 177	24 FW vs. 5 FW	26
PCB 180	92 FW vs. 11 FW	26
PCB 183	37 FW vs. 6 FW	26
PCB 194	20 FW vs. 3 FW	26
PCB 201	64 FW vs. 10 FW	26
PCB 206	26 FW vs. 5 FW	26
PCB 209	6 FW vs. 0.5 FW	26
Total PCBs (from above congeners)		
Blubber	720–1450 FW	26
Heart	18 FW	26
Kidney	26–78 FW	26

Table 24.9 (continued) PCB Concentrations in Field Collections of Selected Aquatic Organisms
 (Concentrations are in micrograms PCBs per kilogram [ppb] fresh weight [FW], dry weight [DW], or lipid weight [LW].)

Taxonomic Group, Organism, PCB Congener, and Other Variables	Concentration ^a (g/kg)	Reference ^b
Liver	98–127 FW	26
Muscle	6–138 FW	26
INTEGRATED STUDIES		
Freshwater lake near Amsterdam, the Netherlands; near dredged materials discharge site		
Sediments		
PCB 28	1.4 DW	29
PCB 52	2.3 DW	29
PCB 101	4.1 DW	29
PCB 138	13.7 DW	29
PCB 153	7.2 DW	29
PCB 180	3.4 DW	29
Plankton, 2 species (whole) vs. zebra mussel, <i>Dreissena polymorpha</i> (soft parts)		
PCB 28	0.2 FW, 68 LW vs. 0.5 FW, 36 LW	29
PCB 52	0.3 FW, 102 LW vs. 0.9 FW, 57 LW	29
PCB 101	0.5 FW, 206 LW vs. 3.8 FW, 220 LW	29
PCB 138	0.7 FW, 259 LW vs. 4.5 FW, 258 LW	29
PCB 153	0.5 FW, 209 LW vs. 5.8 FW, 322 LW	29
PCB 180	0.2 FW, 60 LW vs. 1.2 FW, 75 LW	29
Crustaceans, 3 species (whole) vs. European eel, <i>Anguilla</i> sp. (whole)		
PCB 28	3 FW, 362 LW vs. 4 FW, 21 LW	29
PCB 52	3 FW, 400 LW vs. 15 FW, 83 LW	29
PCB 101	4 FW, 532 LW vs. 28 FW, 186 LW	29
PCB 138	4 FW, 529 LW vs. 97 FW, 986 LW	29
PCB 153	4 FW, 505 LW vs. 89 FW, 932 LW	29
PCB 180	0.8 FW, 107 LW vs. 41 FW, 436 LW	29
Gulf of Mexico; 1986–87; coastal sediments vs. oyster soft parts		
Di-CBs	0.08–0.6 DW vs. 0.4–1.6 DW	39
Tri-CBs	0.6–2.6 DW vs. 7.6–8.3 DW	39
Tetra-CBs	1.8–11.0 DW vs. 26–38 DW	39
Penta-CBs	3.1–13.4 DW vs. 66–78 DW	39
Hexa-CBs	2.7–15.6 DW vs. 26–42 DW	39
Hepta-CBs	1.3–9.5 DW vs. 5–6 DW	39
Octa-CBs	0.3–2.6 DW vs. 0.4–1.0 DW	39
Nona-CBs	0.06–0.4 DW vs. 0.3–0.4 DW	39
Total PCBs	9.8–55.7 DW vs. 134–1734 DW	39
Hudson River (upper), New York; 1983; total PCBs; water column vs. fish muscle	0.14 FW vs. 3800 FW	40
Lake Clear (PCB-contaminated), Canada; 1986–87; vs. Lake Scugog (noncontaminated); total of 19 PCB congeners		
Sediments	571 DW vs. 22 DW	41
Crayfish	73 FW vs. 9 FW	41
Plankton	59 FW vs. ND	41
Fish	90–153 FW vs. 6–27 FW	41
Lake Erie, Hamilton Harbour; 1984		
Water column vs. sediments		
Tri-CBs	0.04 FW vs. 244 FW	42
Tetra-CBs	0.07 FW vs. 405 FW	42
Penta-CBs	0.07 FW vs. 1025 FW	42
Hexa-CBs	0.02 FW vs. 982 FW	42
Hepta-CBs	0.01 FW vs. 983 FW	42

Table 24.9 (continued) PCB Concentrations in Field Collections of Selected Aquatic Organisms
 (Concentrations are in micrograms PCBs per kilogram [ppb] fresh weight [FW], dry weight [DW], or lipid weight [LW].)

Taxonomic Group, Organism, PCB Congener, and Other Variables	Concentration ^a (g/kg)	Reference ^b
Octa-CBs	0.002 FW vs. 246 FW	42
Total PCBs	0.22 FW vs. 3927 FW; Max. 14,185 FW	42
Oligochaetes		
Tri-CBs	33 FW	42
Tetra-CBs	39 FW	42
Penta-CBs	54 FW	42

24.4.4 Other Aquatic Organisms

In comparison to conspecifics from noncontaminated sites, aquatic invertebrates from PCB-contaminated sites contained elevated concentrations of PCBs in tissues (Table 24.9). Adult aquatic insects are one of the groups considered useful and reliable indicators of PCB contamination (Wood et al. 1987; Kovats and Ciborowski 1989). Mayflies (*Hexagenia* spp.) from Lake St. Clair had PCB concentrations that reflected sediment PCB concentrations (Table 24.9). Observed mayfly sediment concentration ratios from PCBs linearly correlated with K_{ow} when expressed on a logarithmic basis (Gobas et al. 1989). PCB congener distributions in lake biota showed that no particular trophic level consistently accumulated the highest PCB concentrations and suggest that accumulations were associated with the organism's lipid concentrations (Table 24.9). A relation was consistent between the concentration of dissolved PCBs and tissue concentrations in mussels from PCB-contaminated sites, such as New Bedford Harbor, Massachusetts. Uptake of PCB congeners in blue mussels

(*Mytilus edulis*) from the dissolved phase of seawater was predictable from the log of the bioconcentration factor and the log K_{ow} of the congeners (Bergen et al. 1993). American oysters (*Crassostrea virginica*) from Galveston Bay, Texas, contained as much as 1100 µg/kg total PCBs DW soft parts, whereas conspecifics from Tampa Bay, Florida, contained only 580 µg/kg DW soft parts; most (54 to 94%) of the relative toxicity in both groups was due to PCBs 77, 126, and 169 (Sericano et al. 1994).

The partitioning of individual, highly chlorinated PCB congeners with small differences in K_{ow} values may not adequately explain the accumulations in aquatic organisms (van der Oost et al. 1988). Hydrophobic chemicals, such as PCBs, are accumulated as a consequence of chemical partitioning between the water column, the organic phase of sediment, and biotic lipids, or from biomagnification, a process reflecting the ratio between uptake rate from food and elimination rate from the organism. Accumulations of six PCB congeners (PCBs 28, 52, 101, 138, 153, 180) in surficial sediments (0 to 20 cm) and in an aquatic food chain in Lake Nieuwe Meer — a freshwater lake near Amsterdam containing contaminated dredged materials discharged over 30 years — were low in sediments; elevated in carnivores, plankton, molluscs, crustaceans, and eels; and independent of fat content (van der Oost et al. 1988). With concentrations in organisms expressed on the basis of lipid content (C_{org}) and concentrations in sediments expressed on the basis of organic carbon (C_{sed}) the median C_{org}/C_{sed} PCB accumulation patterns in aquatic organisms showed significant differences and indicated that mechanisms other than partitioning were operating. In plankton and molluscs, C_{org}/C_{sed} ratios seemed to be independent of hydrophobicity of PCB congeners. But with ascending trophic level from plankton to molluscs to crustaceans to eels, the median C_{org}/C_{sed} ratios of higher chlorinated congeners (PCBs 138, 153, 180) increased. Differences in accumulations of individual congeners were attributed to:

1. Increased biomagnification of higher chlorinated congeners because increasing hydrophobicity decreased elimination rates but not uptake efficiency
2. Greater mobility of eels and different feeding habits of eels and crustaceans that impact accumulation patterns because of biomagnification and partitioning
3. Variability in the time period (limited by lifespan) available in a particular trophic level for equilibration between uptake and clearance
4. The tendency of equilibrium to be established at faster rates in less chlorinated congeners.

In crustaceans, C_{org}/C_{sed} ratios decreased with decreasing hydrophobicity; the opposite occurred in eels and is attributed to differences in uptake efficiencies and low elimination rates of lower-chlorinated congeners in crustaceans (van der Oost et al. 1988).

A correlation exists between the concentration of lipophilic, hydrophobic, chlorinated hydrocarbons in benthic fishes and the concentration of these compounds in sediments. The correlation is affected by the solubility of the contaminants, as reflected by the octanol/water partition coefficient K_{ow} and the carbon content of the sediment (Connor 1984; Breck 1985). Connor (1984) suggested that surface sediments, which change more slowly than the water column, are useful for averaging spatial and temporal contaminant inputs. However, correlations between PCB concentrations in sediment and those in nonbenthic carnivores with limited home ranges are extremely variable. PCBs in a tidal creek in Georgia were traced to Aroclor 1268 used at a former chloralkali plant near the creek. Sediment-ingesting forage fishes, such as the striped mullet (*Mugil cephalus*), efficiently accumulate PCBs and are an important link in the food web transfer of sediment-associated contaminants (Maruya and Lee 1998).

Concentrations of total PCBs — measured as Aroclors 1248, 1254, and 1260 — in adult freshwater fishes in the United States from noncontaminated sites declined between 1976 and 1984 (Table 24.9), and more than 90% of all analyzed samples contained measurable quantities of PCBs during this period (Schmitt et al. 1990). Total PCB concentrations in domestic freshwater fishes in 1986/87 from contaminated sites were as high as 124,000 µg/kg FW (USEPA 1992a). In general, total PCB concentrations in domestic freshwater fishes sampled between 1976 and 1984 were

highest in the industrialized regions of the Northeast, the Great Lakes, the upper Mississippi River, and the Ohio River (Schmitt et al. 1990). Phillips and Birchard (1990) reviewed PCB concentrations (as judged by residues of Aroclors 1016, 1221, 1232, 1242, 1248, 1254, and 1260) in sediments and fish tissues in the United States during 1978 to 1987. During 1978 to 1981, total PCB concentration rankings in sediments were highest in the lower Mississippi, Tennessee, South Atlantic–Gulf of Mexico, and lower Colorado regions and lowest in the Great Lakes, Arkansas, mid-Atlantic, Pacific Northwest, and Rio Grande regions. During this same period, PCB concentrations in fish tissues were highest in the Missouri, upper Colorado, California, and the Great Lakes regions and lowest in the upper Mississippi, New England, Ohio, Pacific Northwest, Tennessee, lower Mississippi, and Rio Grande regions. Sediment PCB rankings during 1982 to 1987 were highest in the Arkansas, California, Ohio, and Missouri regions and lowest in the south Atlantic–Gulf and Colorado regions. Total PCBs were highest in fish tissues in the upper Mississippi region during 1982 to 1987. The fish tissue rankings in descending order assigned to 12 regions with sufficient total PCB data were the upper Mississippi and Missouri regions, Ohio, south Atlantic–Gulf, Arkansas, Great Basin, lower Colorado, California, Pacific Northwest, Ohio, upper Colorado, and lower Mississippi. PCB rankings between fish tissues and sediments were not necessarily comparable because high levels in sediment do not necessarily result in high levels in fishes if bioconversion was significant (Phillips and Birchard 1990). Total PCB concentrations in coastal sediments and fish liver in the United States were highest in the Boston Harbor (17.1 mg/kg DW sediment, 10.5 mg/kg in liver of winter flounder, *Pleuronectes americanus*), San Diego Harbor (0.42 mg/kg DW sediment, 19.7 mg/kg in barred sand bass, *Paralbrax nebulifer*), and Elliot Bay, Washington (0.33 mg/kg sediment, 14.7 mg/kg in flathead sole, *Hippoglossoides elassodon*). Trichloro-PCBs were in sediments at many sites but did not accumulate in fish livers except in the Boston Harbor. Sediments in the Boston Harbor, western Long Island Sound, and Raritan Bay were contaminated with PCB mixtures that were relatively high in tri- and tetrachlorobiphenyl isomers, although penta- and particularly hexachlorobiphenyls were the dominant isomers at most sediment sites. As expected, levels of hexachlorobiphenyls in fish livers were dominant because of the more persistent and lipophilic characteristics of increasingly chlorinated PCBs (NOAA 1987).

Variations in PCB concentrations in sediment and water in the Great Lakes can largely account for the variability in fish PCB residues between different bodies of water. Other variables include fish lipid content, position of the fish species in the food web, and trophic structure of the food chain. Collectively, these variables explain 72% of the variation in PCB concentrations of 25 species of Great Lakes fishes (Rowan and Rasmussen 1992). There is a strong linear correlation between total PCB concentration and percent lipid in five species of Lake Michigan salmonids between 1984 and 1994; however, there is considerable variability among individuals, especially among nonspawning individuals (Stow et al. 1997). Tissue concentrations of PCBs in benthic and lower trophic organisms in lakes can be estimated by assuming equal lipid-normalized concentrations in biota and sediment; however, food chain transport had a greater effect on PCB concentrations in higher trophic levels (Macdonald et al. 1993). Total PCB concentrations in whole body of lake fishes were higher among older piscivores and higher with increasing lipid concentration and seemed to reflect exposure conditions at the capture site (Southworth 1990).

Eggs of chinook salmon (*Oncorhynchus tshawytscha*) from Lake Michigan in 1986 contained AHH-active PCB congeners — including PCBs 77, 105, 118, and 126 — at concentrations from 0.9 to 262 µg/kg FW. Concentrations of these congeners did not correlate with survival (Williams and Giesy 1992). Mortality of chinook salmon eggs was not related to total PCB concentrations as high as 7020 µg/kg FW (Williams and Giesy 1992). In Lake Ontario, the overall trend in total PCB concentrations in whole lake trout (*Salvelinus namaycush*) between 1977 and 1988 was a gradual decline with a half-time persistence of about 10 years (Borgmann and Whittle 1991). In Lake Superior, the PCB congener fingerprint in eggs of the lake trout differed from that of lake trout eggs of other Great Lakes (Mac et al. 1993). A difference between residue patterns was also identified between eggs and the parent fish, suggesting preferential deposition of congeners other

than AHH-active congeners. Concentrations of individual congeners in lake trout have been declining at similar rates in the Great Lakes during a 10-year period (Mac et al. 1993). In Lake Michigan, total PCB concentrations declined 64% in bloaters (*Coregonus hoyi*) from 5700 mg/kg FW in 1972 to 1600 µg/kg FW in 1986 (Hesselberg et al. 1990); however, PCB concentration trends may have been influenced by sampling methodology. During this period, the bloater population increased 40-fold, resulting in a diet shift and a density-dependent decline in growth (Eby et al. 1997). The lower growth rates during the 1980s placed older, more contaminated bloaters in the size range most vulnerable to predators and also in the size range sampled by PCB monitoring programs. Future sampling should include a representative sample of bloaters of known age from the population (Eby et al. 1997).

Distribution patterns of PCB congeners in water, sediment, and four groups of biota from two lakes in Ontario contaminated by known point sources of PCBs (Lake Clear, Rice Lake) were compared with the congener distribution in Lake Scugog, a relatively clean control lake exposed only to atmospheric inputs of PCBs (Macdonald and Metcalfe 1989). Samples were analyzed for 19 PCBs. Those from Lake Clear had a distribution pattern similar to Aroclor 1254 and dominant concentrations of congeners 87, 101, and 118; this lake was contaminated with a PCB mixture similar to Aroclor 1254 in the mid- to late 1970s. The sources to Rice Lake were less clear. Lake Scugog contained a higher proportion of less chlorinated PCBs, in agreement with another study of atmospheric deposition to isolated lakes (Swackhammer et al. 1988). Because the sediments contained elevated levels of organic carbon, the sediments were expected to also hold relatively large concentrations of the higher, more hydrophobic PCBs, in accord with previous reports (Karickhoff 1981; Formica et al. 1988). But this was not the case; subsequent deposition of total and higher chlorinated congeners into the bottom sediments (organic carbon basis) was unexpectedly low. The proportion of higher chlorinated congeners in sediments was also lower than in biota (lipid weight basis) in all three lakes. Because dissolved organic carbon (DOC) increases the solubility of PCBs in water (Gschwend and Wu 1985), the high DOC levels may have caused partitioning of more PCBs into the water and less sorbed onto sediments. The sediments were not efficient at accumulating PCBs, although bottom sediment concentrations were higher in contaminated lakes. Adsorption of PCBs on suspended particles occurred, as anticipated; PCBs on total suspended solids were higher in contaminated lakes (978 µg/kg) than in the control lake (49 µg/kg) and reflected lake concentrations (Gschwend and Wu 1985). In a related study, Macdonald and Metcalfe (1991) analyzed the concentration and distribution of 19 PCB congeners in biota, sediments, water, and suspended solids of isolated oligotrophic lakes in central Ontario that were contaminated by atmospheric deposition. The range of the total congener concentrations was 1 to 2 ng/L dissolved in water, 10 to 50 µg/kg DW in sediment, 5 to 10 µg/kg FW in lower trophic levels, and 10 to 30 µg/kg in fishes from upper trophic levels. The high proportion of trichlorobiphenyls previously reported in vapor (Duinker and Bouchertall 1989; Baker and Eisenreich 1990) and hexachlorobiphenyl congeners 153 and 138 in particulate-bound PCBs (Swackhammer et al. 1988; Duinker and Bouchertall 1989; Baker and Eisenreich 1990) were reflected in the four study lakes. PCB concentrations (lipid basis) were higher in teleosts than in invertebrate prey organisms.

Winter flounder from the PCB-contaminated harbor in New Bedford, Massachusetts, had grossly elevated concentrations of PCBs in their livers (as high as 333,000 µg/kg DW); concentrations were about 5 times higher than in any other fish sample collected worldwide (Table 24.9) (Elskus et al. 1994). PCB patterns in the New Bedford Harbor showed high agreement between the exposure environment (water and sediments) and ribbed mussels (*Geukensia demissa*) and mummichogs (*Fundulus heteroclitus*). However, agreements with American eels (*Anguilla rostrata*) or grass shrimp (*Palaemonetes pugio*) were poor because, in part, of differential metabolism of PCBs by these species (Lake et al. 1995b). PCB concentrations in four species of catfishes from the Mississippi River and its tributaries in summer 1987 were highest from the Illinois River; the Ohio River at Olmsted; and the Mississippi River at Helena, Arkansas, and Arkansas City, Arkansas. These sites seem to be point sources of PCB pollution because PCB residues in catfishes above and below these sites were lower. Although PCBs were banned in 1978, the elevated levels in catfishes suggests

PCB leakage from hazardous waste sites with transformer and hydraulic fluids and flame-resistant plasticizers (Leiker et al. 1991). Findings of high (greater than 4000 µg/kg FW) total PCB levels in mature roe samples of the paddlefish (*Polyodon spathula*) from the Ohio River warranted warnings of the general public about consuming this domestic caviar (Gundersen and Pearson 1992).

The upper Hudson River was massively contaminated with PCBs from an industrial plant for several decades prior to 1975. All fishing in this section in 1976 was banned because of PCB contamination. The prohibition is still in effect because, in part, of measurable PCB residues in caged fishes from this area (Table 24.9) (Jones et al. 1989). Striped bass (*Morone saxatilis*) collected near Troy and Albany, New York, contained higher concentrations in muscle of PCB 77 (37 µg/kg FW) and PCB 126 (8 µg/kg FW) than conspecifics from other locations in New York (Hong et al. 1992). Almost all (99%) the PCB toxicity in muscle of striped bass was attributed to PCBs 77, 105 (62 µg/kg FW), and 126 (Hong et al. 1992).

The most prominent PCB congeners in muscle from 14 species of Wisconsin fishes in 1986/87 were PCBs 28/31, 66/95, 70/76, 101, 105, 110, 118, 138, 146, 149, and 180 (Maack and Sonzogni 1988). Congeners 105 and 118 were found in the greatest amount in fishes at 1 to 5% of the total PCB concentration of each. Congeners with responses similar to 2,3,7,8-TCDD — that is, the planar PCBs — were seldom present above detection levels. The sum of the individual congeners measured in Wisconsin fish muscle were similar to total recorded PCB values (Maack and Sonzogni 1988). Increased fish consumption by Wisconsin anglers in 1985 positively correlated with increased human serum PCB concentrations (Sonzogni et al. 1991). Human consumers of Wisconsin game fishes (chinook salmon, *Oncorhynchus tshawytscha*; yellow perch, *Perca flavescens*; walleye, *Stizostedion vitreum*) in 1986 contained various PCB congeners in their sera. PCB 153 (78% frequency of occurrence) was present at 1.46 (0.6 to 7.3) µg/L human serum; PCB 138 (56%) at 1.32 (0.6 to 6.0) µg/L; PCB 180 (42%) at 1.06 (0.6 to 3.5) µg/L; PCB 118 (34%) at 1.12 (0.6 to 5.7) µg/L; PCB 187 (11%) at 0.98 (0.6 to 2.2) µg/L; PCB 170 (5.8%) at 0.86 (0.6 to 1.4) µg/L; PCB 28 (1.2%) at 0.8 µg/L; PCB 101 (0.58%) at 0.8 µg/L; PCB 70 (0.58%) at 0.7 µg/L; and a single planar PCB — PCB 77 — (0.58% frequency of occurrence) at 1.3 µg/L. PCBs 118, 138, and 180 are potentially most toxic to human consumers, as judged by the concentrations of these congeners in human sera (Sonzogni et al. 1991).

Concentrations of PCBs in female northern pike (*Esox lucius*) from a Scandinavian lake decreased with increasing age, weight, or body length (Larsson et al. 1993). Seasonal elimination of the lipophilic contaminants in roe — which contained as much as 10 times more fat than muscle and more than 10 times the amount of pollutants than muscle — is the major route of PCB loss. Male northern pikes contained higher concentrations of PCBs than females because of the lower elimination by way of gonadal products; males showed no significant relation between age and PCB burdens in tissues (Larsson et al. 1993). Total PCB levels of 7700 to 34,000 µg/kg LW in eggs of the Arctic char (*Salvelinus alpinus*) from Lake Geneva, Switzerland, correlated with a mortality rate of 29 to 100% (Gundersen and Pearson 1992).

On the Pacific coast and in adjacent areas of Mexico, data from more than 150 survey and monitoring programs were summarized on contamination of sediments, invertebrates, and fishes (Mearns 1992). PCBs in sediments seem to be reflected in mussels, and PCB residues from mussels collected at harbor entrances remained unchanged or were increasing. The harbors in Los Angeles–Long Beach and San Diego remained contaminated with PCBs, and PCB concentrations in sediments were reflected in fish livers. Waste management seems to have been effective in the Palos Verdes outfall area. Sediments and mussel samples in Palos Verdes from 1974 to 1988 showed decreasing PCB levels that reflected a 100-fold reduction in PCB wastewater emissions during that period. Contamination of the coastal zone declined to levels found 30 and 40 years ago. PCB levels had declined at least one order of magnitude in teleosts and shellfish at offshore sites since the 1970s. Bays and harbors were more contaminated than the open coastal zone and must be monitored more closely; lower detection levels (0.001 to 0.01 mg/kg FW vs. the current analytical limits of 0.02 mg/kg FW) were proposed to monitor the effectiveness of current source control programs (Mearns 1992).

PCBs in Puget Sound, Washington, were measured in sediments, fish livers, and benthic invertebrates. Maximum total PCB concentrations were 2100 µg/kg DW in sediments near Tacoma, and 32,000 µg/kg DW in crab hepatopancreas and 35,000 µg/kg DW in fish liver near Seattle (Long 1981). PCB concentrations in sediments of the Puget Sound in May 1988 positively correlated with PCB concentrations in livers of several species of flatfishes in these sediments (Stein et al. 1992). Increased sediment PCB concentrations also correlated well with increased hepatic AHH and EROD activities and with increases in total hepatic GSH, all of which are acknowledged early indicators of chemical contamination by PCBs and other organic contaminants (Gooch et al. 1989; Stein et al. 1992).

PCB residues in liver of the European flounder (*Platichthys flesus*) were extremely variable, but residues of individual congeners were usually higher in fall, higher in females, and higher in flounders captured inland near a PCB point source (Marthinsen et al. 1991). A similar pattern was documented in the Atlantic cod (*Gadus morhua*) (Marthinsen et al. 1991). In the dab (*Limanda limanda*), a marine flatfish, the accumulation of PCBs 128, 138, and 163 differs significantly by sex (Knickmeyer and Steinhart 1989). Depletion of lipids from the liver of female dabs during ovary maturation is an important excretory pathway for PCBs during spawning (Knickmeyer and Steinhart 1989). PCB levels in liver of dabs were higher in spring than in winter; livers and ovaries were dominated by penta- and hexachlorobiphenyls, but the dominant PCBs in testes were tri- and tetrachlorobiphenyls (Kammann et al. 1993).

The most prominent PCB congeners at 280 to 323 µg/kg DW in the tilefish (*Lopholatilus chamaeleonticeps*) from Georges Bank in 1981 to 1992 were PCBs 138 and 153 in gonad and liver. At 69 to 82 µg/kg DW, the most prominent PCB congeners in the tilefish from New Jersey during this same period were PCBs 138 and 153 in liver (Steimle et al. 1990). Total PCB concentrations in marine coastal fishes were dominated by the hexachlorobiphenyls (Knickmeyer and Steinhart 1989), but trout from isolated mountain lakes had tri-, tetra-, and pentachlorobiphenyls as the major components of total PCBs (Sanchez et al. 1993).

24.4.5 Reptiles

PCBs accumulate in the fat, testes, and brain of snapping turtles (*Chelydra serpentina*), and concentrations seem to reflect the lipoprotein solubility of individual congeners (Bryan et al. 1987a) (Table 24.10). With increasing hydrophobicity (increasing K_{ow}) of PCB congeners, accumulations increased in livers of snapping turtles; and total liver PCB concentrations in adults increased with increasing age, length, and weight (Hebert et al. 1993). PCB loadings in snapping turtle eggs were not related to the body size of females or to the number of eggs in the clutch (Bishop et al. 1994). However, a positive relation between PCB loadings in liver of adult female snapping turtles and their eggs was significant (Hebert et al. 1993).

PCB 105 may be an important contributor to the toxic burden of snapping turtle populations (Hebert et al. 1993). Eggs of snapping turtles from the Great Lakes had a lower hatch rate and a significantly increased frequency of deformed hatchlings than eggs from a control site, and this seemed to be strongly associated with total PCB concentrations and PCB 105 (Bishop et al. 1991). Of the five toxic PCB congeners measured in the yolks, egg whites, and shells of snapping turtle eggs, PCBs 105 and 167 accounted for more than 99% of the total toxicity — as measured by 2,3,7,8-TCDD TEF equivalents — and 95% of the total toxicity resided in the yolk (Bryan et al. 1987b). Large reserves of fat in eggs of the snapping turtle do not seem to protect against toxic PCB congeners from being dispersed into egg components low in fat (Bryan et al. 1987b).

In loggerhead turtles (*Caretta caretta*), PCB concentrations in the chorioallantoic membrane correlate closely with whole-egg PCB concentrations (Cobb and Wood 1997). The authors recommend the use of chorioallantoic membrane tissues as a nonlethal methodology for predicting PCB concentrations in sea turtle hatchlings.

Table 24.10 PCB Concentrations in Field Collections of Selected Reptiles
 (Concentrations are in g/kg [ppb] fresh weight [FW] or lipid weight [LW].)

Species, Tissue, PCB Congener, and Other Variables	Concentration ^a (g/kg)	Reference ^b
AMERICAN ALLIGATOR, <i>Alligator mississippiensis</i>		
Total PCBs; Florida		
Eggs, 1984	80–170 FW; Max. 670 FW	1
Muscle, 1985	100–2100 LW	2
LOGGERHEAD TURTLE, <i>Caretta caretta</i>		
September 1993; South Carolina; chorioallantoic membrane vs. egg contents		
Total PCBs	10,100 LW vs. 1188 LW	8
DichloroBPs	236 LW vs. 9 LW	8
TrichloroBPs	889 LW vs. 9 LW	8
TetrachloroBPs	2406 LW vs. 120 LW	8
PentachloroBPs	2998 LW vs. 446 LW	8
HexachloroBPs	2707 vs. 427 LW	8
HeptachloroBPs	763 LW vs. 173 LW	8
OctachloroBPs	197 LW vs. 30 LW	8
NonachloroBPs	37 LW vs. 4 LW	8
DecachloroBPs	55 LW vs. 5 LW	8
SNAPPING TURTLE, <i>Chelydra serpentina</i>		
Canada		
Great Lakes (Ontario and Erie) vs. control site in central Ontario; eggs; sum of PCB congeners 105, 118, 138, 153, 170, and 180		
1986–87	2600–2700 FW vs. 80 FW	3
1988–89	300–3300 FW vs. 30 FW	3
Hamilton Harbour; adults; found dead; 1986–87; fat; sum of PCBs 105, 118, 138, 153, 170, and 180	57,700–72,200 LW	3
Lake Ontario; eggs; 1990		
PCB 52	20 (10–40) LW	4
PCB 105	1700 (500–2900) LW	4
PCB 118	7300 (2100–11,700) LW	4
PCB 138	9300 (2000–16,200) LW	4
PCB 153	9300 (2500–16,200) LW	4
PCB 180	6400 LW	4
PCB 194	600 LW	4
Total PCBs	54,300 (13,300–96,400) LW	4
Southern Ontario; adults; 1988–89; muscle; sum of Aroclors 1254 and 1260	7–660 FW; Max. 2120 FW	5
United States		
Contaminated site (South Glen Falls, New York) vs. noncontaminated site (Columbus, New York); adults; total PCBs		
Brain	82,000 LW vs. 1000 LW	6
Heart	49,000 LW vs. 600 LW	6
Kidney	48,000 LW vs. 1200 LW	6
Liver	72,000 LW vs. 1000 LW	6

Pancreas	48,000 LW vs. 1200 LW	6
Testes	100,000 LW vs. 1600 LW	6
Fat	1,600,000 LW vs. 4200 LW	6

Table 24.10 (continued) PCB Concentrations in Field Collections of Selected Reptiles (Concentrations are in g/kg [ppb] fresh weight [FW] or lipid weight [LW].)

Species, Tissue, PCB Congener, and Other Variables	Concentration ^a (g/kg)	Reference ^b
PCB 66	272,000 LW vs. 200 LW	6
PCB 82	100,000 LW vs. 90 LW	6
PCB 99	166,000 LW vs. 50 LW	6
PCB 105	171,000 LW vs. 160 LW	6
PCB 136	297,000 LW vs. 200 LW	6
PCB 176	152,000 LW vs. 300 LW	6
Upper Hudson River, New York; egg yolk		
PCB 105	700–1890 FW	7
PCB 118	16–32 FW	7
PCB 120	120–280 FW	7
PCB 167	200–560 FW	7
PCB 189	60–120 FW	7

^a Concentrations are shown as means, range (in parentheses), and maximum (Max.).

^b 1, Heinz et al. 1991; 2, Delaney et al. 1988; 3, Bishop et al. 1991; 4, Bishop et al. 1994; 5, Hebert et al. 1993; 6, Bryan et al. 1987a; 7, Bryan et al. 1987b; 8, Cobb and Wood 1997.

24.4.6 Birds

Embryos of the double-crested cormorant (*Phalacrocorax auritus*) exposed *in ovo* to elevated mixtures of PCBs in the environment were 25 times more likely to hatch with asymmetric brains than were those from reference sites (Henshel et al. 1997). A high frequency of dead and deformed embryos of double-crested cormorants and Caspian terns was documented in the upper Great Lakes in 1986 to 1991 (Ludwig et al. 1996). Half the embryos found dead in eggs were deformed. Only one of ten cross-billed cormorant embryos survived to hatch and no bill-deformed terns hatched, although tern embryos had a higher frequency of crossed bills than did cormorants. Planar PCB congeners were present at sufficient concentrations to cause the observed effects (Ludwig et al. 1996). A severely deformed bill of the type associated with high environmental levels of PCBs was observed in a newly hatched chick of the shag (*Phalacrocorax aristotelis*); the two dominant congeners in the chick, accounting for about 57% of the total PCB body burden, were PCBs 153 (35%) and 138 (22%), both of which are known to show selective biomagnification (Allen and Thompson 1996).

In general, total PCB concentrations in birds were usually higher in males and in eggs than in livers, in adipose tissues, in fish-eating species, and at PCB-contaminated sites; PCBs 138 and 153 tended to predominate in all samples (Table 24.11). The change in PCB content in livers of Norwegian raptors between 1965 and 1983 was not significant despite a marked reduction in the use of these compounds (Froslie et al. 1986). When total PCB concentrations declined, for example, in eggs of red-breasted mergansers (*Mergus serrator*) between 1977 and 1990, the relative potency of the mixture of PCBs — as measured by 2,3,7,8-TCDD equivalents — was unchanged (Williams et al. 1995).

Commercial PCB mixtures frequently contain impurities that may contribute to the 2,3,7,8-TCDD toxic equivalency factor. These impurities may include other PCBs, dioxins, dibenzofurans, naphthalenes, diphenyl ethers and toluenes, phenoxy and biphenyl anisoles, xanthenes, xanthones, anthracenes, and fluorenes (Jones et al. 1993). PCB concentrations in avian tissues sometimes correlate positively with DDE concentrations (Mora et al. 1993). Eggs of peregrine falcons (*Falco peregrinus*) from California, for example, contained measurable quantities of various organochlorine compounds, including dioxins, dibenzofurans, mirex, hexachlorobenzene, and *p,p'*-DDE at 7.1 to 26.0 mg/kg FW; PCB 126 accounted for 83% of the 2,3,7,8-TCDD equivalents, but its interaction with other detectable organochlorine compounds is largely unknown (Jarman et al. 1993).

There is a relation between PCB uptake and the position of the species in the food chain. In a three-step, central European oak forest food chain involving the great tit (*Parus major*), caterpillars (*Tortrix viridana*, *Operophtera brumata*, *Erannis defoliaria*), and leaves of the red oak (*Quercus* sp.), mean concentrations of PCB 153 — the most abundant measured congener — rose from about 1 µg/kg DW in leaves to 10 in caterpillars to 170 in bird eggs (Winter and Streit 1992). Older juvenile tits contained 307 µg PCB 153/kg whole-body DW; these birds received PCBs from the mother during egg transfer and from the caterpillar food source during the nesting period. PCBs 101, 138, and 180 were also present in most samples but at lower concentrations than PCB 153. Populations of *Parus major* in this area have declined in recent years, and the influence of anthropogenic contaminants may be a factor (Winter and Streit 1992). Fish-eating waterfowl and seabirds had comparatively high total PCB and high planar PCB concentrations in eggs and tissues; waterfowl and seabirds that feed mainly on invertebrates had lower PCB concentrations (Focardi et al. 1988b; Borlakoglu et al. 1990; Gonzalez et al. 1991; Jones et al. 1993). PCB concentrations were higher in adipose tissues of the Arctic tern (*Sterna paradisaea*) than in those of their fish and invertebrate food items (Scharenberg 1991a). PCB concentrations in adipose tissues of cormorants, when compared to their diet of fishes, were 10 to 100 times higher than marine fishes, and 100 to 1000 times higher than freshwater fishes (Scharenberg 1991b). Double-crested cormorants (*Phalacrocorax auritus*) biomagnify total PCBs from their fish diet to their eggs — based on 2,3,7,8-TCDD equivalents — by a factor of 31.3 (Jones et al. 1994). Higher-chlorinated PCBs accumulated in tissues of the herring gull (*Larus argentatus*) to a greater extent than were present in the alewife (*Alosa pseudoharengus*), a primary food item; lower-chlorinated biphenyls, including the tetra- and penta-CBs, did not biomagnify (Braune and Norstrom 1989).

PCBs can move from local sediments into the avian food web, as judged by PCB accumulation rates of tree swallows (*Tachycineta bicolor*) from contaminated and reference sites (Custer et al. 1998). Patterns of relative concentrations of PCB congeners change from sediment to invertebrates, and from tree swallow eggs to nestlings (Froese et al. 1998). Dioxin-like activity (TEF) measured in tree swallow tissues could predict TEF in sediments and the reverse. Models of dioxin-like activity in the sediments of Saginaw Bay, Michigan, predicted that sediments were not harmful to tree swallows from that area (Froese et al. 1998).

Declining populations of Caspian terns (*Sterna caspia*) — especially populations nesting in Green Bay and Saginaw Bay between 1986 and 1990 — were associated with elevated PCB concentrations in blood. The frequency of developmental abnormalities and deformities in Caspian tern populations at Saginaw Bay was almost 100 times above that recorded in the same area between 1962 and 1972 (Table 24.11) (Mora et al. 1993). High concentrations of PCB 126 found in eggs of the bald eagle (*Haliaeetus leucocephalus*) are nearly 20-fold higher than the lowest toxic concentration tested in American kestrels (*Falco sparverius*) and may be a factor in the decline of some eagle populations (Hoffman et al. 1998). High PCB concentrations in tissues of white-tailed eagles (*Haliaeetus albicilla*) are directly connected to high concentrations in eggs and associated with eggshell thinning and low reproductive success (Falandyisz et al. 1994a). A total lack of reproduction among white-tailed sea eagles in the coastal area of the southwestern Baltic Sea in the 1960s and 1970s may be related, in part, to high concentrations of PCBs 105, 118, 126, and 156 in tissues of adult eagles. It is noteworthy that concentrations of planar PCBs in adult white-tailed sea eagles were among the highest reported in wildlife and that total PCB concentrations in this species were similar to those reported in dead eagles from Sweden and Finland in the 1960s and 1970s (Falandyisz et al. 1994a).

PCB 153 is the most widespread PCB in the environment because it is easily stored and retained in adipose tissue. PCB 153 was the main PCB congener in eggs of eight examined species of Italian waterfowl and accounted for 11.4 to 21.2% of the total PCB concentration (Focardi et al. 1988b). Infertile eggs of the endangered imperial eagle (*Aquila heliaca adalberti*) contained as much as 28.9 mg total PCBs/kg FW; PCB 153 constituted 13.5% of the total PCB loading, PCB 180 13%,

PCB 138 3.2%, PCB 101 3.2%, and PCB 118 0.7% (Hernandez et al. 1989). In the endangered Audouin's gull (*Larus audouinii*), most (62%) of the total PCB burden consisted of PCBs 138, 153, 170, and 180. Other important congeners were PCBs 118, 194, and 203, and each contributed about 5% (Leonozio et al. 1989). PCBs 138, 153, and 180 comprised more than 50% of the total PCB burden in eggs of the yellow-legged herring gull (*Larus cachinnans*); a similar case is made for eggs of other species of marine birds (Focardi et al. 1988a). PCBs 138, 153, and 180 were also dominant in tissues of most birds collected in Great Britain between 1988 and 1990, although total PCB concentrations ranged from 0.02 to 105 mg/kg FW and also differed considerably in different tissues from individual birds (Boumphrey et al. 1993). PCBs 138 and 153 were the most prominent congeners in eggs of three species of gulls collected in Spain during 1988, accounting for 10.5% and 8.7%, respectively, of the total PCB burden. Other important congeners were PCBs 180 (7.5%), 170 (3.2%), 101 (1.9%), 151 (1.1%), and 194 (0.9%) (Gonzalez et al. 1991).

PCB signatures in bird eggs are not constant. Eggs of the dipper (*Cinclus cinclus*) from Wales and Ireland were dominated by PCB 118 in 1990, PCB 170 in 1991, and PCB 153 in 1992; six congeners accounted for 26 to 35% of the total PCBs in Welsh eggs and for 10 to 26% of the total in eggs from Ireland (Ormerod and Tyler 1992, 1994). In tissues of birds in Great Britain, the mono-*ortho*-congeners — PCBs 105 and 118 — made a high contribution (70%) to the TEF, whereas the non-*ortho*-congeners (PCBs 77, 126, 169) contributed 20% and the di-*ortho*-congeners (PCBs 138, 153, 180) contributed 10% (Boumphrey et al. 1993). Young of all avian species sampled in Wisconsin accumulated PCBs 77, 105, 126, and 169. Chicks of Forster's terns (*Sterna forsteri*) had daily uptakes of 15 µg total PCBs, 0.07 µg PCB 77, 0.2 µg PCB 105, 0.006 µg PCB 126, and 0.00014 µg PCB 169 (Ankley et al. 1993).

Concentrations of mono-*ortho*-PCBs in yolk sac of cormorants ranged from 10 to 250 mg/kg LW; high PCB residues in yolk were associated with increased cytochrome P-450 and EROD activities and decreased thyroid hormone activity (van den Berg et al. 1992). Embryos of the black-crowned night heron (*Nycticorax nycticorax*) with the greatest burdens of total PCBs had increased cytochrome P-450-associated monooxygenase activities and cytochrome P-450 proteins, which suggests that cytochrome P-450 may be a useful biomarker of exposure to some PCB mixtures (Rattner et al. 1993, 1997). The absence of established thresholds for P-450 induction indicates that more research is needed (Rattner et al. 1994) to make this a useful technique for evaluating PCB exposure.

Table 24.11 PCB Concentrations in Field Collections of Selected Birds (Concentrations are in g/kg [ppb] fresh weight [FW], dry weight [DW], or lipid weight [LW].)

Species, Tissue, PCB Congener, and Other Variables	Concentration ^a (g/kg)	Reference ^b
Northern goshawk, <i>Accipiter gentilis</i> ; liver vs. eggs; total PCBs; Norway, 1965–83; dead on collection	2000 (<100–1,260,000) FW vs. 12,300 (2600–53,000 FW	1
Northern sparrow hawk, <i>Accipiter nisus</i> ; liver vs. eggs; total PCBs; Norway, 1965–83; dead on collection	1100 (<100–107,000) FW vs. 5900 (<100–39,000) FW	1
Sharp-shinned hawk, <i>Accipiter striatus</i> ; blood plasma; total PCBs (as Aroclors 1254 and 1260); Great Lakes, 1985–89	80 (10–190) FW	2
Tengmalm's owl, <i>Aegolius funereus</i> ; liver vs. eggs; total PCBs; Norway, 1965–83; dead on collection	1000 (<100–9400) FW vs. 400 (<100–1300) FW	1
Red-winged blackbird, <i>Agelaius phoeniceus</i> ; eggs (less shell) and chicks (less feathers, feet, beaks, stomach contents, and wings); total PCBs; Green Bay, Wisconsin, 1989	5400–8900 FW	9
Razorbill, <i>Alca torda</i> ; adipose tissue; males vs. females; England, 1988		
PCBs 3, 8, 18	ND vs. ND	3
PCB 28	110 FW vs. ND	3

Table 24.11 (continued) PCB Concentrations in Field Collections of Selected Birds (Concentrations are in g/kg [ppb] fresh weight [FW], dry weight [DW], or lipid weight [LW].)

Species, Tissue, PCB Congener, and Other Variables	Concentration ^a (g/kg)	Reference ^b
PCB 52	140 FW vs. ND	3
PCB 101	310 FW vs. 32 FW	3
PCB 118	2500 FW vs. 500 FW	3
PCB 138	6500 FW vs. 1600 FW	3
PCB 153	4400 FW vs. 1100 FW	3
PCB 180	2600 FW vs. 600 FW	3
Total PCBs	16,500 FW vs. 4100 FW	3
Mallard, <i>Anas platyrhynchos</i>		
Age 12 months; confined to enclosures in lagoon of sewage treatment plant for 100 days then killed; whole duck analyzed less feathers, bill, feet, wings, and gizzard contents; non-detectable PCB concentrations at start		
Total PCBs	16,600 FW	30
PCB 28	6800 FW	30

PCB 170	40 FW	30
Wisconsin; 1984–89; muscle; all seasons; total PCBs	200–700 FW, Max. 21,000 FW; 2000–10,000 LW, Max. 1,313,000 LW	31
Blue-winged teal, <i>Anas discors</i> ; breast muscle with associated skin and fat		
Colombia, South America; 1987–88; all seasons	ND	31
Wisconsin; 1984–89		
Spring	100 FW; 1700 LW	31
Summer	Max. 500 FW, 12,500 LW	31
Fall	100 FW; 900 LW, Max. 6300 LW	31
Imperial eagle, <i>Aquila heliaca adalberti</i> ; infertile eggs; Spain, 1986–87		
PCB 101	9–16 FW; Max. 440 FW	4
PCB 118	1–4 FW; Max. 66 FW	4
PCB 138	7–30 FW; Max. 620 FW	4
PCB 153	37–115 FW; Max. 5300 FW	4
PCB 180	30–110 FW; Max. 4800 FW	4
Total PCBs	280–820 FW; Max. 28,900 FW	4
Golden eagle, <i>Aquila chrysaetos</i> ; liver vs. eggs; total PCBs; Norway, 1965–83; dead on collection	2000 (<100–250,000) FW vs. 1000 (400–5700) FW	1
Grey heron, <i>Ardea cinerea</i>		
England; 1988–90; total PCBs (35 congeners)		
Fat	198,000 FW; 226,000 LW	5
Kidney	3600 FW; 135,000 LW	5
Liver	2800 FW; 936,000 LW	5
Muscle	8100 FW; 139,000 LW	5
France; Lac de Grandlieu; May 1991; eggs; total PCBs	1280 (236–2731) FW	37
Great blue heron, <i>Ardea herodias</i> ; eggs; British Columbia		
PCB 77	0.05–0.2 LW	6
PCB 105	17–31 LW	6

Table 24.11 (continued) PCB Concentrations in Field Collections of Selected Birds (Concentrations are in g/kg [ppb] fresh weight [FW], dry weight [DW], or lipid weight [LW].)

Species, Tissue, PCB Congener, and Other Variables	Concentration ^a (g/kg)	Reference ^b
PCB 118	63–116 LW	6
PCB 126	0.1–0.2 LW	6
PCB 169	0.02–0.04 LW	6
Short-eared owl, <i>Asio flammeus</i> ; liver vs. eggs; total PCBs; Norway, 1965–83; dead on collection	300 (<100–46,000) FW vs. 2100 (2000–22,000) FW	1
Greater scaup, <i>Aythya marila</i> ; total PCBs; carcass; Detroit River, 1981	11,000 FW	25
Eagle owl, <i>Bubo bubo</i> ; liver vs. eggs; total PCBs; Norway, 1965–83; dead on collection	3000 (100–550,000) FW vs. 4000 (2200–29,000) FW	1
Common buzzard, <i>Buteo buteo</i> ; infertile eggs; total PCBs; Spain, 1985–86	1650 (1600–1700) FW	7
Rough-legged buzzard, <i>Buteo lagopus</i> ; liver vs. eggs; total PCBs; Norway, 1965–83; dead on collection	200 (<100–15,000) FW vs. 800 (200–9300) FW	1
White stork, <i>Ciconia ciconia</i> ; infertile eggs; total PCBs; Spain, 1985–86	800 (200–2700) FW	7
Dipper, <i>Cinclus cinclus</i> ; addled eggs; Wales vs. Ireland, 1990–92		
PCB 101	10–20 LW vs. <10 LW	8
PCB 118	10–70 LW vs. 10–1280 LW	8
PCB 138	10–380 LW vs. 10–80 LW	8
PCB 153	20–530 LW vs. 10–160 LW	8
PCB 170	10–190 LW vs. 10–30 LW	8
PCB 180	10–20 LW vs. 10–40 LW	8
Merlin, <i>Falco columbarius</i> ; liver vs. eggs; total PCBs; Norway, 1965–83; dead on collection	400(<100–41,000) FW vs. 4500 (2400–11,000) FW	1
Peregrine, <i>Falco peregrinus</i>		
Liver vs. eggs; total PCBs; Norway, 1965–83; dead on collection	120,000 FW vs. 43,000 FW	1
Eggs; California, 1983–88		
PCB 37	0.18 FW	10
PCB 77	0.93 FW	10
PCB 126	1.0 FW	10
PCB 138	750 FW; Max. 2440 FW	10
PCB 153	1200 FW; Max. 4400 FW	10
PCB 169	0.14 FW	10
Total PCBs	4800 (1400–13,000) FW	10
Tundra peregrine, <i>Falco peregrinus tundrus</i> ; Canadian Arctic; total PCBs		
Addled eggs; 1982–86 vs. 1991–94	8700 (2000–47,800) FW vs. 8300 (1700–45,600) FW	32
Blood plasma; 1982–86 vs. 1991–94		
Males	470 FW vs. 750 FW	32
Females	750 FW vs. 950 FW	32
Chicks; found dead; 1991–94; age 22 days vs. age 29 days		
Breast muscle	400 FW vs. 7400 FW	32
Liver	1600 FW vs. 27,100 FW	32
Adult diet; whole organism		
Long-tailed duck, <i>Clangula hyemalis</i>	6900 (2900–18,900) FW	32
Birds, 8 species	ND–400 FW; Max. 5400 FW	32
Mammals	Usually <3 FW; Max. 4200 FW	32
Gyr falcon, <i>Falco rusticolus</i> ; liver vs. eggs; total PCBs; Norway 1965–83; dead on collection	5000 (300–42,000) FW vs. 12,000 FW	1
Kestrel, <i>Falco tinnunculus</i> ; liver vs. eggs; total PCBs; Norway 1965–83	500 (<100–45,000) FW vs. 600 (<100–1000) FW	1

Species, Tissue, PCB Congener, and Other Variables	Concentration ^a (g/kg)	Reference ^b
Southern fulmar, <i>Fulmarus glacialisoides</i> ; Antarctica; 1993–95; total PCBs in blood of breeding adult female at moment of egg hatching	572 FW	41
Chicken, <i>Gallus</i> sp.; fat vs. feather; total of PCBs 118, 138, 153, and 156; PCB-contaminated area	12,800 LW vs. 200 LW	11
Gull-billed tern, <i> Gelochelidon nilotica</i> ; infertile eggs; Spain, 1988		
PCB 138	Max. 220 FW	12
PCB 153	Max. 90 FW	12
PCB 180	Max. 190 FW	12
White-tailed sea eagle, <i>Haliaeetus albicilla</i>		
Liver vs. eggs; total PCBs; Norway 1965–83	5000 (100–180,000) FW vs. 13,900 (4200–31,000) FW	1
Breast muscle; Poland, 1982–90		
Non-ortho planars		
PCB 77	3–140 FW	13
PCB 126	1–160 FW	13
PCB 169	2–380 FW	13
Mono-ortho planars		
PCB 60	5–760 FW	13
PCB 105	110–9200 FW	13
PCB 118	290–28,000 FW	13
PCB 156	53–9200 FW	13
Di-ortho planars		
PCB 128	ND–600 FW	13
PCB 137	50–6800 FW	13
PCB 138	930–65,000 FW	13
PCB 153	1100–92,000 FW	13
PCB 170	100–22,000 FW	13
PCB 180	330–61,000 FW	13
PCB 194	20–8900 FW	13
Booted eagle, <i>Hieraetus pennatus</i> ; infertile eggs; total PCBs; Spain, 1985–86	1500 (500–8400) FW	7
Loggerhead shrike, <i>Lanius ludovicianus</i> ; eggs vs. carcasses; total PCBs; Virginia, 1985–88	940 FW; Max. 1300 FW vs. <5 FW	14
Herring gull, <i>Larus argentatus</i>		
Eggs; Great Lakes; total PCBs		
Lake Erie		
1972–74 vs. 1977–80	34,700–130,700 FW vs. 14,600–33,100 FW	26
1983 vs. 1987–88	11,800–14,100 FW vs. 5600–21,900 FW	26
Lake Huron		
1971–77 vs. 1980–83	43,000–59,500 FW vs. 8800–10,900 FW	26
1987–88	4500–11,300 FW	26
Lake Ontario		
1971–72 vs. 1974–77	58,800–143,900 FW vs. 36,200–96,600 FW	26
1980–83 vs. 1987	15,900–27,500 FW vs. 14,400–15,800 FW	26
Lake Superior; 1973–77 vs. 1980–87	37,100–46,400 FW vs. 5500–11,400 FW	26
Eggs; Great Lakes		
PCB 77	0.6–3.0 LW	6
PCB 105	50–860 LW	6

Table 24.11 (continued) PCB Concentrations in Field Collections of Selected Birds (Concentrations are in g/kg [ppb] fresh weight [FW], dry weight [DW], or lipid weight [LW].)

Species, Tissue, PCB Congener, and Other Variables	Concentration ^a (g/kg)	Reference ^b
PCB 118	180–2550 LW	6
PCB 126	2–10 LW	6
PCB 169	0.2–9.0 LW	6
Infertile eggs; Spain, 1988		
PCB 138	Max. 450 FW	12
PCB 153	Max. 400 FW	12
PCB 180	Max. 280 FW	12
Total PCBs	2000 (1100–3600) FW	12
Lake Ontario, 1985		
Adults		
Total PCBs		
Carcass	47,000 FW	15
Diet (fish)	510 FW	15
Liver	12,000 FW	15
Total tetrachlorobiphenyls (PCBs 56, 60, 66, and 74); carcass vs. liver	1490 FW vs. 450 FW	15
Total penta-CBs (PCBs 99, 101, 105, 110, and 118); carcass vs. liver	7440 FW vs. 2050 FW	15
Total hexa-CBs (PCBs 128, 132, 137, 138, 141, 146, 149, 153); carcass vs. liver	19,900 FW vs. 5100 FW	15
Total hepta-CBs (PCBs 170, 171, 172, 174, 177, 178, 180, 182, 183, 187, 190, 197); carcass vs. liver	14,400 FW vs. 3700 FW	15
Total octa-CBs, carcass vs. liver	3400 FW vs. 860 FW	15
Eggs		
Total PCBs	16,000 FW	15
Total tetra-CBs	560 FW	15
Total penta-CBs	2880 FW	15
Total hexa-CBs	7250 FW	15
Total hepta-CBs	4340 FW	15
Total octa-CBs	860 FW	15
Yellow-legged herring gull, <i>Larus cachinnans</i> ; eggs; Italy, 1981–86		
Total PCBs (30 congeners)	30,400–56,100 DW	16, 17
PCB 138	4600–6800 DW	16
PCB 153	7800–14,100 DW	16
PCB 180	3900–7000 DW	16
Audouin's gull, <i>Larus audouinii</i> ; eggs		
Italy, 1981–86; total PCBs	28,600–45,900 DW	17
Spain, 1988		
Total PCBs	9000 (4700–20,500) FW	12
PCB 138	Max. 1800 FW	12
PCB 153	Max. 1600 FW	12
PCB 180	Max. 1300 FW	12
Red-breasted merganser, <i>Mergus serrator</i> , eggs; Michigan; 1977–78 vs. 1990		
Total PCBs	23,000 FW vs. 11,100 FW	28
PCB 77	24 FW vs. 20 FW	28
PCB 81	5 FW vs. 3 FW	28
PCB 126	13 FW vs. 6 FW	28
PCB 169	1.6 FW vs. 0.9 FW	28
PCB 105	454 FW vs. 205 FW	28
PCB 118	847 FW vs. 415 FW	28
PCB 101	246 FW vs. 115 FW	28
PCB 138	1417 FW vs. 659 FW	28
PCB 153	2313 FW vs. 1221 FW	28
PCB 180	641 FW vs. 327 FW	28

Table 24.11 (continued) PCB Concentrations in Field Collections of Selected Birds (Concentrations are in g/kg [ppb] fresh weight [FW], dry weight [DW], or lipid weight [LW].)

Species, Tissue, PCB Congener, and Other Variables	Concentration ^a (g/kg)	Reference ^b
Black kite, <i>Milvus migrans</i> ; infertile eggs; total PCBs; Spain, 1985–86	2900 (500–18,700) FW	7
Black-crowned night heron, <i>Nycticorax nycticorax</i>		
Pipping embryos; whole less liver; lipid extracts; 1991; Chincoteague Bay, VA (reference site) vs. Baltimore Harbor, MD (contaminated site)		
PCB 66	3 FW vs. 58 FW	29
PCB 77	508 FW vs. 4982 FW	29
PCB 81	0.04 FW vs. 1.2 FW	29
PCB 105	6 FW vs. 146 FW	29
PCB 114	0.5 FW vs. 5.2 FW	29
PCB 118	10 FW vs. 288 FW	29
PCB 123	0.4 FW vs. 1.3 FW	29
PCB 126	(ND–750) FW vs. 4527 (ND–39,640) FW	29
PCB 156	1.2 FW vs. 15.2 FW	29
PCB 157	2 FW vs. 62 FW	29
PCB 167	3 FW vs. 26 FW	29
PCB 169	32 (ND–190) FW vs. (ND–2210) FW	29
PCB 189	0.4 FW vs. 5.6 FW	29
Embryos; total PCBs		
Control site, Virginia	1130 (240–4000) FW	18
Cat Island, Green Bay, Wisconsin	9300 (2400–53,000) FW	18
San Francisco Bay	900–2600 (ND–12,000) FW	18
Osprey, <i>Pandion haliaetus</i> ; liver vs. eggs; Norway, 1965–83; dead on collection	5000 (<100–26,000) FW vs. 3200 (700–8300) FW	1
Shag, <i>Phalacrocorax aristotelis</i> ; Isle of Man; Irish Sea; 1994; eggs; total PCBs	1100 FW; 6600 (4100–13,400) DW	33
Double-crested cormorant, <i>Phalacrocorax auritus</i>		
Eggs; Great Lakes; total PCBs	900–7300 FW; reduced hatch at >6500 FW	27
Eggs; upper Great Lakes; 1986–91; total PCBs	8200 (5600–10,700) FW	34
Eggs; 1990–91; near Lake Ontario (contaminated site) vs. reference site		
PCB 77	0.3 FW vs. 0.08 FW	35
PCB 105	173 FW vs. 18 FW	35
PCB 118	173 FW vs. 133 FW	35
PCB 126	3.7 FW vs. 0.5 FW	35
PCB 169	0.4 FW vs. 0.09 FW	35
Great cormorant, <i>Phalacrocorax carbo</i>		
Netherlands; yolk sac

24.4.7 Terrestrial Mammals

The highest total PCB concentrations recorded in terrestrial mammalian wildlife occurred in fat and liver tissues of species collected near urban areas; di-*ortho*-congeners were the major contributors to PCB tissue burdens (Table 24.12). Atmospheric transport of PCBs governed uptake in terrestrial mammalian herbivores and predators. For example, PCB residues in tissues of voles and shrews in the Scandinavian peninsula directly correlated with fallout loadings (Larsson et al. 1990). An increase in atmospheric deposition of PCBs increased PCB burdens in plants, herbivores, and predators of the herbivores. But herbivores and predators differentially metabolized PCBs, raising concentrations of highly chlorinated congeners in predators and concentrations of the more easily metabolized low-chlorinated PCBs in herbivores (Larsson et al. 1990).

Populations of mink (*Mustela vison*) declined in many areas of the world, and the declines were linked to exposures to synthetic halogenated hydrocarbons (Giesy et al. 1994b). In the Great Lakes region, mink density is lower along the shores of the Great Lakes and their tributaries where mink have access to fishes from the Great Lakes. Tissue PCB concentrations and their dioxin TEFs were considered critical in the hazard assessment of PCBs. Mink that consumed fishes below dams in Michigan were 10 to 20 times more likely to suffer PCB damage than mink consuming fishes from above the dams, as judged by the elevated concentrations of total PCBs and dioxin TEFs in fishes from below the dams (Giesy et al. 1994b). European polecats (*Mustela putorius*) collected in the Netherlands between 1985 and 1990 had PCB patterns that were independent of diet and seemed to be controlled by anal gland secretions containing elevated PCB residues (Leonards et al. 1994). Juvenile polecats contained higher PCB concentrations than adult males and females, and this is attributed to an increased elimination of PCBs by adults through anal gland secretions. In all examined polecat tissues, PCB 126 accounted for 63 to 98% of the 2,3,7,8-TCDD toxic equivalents (Leonards et al. 1994). Polecats — unlike weasels (*Mustela nivalis*), stoats (*Mustela erminea*), and otters (*Lutra lutra*) — can readily metabolize PCBs 126 and 169 (Leonards et al. 1998). As a consequence, PCBs 126 and 169 are selectively retained in the livers of weasels, stoats, and otters, when compared to polecats. Polecats are less sensitive to PCBs than other mustelids when dietary PCB intakes are similar. However, otters are exposed to high dietary concentrations of PCBs when compared to other species of mustelids and are considered the most vulnerable of all mustelids to PCBs (Leonards et al. 1998).

The use of PCBs in Germany was prohibited in 1989. From 1983 to 1991, the body fat of red foxes (*Vulpes vulpes*) in Germany showed a reduction in the mean concentration of highly chlorinated PCBs (PCBs 138, 153, and 180) but an increase in the lower-chlorinated congeners (PCBs 24, 49, and 52). These findings suggest a trend toward a reduction of environmental contamination with highly chlorinated biphenyls since 1983, perhaps as a consequence of metabolic degradation, whereas contamination with lower-chlorinated biphenyls from diverse sources is increasing (Georgii et al. 1994). Low-chlorinated congeners that are metabolized via reactive intermediates must be evaluated because they show weak tumor-initiating properties (Georgii et al. 1994). At present, PCB congeners considered as indicators of contamination in Germany include PCBs 28, 31, 52, 101, 138, 153, and 180 (Bachour et al. 1998).

Populations of bats in Europe have been declining, and PCBs together with pesticides and wood preservatives are the suspected main causes of the decline (Fernandez et al. 1993). Three species of bats collected in Spain in 1988 to 1990 contained only a few dominant PCB congeners; PCBs 138, 153, and 180 accounted for about 80% of the total PCB burden in whole bats (Fernandez et al. 1993). But the most abundant PCB congeners in brain and liver of European otters (*Lutra*) were in the descending order of PCBs 163, 153, 138, and 170, each constituting at least 10% of the total PCB burden (Mason and Ratford 1994).

Total PCBs in adipose tissue of polar bears (*Ursus maritimus*) throughout their known range, and collected between 1989 and 1993, are as high as 24.3 mg/kg on a lipid weight basis and are dominated by PCBs 153 (46% of total PCBs), 180 (18.5%), 170/190 (8.6%), and 99 (8.3%)

(Norstrom et al. 1998). Total PCBs were higher in adult males than females, and there was no significant trend with age. PCB content was higher in bears from Svalbard, East Greenland, and the Arctic Ocean near Prince Patrick Island than most other areas. Atmospheric, oceanic, and ice transport may contribute to the high concentrations of total PCBs (Norstrom et al. 1998). The PCB composition in tissues of polar bears suggests that polar bears — unlike other mammals — can readily metabolize PCB congeners with unsubstituted *para*-positions and unsubstituted adjacent *ortho-meta*-positions (Norheim et al. 1992). Six PCB congeners (PCBs 99, 138, 153, 170, 180, 194) — all with a minimum 2,2',4,4'-chlorine substitution — accounted for about 99% of the total PCB content in liver and 87% in fat; PCB 153 accounted for 37% of the total PCB loading in liver. The PCB congener pattern in polar bear liver and adipose tissue is similar and seems to be independent of sex, age, nutritional status, collection locale, and PCB body burden (Norheim et al. 1992).

In humans, total PCB concentrations in maternal milk were elevated (>1.1 mg/kg milk fat) in 4 of 122 cases in the New Bedford Harbor vicinity, Massachusetts (Korrick and Altshul 1998). At least one female was occupationally exposed, as judged by the congener profile and history. PCB exposures from fish consumption were likely, but not from residence adjacent to a PCB-contaminated site. In all four cases, their newborns were full-term and healthy (Korrick and Altshul 1998).

Table 24.12 PCB Concentrations in Field Collections of Selected Mammals (Concentrations are in g/kg [ppb] fresh weight [FW] or lipid weight [LW].)

Species, Tissue, PCB Congener, and Other Variables	Concentration ^a (g/kg)	Reference ^b
Bats; whole body less wings, feet, and head; total PCBs; Spain, 1988–90		
Schreiber's bat, <i>Miniopterus schreibersi</i>	760 LW	1
Common pipistrelle, <i>Pipistrellus pipistrellus</i>	1290 LW	1
Greater horseshoe bat, <i>Rhinolophus ferrumequinum</i>	480 LW	1
All species

^a Concentrations are shown as means, range (in parentheses), maximum (Max.), and nondetectable (ND).

^b 1, Fernandez et al. 1993; 2, Georgii et al. 1994; 3, Hong et al. 1994; 4, Mason and Ratford 1994; 5, Leonards et al. 1994; 6, Norheim et al. 1992; 7, USEPA 1994; 8, Korrick and Altshul 1998; 9, Lopez-Martin and Ruiz-Olmo 1996; 10, Poole et al. 1998; 11, Leonards et al. 1998; 12, Norstrom et al. 1998.

24.5 LETHAL AND SUBLETHAL EFFECTS

24.5.1 General

In all tested organisms, PCBs — especially PCBs with 2,3,7,8-TCDD-like activity — adversely affected patterns of survival, reproduction, growth, metabolism, and accumulation. Common manifestations of PCB exposure in animals include hepatotoxicity (hepatomegaly, necrosis), immunotoxicity (atrophy of lymphoid tissues, suppressed antibody responses), neurotoxicity (impaired behavior and development, catecholamine alterations), increased abortion, low birth weight, embryolethality, teratogenicity, gastrointestinal ulceration and necrosis, bronchitis, dermal toxicity (chloracne, edema,

hyperplasia), weak mutagenicity at high doses, and preneoplastic changes at low doses (Hansen 1987). PCBs can mimic female hormones in human cell lines and other mammalian systems and may be associated with learning deficiencies and lowered IQs in children (Bushart et al. 1998). At concentrations above a threshold, PCBs are potent promoters of hepatic carcinogenesis in laboratory rodents. However, there is no clear evidence of carcinogenicity of PCBs to human and animal populations from natural exposure (Hayes 1987). Induction of hepatic microsomal enzymes is one of the earliest and most sensitive responses to PCBs (Hansen 1987).

PCB-induced toxicity patterns are highly variable. Variability, as discussed later, is attributed in part to differences between species and strains in ability to metabolize PCBs and in primary sites of action; in the age, growth rate, biomass, and lipid content of the species; in dose rate, duration of exposure, route of administration, and tested congeners; in physicochemical characteristics of the habitat during exposure; and in PCB interactions with other PCBs, other organochlorine compounds, and heavy metals. Chinook salmon (*Oncorhynchus tshawytscha*) had decreased hatch when eggs contained the equivalent of 0.1 µg 2,3,7,8-TCDD/kg fresh weight (FW); domestic chickens (*Gallus* sp.) had decreased survival and increased developmental abnormalities when embryos had 20 µg PCB 77/kg FW; mink (*Mustela vison*) had reduced growth when fed 100 µg Aroclor 1254/kg BW daily and reduced survival at 50 µg PCB 169/kg diet; rhesus macaques (*Macaca mulatta*) had reproductive impairment when fed more than 8 µg Aroclor 1016/kg BW daily; and rats (*Rattus* sp.) had reduced litter sizes and survival when given 10 µg PCB 126/kg BW daily during gestation.

24.5.2 Aquatic Organisms

PCBs influence patterns of survival, reproduction, growth, enzyme activities, and accumulation in representative aquatic organisms (Table 24.13). Some PCB congeners at laboratory concentrations that were several orders of magnitude higher than those encountered under field conditions killed 47 to 83% of tested freshwater fishes and invertebrates in 24 to 48 h. However, most PCB congeners tested produced negligible mortality under these conditions (Dillon and Burton 1992) (Table 24.13). Mortality increased when PCB 133 or PCB 177 concentrations in whole guppies (*Poecilia reticulata*) exceeded 1 µmole/g, equivalent to more than 200 mg PCB/kg whole-body FW or about 4000 mg PCB/kg on a lipid weight basis (Opperhuizen and Schrap 1988). PCBs — especially those with TCDD-type activity — adversely affect reproductive success of spawning female chinook salmon. Chinook salmon eggs that contained total PCB concentrations equivalent to 0.1 µg 2,3,7,8-TCDD equivalents/kg eggs and higher had a dose-dependent decrease in hatching success (Ankley et al. 1991). PCBs also impair the reproductive capacities of marine mammals (Kannan et al. 1993).

The relation between PCB accumulation by the freshwater alga *Scenedesmus* sp. and the compound's octanol/water partition coefficient (K_{ow}) was measured with 40 PCB compounds in a log K_{ow} range of 4.46 to 8.18, PCB concentrations between 0.03 and 1.1 µg/L, and exposures between 20 and 30 days (Swackhammer and Skoglund 1993). The accumulation process was consistent with partitioning from water into cell lipids but was slower than the growth of *Scenedesmus* (i.e., no significant uptake of PCBs from congeners with $\log K_{ow} > 5.0$ under conditions of rapid growth or $>\log 7.0$ under conditions of slow growth). Thus, under nonwinter field conditions, many PCB congeners never reached equilibrium concentrations (Swackhammer and Skoglund 1993). Similar results are reported of other species of freshwater algae, including *Selenastrum capricornutum*, *Anabaena* sp., and *Synedra* sp. (Stange and Swackhammer 1994). High algal densities alter bioconcentration factors of PCBs. Bioconcentration factors for PCBs 15, 52, and 153 by the alga *Chlorella pyrenoidosa* were higher at comparatively low algal densities (Sijm et al. 1998), suggesting that BCF values determined at high algal densities should be applied with caution to field situations.

Zebra mussels (*Dreissena polymorpha*) accumulated PCB 77 from their diet and from the surrounding lake sediments (Brieger and Hunter 1993). An uptake rate of PCB 77 by zebra mussels followed the descending order of sediment, food, and water. Tissue concentrations in mussels peaked after 10 to 14 days at 3.4 to 3.7 mg PCB 77/kg FW soft parts; equilibrium levels of PCB 77 were near 1.0 mg/kg FW. Zebra mussels are more efficient accumulators of PCBs than other bivalve molluscs to which they are attached; accordingly, high densities of zebra mussels probably influence contaminant dynamics (Brieger and Hunter 1993). A freshwater crustacean (*Mysis relicta*) plays an important role in the transfer of PCBs from sediments into the Lake Champlain food web (Lester and McIntosh 1994), and freshwater grazing and shredding benthic invertebrates promote downstream transport of PCB 153 (Sallenave et al. 1994). Marine invertebrates accumulated PCBs 52, 101, 128, 138, 151, 153, 180, 194, 206, and 209 from PCB-contaminated sediments (Pruell et al. 1993). Clams (*Macoma nasuta*) reached a steady-state equilibrium in 10 days, but sandworms (*Nereis virens*) took 70 to 120 days. Clams showed preferential accumulation of lower-molecular-weight PCB congeners, and this may be due to the comparatively low lipid content in this species. Sandworms and grass shrimp (*Palaemonetes pugio*) metabolized PCBs 52, 101, and 151 (Pruell et al. 1993).

Golden shiners (*Notemigonus crysoleucas*) rapidly accumulated radiolabeled PCBs from water during 96-h exposure (Karara and McFarland 1992). The uptake rate of PCBs from water was controlled by gill blood-flow rate. About 50% of the accumulated PCBs in shiners was eliminated in 4.9 days, and this is similar to PCB elimination rates in striped bass (*Morone saxatilis*) and channel catfish (*Ictalurus punctatus*) (Karara and McFarland 1992). In guppies, residual PCB concentrations increased with increasing duration of exposure. However, steady-state concentrations did not occur during dietary exposure for 65 days (Schrap and Opperhuizen 1988). PCB congeners with *ortho*-chlorine substitutions (PCBs 77, 105, 118, 128, 138) were effective inducers of EROD (7-ethoxyresorufin O-deethylase) and AHH (aryl hydrocarbon hydroxylase) activities in marine mammals (Gooch et al. 1989) and freshwater fishes (Janz and Metcalfe 1991a; Skaare et al. 1992), but were ineffective at doses as high as 10 mg/kg BW in scup (*Stenotomus chrysops*), a marine teleost (Gooch et al. 1989). Industrial mixtures containing both planar and nonplanar PCBs induced AHH in fishes (Skaare et al. 1991). Mixtures of planar PCBs and dioxins, however, produced synergism of AHH activity in fish liver at low doses and antagonism at high doses; the possible antagonistic effects of nonplanar halogenated compounds may further complicate these interactions (Janz and Metcalfe 1991b). Liver is the primary target organ for the induction of cytochrome P-450-dependent monooxygenases by PCBs in fishes, and the most frequently examined organ. However, in salmonids, muscle tissue is also suitable for evaluation of hepatic monooxygenase induction, as judged by PCB concentrations in muscle (Janz et al. 1992).

Table 24.13 Effects of PCBs on Representative Aquatic Organisms

Taxonomic Group, Organism, PCB Congener, Dose, and Other Variables	Effect	Reference ^a
INVERTEBRATES		
Daphnid, <i>Daphnia magna</i> ; early life stages		
PCB 1; 710 µg/L	LC50 (24h)	1
PCB 2; 430 µg/L	LC50 (24h)	1
PCB 3; 420 µg/L	LC50 (24h)	1
PCB 18; 86 µg/L	47% dead in 48 h	1
PCBs 28 (1.5 µg/L), 52 (74 µg/L), 77 (0.3 µg/L), 101 (1.2 µg/L), 116 (2.8 µg/L), 128 (0.4 µg/L), 153 (1.3 µg/L), 171 (1.7 µg/L), 194 (3.0 µg/L)	Negligible mortality; 87–100% survival in 48 h	1
PCB 47; 30 µg/L	LC50 (24h)	1

Table 24.13 (continued) Effects of PCBs on Representative Aquatic Organisms

Taxonomic Group, Organism, PCB Congener, Dose, and Other Variables	Effect	Reference ^a
Zebra mussel, <i>Dreissena polymorpha</i> Fed alga (<i>Chlorella</i> sp.) containing 500 mg PCB 77/kg for 32 days	Maximum tissue concentration of 3.4 mg PCB 77/kg FW soft parts reached in about 14 days; concentration dropped to about 2 mg/kg after 32 days	2
Fed <i>Chlorella</i> containing 500 mg PCB 169/kg for 50 days, then clean <i>Chlorella</i> diet for 45 days	Maximum tissue concentration of 3.7 mg PCB 169/kg soft parts reached in 10 days, then declined during exposure to equilibrium level of about 1 mg/kg soft parts. After 25 days of clearance, soft parts contained 0.1 mg/kg FW	2
Amphipod, <i>Gammarus pseudolimnaeus</i> PCBs 8, 15, 32, 155, 101; initial water concentrations of 70–210 µg/L	LC50 (96 h)	1
Mysid, <i>Mysis relicta</i> ; exposed to radiolabeled PCB 153 for 6 h at 4°C, then transferred to clean water for 26 days	BCF from water of 442,230; calculated half-time persistence of 220 days	10
Amphipod, <i>Pontoporeia hoyi</i> ; exposed to radiolabeled PCB 153 for 6 h at 4°C, then transferred to clean water for 26 days	BCF from water of 101, 660; calculated half-time persistence of 50 days	10
VERTEBRATES		
Zebrafish, <i>Brachydanio rerio</i> Females given diets containing 8, 80, or 400 µg/kg diet containing 20 PCBs for 30 weeks (equal amounts of PCBs 41, 51, 58, 60, 68, 78, 91, 99, 104, 109, 112, 115, 126, 143, 153, 173, 184, 188, 190, and 193) Treatment as above. After 9 weeks, exposed females and normal males were mated	PCBs accumulated in dose-dependent relation. Treated groups had significantly lower whole-body, liver, and ovary weight and increased hepatic EROD Egg production reduced in all treated groups; females in the 8 and 400 µg/kg groups had a reduced number of mature oocytes. Median survival time of larvae in high-dose group was 7.7 days vs. 14 days in controls	21
Beluga whale, <i>Delphinapterus leucas</i> ; isolated blood leukocytes and splenocytes; exposure to various concentrations of PCBs 138, 153, 169, or 180 for 48 h	No marked effect on phagocytosis at 25 mg/kg medium; significant inhibition of proliferative response of splenocytes at 20–25 mg/kg PCB 138, but no inhibition at this concentration by other PCBs; no measurable effect at 5 mg/kg medium for any PCB tested	23
Mummichog, <i>Fundulus heteroclitus</i> Adult females given single ip injection of a mixture of 9 PCBs equivalent to 0.76, 3.8, or 19 mg/kg BW on a fresh weight basis, and observed for about 2 months	High-dose fish had 58% dead; survivors had egg production reduced 77% and their livers had 33 mg total PCBs/kg DW. The two lower dose groups had 60 and 62% reduction in egg production and liver residues of 3 and 12 mg total PCBs/kg DW, respectively. Food consumption declined with increasing dose. Egg production was related to pituitary gonadotropin content and food consumption	15
Adults collected from 4 sites in PCB-contaminated New Bedford Harbor, Massachusetts, in 1993, during their natural spawning season. Transported to laboratory and bred	After 5 weeks, fish from the most heavily contaminated site (2100 mg total PCBs/kg DW sediment) had liver concentrations of non-ortho (PCBs 77, 126, 169) plus mono-ortho PCBs of 29.3 mg/kg DW, reduced growth, and 30% mortality. Progeny of fish from this group had significantly reduced survival and a greater incidence of spinal abnormalities when compared to fish from a reference site	22

Table 24.13 (continued) Effects of PCBs on Representative Aquatic Organisms

Taxonomic Group, Organism, PCB Congener, Dose, and Other Variables	Effect	Reference ^a
Channel catfish, <i>Ictalurus punctatus</i> ; juveniles; exposed to PCB 126, tributyltin, or both.		
Single injected dose of 0.01, 0.1, or 1 mg/kg BW of each, or both in combination	PCB alone, but not TBT alone, induced cytosolic aryl hydrocarbon receptor and cytochrome P-4501A activities	16
Six injections of 0.017, 1.7, or 17 µg/kg BW of each given every 3 days over a 16-day period to yield a cumulative dose of 0.01, 0.1, or 1.0 mg/kg BW. Examined 7 days after final injection for hepatic EROD activity and CYP1A protein	TBT potentiates PCB 126-induced CYP1A at environmentally relevant doses. Low and middle doses of TBT (0.01 and 0.1 mg/kg BW), but not the high dose, potentiated PCB 126-induced activity at these same doses	16
Rainbow trout, <i>Oncorhynchus mykiss</i>		
Eggs injected 24–50 h after fertilization with graded doses of various PCBs		
PCB 4; >24,200 µg/kg egg fresh weight (FW)	LD50, embryos	13
PCB 28; >24,300 µg/kg egg FW	LD50, embryos	13
PCB 52; >30,400 µg/kg egg FW	LD50, embryos	13
PCB 77 0.578 µg/kg egg FW	At age 35 days, sac-fry contained 78% of original dose	13
1348 (1064–1621) µg/kg egg FW	LD50, embryos; blue-sac syndrome	13, 14
PCB 81; 549 µg/kg egg FW	LD50, embryos; blue-sac-syndrome	13
PCB 105 67 µg/kg egg FW >6970 µg/kg egg FW	At sac-fry stage, 78% of original dose remained	13
PCB 118 1330 µg/kg egg FW >6970–>57,400 µg/kg egg FW	LD50, embryos	14
PCB 126 74 (44–83) µg/kg egg FW 1203 µg/kg egg FW	About 81% of original dose present in sac-fry	13
PCBs 128, 138, and 156; >115,000 µg/kg egg FW	LD50, embryos	13, 14
PCB 153; >6200 µg/kg FW	LD50, embryos	14
PCB 169; 7110 (5630–8090) µg/kg egg FW	LD50, embryos; blue-sac syndrome	13
PCB 170; >41,100 µg/kg egg FW	LD50, embryos	13
Larvae; age 3 days posthatch; exposed to 1, 5, or 20 mg Aroclor 1260/L for 3 h and examined 6 months later	All treatment groups accumulated 2.1–2.5 mg Aroclor 1260/kg BW after 3 h. Survival normal for all groups. Altered sex ratios and gonadal abnormalities in juvenile females: reduction in number of females produced in groups that accumulated 2.5 mg/kg BW; about 18% of females that initially contained 2.1 mg/kg BW had abnormal gonads vs. 2.7% in controls	18
Single ip injection; 134 µg/kg BW of PCB 77; or 5.8 µg/kg BW of PCB 126; or 93.7 µg/kg BW of PCB 169; subadults	50% increase in liver EROD activity	12
Single ip injection of 1.0 mg PCB 77/kg BW; livers analyzed 13 days postinjection; subadults	Compared to controls, livers were elevated in levels of cytochrome P-450 (2X), ethoxocoumarin-O-deethylase (10X), and ethoxresorufin-O-deethylase (50X)	11
Injected ip with 2,3,7,8-TCDD at 0.00037, 0.0022 or 0.0045 µmol/kg BW, or with PCB 77 at 0.2, 1.1, or 2.2 µmol/kg BW; subadults	50% induction of AHH (arylhydrocarbon hydroxylase) activity in liver microsomes of sexually immature trout at 0.002 µmol/kg for TCDD and 0.37 µmol/kg for PCB 77	3

Table 24.13 (continued) Effects of PCBs on Representative Aquatic Organisms

Taxonomic Group, Organism, PCB Congener, Dose, and Other Variables	Effect	Reference ^a
Single ip injection of mixture of 0.00018 µmol TCDD/kg BW plus 0.1 µmol/kg PCB 77; or mixture of 0.0011 µmol TCDD/kg BW plus 0.6 µmol PCB 77/kg BW; subadults	Mixtures of TCDD and PCB 77 produced greater than additive AHH responses	3
Single ip injection of mixture of 0.0022 µmol TCDD/kg BW plus 1.1 µmol PCB 77/kg BW; subadults	AHH induction response was less than additive	3
Single ip injection of PCB 77, PCB 126, or 2,3,7,8-TCDD. Liver AHH activity measured 3 days later; subadults	50% AHH induction occurred at 0.005 µmol/kg BW for TCDD, 1.0 for PCB 77 and 2.2 for PCB 126. PCB 77 was 1/200 as effective in inducing AHH activity in liver as TCDD, and PCB 126 was 1/500 as effective	4
Single ip injection of 30 mg PCB 118/kg BW to immatures. Fish killed 4 days later and liver analyzed	Liver EROD (7-ethoxyresorufin O-deethylase) activity was 5.6 times higher than controls; AHH activity was 2.7 times higher than controls	5
Single ip injection of 50 or 250 mg PCB 153/kg BW of juveniles 20–60 g BW; livers examined after 4 weeks	Dose-dependent induction of hepatic EROD activity, CYP1A protein, and CYP1A1 mRNA content	17
Fingerlings were injected ip with ¹⁴ C-labeled PCB mixture at 0.3, 1, 3, 10, and 30 mg PCB/kg BW; tissues sampled up to 70 days postinjection	At 3 days postinjection high doses of 10 and 30 mg PCB/kg BW caused elevation of liver microsomal monooxygenase activity when maximum tissue concentrations, in mg total PCB/kg FW, were 55 in bile, 12 in blood, 8 in muscle, and 8 in liver. Elevated hepatic microsomal monooxygenase activity with muscle and liver PCB concentrations of >0.3 mg/kg FW, but not 0.25 mg/kg FW	6
Juveniles fed diets containing 16 PCBs for 30 days; individual PCBs had high accumulation potential and high persistence in tissues	Half-time persistence of individual PCBs ranged between 24 and 224 days. Increasing persistence was positively related to increasing Log K _{ow} in the range 5–8, with a peak at 7	19
Fathead minnow, <i>Pimephales promelas</i> ; fry PCB 18; 86 µg/L	83% dead in 48h	1
PCBs 28 (1.5 µg/L), 52 (74 µg/L), 77 (0.3 µg/L), 101 (1.2 µg/L), 116 (2.8 µg/L), 128 (0.4 µg/L), 153 (1.3 µg/L), 171 (1.7 µg/L), 194 (3.0 µg/L)	Negligible mortality; 97–100% survival in 48h	1
Guppy, <i>Poecilia reticulata</i> ; adult males Fed diets containing 6–150 mg PCB 133 or PCB 197/kg diet for 191–247 days, or 550–1400 mg/kg diet for 65 days	At 6–150 mg/kg diet, uptake efficiency was near 50%; at higher dietary loadings, uptake efficiency decreased to 25%. No deaths in controls or at low dietary dosages; 13–25% mortality at 550–1400 mg/kg diet. Prior to death, guppies were sluggish, uncoordinated, and darkly colored; fish that died during exposure contained >0.7 µmol PCB/g FW	7
Fed PCB 133 at 550 mg/kg diet FW or PCB 197 at 530 mg/kg diet FW for 65 days, followed by a clean diet for 89 days, then reexposure to the contaminated diet for another 37 days	No PCB clearance during initial exposure; significant elimination of both PCBs when fed a clean diet. During reexposure, uptake efficiency for both PCBs was significantly higher than during the initial exposure	8
Leopard frog, <i>Rana pipiens</i> ; adults; single ip injection of PCB 126 at 0.0, 0.2, 0.7, 2.3, or 7.8 mg/kg BW. Four hepatic monooxygenases were examined	After 1 week, specific activities were not affected at 0.7 mg/kg BW and lower, but were 3–6.4 times higher than controls at 2.3 mg/kg BW and higher — and remained elevated for at least 4 weeks	20

Table 24.13 (continued) Effects of PCBs on Representative Aquatic Organisms

Taxonomic Group, Organism, PCB Congener, Dose, and Other Variables	Effect	Reference ^a
Scup, <i>Stenotomus chrysops</i> ; injected intraperitoneally with 1, 5, or 10 mg/kg BW of PCBs 77, 105, 118, 128, or 138 and examined for increases in ethoxyresorufin O-deethylase (EROD) activity, immunodetectable cytochrome P-450E (the EROD catalyst in scup) and <i>in vitro</i> translatable mRNA for P-450E	Monooxygenase parameters were significantly induced only by PCB 77; translatable mRNA for P-450E was induced at all doses; EROD activity and P-450E were decreased at the 5 and 10 mg/kg BW doses; a positive correlation was established between PCB 77 residues in liver and decreased EROD activity at the higher doses	9

24.5.3 Birds

PCB 126 is among the most toxic of all PCB congeners to birds, and the domestic chicken is the most sensitive tested species (Table 24.14) (Hoffman et al. 1996a, 1998). However, adverse effects of PCBs in birds vary markedly between species and tissues. And birds react differently to different PCB congeners and to PCB–metal mixtures. American kestrels (*Falco sparverius*) differ from Japanese quail (*Coturnix japonica*) after exposure to PCBs 105, 126, and 153; quail accumulated porphyrins in liver, but kestrels did not (Elliott et al. 1991). Japanese quail dosed with PCB 47 or 77 showed marked differences between the abilities of the small intestines and liver to metabolize porphyrin and the induction of cytochrome P-450 isozymes and associated monooxygenases (Miranda et al. 1987). Japanese quail fed different dietary concentrations of Aroclor 1260 for 25 days had a significant dose-dependent correlation between liver monooxygenase activity and PCB levels in blood (Marsili et al. 1996). EROD and porphyrin-induction responses of primary hepatocytes to various PCBs in newly hatched chickens, gulls, terns, and cormorants followed a concentration-dependent increase with significant variability in response between species (Sanderson et al. 1998). Pure hexachlorobiphenyls (HCBs) caused uroporphyrin accumulations and increased delta-aminolevulinic acid synthetase activity in chicken livers, and some HCBs significantly increased cytochrome P-450 and *p*-nitrophenol glucuronyl transferase when given in the feed for 3 weeks at 400 mg/kg ration. However, PCBs 128 and 169 caused greater accumulations of hepatic porphyrins than PCBs 138, 155, and 156 (Goldstein et al. 1976, 1977). PCBs 77, 136, 153, and 159 produced acute histopathological changes in chick embryo livers and selectively induced cytochrome P-448-mediated mixed-function oxidases; the degree of histopathologic change produced by each of the tested PCBs positively correlated with the degree of P-448 inhibition (Rifkind et al. 1984). Interactions of metals with PCBs are not well documented, although some studies with Japanese quail showed that cadmium raises PCB uptake from the diet. In one study, cadmium fed at high dietary levels of 100 mg/kg ration interfered with high levels of dietary PCBs (100 mg/kg ration). In that study, muscle of treated quails had increased loadings of congeners chlorinated in the 2,4,5-positions (such as PCBs 138, 153, 170, and 180), and these are comparatively toxic and resistant to metabolic degradation (Leoncio et al. 1992). More research is needed on variables known to modify PCB uptake, retention, translocation, and toxicity.

Embryos of the domestic chicken (*Gallus* sp.) are unusually sensitive to PCB 77. Mortality and a high incidence of developmental abnormalities — including microphthalmia, beak deformities,

edema, and retarded growth — were recorded in chicks at 0.02 mg PCB 77/kg egg FW, but no deaths or abnormalities were recorded in embryos of ducks, pheasants, and gulls at 0.1 to 1.0 mg PCB 77/kg egg FW (Table 24.14) (Brunstrom and Lund 1988). Chicken embryos were 20 to 100 times more sensitive to PCB 77 than embryos of the wild turkey (*Meleagris gallopavo*), and this sensitivity emphasizes the uncertainties of applying toxicity data from one species of bird to predict toxic effects in other avian species (Brunstrom 1988; Brunstrom and Lund 1988). Differences in sensitivity of birds to PCB 77 may be related to differences in metabolism and in the formation of toxic metabolites and to the increased availability of Ah receptors in chicks (Brunstrom and Reutergardh 1986). For example, Ah receptors were detected in livers of 7-day-old chicken embryos but not in livers of 9-day-old turkey embryos (Brunstrom and Lund 1988). Chicken embryos were extremely sensitive to PCB 126 when compared to embryos of the American kestrel and common tern. LD₅₀ values, in µg/kg FW egg, were 0.4 in chickens, 65.0 in kestrels, and 104.0 in terns; EROD induction in chicken embryo liver by PCB 126 was about 800 times more responsive than in tern and at least 1000 times more responsive than in kestrels (Hoffman et al. 1998).

Birds and mammals exposed to PCB mixtures frequently react differently. PCBs generally elicit large-colloid goiters in birds. These goiters are inherently different from hyperplastic goiters produced in mammals exposed to PCBs (Spear and Moon 1985). Fish-eating seabirds, such as the razorbill (*Alca torda*), can rapidly metabolize PCB congeners that have at least one pair of adjacent unsubstituted *meta-para* combinations in the biphenyl moiety (Borlakoglu et al. 1991b). Razorbills metabolized 4-chlorobiphenyl to 4-chloro-4'-hydroxybiphenyl. However, mice (*Mus sp.*) metabolized the same compound 15 times faster. PCB-exposed razorbills and rock doves (*Columba livia*) had similar concentrations of cytochrome P-450 and glutathione-S-transferase enzymes, but concentrations were significantly higher in rats (*Rattus sp.*) than either avian species (Borlakoglu et al. 1991b). The relative potency of tested PCBs — as measured by EROD activity of microsomal liver enzymes — in fertile eggs of the domestic chicken were 0.02 for PCB 77, and less than 0.001 for PCB 169 (Bosveld et al. 1992); these values differ somewhat from those proposed for mammals of 0.0005 for PCB 77, and 0.01 for PCB 169 (Safe 1990). Lymphoid development in the bursa of Fabricius of the avian embryo is inhibited by TCDD-like congeners. PCB 77, for example, affects the immune system by interacting with the Ah receptor, causing inhibition of lymphoid development in the mammalian thymus and in the avian bursa of Fabricius (Nikolaides et al. 1988). More research seems needed on the relation of avian Ah receptors to natural physiological processes.

Table 24.14 Effects of PCBs on Selected Birds

Species, PCB Congener, Dose, and Other Variables	Effect	Reference ^a
MALLARD, <i>Anas platyrhynchos</i>		
PCB 77; single injection into egg yolk on day 5 of incubation	No effect on hatching rate; chicks normal	1
0.1 mg/kg egg fresh weight (FW)	No effect on embryo survival and no gross abnormalities	2
5.0 mg/kg egg FW	PCB concentrations increased linearly with time of exposure and at day 100 exceeded 16 mg/kg FW in carcass and 3.9 mg/kg FW in breast muscle (26–523 mg/kg LW muscle); these values were 50–1000 times greater than human consumption guidelines for edible poultry in Canada (0.5 mg/kg LW), and 9–176 times greater than consumption guidelines for edible poultry in the U.S. (3.0 mg/kg LW)	18
GREYLAG GOOSE, <i>Anser anser</i>		
PCB 77; single injection into egg yolk on day 5 of incubation; 1.0 mg/kg egg FW	No effect on survival or development	2
GOLDFENEYE, <i>Bucephala clangula</i>		
PCB 77; single injection into egg yolk; 1.0 mg/kg egg FW	33% hatch vs. 52% hatch in controls; chicks normal	1

Table 24.14 (continued) Effects of PCBs on Selected Birds

Species, PCB Congener, Dose, and Other Variables	Effect	Reference ^a
NORTHERN BOBWHITE, <i>Colinus virginianus</i>		
PCB 126; single injection of egg with 0.04–0.07 mg/kg FW	LD50 through hatching	16
JAPANESE QUAIL, <i>Coturnix japonica</i>		
Adults given a single oral dose of either PCB 47 at 87.6 mg/kg body weight (BW), PCB 77 at 87.6 mg/kg BW, or Aroclor 1242 at 100–500 mg/kg BW. Quail were killed 48 h postdosing and liver and intestine analyzed for porphyrins and cytochrome P-450 monooxygenases	All compounds caused a significant increase in EROD activity and porphyrin content in small intestine and liver, and a significant increase in hepatic P-450 content	3
Adults fed diets for 30 days containing 100 mg cadmium/kg diet, 100 mg Aroclor 1260/kg diet, or mixture of 100 mg cadmium plus 100 mg Aroclor 1260/kg	Quail fed the mixture diet had 3 times more PCBs in muscle than the Aroclor group alone, and 70 times more PCBs than controls. The most dominant PCB congeners were 138, 153, 170, and 180	4
Fed in diet for 25 days at 5, 50, or 500 mg Aroclor 1260/kg diet	A dose-response relation was found between dietary PCB concentrations and porphyrins in liver and excreta. PCB concentrations in the 500 mg/kg group were about 900 mg/kg DW liver and 78 mg/kg DW excreta; in the 50 mg/kg group, liver had about 150 mg/kg DW	20
AMERICAN KESTREL, <i>Falco sparverius</i>		
Aroclor 1248; fed diets containing 3 mg/kg ration for 6 months; carcasses and eggs analyzed for total PCBs (Aroclors 1248, 1254, and 1260)	Carcasses of adults had 18.5 mg total PCBs/kg FW (vs. 3.3 in controls); eggs had 5.6 mg/kg FW vs. 1.5 in controls; shell thickness of eggs reduced 5%	5
Fed diets for 4 weeks containing daily doses equivalent to 3 mg PCB 105/kg BW, 0.05 mg PCB 126/kg BW, or 4.0 mg PCB 153/kg BW. Birds were killed 3 days after final treatment and livers analyzed for porphyrins, PCB residues, and activities of ethoxyresorufin O-deethylase-(EROD), aminopyrine-N-demethylase (APND), and aldrin epoxidase (AE)	PCB 105 caused significant APND induction; liver had 182.0 mg PCB 105/kg FW vs. 2.4 in corn oil controls. PCB 126 induced hepatic EROD and AE; liver had 3.3 mg PCB 126/kg FW. PCB 153 induced APND and AE; liver contained 119.0 mg PCB 153/kg FW. For all dose groups, liver weights and liver porphyrin levels were normal	6
Nestlings given daily oral doses of PCBs 77, 105, or 126 for 10 days		
PCB 77; 1.0 mg/kg BW daily	Liver contained 892 µg PCB 77/kg FW; onset of liver necrosis	16
PCB 105; 4.0 mg/kg BW daily	Liver contained 1677 µg PCB 105/kg FW; liver necrosis	16
PCB 126 50 µg/kg BW daily	Liver contained 156 (68–563) µg PCB 126/kg FW; pronounced liver enlargement; lymphoid depletion of spleen; 10-fold increase in hepatic microsomal EROD and benzyloxyresorufin-O-dealkylase; 5-fold increase in methoxyresorufin-O-dealkylase	16, 19
250 µg/kg BW daily	Liver had 380 µg PCB 126/kg FW with increasing necrosis; above effects plus decreased bone growth, decreased spleen weight, and degenerative lesions of thyroid	16, 19
1.0 mg/kg BW daily	Liver had 1.1 (0.6–4.5) mg PCB 126/kg FW; above effects plus decreased body weight, decreased hepatic thiol concentrations, and increased plasma enzyme activities	16, 19

Table 24.14 (continued) Effects of PCBs on Selected Birds

Species, PCB Congener, Dose, and Other Variables	Effect	Reference^a
Eggs injected with PCB 126 through air cell on days 3–4 of incubation 2.3–23 µg/kg FW 65.0 µg/kg egg FW	Malformations and edema at hatching LD50 at hatching	17 16, 17
Eggs injected with 316.0 µg PCB 77/kg FW on day 4 of incubation through air sac	LD50	17
DOMESTIC CHICKEN, <i>Gallus</i> sp.		
PCB 77; single dose injected into egg yolk on day 4 of fertilization 0.0006 mg/kg egg FW 0.004 mg/kg egg FW 0.010 mg/kg egg FW 0.020 mg/kg egg FW	50% increase in AHH activity after 48 h 60% hatch vs. 88% in controls 17% dead in 18 days; reduced thymus weight 70–100% dead by day 18; treated embryos had increased frequency of liver lesions, subcutaneous edema, shortened beaks, and microphthalmia	7 1, 8 7 1, 2, 8
0.050 mg/kg egg FW 0.100 mg/kg egg FW	All dead within 18 days Zero hatch; all dead	7 8
PCB 77; single dose injected into air sac on day 3 of incubation; 0.005 mg/kg egg FW	Whole liver homogenates had increases of 300-fold in 7-ethoxycoumarin O-deethylase and 75-fold in AHH activities between days 5 and 10	15
PCB 77; single dose of 0.0026 mg/kg egg FW injected into air sac on day 4 of incubation	LD50 by time of hatch	17
PCB 77; single dose injected into air sac on day 13 of incubation 0.045 mg/kg egg FW 0.20–0.30 mg/kg egg FW	Reduction by 50% in lymphoid cells in bursa of Fabricius 30-fold increase in AHH activity; bursa almost devoid of lymphoid cells	9 9
PCBs 77, 136, 153, 169; 17-day-old embryos; single injection at 0.5–30,000 nmol/egg; examined for liver histopathology and induction of mixed function oxidases after 24 h	Significant alterations occurred at 0.5 nmol PCB 77/egg (about 0.003 mg/kg egg), at 5 nmol PCB 169/egg, and between 500 and 5000 nmol PCB 153/egg. PCB 136 had no effect on liver pathology at the highest dose tested of 30,000 nmol/egg	10
Single injection of eggs of PCBs 105 (2.2 mg/kg FW), 126 (0.0006–0.0031 mg/kg FW), 157 (1.5–2.0 mg/kg FW), or 169 (0.17 mg/kg FW)	LD50 through hatching	16
PCB 126; single air sac injection on day 4 of egg incubation 0.0003 mg/kg egg FW and higher 0.0004 mg/kg	Malformations and edema noted at hatching LD50 at hatching	17 17
PCBs 128, 136, 153, 155, and 169; each was fed in diets to 1-day-old chicks for 21 days at 400 mg/kg ration PCB 128	Decrease in weight gain; moderate liver pathology; gross accumulations of hepatic porphyrins and increased delta-aminolevulinic acid synthetase activity	11, 12
PCB 136	Decrease in weight gain; comparatively small increase in liver weight	11
PCB 153	Decrease in weight gain; mild liver pathology	11
PCB 155	Largest increase in liver weight; significant liver pathology	11
PCB 169	All dead in 11 days; thymic involution and edema; gross accumulations of uroporphyrins in liver	11, 12

Table 24.14 (continued) Effects of PCBs on Selected Birds

Species, PCB Congener, Dose, and Other Variables	Effect	Reference ^a
HERRING GULL, <i>Larus argentatus</i> PCB 77; single injection into egg yolk on day 5 of incubation; 1.0 mg/kg egg FW	No effect on survival or development	2
BLACK-HEADED GULL, <i>Larus ridibundus</i> PCB 77; single injection into egg yolk of 1.0 mg/kg egg FW	No effect on hatching rate; chicks normal	1
WILD TURKEY, <i>Meleagris gallopavo</i> PCB 77; single injection into air sac of 5-day-old embryos 0.006 mg/kg egg FW 1.0 mg/kg egg FW	50% increase in AHH activity after 48 h 60% dead in 24 days	7 7
DOUBLE-CRESTED CORMORANT, <i>Phalacrocorax auritus</i> PCB 126; yolks of fertilized eggs injected with 70–698 µg PCB 126/kg FW egg prior to incubation	LD50 at hatch was 177 µg/kg. No increase in developmental abnormalities in any treatment group. Hepatic EROD activities higher in all treatment groups when compared to controls	22
RING-NECKED PHEASANT, <i>Phasianus colchicus</i> PCB 77; single injection into egg yolk 0.1 mg/kg egg FW 1.0 mg/kg egg FW	No decrease in hatching rate; chicks normal All embryos died	1 1
PCB 105; adult hens orally dosed with 0, 0.06, 0.6, or 6 mg PCB 105/kg BW weekly for 10 weeks to achieve cumulative doses of 0, 0.6, 6, or 60 mg PCB 105/kg BW after which hens were bred with untreated roosters once a week for 8 weeks	Production of fertilized eggs and survival of embryos and chicks in PCB 105 groups were not different from controls. Hepatic microsomal monooxygenase activities were significantly elevated in chicks at day 1 posthatch from hens given a cumulative dose of 6 mg/kg BW and in chicks at day 21 posthatch from hens given a total dose of 60 mg/kg BW	21
COMMON EIDER, <i>Somateria mollissima</i> Single injection into yolk on day 5 of incubation PCB 77; 1.0 mg/kg egg FW PCB 126; 0.1 mg/kg egg FW	No effect on survival 35% dead on day 24 of incubation vs. 20% dead in controls	13 13
COMMON TERN, <i>Sterna hirundo</i> PCB 126 Single egg injection with 0.045 mg/kg FW Single egg injection of 0.104 mg/kg egg FW via air sac on day 4 of incubation	35% embryo mortality through hatching LD50 at hatch; beak defects in survivors, especially crossed beaks	16 17
RINGED-TURTLE DOVE, <i>Streptopelia risoria</i> Fed iodine-deficient diet PCB 77; given 20 mg/kg BW 3 times over a 28-day period PCB 77; single dose of 60 mg/kg BW	Thyroid hyperplasia caused by low iodine diet was not enhanced by PCB 77 Thyroid hyperplasia reversed within 7 days	14 14

^a 1, Brunstrom and Reutergardh 1986; 2, Brunstrom 1988; 3, Miranda et al. 1987; 4, Leonzio et al. 1992; 5, Lowe and Stendell 1991; 6, Elliott et al. 1991; 7, Brunstrom and Lund 1988; 8, Brunstrom and Darnerud 1983; 9, Nikolaides et al. 1988; 10, Rifkind et al. 1984; 11, McKinney et al. 1976; 12, Goldstein et al. 1976; 13, Brunstrom et al. 1990; 14, Spear and Moon 1985; 15, Brunstrom 1986; 16, Hoffman et al. 1996a; 17, Hoffman et al. 1998; 18, Custer et al. 1996; 19, Hoffman et al. 1996b; 20, Fossi et al. 1996; 21, Hornung et al. 1998; 22, Powell et al. 1998.

24.5.4 Mammals

Deleterious effects were significant on growth, survival, reproduction, or metabolism from chronic exposures of sensitive species of tested rodents, primates, and mustelids to daily concentrations as low as 0.008 mg/kg BW of Aroclor 1016, 0.01 to 0.02 mg/kg BW of PCB 126, 0.01 to 0.05 mg/kg diet or 0.1 mg/kg BW of PCB 169, 0.09 mg/kg BW of Aroclor 1246, 0.1 mg/kg BW of Aroclor 1254, and 0.3 to 1.0 mg/kg diet or 0.6 mg/kg BW of PCB 77 (Table 24.15). Several PCBs had negligible adverse effects on tested mammals during chronic daily exposures to doses of at least 5 mg/kg ration or 5 mg/kg BW — specifically, PCBs 4, 15, 47, 52, 80, 136, 153, 155, and 167 (Table 24.15). Although subhuman primates seem to be more sensitive to reproductive and other adverse effects of PCBs than humans, no clear and convincing evidence associated PCB exposures with human cancers and reproductive problems (Kimbrough 1995). At present, no meaningful reproductive problems have been identified in female capacitor workers, and no carcinogenicity was evident in humans having more than 1.0 mg total PCBs/L serum or more than 400 mg total PCBs/kg adipose fat (Kimbrough 1995).

The mink (*Mustela vison*) is among the most sensitive mammals to PCB toxicity (Aulerich et al. 1987; Edqvist et al. 1992) (Table 24.15). Reproductive failure, especially fetal death and resorption, of PCB-fed mink is well documented (Backlin and Bergman 1992; Bergman et al. 1992b; Edqvist et al. 1992; Madej et al. 1992). The mechanisms of intrauterine death of mink fetuses after PCB exposure are not fully understood (Backlin and Bergman 1992), although planar PCB congeners seem to be implicated (Hakansson et al. 1992). Studies showed that EROD and AHH activities were maximally induced in adult mink by PCB fractions containing non-*ortho*- or mono-*ortho*-chlorobiphenyls and that mink kits are about 10 times more sensitive to P-450-inducers than adults (Brunstrom 1992; Kihlstrom et al. 1992). PCB-dosed mink also show altered blood chemistry (Edqvist et al. 1992), abnormal liver metabolism and histology (Edqvist et al. 1992; Bergman et al. 1992b), raised cortisol excretion (Madej et al. 1992), enhanced EROD activity (Brunstrom 1992), and altered metabolism of Vitamin A (Hakansson et al. 1992). Selective retention of certain PCBs and their hydroxylated metabolites occurred in mink muscle after 3 months of a diet containing a PCB mixture (Bergman et al. 1992a). Retention of PCBs 99, 105, 118, 138, 153, 156, and 180 was high in muscle of mink on the diet. Not retained and presumably metabolized were PCBs 44, 49, 52, 91, 92, 95, 97, 107, 132, 149, and 174 (Bergman et al. 1992a).

Estrogen receptors bind to many compounds other than natural estrogen. Several organochlorine compounds, including certain PCBs, reportedly act as estrogen mimics (Hileman 1994). Many estrogen mimics are persistent, lipid-soluble compounds defined by their ability to stimulate the proliferation of cells in the uterus of the mouse (*Mus spp.*). In males, these mimics may also inhibit sperm production and testes growth. PCBs and their metabolites may be estrogenic to wildlife, although the evidence is not conclusive (Hileman 1994). PCB mixtures and pure individual chlorobiphenyls with a significant degree of *ortho*-substitution have elevated estrogenic activity; Aroclor 1221, for example, rich in *ortho*-chlorobiphenyl, has estrogenic activity in female rats (Korach et al. 1988). Hydroxylated metabolites of PCBs also show estrogenic hormonal activity (Korach et al. 1988; Li et al. 1994). Hydroxylation of PCBs occurs in amphibians and teleosts but at a much slower rate than that of mammals (Safe et al. 1976). Hydroxylated metabolites of PCB 3 include 4'-chloro-4-biphenylol, 4'-chloro-3,4-biphenyldiol, and 4'-chloro-3-methoxy-4-biphenylol; PCB 15 gave 4,4'-dichloro-3-biphenylol; and Aroclor 1254 yielded mono-, di-, and tri-chlorophenylols (Safe et al. 1976). PCB 77 is detoxified by metabolic hydroxylation to hydroxybiphenyl metabolites (Borlakoglu et al. 1991a). Hydroxylated PCB metabolites may be more toxic than the parent product because of their (1) estrogenic properties (Yoshimura et al. 1987); (2) tendency to accumulate in the fetus (Darnerud et al. 1986), and (3) interference with thyroxine metabolism (Brouwer et al. 1990). The ability of hydroxylated PCB metabolites to bind to the uterine estrogen receptor in rats was, in increasing order of effectiveness, 4-hydroxy-3,5,4'-trichlorobiphenyl, 4,4'-dihydroxy-3,5,3',5'-tetrachlorobiphenyl, 4-hydroxy-2-chlorobiphenyl, 4-hydroxy-4'-chlorobiphenyl,

4,4'-dihydroxy-2',3',5',6'-tetrachlorobiphenyl, 4,4'-dihydroxybiphenyl, 4-hydroxybiphenyl. PCB compounds that demonstrated appreciable receptor binding activity were also active in stimulating uterine weight increases (Korach et al. 1988). More research seems needed on the estrogenic properties of hydroxylated PCB metabolites.

Long-term neurobehavioral changes were reported in children, monkeys, and rodents exposed to commercial PCB mixtures during fetal and neonatal development (Schantz et al. 1995). Perinatal exposure of rats (*Rattus* sp.) to *ortho*-substituted PCBs (PCBs 28, 118, 153) can cause long-lasting learning deficits in females; males were not affected (Table 24.15). The PCB-induced deficit in spatial learning did not appear to be mediated by decreased thyroid hormone levels; however, neonatal hyperthyroid rats exposed to low concentrations of PCBs 77 and 126 *in utero* and during lactation had enhanced spatial learning (Schantz et al. 1997).

In comparison to primates and mustelids, rodents are only moderately sensitive to intoxication by most PCBs (Abdel-Hamid et al. 1981). In rodents, PCBs 77 and 169 cause effects that are characteristic of the dioxins and furans, including P-450 induction, porphyrin accumulations, and atrophy of the lymphatic organs (Abdel-Hamid et al. 1981), as well as teratogenicity in mice (Darnerud et al. 1986). Exposure of rats to PCB 126 *in utero* and through lactation produced fetotoxic effects, delayed physical maturation, and induced liver xenobiotic metabolizing enzymes without causing neurobehavioral effects (Bernhoft et al. 1994). In mice, PCBs 77, 126, and 169 were teratogenic in a high percentage of the fetuses from treated dams but without apparent effect on the dams (Marks et al. 1981). PCB 77, for example, was toxic to the conceptus at dose levels below those toxic to the dam when administered to pregnant CD-1 mice on days 6 to 15 of gestation (Marks et al. 1989). The predominant PCB-induced fetal malformations in mice were cleft palate and hydronephrosis (Marks et al. 1981). PCB 77 also interferes with retinyl ester hydrolase (REH), the enzyme responsible for the hydrolysis of Vitamin A into free retinol, lowering levels of Vitamin A in liver and decreasing serum concentrations of REH and retinol (Mercier et al. 1990).

Toxicokinetics of PCBs in rodents were altered when administered in mixtures (de Jongh et al. 1992). PCBs 153, 156, and 169 produced biphasic elimination patterns in mice when administered in combinations, but single-phase elimination when administered alone. Elimination of all PCBs was more rapid after coadministration. Mixtures of PCBs 153 and 156 raised EROD activity and lengthened retention of each congener in liver; however, a mixture of PCB 153 and 169 lowered EROD activity (de Jongh et al. 1992). Selected PCBs of low acute toxicity may increase the toxicity of compounds such as 2,3,7,8-TCDD (Birnbaum et al. 1985). Thus, PCB 153 or 157 at sublethal dosages (20 to 80 mg/kg BW) did not produce cleft palate deformities in mouse embryos. But a mixture of PCB 157 and 2,3,7,8-TCDD produced a tenfold increase in the incidence of palate deformities that were expected of 2,3,7,8-TCDD alone; palate deformities did not increase with a mixture of PCB 153 and 2,3,7,8-TCDD. The widespread environmental occurrence of PCB-PCDD and PCB-PCDF combinations suggests a need for further evaluation of the mechanism of this interaction (Birnbaum et al. 1985).

Intraspecific variability to PCBs was high in fish-eating mammals (Boon et al. 1997), and genetically inbred AHH-responsive and AHH-nonresponsive strains of mice (Robertson et al. 1984). In fish-eating mammals, the ability to metabolize PCB congeners with H-atoms only in the *ortho*- and *meta*-positions and with one *ortho*-chlorine substituent generally increased in the order phocid seals > cetaceans > otters. But the metabolism of PCB congeners with H-atoms in the *meta*- and *para*-positions and with two *ortho*-chlorines increased in the order otter > seals > cetaceans. Both categories of congeners were probably metabolized by different families of cytochrome P-4501A and P-4502B, of which levels were different between the cetaceans, pinnipeds, and otters. Within-species PCB patterns differed in a concentration-dependent manner; the induction of cytochrome P-450 enzymes is the most likely explanation for this phenomenon, although starvation could have a similar effect (Boon et al. 1997). In mice, PCB 77 was metabolized and excreted more rapidly than 2,3,7,8-TCDD (d'Argy et al. 1987). In rats, PCB 77 was excreted more rapidly than PCB 47 (Shimada and Sawabe 1984). PCBs that lack adjacent hydrogen atoms in at least one of the rings

are enriched in rat tissues, indicating that accumulation exceeds elimination by metabolism and excretion. PCBs with a tendency to accumulate were non-*ortho*- and mono-*ortho*-substituted congeners; however, PCBs with *meta*-*para*-unsubstituted carbon atoms in at least one ring were not enriched in tissues (Borlakoglu et al. 1991a). Uptake and retention of individual PCB congeners in rats are related to properties associated with K_{ow} and high chlorination, especially in the tetra- and penta-chlorobiphenyls (Shain et al. 1986). The highly chlorinated hexa- and octa-chlorobiphenyls produced morphological changes in rats comparable to those produced by DDT, Aroclor 1254, and Aroclor 1260 (Hansell and Ecobichon 1974).

Table 24.15 Effects of PCBs on Selected Mammals

Species, PCB Congener, Dose, and Other Variables	Effect	Reference ^a
COTTON TOP MARMOSET MONKEY, <i>Callithrix jacchus</i>		
PCB 77; adult females orally dosed with 0.1, 1.0, or 3.0 mg/kg body weight (BW) twice weekly for 18–28 weeks	Severe toxicity in the 3.0 mg/kg group that included body weight loss, hair loss, abnormal nail growth, scaly skin, anemia, elevated blood triglyceride and cholesterol levels, and tissue histopathology. Toxicity was less severe in the 1.0 mg/kg group and minor in the low-dose group	1
RHESUS MACAQUE, <i>Macaca mulatta</i>		
Aroclor 1016		
>0.008 mg/kg BW daily via the diet	Adverse effects on reproduction	2
>0.028 mg/kg BW daily	Adverse effects on growth	2
Aroclor 1248; >0.09 mg/kg BW daily	Adverse effects on growth	2
Aroclor 1254; females were fed 0, 5, 20, 40, or 80 µg/kg BW daily for 6 years. During this time, females were bred with non-dosed males. Resultant offspring were nursed for 22 weeks and fed no additional PCBs until they were necropsied at age 120 weeks	Total PCB concentrations in all tissues of adult females increased with increasing dosage; highest levels were in adipose tissue (Max. 141 mg/kg fresh weight [FW]; Max. 171 mg/kg lipid weight [LW]) and lowest in brain (1.1 mg/kg FW; 12.9 mg/kg LW). PCB concentrations were higher in infants from dosed dams than those nursed by controls; higher in females having a stillborn infant than those with a viable infant; and higher in those in poor health. The PCB distribution pattern in tissues from a dosed mother/infant pair was different; more hepta-chlorobiphenyls were found in the infant than in the dam	28
PCB 52	No clinical effects or pathologic lesions	3, 4
Fed diets containing 3.0–5.0 mg/kg for 180–200 days		
PCB 77		
Fed diets containing 0.3–3.0 mg/kg ration for 1–6 months	Dose-and time-dependent increase in chloracne; weight loss; death; and histopathology of sebaceous glands, thymus, and gastric mucosa	3
Fed diet containing 1.0 mg/kg ration for 38 days	Adverse effects on survival	4
Immature males fed diets containing 1.0 or 3.0 mg/kg ration	All were moribund in 7–14 weeks; abnormal gastric histology	5
Adult females received a total of 9 intragastric doses 20–40 days postconception; total doses were 0.6 or 3.15 mg/kg BW	All animals in both dose groups survived, but all aborted	4
Adult females given a single intravenous injection of 0.6 mg/kg BW; blood measured 1 h to 42 days postinjection	As a percentage of the total dose administered, PCB 77 concentrations in blood fell from 4.4% at 1 h to 0.14% at 42 days. About 60% of the total dose was excreted in feces, and 10% in urine	18
PCBs 136, 153, or 155; each fed in diet at 15–65 mg/kg ration for 63–122 days	No discernible deleterious effects	4

Table 24.15 (continued) Effects of PCBs on Selected Mammals

Species, PCB Congener, Dose, and Other Variables	Effect	Reference ^a
PCB 169; fed diet containing 400.0 mg/kg ration for 40 days	Concentrations in body fat increased steadily during exposure; recovery was protracted and incomplete during a 6-month observation period	4
MOUSE, <i>Mus</i> sp.		
Aroclor 1254	Adverse effects on reproduction	2
>1.3 mg/kg BW daily via diet	In carcass fat, net PCB loss was attributed to metabolic loss of PCBs 105 and 138. In lung, all congeners except 153 were retained and decreased only as a function of dilution due to growth. In liver, all congeners were retained and PCB 105 was enriched. Total PCBs in carcass averaged 80.8 mg/kg BW 24 h after treatment and about 10 mg/kg BW after 16 weeks; similar trends occurred in liver and lung. Tb 1/2 for PCB 153 was 81–101 days	6
Single ip injection of 500 mg/kg BW (a dose that promoted nitrosamine-initiated lung and liver tumors). The amounts of the 9 congeners that made up >90% of the PCBs present 1 day after treatment (PCBs 99, 105, 118, 128, 138, 153, 156, 170, 180) were quantified in liver, lung, and whole body for 112 days after dosing	Toxic to dams at 64 mg/kg BW daily, but no embryotoxicity	7
PCB 15; pregnant mice given daily doses of 16, 32, or 64 mg/kg BW on days 6–15 of gestation and killed on day 18	Dose-dependent increase in incidence of malformed fetuses — especially cleft palate and hydronephrosis — at 4 mg/kg BW daily and higher. At 16 mg/kg BW and higher, dams had dose-dependent increase in weight loss, frequency of vaginal bleeding, and other evidence of abortion	7
PCB 77	Radioactivity levels were elevated in uterine fluid and in fetuses in late gestation. No unmetabolized PCB 77 was detected in fetuses, but PCB 77 metabolites (including 3,3',4,4'-tetrachloro-2-biphenylol, and methylsulphonyl-tetrachloro-biphenyl) were found in fetuses in late gestation	8
Pregnant mice given single iv injection of 3.5 mg/kg BW of ¹⁴ C-labeled PCB 77 on days 4–17 of gestation and killed 4–96 h later	30–40% reduction of retinol and retinyl palmitate concentrations in liver within 2–4 days	9
Strain C57BL/R _j given single ip injection 15 mg/kg BW	50% reduction in hepatic retinyl palmitate	9
17 mg/kg BW	50% reduction in hepatic retinol	9
32 mg/kg BW	No reduction in hepatic retinoids	9
Strain DBA/2; single ip injection of 729 mg/kg BW	Dose-dependent increase in embryo deaths, resorption of the conceptus, and frequency of developmental abnormalities (cleft palate, dilated kidney pelvis, thymus hypoplasia). ED ₅₀ for cleft palate was about 100 mg PCB 77/kg BW	10
Single oral dose of 25, 50, or 100 mg/kg BW given to Ah-responsive pregnant mice on gestation day 11, 12, or 13; mice killed on day 18 of gestation	Permanent motor dysfunction in weaning mice characterized by swift circling movements, restlessness, and hyperkinesia; spinal and cranial nerve roots abnormal	11
Dams received oral dose of 32 mg/kg BW daily on days 10–16 of gestation	Both groups had increased body weight, increased blood EROD activity, decreased plasma retinol levels, and increased plasma total thyroid hormone levels. The Ah-responsive group also had increased hepatic pentoxyresorufin-O-deethylase activity, increased liver cytochrome P-450 activity, and increased liver weight	12
Ah-responsive and Ah-nonresponsive strains; females, age 10 weeks; given single ip injection of 50 mg/kg BW; killed after 7 days		

Table 24.15 (continued) Effects of PCBs on Selected Mammals

Species, PCB Congener, Dose, and Other Variables	Effect	Reference ^a
PCB 80; pregnant mice given 64 mg/kg BW daily on days 6–15 of gestation and killed on day 18	No effect on maternal or developmental toxicity	7
PCB 169; pregnant mice given daily doses of 0.1, 1, 2, 4, 8, or 16 mg/kg BW by gavage on days 6–15 of gestation; mice killed on day 18 and dams evaluated for reproductive health and fetuses for malformations	All dams survived all treatments; some lost weight during pregnancy at 8 mg/kg BW and higher. Incidence of malformed fetuses increased from 0.9% in controls, to 3.6–4.3% in the 0.1–1.0 mg/kg groups, to 37% in the 4 mg/kg group to 61–66% in the 8–16 mg/kg groups. Fetal deaths increased at daily doses of 4 mg/kg BW and higher, and abortions increased in the 8 and 16 mg/kg groups. Fetal liver discolored at 1 mg/kg BW daily	13
MINK, <i>Mustela vison</i>		
Aroclor 1254		
0.1 mg/kg BW daily	Adverse effects on growth	2
0.115 mg/kg BW daily (1.64 mg daily)	Adverse effects on reproduction	2, 16
PCB 47; subadult females given daily ip injections of 50 mg/kg BW for 3 days and killed 7 days after last dose	No evidence of illness or pathology. PCB 47 residues, in mg/kg FW, were 389 in fat and 38 in liver	14, 15
PCB 77; subadult females given daily ip injections of 50 mg/kg BW for 3 days and killed 7 days after last dose	Severe anorexia, diarrhea, and melena. Significant histopathology of mucosa of the small intestine. PCB residues, in mg/kg FW, were 139 in fat and 16 in liver	14, 15
PCBs 136 and 167; each fed to adult females in the diet at 5 mg/kg ration for 3 months	No adverse effects on reproduction	16
PCB 169; fed in diet at concentrations of 0.01–0.5 mg/kg ration for 135 days		
0.01 mg/kg diet	No deaths; some weight loss and liver enlargement	17
0.05 mg/kg diet	50% mortality in 135 days	17
0.1 mg/kg diet	50% dead in 75 days	17
0.5 mg/kg diet	All dead within 73 days	17
Fed PCB-contaminated common carp (<i>Cyprinus carpio</i>) from Saginaw Bay, Lake Huron. Total PCBs in diet was 8.4 mg/kg FW ration (including, in µg/kg FW, 0.3 of PCB 81, 1.5 of 77, 0.6 of 126, 0.07 of 169, 6.9 of 123, 262 of 118, 9.1 of 114, 87 of 105, 8.5 of 167, 9.6 of 156, 1.9 of 157, and 1.3 of 189); also 15 µg total dioxins/kg FW ration and 1 µg total dibenzofurans/kg. A multigenerational study on reproduction and health. Mink were fed diets containing 0, 0.25, 0.5, or 1.0 mg total PCBs/kg ration through substitution of carp for ocean fish in the diets. Half the P ₁ animals were switched from respective diets to control diets after whelping the first of two F ₁ generations; half the first-year F ₁ offspring (kits) were switched to the control diet at weaning, while the other continued on the parental diet	Continuous exposure to 0.25 mg total PCBs/kg ration and higher delayed the onset of estrus and lessened the whelping rate. Litters whelped by females continually exposed to 0.5 mg/kg and higher had lower survival and reduced body weights. Those continually exposed to 1.0 mg total PCBs/kg ration had altered weights of kidney, brain, liver, spleen, heart, and thyroid. Plasma and liver PCB concentrations of adults and kits reflected dietary concentrations of PCBs and duration and time of exposure. Short-term parental exposure to PCBs had adverse effects on survival of subsequent generations of mink conceived months after the parents were placed on uncontaminated food	32
Exposure as above	Continuous exposure to diets containing PCBs from Saginaw Bay carp induced cytochrome P-450 activity in a dose-dependent manner. Cytochrome P-450 activity in animals switched to the control diet from the PCB-containing diet was the same as controls. EROD hepatic activity is a potential biomarker for current exposure to PCBs and other similar cytochrome P-450 inducers	33

Table 24.15 (continued) Effects of PCBs on Selected Mammals

Species, PCB Congener, Dose, and Other Variables	Effect	Reference ^a
Exposure as above	PCB diets were associated with reproductive impairment including anovulation, fetal resorption, delayed ovulation, increased gestation, and decreased litter size. Hepatic estrogen binding site concentrations decreased with increasing dietary PCB concentrations but not uterine estrogen receptor sites	34
LABORATORY WHITE RAT, <i>Rattus</i> sp.		
Aroclor 1254		
Dams and resultant pups fed diets containing 0, 3, 30, or 300 mg Aroclor 1254/kg ration from conception to weaning	Most congeners that accumulated in pup tissues were concentrated in the dam's milk when compared to the feed. PCB uptake by pups was greater during lactation than during gestation. Congeners that accounted for 46% of the brain PCB content and also accumulated in a dose-dependent manner were PCBs 105, 138, 141, 153, 168, 178, 179, and 186	19
0.25 mg/kg BW daily via the diet	Adverse effects on reproduction	2
Males held on soil containing 207 mg Aroclor 1254/kg soil for 3 days. Soils also contained 2.7 mg total PAHs/kg, 1200 mg Pb/kg, and 2270 mg Zn/kg	PCB concentrations, in µg Aroclor 1254/kg, were 1845 in liver and 241 in lung; EROD activity was induced in both tissues. When soils were diluted with uncontaminated soils, a dose-response relation was found between PCBs in litter and EROD activity, suggesting that EROD activity and tissue residues can be used to assess bioavailability of PCBs from soils to mammals	30
PCB 4; young males given ip injections of 50 mg/kg BW daily for 3 days and killed 4 days after last injection	Negligible morphological effects on liver when compared to PCBs 15, 52, and 77 groups dosed at same regimens	20
PCB 28; dams dosed on days 10–16 of gestation by gavage with 8 or 32 mg/kg BW daily; offspring tested in mazes at age 12–16 weeks	Birth weight lower in high-dose group; female pups — but not males — in the high-dose group had learning deficits	27, 29
PCB 47; subadult females given 3 daily injections of 50 mg/kg BW and killed 7 days after last injection	No clinical signs of illness and no significant gross or microscopic lesions. PCB 47 residues, in mg/kg FW, were 747 in fat and 28 in liver	14, 15
PCB 77	In males (females), adipose tissue 4 h postinjection contained 23% (12%) of the total dose administered, skin 14% (16%), liver 6.8% (8.8%), muscle 6.7% (16.2%), and blood 4.1% (4.0%); after 7 days, adipose tissue contained 2.7% (7.4%) and other tissues 0.5–2.2% (1.0–3.4%)	18
Pregnant rats dosed orally on days 6–18 of gestation with 1, 3, or 10 mg/kg BW daily; fetuses were examined on day 19 for developmental abnormalities	A dose-dependent increase in mortality, intestinal histopathology, and external malformations, and decrease in fetal size and length of tibias. A daily dose of 3 mg/kg BW significantly affected fetus growth, bone development, and survival	21
Single ip injection of 15 mg/kg BW	Significant reduction in liver and heart retinol and in liver retinylester concentrations	22
Single ip injection of 50 mg/kg BW	Metabolites in feces included 5-hydroxy-3,4,3',4'-tetrachlorobiphenyl, 4-hydroxy-3,5,3',4'-tetrachlorobiphenyl, and a dihydroxy- and monohydroxy trichlorophenyl. After 5 days, unchanged PCB 77 in feces accounted for 0.8% of the initial dose, but hydroxylated metabolites constituted about 32%	23

Table 24.15 (continued) Effects of PCBs on Selected Mammals

Species, PCB Congener, Dose, and Other Variables	Effect	Reference ^a
Subadult females given 3 daily ip injections of 50 mg/kg BW and killed 7 days after last injection	No signs of illness or histopathology. PCB 77 residues, in mg/kg FW, were 148 in fat and 138 in liver	14, 15
Adults injected ip for 3 days at 80 mg/kg BW daily then killed 24 h after last injection	Heme destruction in the P-448-containing reconstituted monooxygenase system; reactive epoxide, or possibly nonepoxyde, intermediate metabolites may participate in cytochrome P-448 destruction	24
PCB 118; dams dosed on days 10–16 of gestation by gavage with 4 or 16 mg/kg BW daily; offspring tested in mazes at age 12–16 weeks	Birth weight lower in high-dose group; female offspring, but not males, in high-dose group had learning deficits	27, 29
PCB 126; dams given 0.01 or 0.02 mg/kg BW by gavage every second day from days 9–19 of gestation	Reduction in litter size, body weight, and survival of sucklings; delayed spontaneous movement and neuromuscular maturation. Dams and pups had reduced body weight, and increased cytochrome P-4501A1 activity	25
PCB 126; isolated rat hepatoma cells; 49–3140 pM	EROD activity increases in dose-dependent manner; potentiated by coexposure to low noncytotoxic concentrations of tributyltin	31
PCB 153	Female offspring from high-dose group had learning deficits; males were not affected	27, 29
Dams dosed on days 10–16 by gavage with 16 or 64 mg/kg BW daily; offspring tested in mazes at age 12–16 weeks	Increased uterine weight at 25 and 51 mg/kg BW, but not in other groups	26
Immature female pups given 8, 11, 25, 51, or 59 mg/kg BW on days 20 and 21; killed on day 22

24.6 RECOMMENDATIONS

Proposed PCB criteria for the protection of natural resources are predicated on total PCBs and selected Aroclor compounds (Table 24.16) and offer minimal insight into PCB toxicokinetics. Most authorities now agree that future PCB risk assessments require (Eisler 1986; Maack and Sonzogni 1988; Tanabe 1988; Gooch et al. 1989; Hernandez et al. 1989; Kannan et al. 1989; Tanabe et al. 1989; Borlakoglu et al. 1990; Hebert et al. 1993; Giesy et al. 1994a; Safe 1994; Walker and Peterson 1994; Eisler and Belisle 1996; Weihe et al. 1996; Gribaldo et al. 1998):

1. Analysis of non-*ortho*-PCBs and selected mono-*ortho*-PCBs
2. Exposure studies of individual species to specific congeners alone or in combination with other compounds, including other PCB congeners, dioxins, and dibenzofurans
3. Clarification of existing structure-induction relations
4. More refined analytical techniques

Because component-based analysis of PCBs has limited the usefulness of the historical database for current environmental research and in formulation of regulatory criteria, procedures were

developed to accurately detect, speciate, and quantify mixtures of multiple Aroclors (Newman et al. 1998). Aroclor conversion factors have been calculated for 14 PCB congeners (PCBs 18, 28, 31, 99, 118, 128, 138, 149, 153, 180, 194, 195, 201, and 203), allowing quantification of PCB profiles as Aroclors 1248, 1254, and 1260 using measurements of these congeners (Newman et al. 1998).

Marked differences between species in their abilities to metabolize specific PCB congeners must be considered in toxicity testing. Foxes and dogs, for example — in contrast to monkeys and rats — can degrade the otherwise highly persistent PCB 153 because they possess an unusual cytochrome P-450 isoenzyme that metabolizes PCB 153 (Georgii et al. 1994). Also, low-chlorinated congeners that are metabolized via reactive intermediates must be critically evaluated because they show weak tumor-initiating properties (Georgii et al. 1994). Intraspecies differences are also documented. Three populations of the harbor porpoise (*Phocoena phocoena*) from Newfoundland, St. Lawrence River, and the Gulf of Maine are distinguishable based on PCB levels in blubber (Westgate and Tolley 1999).

To complement PCB chemical residue analyses, the rat hepatoma cell bioassay was useful for assessing the toxic potency of PCBs in extracts from environmental samples (Tillitt et al. 1991). This *in vitro* bioassay of cytochrome P-450IA1 catalytic activity in the H4IIE cells in response to planar halogenated hydrocarbons was considered accurate and precise. Comparison of the responses of the H4IIE cells was calibrated against their responses to 2,3,7,8-TCDD (Tillitt et al. 1991). EROD (ethoxyresorufin-*O*-deethylase) and porphyria induction measurements also potentially complement PCB chemical residue analyses and have been used to determine the toxic potencies of complex mixtures of PCBs and other halogenated aromatic hydrocarbons extracted from wildlife tissues (Kennedy et al. 1992). In one case, extracts of PCB-contaminated eggs of herring gulls (*Larus argentatus*) from the Great Lakes and of great blue herons (*Ardea herodias*) from British Columbia induced EROD and porphyria in primary cultures of chicken embryo hepatocytes (Kennedy et al. 1992). Porphyrins in feces as a nondestructive biomarker is recommended as an alternative to the traditional liver porphyrins in the hazard assessment of birds contaminated with PCBs (Fossi et al. 1996). Hepatic cytochrome P-450-associated monooxygenases and cytochrome P-450 proteins in embryos of the black-crowned night-heron (*Nycticorax nycticorax*) were associated with concentrations of total PCBs and 11 PCB congeners that express toxicity through the Ah receptor, and also should be considered as biomarkers for assessing PCB contamination of wetlands (Rattner et al. 1994). Hepatic cytochromes P-450, P-420 (degraded P-450), and mixed-function oxidases are recommended as biomarkers of PCB exposure in harbor seals (*Phoca vitulina*); total PCB burdens in both blubber and liver had positive correlations with P-450, P-420, and MFO activity levels (Troisi and Mason 1997).

The interpretation of PCB residue data is challenging from several perspectives, as judged by analysis of eggs of Forster's terns (*Sterna forsteri*) from Wisconsin (Schwartz and Stalling 1991):

1. Data from a single analysis frequently contained measurable concentrations of 100 to 150 PCB congeners.
2. A single sample was not sufficient to understand the environmental distribution of PCBs.
3. Source profiles of PCB inputs into the environment were poorly characterized.
4. PCB congeners in the original polluting material often merged with congeners from other sources.
5. The contaminant mixture may have been altered by metabolism and subsequent partition into multiple environmental compartments that may be further changed by weathering or degradation.

To understand these processes and correlate residue profiles with specific toxic responses required congener-specific methods of analysis and complex statistical techniques (principal component analysis). Using these techniques, it was established that eggs of Forster's terns of two colonies differed significantly in PCB composition (Schwartz and Stalling 1991). Similar techniques were used to identify various PCB-contaminated populations of harbor seals (*Phoca vitulina*) in Denmark (Storr-Hansen and Spliid 1993).

Selected congeners should be quantified in human foodstuffs and tissues, as determined from a survey of PCB congener frequency in commercial formulations, environmental and biological samples and human tissues, and a consideration of the relative toxicity and persistence of the congeners (Jones 1988). PCBs 28, 74, 77, 99, 105, 118, 126, 128, 138, 153, 156, 169, 170, 179, and 180 reportedly account for more than 70% of the total PCB burden in any sample and should be quantified. Additionally, PCBs 8, 37, 44, 49, 52, 60, 66, 70, 82, 87, 101, 114, 158, 166, 183, 187, and 189 should be considered for quantification because of their reported occurrence or toxicity. Some PCBs are particularly prevalent in aquatic animals, especially PCBs 95, 101, 110, 118, 138, 149, 153, 180, and 187. Also detected in aquatic biota and reported as important components were PCBs 26, 52, 66, 70, 99, 105, 132, 151, 170, 177, 201, and 206. In the Netherlands, maximum PCB limits in fishes as dietary items for human health protection are now derived from the sum of PCBs 28, 95, 101, 138, 149, 153, and 180. From a toxicological viewpoint, other congeners may be more important. These have been identified (on the basis of ability to induce AHH) as the most toxic planars (PCBs 15, 37, 77, 81, 126, and 169), the mono-*ortho*-analogues of the planar PCBs (PCBs 105, 114, 123, 156, and 189), and the di-*ortho*-analogues (PCBs 128, 138, 158, 166, and 170). Of these compounds, PCBs 37, 105, 114, 128, 138, 156, and 158 occur in human tissues, and PCBs 15, 77, 81, 123, 126, 166, and 169 do not occur (Jones 1988). In Germany, PCB congeners 49, 118, 156, and 170 are considered carcinogen initiators; these four congeners and PCBs 28, 31, 52, 101, 138, 153, and 180, are proposed as indicators of PCB contamination in that country (Bachour et al. 1998). *In vitro* studies with PCBs 138 and 169 indicate a relation between PCB structure, bioavailability, and the capacity to stimulate oncogene expression, strongly indicating the need for more research in this subject area (Gribaldo et al. 1998).

Ecological considerations in setting limits in foods for human consumption are complex. In Lake Ontario, for example, stocking rates of the alewife (*Alosa pseudoharengus*) — the main food of all Great Lakes sportfishes — necessary to achieve PCB consumption advisories of <0.5 mg total PCBs/kg FW fish muscle, carry about a 90% probability of an alewife population crash (Jackson 1977). It is postulated that increases of 25% in current stocking rates of chinook salmon would decrease PCB concentrations of chinook salmon without a large increase in the probability that the alewife population would crash. These scenarios are applicable to species of salmonids in the Great Lakes because they, too, exhibit size-selective predation and their recruitment is largely determined by stocking (Jackson 1997).

Table 24.16 Proposed PCB Criteria for the Protection of Natural Resources and Human Health

Resource, Criterion, and Other Variables	Effective Concentration	Reference ^a
AQUATIC LIFE PROTECTION		
Fish, total PCBs		
Diet	<500 µg/kg fresh weight (FW)	1
Eggs	<300 µg/kg FW	1
Whole body	<400 µg/kg FW	1
Adverse effects, total PCBs		
Invertebrates, whole	>25 mg/kg FW	8
Fish, whole	>50 mg/kg FW	8

24.7 SUMMARY

Ecological and toxicological aspects of polychlorinated biphenyls (PCBs) in the environment are reviewed, with emphasis on biologically active congeners and fish and wildlife. Subtopics include sources and uses, chemical and biochemical properties, concentrations in field collections, lethal and sublethal effects, and recommendations for the protection of sensitive resources. All production of PCBs in the United States ceased in 1977. Of the 1.2 million tons of PCBs manufactured to date, about 65% are still in use in electrical equipment and 31% in various environmental compartments, and 4% were degraded or incinerated. The 209 PCB congeners and their metabolites show wide differences in biological effects. A significant part of the toxicity associated with commercial PCB mixtures is related to the presence of about 20 planar congeners (i.e., congeners without chlorine substitution in the *ortho*-positions). Toxic planar congeners, like other PCB congeners, have been detected in virtually all analyzed samples, regardless of collection locale. Planar PCB concentrations were usually highest in samples from near urban areas and in fat and liver tissues, filter-feeding bivalve molluscs, fish-eating birds, and carnivorous marine mammals. Adverse effects of planar PCBs on growth, survival, and reproduction are highly variable because of numerous biotic and abiotic modifiers, including interaction with other chemicals. In general, embryos and juveniles were the most sensitive stages tested to planar PCBs, and the chinook salmon (*Oncorhynchus tshawytscha*), domestic chicken (*Gallus* sp.), mink (*Mustela vison*), rhesus macaque (*Macaca mulatta*), and laboratory white rat (*Rattus* sp.) were among the most sensitive species. For protection of natural resources, most authorities now recommend:

1. Analysis of environmental samples for planar and other potentially hazardous congeners
2. Exposure studies with representative species and specific congeners, alone and in combination with other environmental contaminants
3. Clarification of existing structure-induction-metabolism relations
4. More research on physiological and biochemical indicators of PCB-stress

CHAPTER 25

Polycyclic Aromatic Hydrocarbons

25.1 INTRODUCTION

Several polycyclic aromatic hydrocarbons (PAHs) are among the most potent carcinogens known to exist, producing tumors in some organisms through single exposures to microgram quantities. PAHs act at both the site of application and at organs distant to the site of absorption. Their effects have been demonstrated in nearly every tissue and species tested, regardless of the route of administration (Lee and Grant 1981; Schnitz and O'Connor 1992). The evidence implicating PAHs as an inducer of cancerous and precancerous lesions is overwhelming, and this class of substances is probably a major contributor to the increase in cancer rates reported for industrialized nations (Cooke and Dennis 1984). PAHs were the first compounds known to be associated with carcinogenesis (Lee and Grant 1981). Occupational skin cancer was first documented in London chimney sweeps in 1775 and in German coal tar workers in the late 1800s. By the early 1900s, soot, coal tar, and pitch were all found to be carcinogenic to humans. By 1918, it was shown that topical applications of coal tar produced skin tumors in mice and rabbits; benzo[*a*]pyrene, a PAH, was identified as one of the most carcinogenic compounds in coal tar (Dipple 1985). The carcinogenic activity to humans of soots, tars, and oils is beyond dispute. In addition to the skin cancers noted initially, higher incidences of respiratory tract and upper gastrointestinal tract tumors were associated with occupational exposures to these carcinogens (Dipple 1985). PAH-induced cancers in laboratory animals are well documented. Benzo[*a*]pyrene, for example, has produced tumors in mice, rats, hamsters, guinea pigs, rabbits, ducks, and monkeys following administration by oral, dermal, and intraperitoneal routes (Pucknat 1981). Teratogenic or carcinogenic responses have been induced in sponges, planarians, echinoderm larvae, teleosts, amphibians, and plants by exposure to carcinogenic PAHs (Neff 1979, 1982b; Michel et al. 1992). An unusually high prevalence of oral, dermal, and hepatic neoplasms has been observed in bottom-dwelling fish from polluted sediments containing grossly elevated PAH levels (Balch et al. 1985; Couch and Harshbarger 1985; Fabacher et al. 1991; Baumann and Harshbarger 1995). Hepatic disorders, including adenomas and carcinomas, were found in common carp (*Cyprinus carpio*) from West Point Lake in Georgia in 1991 and are linked to elevated concentrations in lake sediments (Pritchard et al. 1996). PAH compounds have damaged chromosomes in cytogenetic tests, have produced mutations in mammalian cell culture systems, and have induced DNA repair synthesis in human fibroblast cultures (U.S. Environmental Protection Agency [USEPA] 1980). While some PAHs are potent mutagens and carcinogens, others are less active or suspected carcinogens. Some, especially those of biological origin, are probably not carcinogens (Jackim and Lake 1978). Certain lower-molecular-weight, noncarcinogenic PAHs, at environmentally realistic levels, were acutely toxic to aquatic organisms, or produced deleterious sublethal responses (Neff 1985). However, few generalizations can be made about the class of PAH compounds because of the extreme variability in toxicity and physicochemical properties of PAHs and their various effects on individual species (Lee and Grant 1981).

PAHs are widely distributed in the environment and have been detected in animal and plant tissues, sediments, soils, air, surface water, drinking water, industrial effluents, ambient river water, well water, and groundwater (USEPA 1980; Schnitz and O'Connor 1992). Humans have probably always been exposed to PAHs from the natural background level in soils and plants (Harrison et al. 1975). Avoiding exposure to nanogram quantities of these substances on a daily basis is now considered essentially impossible for all living resources (Dipple 1985). Ever since benzo[a]pyrene was recognized as a carcinogen at the beginning of this century, the presence of it and of other PAHs in the environment has received continuous attention. As one consequence, many reviews have been published on ecological and toxicological aspects of PAHs in the environment, with special reference to their carcinogenic properties (Harrison et al. 1975; Barnett 1976; Suess 1976; Gelboin and Ts'o 1978a, 1978b, 1981; Jackim and Lake 1978; Jones and Freudenthal 1978; Lo and Sandi 1978; Jones and Leber 1979; Neff 1979, 1982a, 1982b, 1985; Tsang and Griffin 1979; Bjorseth and Dennis 1980; USEPA 1980; Cooke and Dennis 1981, 1983, 1984; Futoma et al. 1981; Lee and Grant 1981; Pucknat 1981; Sims and Grover 1981; Stegeman 1981; Cooke et al. 1982; Richards and Jackson 1982; Couch et al. 1983; Edwards 1983; Grimmer 1983; Quaghebeur et al. 1983; Sims and Overcash 1983; Couch and Harshbarger 1985; Harvey 1985; Johnson et al. 1985; Sugimura 1986; Eisler 1987; U.S. Public Health Service [USPHS] 1995; Hellou 1996).

25.2 ENVIRONMENTAL CHEMISTRY, SOURCES, AND FATE

25.2.1 Properties

Polycyclic aromatic hydrocarbons (PAHs), also known as polynuclear aromatic hydrocarbons (PNAs) and polycyclic organic matter (POM), are composed of hydrogen and carbon arranged in the form of two or more fused benzene rings in linear, angular, or cluster arrangements, which may or may not have substituted groups attached to one or more rings (Sims and Overcash 1983). In some cases, the newly defined substituted PAH has strikingly greater toxicological effects than does the parent compound (Cooke and Dennis 1984). The nomenclature of PAH compounds has been ambiguous in the past due to different peripheral numbering systems. The currently accepted nomenclature is shown in [Figure 25.1](#).

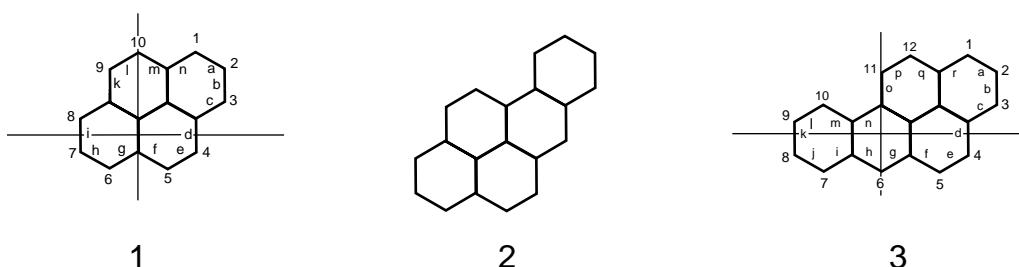

Figure 25.1 Nomenclature of PAHs. (Modified from Lee and Grant 1981; Grimmer 1983.) The PAH formula is oriented so that the greatest number of rings are in a horizontal row and a maximum number of rings are above and to the right of the horizontal row. The first carbon atom that belongs to the uppermost ring and is not engaged in ring fusion with another ring is given the number C-1; numbering continues in a clockwise direction, omitting those carbon atoms that do not carry a hydrogen atom. The bond between C-1 and C-2 is designated as side "a"; other peripheral sides continue in clockwise direction in alphabetical order. Examples are: (1) pyrene (correctly oriented, numbered, and lettered), (2) benzo[a]pyrene (not oriented correctly), and (3) benzo[a]pyrene (correctly oriented, numbered, and lettered).

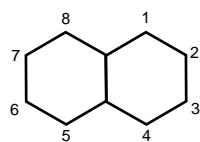

Of major environmental concern are mobile PAHs that vary in molecular weight from 128.16 (naphthalene, C₁₀H₈) to 300.36 (coronene, C₂₄H₁₂). Higher-molecular-weight PAHs are relatively immobile because of their large molecular volumes and their extremely low volatility and solubility. Among the mobile forms are thousands of compounds that differ in the number and position of aromatic rings, and in the position of substituents on the basic ring system. The lower-molecular-weight, unsubstituted PAH compounds, containing two to three rings, such as naphthalenes, fluorenes, phenanthrenes, and anthracenes ([Figure 25.2](#)), have significant acute toxicity to some organisms, whereas the higher-molecular-weight, four- to seven-ring aromatics do not. However, all known PAH carcinogens, cocarcinogens, and tumor producers are in the high-molecular-weight PAH group ([Figure 25.3](#)).

Physical and chemical characteristics of PAHs generally vary with molecular weight. With increasing molecular weight, aqueous solubility decreases, and melting point, boiling point, and the log K_{ow} (octanol/water partition coefficient) increase ([Table 25.1](#)), suggesting increased solubility in fats, a decrease in resistance to oxidation and reduction, and a decrease in vapor pressure. Accordingly, PAHs of different molecular weight vary substantially in their behavior and distribution in the environment and in their biological effects. Additional and more comprehensive data on the physical and chemical properties of PAHs are given in Barnett (1976), Lo and Sandi (1978), Neff (1979, 1985), USEPA (1980), Futoma et al. (1981), Lee and Grant (1981), Pucknat (1981), Edwards (1983), Grimmer (1983), Sims and Overcash (1983), Whitehouse (1985), and de Maagd et al. (1998). Measurements of various PAH metabolites, especially naphthalene and benzo[*a*]pyrene-type metabolites, in bile and other tissues are now conducted routinely using high-performance liquid chromatography with fixed-wavelength fluorescence (Lin et al. 1996).

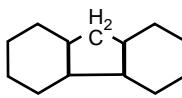

25.2.2 Sources

About 43,000 metric tons of PAHs are discharged into the atmosphere each year, and another 230,000 tons enter aquatic environments ([Table 25.2](#)). PAHs are ubiquitous in nature as a consequence of synthesis in terrestrial vegetation, microbial synthesis, and volcanic activity, but quantities formed by these natural processes are small in comparison with those produced from forest and prairie fires and anthropogenic sources (Barnett 1976; Suess 1976; Lo and Sandi 1978; Neff 1979, 1985; USEPA 1980; Lee and Grant 1981; Pucknat 1981; Edwards 1983; Grimmer 1983; Sims and Overcash 1983). Anthropogenic activities associated with significant production of PAHs include: coke production in the iron and steel industry; catalytic cracking in the petroleum industry; the manufacture of carbon black, coal tar pitch, and asphalt; heating and power generation; controlled refuse incineration; open burning; and emissions from internal combustion engines used in transportation. Thus, the formation of PAHs in the environment is due to an endogenous synthesis by microorganisms, algae, and macrophytes that provide natural background, and to a second process that is connected to human-controlled, high-temperature (>700°C) pyrolysis of organic materials, to open burning, and to natural volcanic activities. The discovery in fossil fuels of complex mixtures of PAHs spanning a wide range of molecular weights has led to the conclusion that, given sufficient time (i.e., millions of years), pyrolysis of organic materials at temperatures as low as 100 to 150°C can also lead to production of PAHs (Neff 1985).

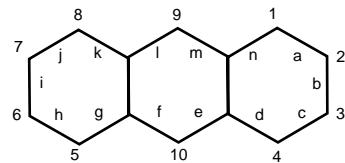

Forest and prairie fires release much greater amounts of PAHs to the atmosphere than does fossil fuel burning. Nearly all of the airborne PAHs produced by flame pyrolysis are associated with the particulate fraction produced during combustion, and these are significantly modified by the chemical composition of the fuel, the pyrolysis temperature, the duration of exposure to elevated temperature, and to other factors (Neff 1979; Edwards 1983). In one study, a PAH profile was established for a series of laboratory fires simulating the prescribed burning of pine needle litter (McMahon and Tsoukalas 1978). Heading fires (moving with wind) produced more total particulate matter than backing fires (moving against wind), but backing fires produced significantly higher amounts of PAHs, with the actual amounts formed dependent on fuel loading and the residence

Figure 25.2 Ring structures of representative noncarcinogenic PAHs. (Modified from Lee and Grant 1981; Neff 1985.) The numbering and lettering system for several PAHs is also given. Compounds are: (1) naphthalene, (2) fluorene, (3) anthracene, (4) phenanthrene, (5) aceanthrylene, (6) benzo[a]-fluorene, (7) benzo[a]-phenanthrene, (8) benzo[a]-anthracene, (9) fluoranthene, (10) naphthacene, (11) pyrene, (12) benzo[a]-naphthacene, (13) benzo[g,h,i]fluoranthene, (14) perylene, (15) benzo[e]pyrene, (16) benzo[g,h,i]perylene, (17) anthanthrene, and (18) coronene.

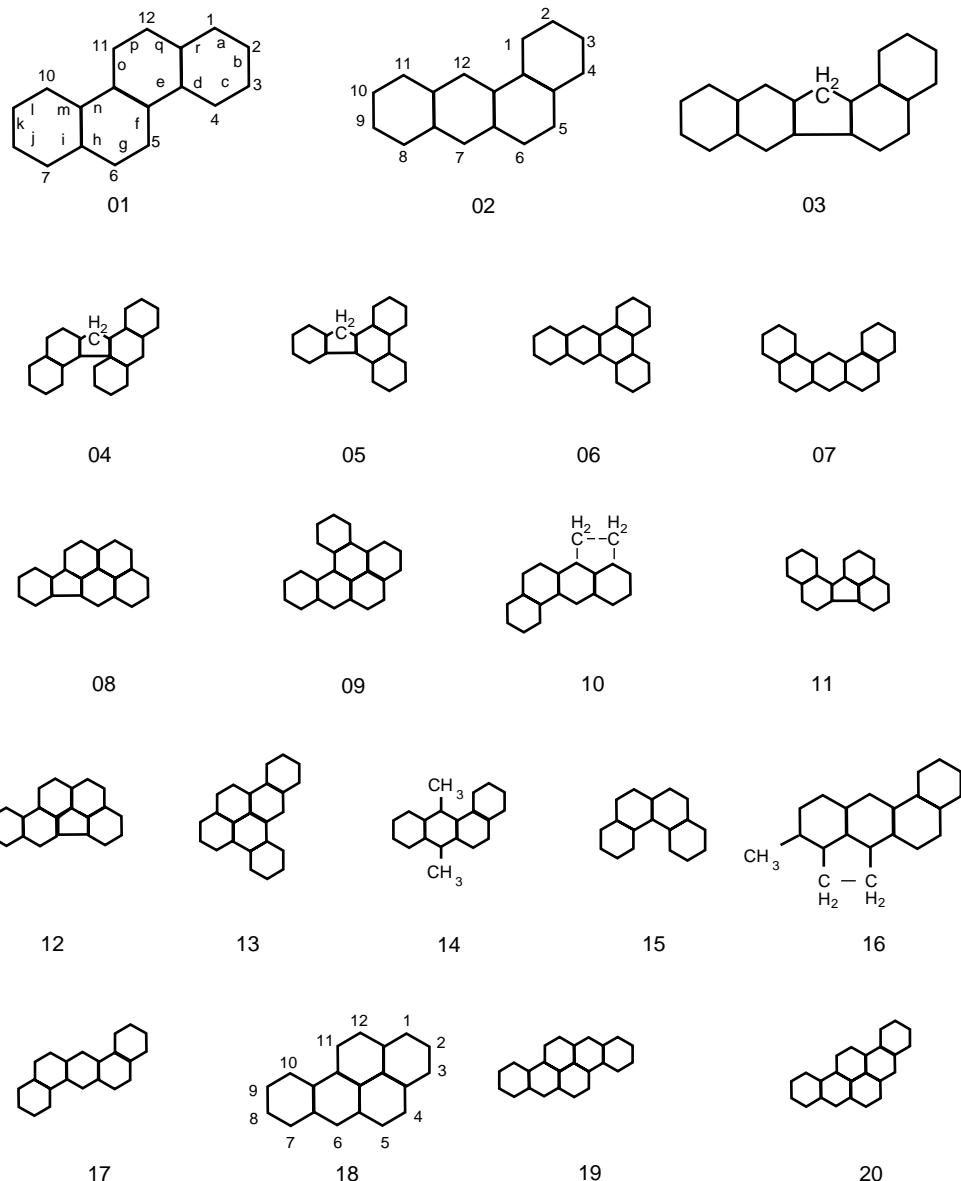

Figure 25.3 Ring structures of representative tumorigenic, cocarcinogenic, and carcinogenic PAHs. (Modified from Lee and Grant 1981.) The numbering and lettering system for several PAHs is also given. Compounds are: (1) chrysene, (2) benz[a]anthracene, (3) dibenz[a,h]fluorene, (4) dibenz[a,g]fluorene, (5) dibenzo[a,c]fluorene, (6) dibenzo[a,j]anthracene, (7) dibenzo[a,j]anthracene, (8) indeno [1,2,3-cd] pyrene, (9) dibenzo[a,1]pyrene, (10) cholanthrene, (11) benzo[j]fluoranthene, (12) benzo[b]fluoranthene, (13) dibenzo[a,e]pyrene, (14) dimethylbenz[a]anthracene, (15) benzo[c]phenanthrene, (16) 3-methylcholanthrene, (17) dibenz[a,h]anthracene, (18) benzo[a]pyrene, (19) dibenzo[a,h]pyrene, (20) dibenzo[a,i]pyrene. Compounds 1 to 9 are weakly carcinogenic, cocarcinogenic, or tumorigenic; compounds 10 to 13 are carcinogenic; and compounds 14 to 20 are strongly carcinogenic.

time of combustible gases in the burning zone. Emission factors for benzo[a]pyrene varied from 238 to 3454 µg/kg in backing fires and 38 to 97 µg/kg in heading fires.

PAHs present in the atmosphere enter rain as a result of in-cloud and below-cloud scavenging (van Noort and Wondergem 1985). Total PAHs deposited on land and water are almost equivalent

Table 25.1 Some Physical and Chemical Properties of Selected PAHs

Compound	Number of Rings	Approximate Molecular Weight	Melting Point (°C)	Solubility in Water (mg/L)	Log K _{ow}
Naphthalene	2	128	80	30.0	3.37
Anthracene	3	178	216	0.07	4.45
Benz[a]anthracene	4	228	158	0.014	5.61
Benz[a]pyrene	5	252	179	0.0038	6.04
Benz[g,h,i]perylene	6	276	222	0.00026	7.23

to PAH content in rainfall. Significant quantities of PAHs are found in presumed pollution-free areas, indicating the importance of rain in transport and distribution of PAHs (Quaghebeur et al. 1983).

PAHs may reach aquatic environments in domestic and industrial sewage effluents, in surface runoff from land, from deposition of airborne particulates, and especially from spillage of petroleum and petroleum products into water bodies (Jackim and Lake 1978; Lake et al. 1979; Neff 1979; USEPA 1980; Martens 1982; Boehm and Farrington 1984; Hoffman et al. 1984; Prahl et al. 1984; von Hofe and Puffer 1986). The majority of PAHs entering aquatic environments remains close to sites of deposition, suggesting that lakes, rivers, estuaries, and coastal marine environments near centers of human populations are the primary repositories of aquatic PAHs (Neff 1979). Large variations in aquatic PAH contents were evident due to localized source inputs and physicochemical conditions. For example, urban runoff from stormwater and highways to Narragansett Bay, Rhode Island, accounted for 71% of the total inputs for higher-molecular-weight PAHs, and 36% of the total PAHs (Hoffman et al. 1984). More than 30% of all combustion-derived PAHs in coastal sediments of Washington state is supplied by riverine transport of suspended particulate materials, while direct atmospheric input accounts for a maximum of 10% (Prahl et al. 1984). In contrast, concentrations of PAHs in sediments from the vicinity of Georges Bank, off the U.S. northeastern coast, varied from 1 to 100 µg/kg dry weight, and were directly related to total organic carbon, silt, and clay contents in sediments. Combustion-derived PAHs dominated at the higher concentrations, while lower levels were often associated with a fossil fuel origin (Boehm and Farrington 1984).

Human activities have resulted in exposure of Antarctic fishes to petroleum-derived PAHs (McDonald et al. 1992). Fish captured near Palmer station on the Antarctic peninsula had induced EROD activities and elevated concentrations of biliary PAH metabolites of phenanthrene and naphthalene when compared to conspecifics from reference sites (McDonald et al. 1995). Artificial reefs consisting of oil and coal flyash stabilized with cement and lime in Florida waters near Vero Beach contained elevated PAH levels ranging from as high as 1.2 mg fluoranthene/kg and 0.25 mg naphthalene/kg. But there is negligible leaching because seawater is not an effective medium for removing PAHs from reef bricks or the ash (Frease and Windsor 1991).

Discharge water from hydrostatic testing of natural gas pipelines is a significant source of PAH loading into aquatic environments, contributing as much as 32,000 µg PAHs/L of discharge water, mostly as naphthalenes (Eiceman et al. 1984). More than 25 PAHs, primarily anthracenes and pyrenes, were detected in pipeline residues on inner walls of natural gas pipelines at concentrations up to 2400 µg/m² of inner surface; the same compounds may be reasonably expected in aqueous waste from pipeline maintenance (Eiceman et al. 1985). Release of these, or similar, discharge waters directly into aquatic environments will result in contamination similar to that caused by oil spills. However, these sites for pollution may occur in locations far distant from oil production and refinery activities (Eiceman et al. 1984). PAHs are also present in tap water at concentrations of 0.1 to 1.0 ng/L, primarily as mono- and di-chlorinated derivatives of naphthalene, phenanthrene, fluorene, and fluoranthene (Shiraishi et al. 1985). The presence of PAHs and chlorinated PAHs in tap water indicates the reaction of PAHs with chlorine; however, their significance to human health and to aquatic biota is unknown.

Creosote (about 85% PAHs) has been used extensively as a long-term wood preservative for marine and freshwater support structures such as pilings, railway ties, and utility poles (Bestari et al. 1998b). About 75% of the creosote applied to marine pilings will remain in the wood after 40 years of service. Most of the PAHs leached into water from creosote-treated pilings is rapidly lost owing to volatility, photodegradation, and microbial degradation pathways (Bestari et al. 1998b).

Table 25.2 Major Sources of PAHs in Atmospheric and Aquatic Environments

Ecosystem and Sources	Annual Input (metric tons)

25.2.3 Fate

Concern about PAHs in the environment is due to their persistence and to the fact that some are known to be potent mammalian carcinogens, although environmental effects of most noncarcinogenic PAHs are poorly understood (Neff 1985). Prior to 1900, a natural balance existed between the production and degradation of PAHs. Synthesis of PAHs by microorganisms and volcanic activity and production by man-made, high-temperature pyrolytic reactions and open burning seemed to be balanced by PAH destruction via photodegradation and microbial transformation. With increased industrial development and increased emphasis of fossil fuels as energy sources, the balance has been disturbed to the extent that PAH production and introduction into the environment greatly exceeds known PAH removal processes (Suess 1976; Sims and Overcash 1983). Mass balance models that quantitatively estimate PAH cycling in various aquatic systems seem

promising. In one case, a steady-state model for naphthalene, phenanthrene, and benzo[*a*]pyrene in Saguenay Fjord, in Quebec, has been constructed incorporating atmospheric and industrial sources, and transport and transformation rates (Lun et al. 1998). More research on mass balance models is needed.

When released into the atmosphere, PAH compounds will become associated with particulate materials. Their residence time in the atmosphere and transport to different geographic locations are governed by particle size, meteorological conditions, and atmospheric physics. The highly reactive PAHs photodecompose readily in the atmosphere by reaction with ozone and various oxidants; degradation times range from several days to 6 weeks for PAHs adsorbed onto particulates <1 µm in diameter (in the absence of rainfall), to <1 day to several days for those adsorbed to larger particles (Suess 1976). Smaller atmospheric particulates containing PAHs are easily inhaled (Lee and Grant 1981), and may pose special problems, as yet unevaluated, for airborne organisms such as birds, insects, and bats. Photooxidation, one of the most important processes in the removal of PAHs from the atmosphere, can also produce reaction products that are carcinogenic or mutagenic, although little is known of their persistence (Edwards 1983). One of the more common photooxidation reactions of PAHs is the formation of endoperoxides that ultimately undergo a series of reactions to form quinones (Edwards 1983). Various parameters may modify chemical and photochemical transformation of PAHs in the atmosphere, including light intensity, concentration of gaseous pollutants (O_3 , NO_x , SO_x), and chemicophysical characteristics of particulates or substrates into which the PAHs are adsorbed. Depending on these variables, the half-life of benzo[*a*]pyrene in the atmosphere varies from 10 min to 72 days (Valerio et al. 1984). Atmospheric PAHs are transported over relatively long distances from industrial areas and from natural forest and prairie fires (Edwards 1983). However, sites nearer urban centers have much higher PAH deposition rates than more rural areas (Hites and Gschwend 1982).

Much of the PAHs released into the atmosphere eventually reaches the soil by direct deposition or by deposition on vegetation (Edwards 1983). In soils, adsorption of naphthalene mainly occurs on the organic matter and is not related to the size of the soil particles (Bayard et al. 1998). The PAHs may be adsorbed or assimilated by plant leaves before entering the animal food chain, although some adsorbed PAHs may be washed off by rain, chemically oxidized to other products, or returned to the soil as the plants decay (Edwards 1983). PAHs assimilated by vegetation may be translocated, metabolized, and possibly photodegraded within the plant. In some plants growing in highly contaminated areas, assimilation may exceed metabolism and degradation, resulting in an accumulation in plant tissues (Edwards 1983).

In water, PAHs may either evaporate, disperse into the water column, become incorporated into bottom sediments, concentrate in aquatic biota, or experience chemical oxidation and biodegradation (Suess 1976). The most important degradation processes for PAHs in aquatic systems are photooxidation, chemical oxidation, and biological transformation by bacteria and animals (Neff 1979). Most PAHs in aquatic environments are associated with particulate materials; only about 33% are present in dissolved form (Lee and Grant 1981). PAHs dissolved in the water column will probably degrade rapidly through photooxidation (USEPA 1980) and degrade most rapidly at higher concentrations, at elevated temperatures, at elevated oxygen levels, and at higher incidences of solar radiation (McGinnes and Snoeyink 1974; Suess 1976; Bauer and Capone 1985). Microcosm studies with creosote-associated PAHs showed that initial concentrations of 7 µg total PAHs/L degraded to 0.8 µg/L in 84 days, and 5803 µg/L to 14 µg/L in the same time frame (Bestari et al. 1998a). Low- and high-molecular-weight PAHs were lost first from the water column followed by PAHs of intermediate molecular weight (i.e., those with four to five aromatic rings). The half-time persistence in water of most PAHs in that study was about 1 week. In sediments, PAHs peaked at about 8 weeks, with little degradation during the next 6 weeks (Bestari et al. 1998a).

The ultimate fate of those PAHs that accumulate in sediments is believed to be biotransformation and biodegradation by benthic organisms (USEPA 1980). PAHs in aquatic sediments, however, degrade very slowly in the absence of penetrating radiation and oxygen (Suess 1976), and may

persist indefinitely in oxygen-poor basins or in anoxic sediments (Neff 1979). Persistence of phenanthrene and naphthalene is high in Cook Inlet, Alaska, where the sediments are organic rich and contain low numbers of microbial degraders (Braddock and Richter 1998). Carroquino and Alexander (1998) aver that the presence of microorganisms accelerates degradation of phenanthrene and other PAHs and is a better predictor of maximum biodegradation rate than media without microorganisms. PAH degradation in aquatic environments occurs at a slower rate than that in the atmosphere (Suess 1976), and the cycling of PAHs in aquatic environments, as is true for other ecological systems, is poorly understood (Neff 1979). Degradation rates of fluoranthene and other PAHs are dependent on the presence of sediments and other PAHs (Beckles et al. 1998). In sediment-free systems, fluoranthene biodegradation did not occur when it was present alone or in combination with acenaphthene, but was degraded when combined with naphthalene. Naphthalene and acenaphthene degradations were not influenced by fluoranthene. In sediment-containing systems, fluoranthene degradation occurred only in the presence of naphthalene. After complete degradation of naphthalene, fluoranthene degradation ceased (Beckles et al. 1998).

Animals and microorganisms can metabolize PAHs to products that may ultimately experience complete degradation. The degradation of most PAHs is not completely understood. Those in the soil may be assimilated by plants, degraded by soil microorganisms, or accumulated to relatively high levels in the soil. High PAH concentrations in soil can lead to increased populations of microorganisms capable of degrading the compounds. Of equal importance to PAH cycling dynamics is the physical state of the PAH (i.e., whether in vapor phase or associated with particles such as flyash). Particles may increase or decrease the susceptibility of PAHs to degradation, depending on the PAH and particles involved (Edwards 1983).

PAHs can be taken into the mammalian body by inhalation, skin contact, or ingestion, although they are poorly absorbed from the gastrointestinal tract. The main routes of elimination of PAHs and their metabolites include the hepatobiliary system and the gastrointestinal tract (Sims and Overcash 1983; Batel et al. 1985). In mammals, an enzyme system variously known as the cytochrome P-450-dependent mixed-function oxidase, mixed-function oxidase, mixed-function oxygenase, aryl hydrocarbon hydroxylase, or drug metabolizing system is responsible for initiating the metabolism of various lipophilic organic compounds, including PAHs. The primary function of this system is to render poorly water-soluble lipophilic materials more water soluble, and therefore more available for excretion. Some PAHs are transformed to intermediates, which are highly toxic, mutagenic, or carcinogenic to the host. Oxidative metabolism of PAHs in this system proceeds via high electrophilic intermediate arene oxides, some of which bind covalently to cellular macromolecules such as DNA, RNA, and protein. Most authorities agree that metabolic activation by the mixed-function oxidase system is a necessary prerequisite for PAH-induced carcinogenesis and mutagenesis (Neff 1979; Johnson 1993). This enzyme system is known to be present in rodent tissues, and human liver, skin, placenta, fetal liver, macrophages, lymphocytes, and monocytes (Lo and Sandi 1978; Yu et al. 1995). Studies with rodents have shown that the mixed-function oxidase system can convert PAHs to various hydroxylated derivatives, including phenols, quinones, and epoxides, and can also activate PAHs to produce carcinogenic metabolites (Lo and Sandi 1978). Oxygenated groups of xenobiotics are then conjugated with glutathione-S-transferase and other transferase enzymes. The resulting polar and water-soluble end product is excreted via the bile or urine (Arinc and Sen 1994). Fish and most crustaceans tested to date possess the enzymes necessary for activation (Statham et al. 1976; Varanasi et al. 1980; Fabacher and Baumann 1985), but some molluscs and other invertebrates are unable to efficiently metabolize PAHs (Jackim and Lake 1978; Varanasi et al. 1985). Although many aquatic organisms possess the requisite enzyme systems for metabolic activation of PAHs, it is not certain in many cases whether these enzymes produce the same metabolites as those produced by mammalian enzymes (Neff 1979).

Virtually all organisms possess biotransformation or detoxification enzymes that convert lipophilic xenobiotics to water-soluble and excretable metabolites (Yu et al. 1995). In the metabolic process, PAHs are altered by Phase I metabolism into various products such as epoxides, phenols,

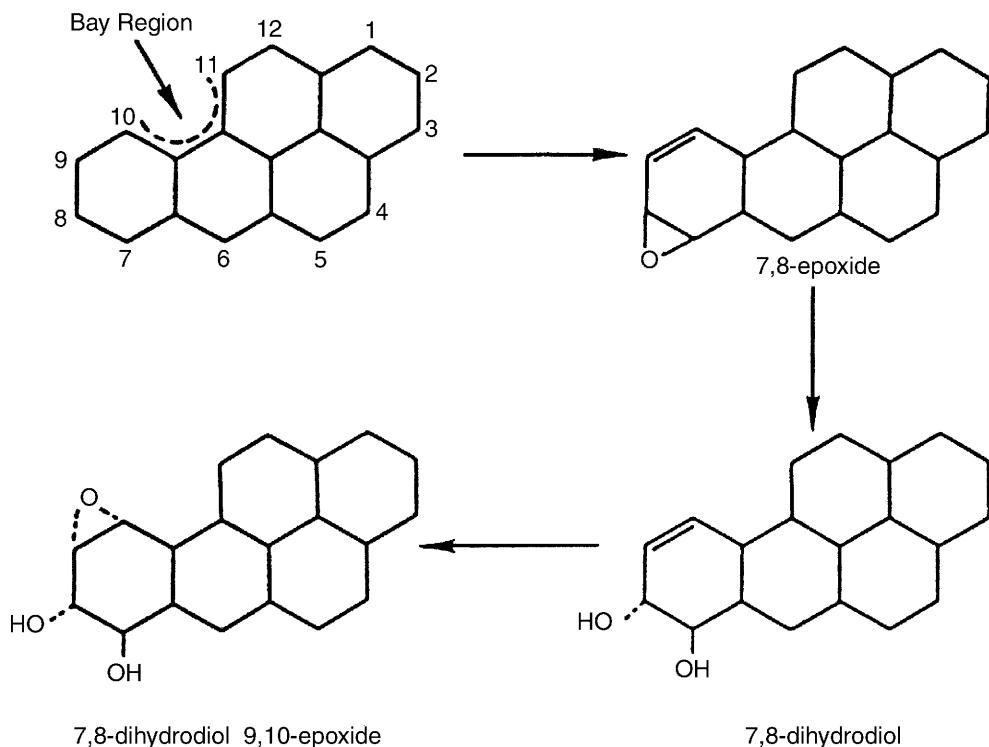

Figure 25.4 The bay region dihydrodiol epoxide route of benzo[a]pyrene. (Modified from Dipple, A. 1985. Polycyclic aromatic hydrocarbon carcinogenesis: an introduction. Pages 1-17 in R.D. Harvey (ed.), *Polycyclic Hydrocarbons and Carcinogenesis*. ACS Symp. Ser. 283. Amer. Chem. Soc., Washington, D.C.)

quinones, dihydrodiols, dihydrodiol epoxides, tetrahydrotriols, and tetrahydrotetrols. The intermediate metabolites have been identified as the mutagenic, carcinogenic, and teratogenic agents (Sims and Overcash 1983). The activation mechanisms occur by hydroxylation or production of unstable epoxides of PAHs which damage DNA, initiating the carcinogenic process (Jackim and Lake 1978; Schnitz and O'Connor 1992). Metabolic formation of bay region diol epoxides represents an important pathway by which PAHs are activated to carcinogens (Figure 25.4). Such metabolic activation proceeds via initial formation of the dihydrodiol with the bay region double bond, followed by subsequent oxidation of the dihydrodiol to the bay region diol epoxide (Sims and Overcash 1983). Active epoxides may be converted to less toxic products by various enzymatic and other reactions (Neff 1979). In the case of benzo[a]pyrene, the “ultimate carcinogen” (7-beta,8-alpha-dihydroxy-7,8,9,10-tetrahydrobenzo[a]pyrene-9-alpha,10-alpha-epoxide) reacts with the guanine of RNA and DNA, the linkage taking place between the C-10 atom of benzo[a]pyrene and the C-2 amino group of guanine (Grimmer 1983; Dipple 1985; Fernandez and L'Haridon 1994) (Figure 25.4). Additional information on actual and theoretical mechanisms involved in the metabolic activation of PAHs is given in Cavalieri et al. (1978, 1980), Bjorseth and Dennis (1980), Herd and Greene (1980), Cooke and Dennis (1981), Sims and Grover (1981), Grimmer (1983), Szentpaly (1984), Harvey (1985), Yan (1985), Steward et al. (1990, 1991), Collier and Varanasi (1991), McElroy et al. (1991), Sikka et al. (1991), Michel et al. (1992), Schnitz and O'Connor (1992), Lemaire et al. (1994), and Ueng et al. (1994). In Phase II metabolism, these products are converted into highly water-soluble conjugates with a large water-soluble moiety, such as the tripeptide glutathione or sugar derivative glucuronic acid (Kennedy 1990; Yu et al. 1995).

There is considerable variability between species in their ability to metabolize benzo[a]pyrene (BaP). For example, two bottom-dwelling species of fish (common carp, *Cyprinus carpio*; brown bullhead, *Ictalurus nebulosus*) differ by a factor of about 12 in the rate at which liver microsomes degrade BaP to metabolites, with carp degrading BaP more rapidly (Sikka et al. 1990). Major BaP metabolites from both species included BaP-7,8-diol, BaP-8,9-diol, 3-hydroxy-BaP, 9-hydroxy-BaP, BaP-1,6-quinone, BaP-3,6-quinone, and BaP-6,12-quinone. Carp liver microsomes converted a much greater proportion of BaP to benzo-ring dihydriodols than did bullhead liver microsome; bullhead liver microsomes formed a significantly higher percentage of BaP-quinones (Sikka et al. 1990). In other species, glutathione conjugation represented the major hepatic detoxification pathway of benzo[a]pyrene, as was the case for white suckers (*Catostomus commersonii*) (Kirby et al. 1990).

25.3 CONCENTRATIONS IN FIELD COLLECTIONS

25.3.1 General

PAHs are ubiquitous in the environment. In nonbiological materials, concentrations are elevated in the vicinity of urban industrialized locales, and from areas of significant wood-burning activities such as forest fires and residential home heating. Terrestrial vegetation and aquatic invertebrates can accumulate significant concentrations of PAHs, possibly due to inefficient or missing mixed-function oxidase systems. Fish do not appear to contain grossly elevated PAH residues. This may be related to their efficient degradation system. At present, data are scarce on PAH background concentrations in natural populations of birds and other wildlife — although it seems unlikely that significant accumulations will occur. Some investigators have shown that aquatic invertebrates, fish, and amphibians collected from areas of high sediment PAH content show elevated frequencies of hyperplasia and neoplasia (Rose 1977; Mix 1982; Black 1983; Malins et al. 1984, 1985a, 1985b; Black et al. 1985; Baumann et al. 1987; Baumann and Whittle 1988), and that hepatic carcinoma has been induced in rainbow trout (*Oncorhynchus mykiss*) by benzo[a]pyrene through dietary and intraperitoneal injection routes (Hendricks et al. 1985).

More comprehensive information on PAH background levels in various biological and nonbiological compartments is given in Lo and Sandi (1978), Neff (1979, 1985), Pucknat (1981), Edwards (1983), Grimmer (1983), and Sims and Overcash (1983).

25.3.2 Nonbiological Samples

Total PAH levels in air are usually much higher in winter than in summer, higher in urban communities than in rural areas (Table 25.3) (Grimmer 1983), and appear to be related primarily to the weight of total suspended particulates in the atmosphere (Hites and Gschwend 1982; Greenberg et al. 1985; Srivastava et al. 1985; Ang et al. 1986). PAH levels in precipitation are significantly higher in winter than in summer, primarily due to emissions from household heating (Quaghebeur et al. 1983; van Noort and Wondergem 1985). Among industrial sources, the production of metallurgical coke is the single most significant source of atmospheric PAHs in Ontario, Canada. Coke production in 1977 represented about 52% of all PAH emissions from Ontario sources versus about 46% formed as a result of forest fires (Potvin et al. 1981). Beyond 2 km distant from the coke point source, PAH concentrations in air were typical of those measured in major urban nonindustrialized areas (Table 25.3) (Potvin et al. 1981). A variety of PAHs have been detected in ambient air in the United States and elsewhere. Benzo[a]pyrene (BaP), because of its carcinogenic properties, has been monitored extensively, and has frequently been used as an indicator of PAHs (USEPA 1980). In general, total PAHs in air are about 10 times higher than BaP levels, although this relation is extremely variable (Lee and Grant 1981). BaP levels, like total PAHs, were higher in winter than

summer, probably due to residential and industrial heating; air levels in urban areas with coke ovens were 40 to 70% higher than in cities without coke ovens, but this may be related to higher industrial emissions in those cities (Lee and Grant 1981). In one case, BaP levels in air from the center of a remote mountain community in Colorado were several times higher than those usually found in U.S. metropolitan areas and was attributed to extensive residential wood burning (Murphy et al. 1982). Average concentrations of BaP in urban air nationwide declined from 3.2 ng/m³ in 1966 to 0.5 ng/m³ in 1978, an 80% decrease (Lee and Grant 1981). These decreases are believed to be due primarily to decreases in coal consumption for commercial and residential heating, improved disposal of solid wastes, and restrictions on open burning (USEPA 1980).

A major source of PAHs in soils and soil litter is from emissions and deposition from forest fires. In a controlled burn study, Sullivan and Mix (1985) showed that lower-molecular-weight PAHs, such as phenanthrene and fluorene, which had been deposited in soil litter, degraded to nondetectable levels within 2 years after burning. Higher-molecular-weight PAHs, such as benzo[k]fluorene, benzo[a]pyrene, benzo[g,h,i]perylene, perylene, and indeno[1,2,3-cd]pyrene, were more persistent in litter, decreasing after 5 years to about 20% of initial deposition. Although movement into the top 2 cm of the soil profile was initially more pronounced for lower-molecular-weight PAHs, all compounds appeared to reach equilibrium between litter and soil on the basis of organic content within 1 year postburn. Differential persistence and fate of PAHs on slash burn sites is explained by solubility, K_{ow}, and other physicochemical properties (Sullivan and Mix 1985). PAHs from vehicle emissions constitute a minor, but measurable, source of soil PAHs (Table 25.3). The majority of highway-derived PAHs appears to be deposited within 3.8 m of the road, but the influence of the highway may extend to nearly 70 m (Johnston and Harrison 1984). The use of composted municipal wastes for conditioning agricultural soils is not recommended, as these contain at least nine identified carcinogenic PAHs (Martens 1982).

PAH-contaminated sediments are involved in epizootics of neoplasms in native fishes at contaminated sites (Fabacher et al. 1991), and other adverse biological effects. In the Detroit River, Michigan, brown bullheads (*Ameiurus nebulosus*) from sediments with the highest PAH concentration of 346 mg/kg DW had the highest prevalence of external abnormalities (lip and skin lesions, truncated barbels) and liver lesions, and these were positively correlated with concentrations of total PAHs in the sediments (Leadley et al. 1998). In the Black River, Ohio, between 1980 and 1982, PAH concentrations declined by 65% and in tissues of brown bullheads by 93%. By 1987, sediment PAHs declined an additional 99%, coincident with closure of a coking facility in 1983. Liver cancer frequency in 3- to 4-year-old bullheads declined to 10% frequency in 1987 vs. 39% frequency in 1982; livers without lesions increased from 20% frequency in 1982 to 42% in 1987 (Baumann and Harshbarger 1995). Sediments and sediment extracts from the Buffalo River, New York, contained elevated levels of carcinogenic PAHs (1000 to 16,000 µg/kg). Brown bullheads, in response to repeated applications of Buffalo River sediment extracts, showed epidermal hyperplasia and neoplasia when compared to controls (Black 1983). Extraction of PAHs from industrially contaminated sediments of Lake Erie and its tributaries (27,000 to 363,000 mg/kg dry weight total PAHs) established the presence of chemical mutagens that could be correlated with neoplasms in fish from many of the sites (Fabacher et al. 1988). In the Netherlands, high-molecular-weight PAHs dominated in the sediments, fluoranthene and pyrene in freshwater isopods, and naphthalene in water. Lipid-based bioconcentration factors increased with increasing hydrophobicity, that is, with increasing K_{ow} (van Hottum et al. 1998). Elevated PAH concentrations in sediments from the North Sea were positively correlated with increasing DNA breaks in the pyloric caeca of resident starfish (*Asterias rubens*) (Everaarts et al. 1994). PAH concentrations in sediments from the Great Barrier Reef, Australia, were always <0.8 µg/kg dry weight, except in small areas close to sites frequently visited by power boats. In those instances, total PAH levels exceeded 13,400 µg/kg (Smith et al. 1985). Highest PAH levels measured in sediments of Cayuga Lake, New York, were found in

marinas or areas of the lake receiving urban runoff, and were apparently not related to stack emissions from a nearby coal-fired power plant; Heit (1985) believed that stack emissions were either masked by other sources or were atmospherically transported and deposited elsewhere. Coastal and offshore sediments are subject to highly elevated PAH levels from a variety of sources, mostly unknown, relative to preindustrial times (Johnson et al. 1985). For example, PAH levels in sediments of Penobscot Bay, Maine, fell within the range found in sediments near industrialized regions and were significantly higher than expected for an area previously considered to be uncontaminated (Table 25.3) (Johnson et al. 1985).

Sewage effluents usually contained measurable levels of PAHs, although extreme variability between and among sites is common. During a heavy storm, individual PAH levels in a sewage works may increase more than 100 times over a dry weather period (Harrison et al. 1975). Conventional sewage treatment plant processes remove up to 90% of carcinogenic PAHs, and this may be increased to 99% using percolating filters and activated sludge processes (Harrison et al. 1975). Tiger salamanders (*Ambystoma tigrinum*), collected in 1975 from a 13-ha sewage effluent lagoon at Reese Air Force Base, Texas, showed a remarkably high incidence (53%) of neoplastic and other lesions (Rose 1977). Analysis of sludge composites showed elevated PAH levels, especially perylene; levels of organochlorine and organophosphorus pesticides, nitrosamines, and heavy metals were judged to be nonelevated (Rose 1977). Careful disposal of used motor oils is warranted, as these contain high quantities of mutagenic and carcinogenic PAHs (Table 25.3) (Pasquini and Monarca 1983).

All but the most heavily contaminated fresh and marine waters contain total PAH concentrations in the part-per-trillion or low part-per-billion range (Table 25.3) (Neff 1982b). A large proportion of the PAH content in water is probably adsorbed onto suspended solids (Harrison et al. 1975). In Lake Michigan, concentrations of total PAHs in the surface microlayer varied from 0.15 to 0.45 µg/L, representing on a relative scale, 106 times the concentration in air, suggesting that aerosols are a major source of these compounds and that the microlayer is a repository until the PAHs are removed by adsorption and sedimentation (Strand and Andren 1980).

25.3.3 Biological Samples

Carcinogenic PAHs have been extracted from a large variety of fresh plants, including root and leaf vegetables, fruits, grains, and edible mushrooms, as well as from various marine bacteria and phytoplankton under circumstances suggesting that PAHs were present due to local biosynthesis (Suess 1976). PAH concentrations in terrestrial vegetation were lower at higher altitudes and higher near highways when compared to conspecifics from lower altitudes and further from the highway (Lodovici and Akpan 1997). Vegetation and soil near known PAH sources are more highly contaminated with PAHs than those collected at greater distances (Edwards 1983). PAH levels in lettuce (*Lactuca sativa*) grown in Sweden seemed to be directly related to its proximity to local recognized point sources of PAH emitters (Table 25.4; Larsson and Sahlberg 1982). Washing lettuce with water had little effect on phenanthrene levels, but significantly reduced other PAHs, such as benzo[*a*]pyrene, benz[*a*]anthracene, and benzo[*g,h,i*]perylene by 68 to 87% (Larsson and Sahlberg 1982). Fruits and vegetables grown in polluted atmospheres may contain up to 100-fold higher levels of total PAHs than those grown in unpolluted environments (USEPA 1980; Lee and Grant 1981). PAH concentrations for plants are generally greater on plant surfaces than in internal tissues, greater in above-ground plant parts than those below ground, and greater in plants with broad leaves (greater surface area) than those with narrow leaves (Edwards 1983). Plants can become contaminated with PAHs through environmental pollution, particularly through deposition from the atmosphere, and also through food processing. For example, the bran portion of milled wheat, as well

as finished bran cereal, had a considerably higher PAH content than other fractions or finished products (Lawrence and Weber 1984b). Enrichment of PAHs in plants is associated with deposition of atmospheric particulate matter with relatively small particle sizes; thus, PAH content is usually in the order of humus > mosses > lichens (Thomas et al. 1984). Mosses appear to be good indicators of regional PAH air pollution and have been recommended for this purpose (Herrmann and Hubner 1984). Concentrations of total PAHs in soils, usually the sum of 5 to 20 PAHs, typically exceeded benzo[a]pyrene levels by at least one order of magnitude; however, concentrations of benzo[a]pyrene in vegetation were generally less than those in soil where plants were growing (Edwards 1983).

PAH accumulations in marine molluscs have been reported (Table 25.4). However, some of these data may be misleadingly low. For example, lengthy cold storage of 10 months can result in loss of volatile PAHs, such as anthracene, in tissues of mussels (Smith et al. 1984); accordingly, background concentrations in these organisms may be underreported. Bivalve molluscs tend to accumulate high PAH levels due to their inability to metabolize and excrete them (Lawrence and Weber 1984a), presumably due to inefficient or missing mixed-function oxidase systems (Sirota and Uthe 1981). Cellular proliferative disorders, resembling neoplastic conditions in vertebrates, were found in mussels with the greatest PAH concentrations: 9.5% vs. 0.7% in control site (Mix 1982). Baseline levels of PAHs in indigenous bivalve molluscs reflected the degree of human onshore activity at the various sample sites, and presumably the level of water contamination; however, little relation was evident between accumulated levels of individual PAHs and total PAHs (Mix 1982). Elevated PAH concentrations, especially benz[a]anthracene, chrysene, fluorene, phenanthrene, and pyrene in oyster tissues and sediments were measured in samples from the vicinity of marinas and were higher in oysters in cooler months when lipids and glycogen were being stored preparatory to spawning (Marcus and Stokes 1985). In general, PAH concentrations in marine clams and mussels were highest in areas adjacent to industrialized bayfronts and lowest in more remote areas; higher in larger animals and in those with higher lipid concentrations; and lowest in autumn–winter, and highest during spring–summer (Mix and Schaffer 1983a; Hellou 1996). A similar pattern was observed in mussels, *Mytilus edulis*, with the more water-soluble, lower-molecular-weight PAHs bioconcentrated 10 to 100 times above that of the higher-molecular-weight, less water-soluble PAHs (Mix and Schaffer 1983b; Baumard et al. 1998). PAH levels in mussels seemed to be independent of water salinity (Mix and Schaffer 1979). Clams contaminated with PAHs and removed to clean seawater for 24 h showed significant depuration of unsubstituted 3- and 4-ring PAHs. In contrast, concentrations of all 5-, 6-, and 7-ring compounds, which includes most of the carcinogenic PAHs, were not significantly depurated (Mix 1982). A positive relation exists between PAH isomers in sediments, soft tissues of the mussel *Mytilus edulis*, and a seaweed (*Fucus* sp.) collected at Vancouver, British Columbia (Dunn 1980). For mussels, the general trend toward lower levels of higher-molecular-weight PAHs relative to levels in sediments suggests an uptake mechanism that involves the solution of PAHs in water; superimposed on this pattern is the more rapid turnover and shorter half-life of lower-molecular-weight PAHs in mussels (Dunn 1980; Baumard et al. 1998).

PAH residues were higher than expected in American lobsters (*Homarus americanus*) collected offshore (mean weight 3.6 kg) when compared to smaller (0.6 kg) lobsters collected inshore (Sirota and Uthe 1981), suggesting that age or body size are important modifiers in PAH accumulation dynamics. PAH concentrations in sediments collected near a coking facility in Nova Scotia in 1980 contained up to 2830 mg/kg dry weight, or more than 20 times the levels recorded in Boston (MA) Harbor; concentrations in excess of 100 mg/kg dry weight sediment were recorded for phenanthrene, fluorene, pyrene, benz[a]anthracene, chrysene, benzo[e]pyrene, benzo[b]fluoranthene, and benzo[a]pyrene, and these seemed to reflect the elevated tissue levels in American lobsters collected from that locale (Sirota et al. 1983). PAH residues in digestive glands of American lobsters collected in 1979 in Nova Scotia from the vicinity of a major oil spill were higher than those from coastal

control sites; however, PAH contents of edible muscle from control and oiled lobsters were similar (Sirota and Uthe 1981).

PAH levels in fish are usually low because this group rapidly metabolizes PAHs (Lawrence and Weber 1984a; Lemaire et al. 1990, 1992b; van der Weiden et al. 1994). Furthermore, higher-molecular-weight PAHs, which include the largest class of chemical carcinogens, do not seem to accumulate in fish (West et al. 1984). Tissue lipid concentration was the primary factor in determining PAH concentrations in fishes (Kayal and Connell 1995). Raw fish from unpolluted waters usually do not contain detectable amounts of PAHs, but smoked fish contain elevated concentrations of PAHs (Akpan et al. 1994) (Table 25.4). The concentration of benzo[a]pyrene in skin of cooked fish was much higher than in other tissues, suggesting that skin may serve as a barrier to the migration of PAHs in body tissues (USEPA 1980).

In many cases, aquatic organisms from PAH-contaminated environments have a higher incidence of tumors and hyperplastic diseases than those from nonpolluted environments. Carcinogenic PAHs have not been unequivocally identified as the causative agent for an increased incidence of cancer in any natural population of aquatic organisms, according to Neff (1982b). However, a growing body of evidence links PAHs to cancer in feral fish populations, especially bottom-dwelling fish from areas with sediments heavily contaminated with PAHs (Baumann and Whittle 1988; Black et al. 1988; Baumann 1989).

Sediments and biota collected from the Hersey River, Michigan, in 1978, were heavily contaminated with phenanthrene, benz[a]anthracene, and benzo[a]pyrene when compared to a control site. Elevated PAH concentrations were recorded in sediments, whole insect larvae, crayfish muscle, and flesh of lampreys (family Petromyzontidae), brown trout (*Salmo trutta*), and white suckers (*Catostomus commersoni*), in that general order (Black et al. 1981). The polluted collection locale was the former site of a creosote wood preservation facility between 1902 and 1949, and, at the time of the study, received Reed City wastewater treatment plant effluent, described as an oily material with a naphthalene-like odor (Black et al. 1981). In San Francisco Bay, elevated PAH concentrations in fish livers reflected elevated sediment PAH concentrations (Stehr et al. 1997). In Chesapeake Bay, spot (*Leiostomus xanthurus*) collected from a PAH-contaminated tributary (up to 96 mg PAHs/kg DW sediment) had elevated cytochrome P-450 and EROD activity in liver and intestine microsomes (Van Veld et al. 1990). Intestinal P-450 activity was 80 to 100 times higher in fish from highly contaminated sites than in conspecifics from reference sites; intestinal EROD activity had a similar trend. Liver P-450 and EROD activity was about 8 times higher in spot from the contaminated sites when compared to the reference sites. Liver P-450 activity correlated positively with sediment PAH, but intestinal P-450 activity seemed to reflect dietary exposure (Van Veld et al. 1990). The poor correlation between hepatic concentrations of PAHs and P-4501A is attributed to the rapid metabolism of these compounds (van der Weiden et al. 1994).

Embryos of the common tern (*Sterna hirundo*) from eight colonies in the Netherlands and Belgium were analyzed for PAHs in May–July 1991. In general, eggs containing embryos with elevated PAH concentrations in the yolk sac and with elevated hepatic EROD activity levels were laid later, had a more prolonged incubation period, were of smaller volume, and produced smaller chicks (Murk et al. 1996).

Norway rats (*Rattus norvegicus*) from a PAH-contaminated site near Lyon, France, when compared to conspecifics from a reference site, had altered liver and lung monooxygenases and altered antioxidant enzyme activities in liver, lungs, and erythrocytes (Fouchecourt and Riviere 1995). PAH concentrations in muscle tissues of 10 species of marine mammals from Newfoundland–Labrador waters in 1988/89 were highest in harbor porpoise (*Phocoena phocoena*) and lowest in large whales and hooded seals (*Cystophora cristata*; Hellou et al. 1990). Benzo[a]pyrene was specifically related to the presence of tumors in beluga whales (*Delphinapterus leucas*) from the Gulf of St. Lawrence in Canada (Hellou et al. 1990).

25.4 LETHAL AND SUBLETHAL EFFECTS

25.4.1 General

A wide variety of PAH-caused adverse biological effects have been reported in numerous species of organisms under laboratory conditions, including effects on survival, growth, reproduction, metabolism, and especially tumor formation. Inter- and intraspecies responses to carcinogenic PAHs were quite variable, and were significantly modified by many chemicals, including other PAHs, that are weakly carcinogenic or noncarcinogenic. Until these interaction effects are clarified, the results of single-substance laboratory tests may be extremely difficult to apply to field situations of suspected PAH contamination.

25.4.2 Fungi

Fungal degradation of PAHs may be important in the detoxification and elimination of PAHs in the environment. The fungus *Cunninghamella elegans*, for example, inhibited the mutagenic activity of benzo[*a*]pyrene, 3-ethylcholanthrene, benz[*a*]anthracene, and 7,12-dimethylbenz[*a*]anthracene, as judged by results of the Ames test using *Salmonella typhimurium* (Cerniglia et al. 1985). The rate of decrease in mutagenic activity in bacterial cultures incubated with PAHs was coincident with the rate of increase in fungal metabolism. *C. elegans* metabolized PAHs to dihydrodiols, phenols, quinones, and dihydrodiol epoxides, and to sulfate, glucuronide, and glucoside conjugates of these primary metabolites in a manner similar to that reported for mammalian enzyme systems, suggesting

that this organism (and perhaps other fungi) is important in PAH metabolism and inactivation (Cerniglia et al. 1985).

25.4.3 Terrestrial Plants

Biological effects of PAHs on terrestrial vegetation have been reviewed by the USEPA (1980), Lee and Grant (1981), Wang and Meresz (1982), Edwards (1983), and Sims and Overcash (1983). In general, these authorities agreed on several points. First, plants and vegetables can absorb PAHs from soils through their roots and translocate them to other plant parts such as developing shoots. Uptake rates were governed, in part, by PAH concentration, PAH water solubility, soil type, and PAH physicochemical state (vapor or particulate). Lower-molecular-weight PAHs were absorbed by plants more readily than higher-molecular-weight PAHs. Under laboratory conditions, some plants concentrated selected PAHs above that of their immediate geophysical surroundings, but this has not been conclusively demonstrated in field-grown cultivated crops or other vegetation. Second, above-ground parts of vegetables, especially the outer shell or skin, contained more PAHs than underground parts, and this was attributed to airborne deposition and subsequent adsorption. Externally deposited PAHs in vegetables were difficult to remove with cold-water washings; not more than 25% were removed from lettuce, kale, spinach, leeks, and tomatoes using these procedures. Third, PAH-induced phytotoxic effects were rare; however, the database on this subject is small. Fourth, most higher plants can catabolize benzo[a]pyrene, and possibly other PAHs, but metabolic pathways have not been clearly defined. Finally, the biomagnification potential of vegetation in terrestrial and aquatic food chains needs to be measured; this work should be conducted with a variety of PAHs in both field and laboratory experiments.

Some plants contain chemicals known to protect against PAH effects. Certain green plants contain ellagic acid, a substance that can destroy the diol epoxide form of benzo[a]pyrene, inactivating its carcinogenic and mutagenic potential (Edwards 1983). PAHs synthesized by plants may act as plant growth hormones (Edwards 1983). Some vegetables, such as cabbage, brussels sprouts, and cauliflower, contain naturally occurring antineoplastic compounds, including benzyl isothiocyanate and phenethyl isothiocyanate. These compounds are known to inhibit mammary cancers, stomach tumors, and pulmonary edemas induced in rats by benzo[a]pyrene and 7,12-dimethylbenz[a]anthracene (USEPA 1980). Decreased activation of carcinogens has also been demonstrated in animals fed diets that were high in protein, low in carbohydrate, and containing adequate choline; the reverse was observed in diets high in carbohydrate, low in protein, or containing certain organophosphorus insecticides, piperonyl butoxide, carbon tetrachloride, nickel carbonyl, or tin (USEPA 1980). In cases where dietary constituents can alter the metabolism of foreign agents, such as PAHs, the anticarcinogenic effect may result from an alteration of steady-state levels of activated vs. detoxified metabolites (USEPA 1980). The implications of these observations to herbivorous wildlife are unknown at present.

25.4.4 Aquatic Biota

PAHs vary substantially in their toxicity to aquatic organisms ([Table 25.5](#)). In general, toxicity increases as molecular weight increases (although high-molecular-weight PAHs have low acute toxicity, perhaps due to their low solubility in water) and with increasing alkyl substitution on the aromatic ring. Toxicity is most pronounced among crustaceans and least among teleosts (Neff 1979) ([Table 25.5](#)). In all but a few cases, PAH concentrations that are acutely toxic to aquatic organisms are several orders of magnitude higher than concentrations found in even the most heavily polluted waters (Neff 1979). Sediments from polluted regions, however, may contain PAH concentrations similar to those that are acutely toxic, but their limited bioavailability would probably render them substantially less toxic than PAHs in solution (Neff 1979).

Several PAHs accumulated by aquatic organisms during exposure are severely toxic when the contaminated organisms were exposed to sunlight or ultraviolet radiation (Nagpal 1994). PAHs that have exhibited photoinduced toxicity in fishes, daphnids, frogs, or algae and macrophytes at PAH concentrations well below their aqueous solubility due to simultaneous UV radiation exposure include fluoranthene, pyrene, benzo[a]pyrene, benz[a]anthracene, acridine, and benz[a]fluorene (Gala and Giesy 1994; Hatch and Burton 1998; Walker et al. 1998). Anthracene, for example, is not acutely toxic to fish and algae within its aqueous solubility range (about 35 µg/L at 25°C) unless the exposure is performed in the presence of ultraviolet radiation from simulated or natural sunlight. Anthracene is phototoxic in this concentration range to mosquito larvae, bluegills, and leopard frog embryos (McCloskey and Oris 1991, 1993). Anthracene is phototoxic to alga (*Selenastrum capricornutum*), with growth inhibition of 50% at 16.1 µg/L in 28 h and 10% inhibition at 8.3 µg/L (Gala and Giesy 1994). PAH phototoxicity is due to PAH concentrations in tissues, length of exposure to radiation and absorption, efficiency of the photoconversion process, and the probability of the excited intermediary reacting with a target molecule (Nagpal 1994). Studies with larvae of the bullfrog (*Rana catesbeiana*) and phototoxic effects of fluoranthene suggest that behavioral and histopathological endpoints — especially skin histology — are more sensitive than survival (Walker et al. 1998). Sediments contaminated with complex mixtures of PAHs also show enhanced toxicity to aquatic species under conditions of ultraviolet light representative of sunlight. In one case, interstitial sediment pore water from sediments near an oil refinery discharge was toxic to a freshwater oligochaete worm (*Lumbriculus variegatus*) following exposure to UV light, but worms exposed to the same pore water without UV treatment were unaffected (Kosian et al. 1998). Electron density shape features have been used to model photoinduced toxicity of 16 PAHs to duckweed (*Lemna gibba*), with good correlation between detailed molecular shape features and toxicity (Mezey et al. 1998).

^a m = months, d = days, h = hours.^b 1, USEPA 1980; 2, Neff 1979; 3, Schultz and Schultz 1982; 4, Finger et al. 1985; 5, Neff 1985; 6, Nagpal 1994; 7, McCloskey and Oris 1991; 8, Hatch and Burton 1998; 9, Walker et al. 1998; 10, Donohoe et al. 1998.

A growing literature exists on uptake, retention, and translocation of PAHs by aquatic plants and animals. Authorities generally agree that most species of aquatic organisms studied to date rapidly accumulate (i.e., bioconcentrate) PAHs from low concentrations in the ambient medium. Uptake of PAHs is highly species specific, being higher in algae, molluscs, and other species that are incapable of metabolizing PAHs. Bioconcentration factors (BCF) tend to increase as the molecular weight of the PAH increases, with increasing octanol/water partition coefficient values, with time until approaching an apparent equilibrium level (sometimes within 24 h), and with

increases in dissolved organic matter in the medium, lipid content of organism, and a variety of endogenous and exogenous factors (Jackim and Lake 1978; Southworth et al. 1978; Lee and Grant 1981; Neff 1982a; Ma et al. 1998). BCF values have been determined for selected PAHs and aquatic organisms (Table 25.6). Additional BCF data for aquatic biota are available for plants (Dobroski

^b 1, USEPA 1980; 2, Southworth 1979; 3, Southworth et al. 1978; 4, Neff 1985; 5, Linder et al. 1985; 6, Neff 1979; 7, Leversee et al. 1981; 8, Kuhnhold and Busch 1978; 9, Gerhart and Carlson 1978; 10, Balk et al. 1984; 11, Lu et al. 1977; 12, McCarthy and Jimenez 1985; 13, Hose et al. 1982; 14, Miller et al. 1982; 15, Finger et al. 1985; 16, Neff 1982a; 17, Hose and Puffer 1984; 18, de Voogt et al. 1991.

and Epifanio 1980; Boyle et al. 1984), crustaceans (Southworth 1979; Sirota and Uthe 1981; Fox and Rao 1982; Neff 1982a; Williams et al. 1985), tunicates (Baird et al. 1982), molluscs (Jackim and Wilson 1979; Dobroski and Epifanio 1980; Neff 1982a), annelids (Ma et al. 1998; Penry and Weston 1998), and fishes (Southworth 1979; Neff 1982a; Stoker et al. 1984). Algal accumulation of benzo[a]pyrene increased linearly in a 24-h exposure period, and correlated positively with surface area (Leversee et al. 1981), suggesting adsorption rather than absorption. Algae readily transform benzo[a]pyrene to oxides, peroxides (Kirso et al. 1983), and dihydrodiols (Warshawsky et al. 1983). Photosynthetic rates of algae, and presumably PAH accumulations, were significantly modified by light regimens. For reasons still unexplained, algae grown in "white" light (major energy in blue-green portion of the spectrum) were more sensitive to benzo[a]pyrene than were cultures grown in "gold" light (Warshawsky et al. 1983; Schoeny et al. 1984).

Accumulation by American oysters (*Crassostrea virginica*) and clams (*Rangia cuneata*) of naphthalene, phenanthrene, fluorene, and their methylated derivatives increased with increasing methylation and PAH molecular weight; uptake was more rapid under conditions of continuous flow than in static tests (Neff et al. 1976). When returned to PAH-free seawater, molluscs released PAHs to nondetectable levels in about 60 days, with high-molecular-weight PAHs depurated more slowly than low-molecular-weight compounds. Brown shrimp (*Penaeus aztecus*) and longnose killifish (*Fundulus similis*), which can metabolize PAHs, lost PAHs more quickly than clams and oysters, which apparently lack the detoxifying enzymes (Neff et al. 1976). Pink shrimp (*Penaeus duorarum*) exposed to 1.0 µg chrysene/L for 2 days and then transferred to unpolluted seawater for an additional 28 days contained concentrations of chrysene (91 µg/kg fresh weight in abdomen, 48 µg/kg in cephalothorax) that were considered potentially hazardous to human consumers over extended periods (Miller et al. 1982). Eggs of the sand sole (*Psettidichthys melanostictus*) exposed to 0.1 µg benzo[a]pyrene/L for 5 days showed reduced and delayed hatch and, when compared to controls, produced larvae with high accumulations (2.1 mg/kg fresh weight) and gross abnormalities, such as twinning and tissue overgrowths, in 50% of the test larvae (Hose et al. 1982). Naphthalene and benzo[a]pyrene were rapidly accumulated from the medium by three species of California marine teleosts; loss was rapid, being >90% for naphthalene in 24 h, and 20% (muscle), to 90% (gill) for benzo[a]pyrene in a similar period (Lee et al. 1972). Phenanthrene is metabolized by many species of aquatic organisms, including fish. A marine flounder *Platichthys flesus*, given a single oral dose of 0.7 mg phenanthrene/kg body weight, contained elevated phenanthrene concentrations in lipids, melanin-rich tissues (such as skin), and the eye lens; most was eliminated within 2 weeks (Solbakken et al. 1984). Studies on uptake rates of radiolabeled phenanthrene by marine polychaetes (*Aberenicola pacifica*) from PAH-contaminated sediments of high or low organic content showed that rates increased when worms were acclimatized for 48 h to sediments of low organic content (Penry and Weston 1998). Different rates of accumulation and depuration of benzo[a]pyrene and naphthalene in bluegill (*Lepomis macrochirus*) and *Daphnia magna* have been documented by McCarthy and Jimenez (1985) and McCarthy et al. (1985). Benzo[a]pyrene accumulations in bluegill, for example, were 10 times greater than naphthalene, but benzo[a]pyrene is extensively metabolized, whereas naphthalene is not. Consequently, postexposure accumulations of naphthalene greatly exceeded that of the parent benzo[a]pyrene. Because the more hydrophobic PAHs, such as benzo[a]pyrene, show a high affinity for binding to dissolved humic materials and have comparatively rapid biotransformation rates, these interactions may lessen or negate bioaccumulation and food chain transfer of hydrophobic PAHs (McCarthy and Jimenez 1985; McCarthy et al. 1985).

Time to depurate or biotransform 50% of accumulated PAHs (T_b 1/2) varied widely. T_b 1/2 values for *Daphnia pulex* and all PAH compounds studied ranged between 0.4 and 0.5 h (Southworth et al. 1978). In rainbow trout given an intraarterial injection of 10 mg/kg BW of 2-methylnaphthalene, fluorene, or pyrene, the T_b 1/2 values ranged between 9.6 and 12.8 h; when route of exposure was intragastric and doses were 50 mg/kg BW, there was negligible uptake (Kennedy and Law 1990). For marine copepods and naphthalene, a T_b 1/2 of about 36 h was recorded (Neff 1982a).

For most marine bivalve molluscs, Tb 1/2 values ranged from 2 to 16 days. Some species, such as the hardshell clam (*Mercenaria mercenaria*), showed little or no depuration, while others, such as oysters, eliminated up to 90% of accumulated PAHs in 2 weeks — although the remaining 10% was released slowly and traces may remain indefinitely (Jackim and Lake 1978). Percent loss of various PAHs in American oysters (*Crassostrea virginica*), 7 days postexposure, ranged from no loss for benzo[a]pyrene to 98% for methylnaphthalene; intermediate were benz[a]anthracene (32%), fluoranthene (66%), anthracene (79%), dimethylnaphthalene (90%), and naphthalene (97%) (Neff 1982a). Teleosts and arthropods usually had low Tb 1/2 values. In bluegill, 89% loss of benzo[a]pyrene was recorded 4 h postexposure. For midge larvae, it was 72% in 8 h; and for daphnids, it was 21% in 18 h (Leversee et al. 1981).

The role of sediments in PAH uptake kinetics should not be discounted (Hontela et al. 1992; van der Weiden et al. 1993; Hellou et al. 1994b). Yellow perch (*Perca flavescens*) and northern pike (*Esox lucius*) exposed to sediments contaminated with up to 3.7 mg PAHs/kg had pituitary damage and were unable to increase serum cortisol in response to the acute stress of capture when compared to conspecifics from uncontaminated sites, suggesting that life-long exposure to PAHs will destabilize the cortisol-producing endocrine system (Hontela et al. 1992). Male winter flounders (*Pleuronectes americanus*) exposed to PAH-contaminated sediments at concentrations as low as 1 mg/kg for 4 months had altered mixed-function oxygenase levels and fat content of liver (Payne et al. 1988). Sediment-associated anthracene contributed about 77% of the steady-state body burden of this compound in the amphipod *Hyalella azteca* (Landrum and Scavia 1983). For benzo[a]pyrene and the amphipod *Pontoporeia hoyi*, the sediment source (including interstitial water) accounted for 53% in amphipods collected at 60 m, but only 9% at 23 to 45 m (Landrum et al. 1984). Benthos from the Great Lakes, such as oligochaete worms (*Limnodrilus* sp., *Stylodrilus* sp.) and amphipods (*Pontoporeia hoyi*), obtain a substantial fraction of their PAH body content from the water when sediment PAH concentrations are low. However, when sediment PAH concentrations are elevated, benthos obtain a majority of their PAHs from that source through their ability to mobilize PAHs from the sediment/pore water matrix; the high concentrations of phenanthrene, fluorene, benzo[a]pyrene, and other PAHs measured in these organisms could provide a significant source of PAHs to predator fish (Eadie et al. 1983). Great Lakes benthos appear to contain as much PAHs as the fine-grain fraction of the sediment that serves as their food, although overlying water or pore water appears to contribute a larger proportion of PAHs to the organism's body burden than do sediments (Eadie et al. 1984). Marine mussels (*Mytilus edulis*) and polychaete annelid worms (*Nereis virens*) exposed for 28 days to sediments heavily contaminated with various PAH compounds accumulated significant concentrations (up to 1000 times control levels) during the first 14 days of exposure, and little thereafter; during a 5-week postexposure period, depuration was rapid, with the more water-soluble PAHs excreted most rapidly; PAH levels usually remained above control values to the end of the postexposure period (Lake et al. 1985). English sole (*Pleuronectes vetulus*), during exposure for 11 to 51 days to PAH-contaminated sediments, showed significant accumulations of naphthalenes in liver (up to 3.1 mg/kg dry weight) after 11 days, with concentrations declining markedly thereafter; uptake of phenanthrene, chrysene, and benzo[a]pyrene was negligible during the first 7 days (Neff 1982a).

Selected studies on effects of benzo[a]pyrene to aquatic vertebrates are summarized in [Table 25.7](#) and demonstrate dose-dependent increases in death, enzyme disruption, liver and intestinal histopathology, carcinogenic and mutagenic effects, and behavioral deficits. In general, effects of benzo[a]pyrene were exacerbated by poor health, and by interactions with radiation or cadmium; effects were modified by route of exposure, diet, and organism age ([Table 25.7](#)). Exposure of fishes to BaP at early life stages has potential life-long significance. Embryonic sublethal doses of BaP are capable of inducing sublethal changes in behavior weeks or even months following hatching of salmon and trout (Ostrander et al. 1988, 1990).

Fluorene effects in freshwater pond ecosystems have been evaluated (Boyle et al. 1984, 1985; Finger et al. 1985). In ponds exposed to initial fluorene concentrations of 0.12 to 2.0 mg/L, Tb 1/2

Table 25.7 Benzo[a]pyrene Effects on Selected Aquatic Vertebrates

Organism, Dose, and Other Variables	Effect	Reference ^a
EUROPEAN EEL, <i>Anguilla anguilla</i>		
Seawater-adapted eels were exposed for 24 days to 0 or 5 µg cadmium/L, then given a single intraperitoneal (ip) injection of 20 mg BaP/kg BW and killed 24 h later	BaP alone produced glycogen depletion in liver; cadmium alone caused hepatic perivasicular fibrosis. Mixture produced complete disorganization of the hepatic parenchyma, including nuclear degeneration; higher increase in EROD activity (by 19-fold), BaP hydroxylase activity (by 71-fold), and cytochrome P-450 microsomal content by 2-fold	1
WHITE SUCKER, <i>Catostomus commersonii</i>		
Suckers with diseased bile ducts were given a single oral dose of BaP	Bile duct disease does not appear to restrict the metabolism and excretion of BaP. However, BaP metabolite levels were 57% higher in livers of affected suckers than controls, and may be due to bile retention within the diseased bile ducts	2
COMMON CARP, <i>Cyprinus carpio</i>		
Single ip injection of radiolabeled BaP	After 72 h, bile contained 25% of the total radioactivity; major BaP metabolites were glucuronides (54%), sulfates (12%), and unmetabolized BaP(14%). The potentially genotoxic metabolite BaP-7,8-dihydrodiol and its glucuronide represented 0.7 and 2.0%, respectively, of the bile radioactivity	3
Single ip injection of 99.5 µmol/kg BW of BaP, chrysene, fluoranthene, pyrene, or benzo[ghi]perylene	BaP and chrysene were most efficient in elevating EROD activities, cytochrome P-4501A protein levels, and total cytochrome P-450 content 1–14 days postinjection. Less pronounced increases were caused by fluoranthene and pyrene; B[ghi]PER did not affect these parameters	4
EUROPEAN SEA BASS, <i>Dicentrarchus labrax</i>		
Single ip injection of radiolabeled BaP	Half-time persistence (T _b 1/2) ranged from 2.2–2.4 days for liver, gills, gonads, and whole body; 2.9–5.1 days for muscle, spleen, gall bladder, and intestine; 6.5 days for kidney; and 12.4 days for fat	5
Immatures given single ip injection of 20 mg/kg BW, or by force feeding 20 mg/kg BW. Liver and intestine examined for pathology 17 days after treatment	Injection route of intoxication produced severe liver histopathology when compared to dietary route; intestinal histopathology observed with dietary route but not with injection route	6
Force feeding radiolabeled BaP to immatures; single administration	Gallbladder had 85% of radioactivity. T _b 1/2 values were 0.8 days for liver, 3.3 days for intestine, 3.5 days for gallbladder, and 8.2 days for liver	7
Fed diets containing fish oil vs. no fish oil diet for 5 months, then given single ip injection of BaP. Hepatic transformation enzymes measured 14 days postinjection	Diets rich in fish oils produced marked increases in activities of P-450 cytochromes, 7-EROD, and other enzyme activities; bass fed diets devoid of fish oil had lower microsomal enzyme activities	8
GIZZARD SHAD, <i>Dorosoma cepedianum</i>		
Single ip injection equivalent to 0, 0.1, 1, 10, or 50 mg BaP/kg BW and killed 72 h later	Maximum EROD activity was reached in the 10 and 50 mg/kg groups; no effect on EROD activity at 1 mg/kg BW and lower	9
Held for 10–20 days in water containing 0, 0.14, 0.24, 0.44, or 0.76 µg BaP/L	After 10 days, no effect on EROD enzyme activity at 0.24 µg/L and lower; EROD activity significantly elevated at 0.44 µg/L and higher. Concentration of parent BaP in whole fish after 20 days ranged from 20 µg/kg FW in the 0.14 µg/L group to 26.5 µg/kg FW in the 0.76 µg/L group	9

Table 25.7 (continued) Benzo[a]pyrene Effects on Selected Aquatic Vertebrates

Organism, Dose, and Other Variables	Effect	Reference ^a
MOSQUITOFISH, <i>Gambusia affinis</i>		
Exposed for 48 h in water containing 1–100 µg BaP/L	Dose-dependent increase in liver BaP monooxygenase activity; adverse effect on liver DNA at high dose	10
BROWN BULLHEAD, <i>Ictalurus nebulosus</i>		
Subadults given single ip injection of radiolabeled BaP and killed 72 h later	Biliary radioactivity accounted for 16% of the radioactivity; the potentially genotoxic metabolite BaP-7,8-dihydrodiol accounted for 3% of the bile radioactivity. Other accumulation sites were muscle, liver, and kidney	11
Adults given single ip injection of 0, 5, 25, or 125 mg BaP/kg BW and observed for 18 months	At 18 months, dose-dependent changes in liver pigmentation; no evidence of long-term DNA alterations; no neoplasms detected	12
BLUEGILL, <i>Lepomis macrochirus</i>		
Held for 40 days in 1 µg BaP/L, then for 45 days in uncontaminated media	Hypomethylation, as judged by loss of 5-methyl deoxycytidine content from DNA, occurred shortly after BaP exposure and continued upon termination of exposure conditions. Onset and persistence of hypomethylation were correlated with other types of DNA-damaging events, including strand breaks and DNA adduct formation	13
Chironomids (<i>Chironomus riparius</i>) held for 72 h on sediments with 47–4040 µg BaP/kg contained a maximum of 6030 µg BaP/kg DW; chironomids were fed to bluegills for 96 h	BaP was not detectable in muscle and gut, indicating that BaP on sediments may be mobilized and made available to benthic invertebrates and fish but that the process was highly inefficient with minor biomagnification; a similar case is made for fluoranthene	14
SUNFISH, <i>Lepomis</i> spp. hybrids		
Single ip injection of 8 mg BaP/kg BW and killed 4–5 days later	Hepatotoxicity. Decreased glutathione S-transferase activity in liver	15
RAINBOW TROUT, <i>Oncorhynchus mykiss</i>		
Juveniles given single intramuscular (im) injection of radiolabeled BaP	After 48 h, liver DNA and RNA contained 1–2.4% of administered dose; a similar case is made for 7,12-dimethylbenz[a]anthracene	16
Two days prior to hatch fertilized eggs were given a single transchorionic injection of 0.09–18.0 µg BaP/egg, equivalent to 1.2–197.8 mg BaP/kg FW egg. Mortality and neoplasms documented over the next 12 months	Control mortality ranged between 6.5 and 10%; mortality in BaP-treated fish ranged between 40 and 78% in a dose-dependent manner. Liver neoplasm frequency in controls at age 1 year was 1.8%; for the 4.5–9.0-µg groups (49.5–91.0 mg/kg), these values ranged between 5 and 6%; for the 18-µg group (197.8 mg/kg FW), the liver neoplasm frequency was 16% at age 12 months after a single-dose exposure as embryos	17
Newly fertilized embryos were incubated in water containing 0, 0.08, 0.2, 0.4, 1.5, 2.4, or 3.0 µg BaP/L. Alevins examined	Histologic and skeletal abnormalities in all BaP-exposed groups; depressed mitotic rates in retina and brain in groups exposed to 0.08 µg/L and higher; muscle necrosis in all groups exposed to 0.2 µg/L and higher; microphthalmia was observed in 17% of BaP-treated trout	18
Subadults exposed to 0.4 or 1.2 µg BaP/L for 30 days	No DNA adducts detected in liver	19
Subadults exposed to 0.5 µg BaP/L for 15 days then a pulse of 60 µg/L which naturally declined to 2.0 µg/L for another 15 days	Liver DNA adducts detected	19

Table 25.7 (continued) Benzo[a]pyrene Effects on Selected Aquatic Vertebrates

Organism, Dose, and Other Variables	Effect	Reference^a
Subadults given single ip injection of 20 mg/kg BW and killed after 7 days	No DNA adducts found in liver	19
Subadults given two ip injections of 25 mg/kg BW separated by 7 days and killed 14 days after the second injection	DNA adducts found in liver	19
Subadults fed diets for 6 days containing either 58 or 288 µg BaP daily, equivalent to 43 mg/kg BW or 216 mg/kg BW	Liver DNA adducts detected in both cases	19
Embryos exposed for 24 h to 25 mg BaP/L, one week prior to hatch	No effect on hatch, but alevins showed decreased tendency to orient upstream	20
COHO SALMON, <i>Oncorhynchus kisutch</i>		
Fertilized eggs exposed to 7, 10, or 25 mg BaP/L for 24 h at 1 week prior to hatch or 24 h after fertilization	BaP was easily accumulated and rapidly lost. Altered hatching rate and reduced survival at higher concentrations. Significant behavioral alterations in the months following hatching, including difficulty in upstream orientation, swimming, and foraging ability; fry were the most sensitive stage	21, 22
GULF TOADFISH, <i>Opsanus tau</i>		
Isolated hepatocytes acclimatized to 18 or 28°C, then exposed to BaP at 18, 23, or 28°C for about 2 h	Dose-dependent increase in metabolite production. Rapid metabolism of BaP independent of temperature	23
Isolated gill cells acclimatized to either 18 or 28°C for 3 weeks and exposed for 8 h to 1–100 mg BaP/L at incubation temperatures of 18, 23, and 28°C	Accumulation followed a dose-concentration gradient; uptake rate was higher for cells acclimatized to 18°C than those acclimatized to 28°C at all incubation temperatures. When cells were exposed to BaP at the respective acclimatization temperatures, uptake rates were similar	24
NILE TILAPIA, <i>Oreochromis niloticus</i>		
Single ip injection, various doses	Dose-dependent reduction in pronephros cell counts	25
MEDAKA, <i>Oryzias latipes</i>		
Exposed to approximately 5, 40, or 200 µg BaP/L for 6 h, once weekly, for up to 4 weeks; 6–10-day-old fish	Liver neoplasms at intermediate and high concentration exposures	26
NEWT, <i>Pleurodeles waltli</i>		
Embryos and larvae exposed to visible light alone, ultraviolet radiation alone, BaP alone at 12.5–500 µg/L, or combinations	Visible light alone, UV radiation alone, or BaP alone had no toxic effects. Genotoxic effects were observed at 500 µg BaP/L plus visible light, or 25 µg BaP/L plus UV radiation	27
WINTER FLOUNDER, <i>Pleuronectes americanus</i>		
Single oral dose of radiolabeled BaP and killed 8–96 h after dosing	After 8 h, 8.1% of the original dose administered was in intestine, 3.9% in blood, 1.6% in liver, 0.6% in bile, and <0.01% in urine. After 96 h, these values were 5.1% in bile, 1.1% in liver, 1.2% in intestine, and lesser amounts in blood, urine, and other tissues	28
ENGLISH SOLE, <i>Pleuronectes vetulus</i>		
Single ip injection of 5 mg/kg BW	Rapid increase in certain liver xenobiotic metabolizing enzymes (AHH), but no increase in GSH and epoxide hydrolase — even up to 42 days after exposure	29

Table 25.7 (continued) Benzo[a]pyrene Effects on Selected Aquatic Vertebrates

Organism, Dose, and Other Variables	Effect	Reference ^a
GUPPY, <i>Poecilia reticulata</i> Exposed to approximately 4, 47, or 270 µg BaP/L for 6 h, once weekly for 2–4 weeks	Hepatic neoplasms at intermediate and high concentration exposures; 7,12-dimethylbenz[a]-anthracene was more potent than BaP, and medakas were more sensitive than guppies	26
TOPMINNOW, <i>Poeciliopsis</i> spp. 1 mg BaP/L for 48 or 90 h	Induction of P-4501A proteins in multiple cell types in many organs with some sites of induction (olfactory epithelium) related to exposure route	30
GILTHEAD SEABREAM, <i>Sparus aurata</i> 25 mg BaP/kg BW by ip injection daily for 5 consecutive days	A 2- to 3-fold increase in 7-EROD activity of liver microsomes	31

values in water ranged from 6 to 11 days. Ten weeks after fluorene introduction, little degradation had occurred in the organic bottom sediments; fluorene residues were present in fish, invertebrates, and rooted submerged macrophytes. Studies with fingerling bluegills showed that 0.062 mg fluorene/L adversely affected their ability to capture chironomid prey, 0.12 mg/L reduced growth, and 1.0 mg fluorene/L increased their vulnerability to predation by largemouth bass (*Micropterus salmoides*). The authors concluded that fluorene, at concentrations well below its solubility and at levels that could realistically occur in the environment, represents a potential hazard to aquatic organisms.

Large interspecies differences in ability to absorb and assimilate PAHs from food have been reported. For example, crustaceans (Neff 1982a; McElroy and Colarusso 1988) and fish (Maccubbin et al. 1985; Malins et al. 1985a, 1985b; McElroy and Colarusso 1988) readily assimilated PAHs from contaminated food, whereas molluscs and polychaete annelids were limited (Neff 1982a). In all cases where assimilation of ingested PAHs was demonstrated, metabolism and excretion of PAHs were rapid (Neff 1982a). Thus, little potential exists for food chain biomagnification of PAHs (Southworth 1979; Dobroski and Epifanio 1980; Neff 1982a; Kayal and Connell 1995). In laboratory aquatic ecosystem studies, Lu et al. (1977) found that benzo[a]pyrene can be accumulated to high, and potentially hazardous, levels in fish and invertebrates. In the case of mosquitofish (*Gambusia affinis*), almost all of the accumulated benzo[a]pyrene was from its diet, with negligible accumulations from the medium. However, mosquitofish degraded benzo[a]pyrene about as rapidly as it was absorbed, in contrast to organisms such as snails (*Physa* sp.) which retained most (88%) of the accumulated benzo[a]pyrene for at least 3 days postexposure, presumably due to deficiencies in their mixed-function oxidase detoxication system (Lu et al. 1977). Benzo[a]pyrene, when administered to northern pike (*Esox lucius*) through the diet or the medium, followed similar pathways: entry via the gills or gastrointestinal system, metabolism in the liver, and excretion in the urine and bile (Balk et al. 1984). Benthic marine fishes exposed to naphthalene or benzo[a]pyrene, either in diet or through contaminated sediments, accumulated substantial concentrations in tissues and body fluids (Varanasi and Gmur 1981). The tendency of fish to metabolize PAHs extensively and rapidly may explain why benzo[a]pyrene, for example, is frequently undetected, or only detected in low concentrations in livers of fish from environments heavily contaminated with PAHs (Varanasi and Gmur 1980, 1981). Extensive metabolism of benzo[a]pyrene plus the presence of large

proportions of polyhydroxy metabolites in liver of English sole indicates the formation of reactive intermediates such as diol epoxides and phenol epoxides of benzo[*a*]pyrene, both of which are implicated in mammalian mutagenesis and carcinogenesis (Varanasi and Gmür 1981).

Cytotoxic, mutagenic, and carcinogenic effects of many PAHs are generally believed to be mediated through active epoxides formed by interaction with microsomal monooxygenases. These highly active arene oxides can interact with macromolecular tissue components and can be further metabolized or rearranged to phenols or various conjugates. They can also be affected by epoxide hydrolase to form dihydrodiols, which are precursors of biologically active diol epoxides — a group that has been implicated as ultimate carcinogens. Investigators generally agree that marine and freshwater fishes:

- Are as well equipped as mammals with liver PAH-metabolizing enzymes
- Rapidly metabolize PAHs by liver mixed-function oxidases, with little evidence of accumulation
- Translocate conjugated PAH metabolites to the gall bladder prior to excretion in feces and urine
- Have mixed-function oxidase degradation rates that are significantly modified by sex, age, diet, water temperature, dose-time relationships, and other variables.

In addition, many species of fishes can convert PAHs, benzo[*a*]pyrene for example, to potent mutagenic metabolites, but because detection of the 7,8-dihydrodiol-9,10-epoxide by analytical methods is difficult, most investigators must use biological assays, such as the Ames test, to detect mutagenic agents. The interaction effects of PAHs with inorganic and other organic compounds are poorly understood. Specific examples of the above-listed phenomena for PAH compounds and teleosts are documented for benzo[*a*]pyrene (Ahokas et al. 1975; Lu et al. 1977; Gerhart and Carlson 1978; Melius et al. 1980; Varanasi et al. 1980, 1984; Stegeman et al. 1982; Couch et al. 1983; Hendricks 1984; Melius 1984; Schoor 1984; Schoor and Srivastava 1984; Hendricks et al. 1985; Neff 1985; Fair 1986; von Hofe and Puffer 1986; Baumann and Whittle 1988; Ueng et al. 1994), 3-methylcholanthrene (Gerhart and Carlson 1978; Melius et al. 1980; Melius and Elam 1983; Schoor and Srivastava 1984; Neff 1985; Ueng et al. 1994), benz[*a*]anthracene, chrysene and pyrene (Gerhart and Carlson 1978; Gagne et al. 1995), fluoranthene (Baumann and Whittle 1988; Gagne et al. 1995), and 7,12-dimethylbenz[*a*]anthracene (Stegeman et al. 1982).

Baumann et al. (1982) summarized reports on increasing frequencies of liver tumors in wild populations of fish during the past decade, especially in brown bullhead (*Ictalurus nebulosus*) from the Fox River, Illinois (12% tumor frequency), in Atlantic hagfish (*Myxine glutinosa*) from Swedish estuaries (6%), in English sole from the Duwamish estuary, Washington (32%), and in tomcod (*Microgadus tomcod*) from the Hudson River, New York (25%). In all of these instances, significant levels of contaminants were present in the sediments, including PAHs. PAHs have been identified as genotoxic pollutants in sediments from the Black River, Ohio, where a high incidence of hepatoma and other tumors has been observed in ictalurid fishes (West et al. 1984, 1986). Reports of tumors in Great Lakes fish populations have been increasing. Tumors of thyroid, gonad, skin, and liver are reported, with tumor frequency greatest near areas contaminated by industrial effluents such as PAHs; liver tumors were common among brown bullhead populations at sites with large amounts of PAHs in sediments (Baumann 1984; Baumann and Whittle 1988). A positive relationship was finally established between sediment PAH levels and prevalence of liver lesions in English sole in Puget Sound, Washington (Malins et al. 1984; Varanasi et al. 1984), and sediment levels and liver tumor frequency in brown bullheads from the Black River, Ohio (Baumann and Harshbarger 1985; Black et al. 1985). Sediment PAH levels in the Black River, Ohio, from the vicinity of a coke plant outfall, were up to 10,000 times greater than those from a control location: concentrations were greater than 100 mg/kg for pyrene, fluoranthene, and phenanthrene; between 50 and 100 mg/kg for benz[*a*]anthracene, chrysene, and benzofluoranthenes; and between 10 and 50 mg/kg for individual naphthalenes, benzo[*e*]pyrene, benzo[*a*]pyrene, perylene, indeno[*1,2,3-cd*]pyrene, benzo[*g,h,i*]perylene, and anthanthrene (Baumann et al. 1982). Brown bullheads from this

location contained >1.0 mg/kg of acenaphthalene (2.4), phenanthrene (5.7), fluoranthene (1.9), and pyrene (1.1), and lower concentrations of heavier molecular weight PAHs. Bullheads also exhibited a high (33%) liver tumor frequency, which seemed to correspond to their PAH body burdens. Investigators concluded that the elevated frequency of liver neoplasia in Black River bullheads was chemically induced and was the result of exposure to PAHs (Baumann et al. 1982; Baumann and Harshbarger 1985).

Neoplasms in several species of fishes have been produced experimentally with 3-methylcholanthrene, acetylaminofluorene, benzo[a]pyrene, and 7,12-dimethylbenz[a]anthracene, with tumors evident 3 to 12 months postexposure (Couch and Harshbarger 1985; Hendricks et al. 1985; Hawkins et al. 1989). Under laboratory conditions, liver neoplasms were induced in two species of minnows (*Poeciliopsis* spp.) by repeated short-term exposures (6 h once a week, for 5 weeks) to an aqueous suspension of 5 mg/L of 7,12-dimethylbenz[a]anthracene. About 44% of the fish surviving this treatment developed hepatocellular neoplasms 6 to 9 months postexposure (Schultz and Schultz 1982). Guppies developed hepatic and extrahepatic neoplasms within 6 months following brief (6-h exposure, once weekly for 4 weeks) waterborne exposures to very low (20 to 35 µg/L) concentrations of 7,12-dimethylbenz[a]anthracene (Hawkins et al. 1989). Eastern mudminnows (*Umbra pygmaea*) kept in water containing up to 700 µg PAHs/L for 11 days showed increased frequencies of chromosomal aberrations in gills: 30% vs. 8% in controls (Prein et al. 1978). High dietary benzo[a]pyrene levels of 500 mg/kg produced significant elevations in hepatic mixed-function oxidase levels in rainbow trout after 9 weeks (Hendricks et al. 1985). Rainbow trout fed diets containing 1006 mg benzo[a]pyrene/kg for 12 months developed liver tumors (Couch et al. 1983). About 25% of rainbow trout kept on diets containing 1000 mg benzo[a]pyrene/kg for 18 months had histologically confirmed liver neoplasms as compared to 15% after 12 months, with no evidence of neoplasia in controls (Hendricks et al. 1985). Young English sole may activate and degrade carcinogenic PAHs, such as benzo[a]pyrene, to a greater extent than adults, but additional research is needed to determine if younger fish are at greater risk than older sole to PAH-induced toxicity (Varanasi et al. 1984). In English sole, a high significant positive correlation between PAH metabolites (1- and 3-hydroxy benzo[a]pyrene, hydroxy and dehydrodiol metabolites of pyrene and fluoranthene) in bile, and idiopathic liver lesions, prevalence of neoplasms, megalocytic hepatosis, and total number of hepatic lesions (Krahn et al. 1986) suggests that selected PAH metabolites and key organs or tissues may be the most effective monitors of PAH contamination in aquatic organisms.

In addition to those effects of PAHs emphasizing survival, uptake, depuration, and carcinogenesis previously listed, a wide variety of additional effects have been documented for aquatic organisms. These include:

- Inhibited reproduction of daphnids and delayed emergence of larval midges by fluorene (Finger et al. 1985)
- Reproductive impairment in fish by anthracene (Hall and Oris 1991) and elevated concentrations of total PAHs in sediments (Johnson et al. 1998)
- Generalized disruption of cell membrane function in fishes by anthracene (McCloskey and Oris 1993)
- Decreased respiration and heart rate in mussels (*Mytilus californianus*) by benzo[a]pyrene (Sabourin and Tullis 1981)
- Increased weight of liver, kidney, gall bladder, and spleen of sea catfish (*Arius felis*) by 3-methylcholanthrene, which was dose-related (Melius and Elam 1983)
- Photosynthetic inhibition of algae and macrophytes by anthracene, naphthalene, phenanthrene, pyrene (Neff 1985), and fluorene (Finger et al. 1985)
- Immobilization of the protozoan *Paramecium caudatum* by anthracene, with an EC50 (60 min) of 0.1 µg/L (USEPA 1980)
- Perylene accumulation by algae (Stegeman 1981)

- Accumulation without activation of benzo[a]pyrene and benzo[a]anthracene by a marine protozoan (*Parauronema acutum*), and biotransformation of various fluorenes by *P. acutum* to mutagenic metabolites (Lindmark 1981)
- Interference by toluene and anthracene with benzo[a]pyrene uptake by freshwater amphipods (Landrum 1983)
- Abnormal blood chemistry in oysters (*Crassostrea virginica*) exposed for 1 year to 5 µg 3-methylcholanthrene/L (Couch et al. 1983)
- Enlarged livers in brown bullheads from a PAH-contaminated river (Fabacher and Baumann 1985).

25.4.5 Amphibians and Reptiles

In vitro studies with abdominal skin of *Rana pipiens* demonstrated that naphthalene inhibited sodium transport after exposure to 4.4 mg/L for 30 min (Blankemeyer and Hefler 1990). Some data were available on biological effects of benzo[a]pyrene, 3-methylcholanthrene, and perylene to reptiles and amphibians (Balls 1964; Stegeman 1981; Anderson et al. 1982; Schwen and Mannering 1982a, 1982b; Couch et al. 1983). Implantation of 1.5 mg benzo[a]pyrene crystals into the abdominal cavity of adult South African clawed frogs (*Xenopus laevis*) produced lymphosarcomas in 11 of the 13 frogs (85%) after 86 to 288 days (Balls 1964). Immature frogs were more resistant, with only 45% bearing lymphoid tumors of liver, kidney, spleen, or abdominal muscle 272 to 310 days after implantation of 1.5 mg of benzo[a]pyrene crystals in the dorsal lymph sac or abdominal cavity. Implantation of 3-methylcholanthrene crystals into *X. laevis* provokes development of lymphoid tumors similar to those occurring naturally in this species. Moreover, these tumors are readily transplantable into other *Xenopus* or into the urodele species *Triturus cristatus* (Balls 1964). Intraperitoneal injection of perylene into tiger salamanders can result in hepatic tumors (Couch et al. 1983).

A critical point of interaction between PAHs and reptiles or amphibians involves the transformation of these compounds by cytochrome P-450-dependent monooxygenase systems (Stegeman 1981); in general, reaction rates in this group are considerably slower than those observed in hepatic microsomes from mammals (Schwen and Mannering 1982a). Mixed-function oxidation systems can be induced in liver and skin of tiger salamanders by perylene (Couch et al. 1983) and 3-methylcholanthrene (Anderson et al. 1982), and in liver of the leopard frog (*Rana pipiens*) and garter snake (*Thamnophis* sp.) by benzo[a]pyrene and 3-methylcholanthrene (Stegeman 1981; Schwen and Mannering 1982a, 1982b). A single dose of 40 mg/kg body weight of 3-methylcholanthrene was sufficient to induce mixed-function oxidase activity for several weeks in the leopard frog (Schwen and Mannering 1982b). Amphibians, including tiger salamanders, are quite resistant to PAH carcinogenesis when compared to mammals, according to Anderson et al. (1982). This conclusion was based on studies with *Ambystoma* hepatic microsomes and their inability to produce mutagenic metabolites of benzo[a]pyrene and perylene (as measured by bacterial *Salmonella typhimurium* strains used in the Ames test). However, rat liver preparations did produce mutagenic metabolites under these procedures (Anderson et al. 1982).

25.4.6 Birds

In birds, PAHs were associated with impaired reproduction, growth retardation, morphological abnormalities, behavioral changes, and alterations in Vitamin A and thyroid hormone metabolism (Murk et al. 1996). In one study, fertilized eggs of the chicken (*Gallus domesticus*) and the common eider duck (*Somateria mollissima*) were injected with a mixture of 16 PAHs at 0.2 mg PAH/kg egg FW on day 4 of incubation (Naf et al. 1992). In chicken eggs, 94% of the administered dose was metabolized within the egg by day 18. In embryos of both chickens and eiders, PAH concentrations were highest in gallbladder, followed by liver, kidney, and adipose tissues. Eiders had 40% of the total PAH content in these organs vs. 16% for chickens. Chick embryos, eider embryos, and

juvenile eiders had similar PAH concentrations and PAH profiles. The largest PAH molecule studied, coronene, was not taken up from the yolk by the embryo as efficiently as other PAHs, but once taken up it was metabolized as readily as the other PAHs. AHH activities of chick and eider embryos were of similar magnitude (Naf et al. 1992). Studies with European starlings (*Sturnus vulgaris*) and 7,12-dimethylbenz[*a*]anthracene show that effects on the immune function and hepatic mixed-function oxygenase activity were more pronounced when administered by subcutaneous injection when compared to an oral route of exposure, and more pronounced in nestlings than in adults. Serious adverse effects were noted in adults at total administered doses of 125 mg/kg BW via injection or orally, and 100 mg/kg BW in nestlings (Trust et al. 1994).

Mallards (*Anas platyrhynchos*) fed diets that contained 4000 mg PAHs/kg (mostly as naphthalenes, naphthenes, and phenanthrene) for a period of 7 months had normal survival and no visible signs of toxicity during exposure. However, liver weight increased 25% and blood flow to liver increased 30%, when compared to controls (Patton and Dieter 1980). In another study with mallards, Hoffman and Gay (1981) measured embryotoxicity of various PAHs applied externally, in a comparatively innocuous synthetic petroleum mixture, to the surface of mallard eggs. The most embryotoxic PAH tested was 7,12-dimethylbenz[*a*]anthracene: approximately 0.002 µg/egg (equivalent to about 0.036 µg/kg fresh weight, based on an average weight of 55 g per egg) caused 26% mortality in 18 days, and, among survivors, produced significant reduction in embryonic growth and a significant increase in the percent of anomalies (e.g., incomplete skeletal ossification, defects in eye, brain, liver, feathers, and bill). At 0.01 µg 7,12-dimethylbenz[*a*]anthracene/egg, only 10% survived to day 18. Similar results were obtained with 0.015 µg (and higher) chrysene/egg. For benzo[*a*]pyrene, 0.002 µg/egg did not affect mallard survival, but did cause embryonic growth reduction and an increased incidence of abnormal survivors. At 0.01 µg benzo[*a*]pyrene/egg, 60% died in 18 days; at 0.05 µg/egg, 75% were dead within 3 days of treatment (Hoffman and Gay 1981). Embryos may contain microsomal enzymes that can metabolize PAHs to more highly toxic intermediates than can adults, and avian embryos may have a greater capacity to metabolize PAHs in this manner than do mammalian embryos and fetuses (as quoted in Hoffman and Gay 1981); this observation warrants additional research. Several investigators have suggested that the presence of PAHs in petroleum, including benzo[*a*]pyrene, chrysene, and 7,12-dimethylbenz[*a*]anthracene, significantly enhances the overall embryotoxicity in avian species, and that the relatively small percent of aromatic hydrocarbons contributed by PAHs in petroleum may confer much of the adverse biological effects reported after eggs have been exposed to microliter quantities of polluting oils (Hoffman and Gay 1981; Albers 1983).

25.4.7 Mammals

Numerous PAH compounds are distinct in their ability to produce tumors in skin and in most epithelial tissues of practically all animal species tested. Malignancies were often induced by acute exposures to microgram quantities. In some cases, the latency period can be as short as 4 to 8 weeks, with the tumors resembling human carcinomas (USEPA 1980). Carcinogenic potential values of individual PAHs via dermal exposure, when compared to benzo[*a*]pyrene with an assigned value of 1.0, were 5.0 for dibenz[*a,h*]anthracene; 0.1 for benzo[*a*]anthracene, benzo[*b,k*]fluoranthene, and indeno[1,2,3-*cd*]perylene; 0.01 for benzo[*g,h,i*]perylene and chrysene; and 0.001 for fluoranthene, fluorene, phenanthrene, and pyrene (Hussain et al. 1998). Certain carcinogenic PAHs are capable of passage across skin, lungs, and intestine, and can enter the rat fetus, for example, following intragastric or intravenous administration to pregnant dams (USEPA 1980). In most cases, the process of carcinogenesis occurs over a period of many months in experimental animals, and many years in humans. The tissue affected is determined by the route of administration and species under investigation. Thus, 7,12-dimethylbenz[*a*]anthracene is a potent carcinogen for the mammary gland of young female rats after oral or intravenous administration; dietary benzo[*a*]pyrene leads

to leukemia, lung adenoma, and stomach tumors in mice, and both PAH compounds can induce hepatomas in skin of male mice when injected shortly after birth (Dipple 1985). Mammary tumors were observed in female rats 6 weeks after they were given the first of 4 weekly intragastric doses of 5 mg 7,12-dimethylbenz[a]anthracene/rat; exposure to magnetic fields of low flux density may promote the growth and development of mammary tumors (Mevissen et al. 1998). Acute and chronic exposure to various carcinogenic PAHs have resulted in destruction of hematopoietic and lymphoid tissues, ovotoxicity, antispermatozoic effects, adrenal necrosis, changes in the intestinal and respiratory epithelia, and other effects (Table 25.8) (USEPA 1980; Lee and Grant 1981). For the most part, however, tissue damage occurs at dose levels that would also be expected to induce carcinomas, and thus the threat of malignancy predominates in evaluating PAH toxicity. There is a scarcity of data available on the toxicological properties of PAHs that are not demonstrably carcinogenic to mammals (USEPA 1980; Lee and Grant 1981).

Table 25.8 Some Effects of PAHs on Selected Laboratory Mammals

Effect (units), Organism, PAH Compound	Concentration	Reference ^a

^a 1, Sims and Overcash 1983; 2, Lo and Sandi 1978; 3, Schafer and Bowles 1985; 4, USEPA 1980; 5, Mattison 1980; 6, Yoshikawa et al. 1985.

Target organs for PAH toxic action are diverse, due partly to extensive distribution in the body and also to selective attack by these chemicals on proliferating cells (USEPA 1980). Damage to the hematopoietic and lymphoid system in experimental animals is a particularly common observation (USEPA 1980). In rats, the target organs for 7,12-dimethylbenz[*a*]anthracene are skin, small intestine, kidney, and mammary gland, whereas in fish the primary target organ is liver (Schultz and Schultz 1982). Application of carcinogenic PAHs to mouse skin leads to destruction of sebaceous glands and to hyperplasia, hyperkeratosis, and ulceration (USEPA 1980). Tumors are induced in mouse skin by the repeated application of small doses of PAHs, by a single application of a large dose, or by the single application of a subcarcinogenic dose (initiation) followed by repeated application of certain noncarcinogenic agents (promotion) (Dipple 1985). Newborn mice were highly susceptible to 3-methylcholanthrene, with many mice dying from acute or chronic wasting disease following treatment; some strains of mice eventually developed thymomas, but other strains showed no evidence despite serious damage to the thymus (USEPA 1980). In general, PAH

carcinogens transform cells through genetic injury involving metabolism of the parent compound to a reactive diol epoxide. This, in turn, can then form adducts with cellular molecules, such as DNA, RNA, and proteins, resulting in cell transformation (Dipple 1985; Ward et al. 1985). In the case of benzo[*a*]pyrene, one isomer of the 7,8-diol,9,10-epoxide is an exceptionally potent carcinogen to newborn mice and is believed to be the ultimate carcinogenic metabolite of this PAH (Slaga et al. 1978). One of the most toxicologically significant processes involved in the response to PAH absorption is the interaction with drug-metabolizing enzyme systems (Lee and Grant 1981). Increased production of mixed-function oxidase enzymes in various small mammals has been induced by halogenated naphthalenes (Campbell et al. 1983), 3-methylcholanthrene (Miranda and Chhabra 1980), and numerous other PAHs (USEPA 1980). PAH metabolites produced by microsomal enzymes in mammals can be arbitrarily divided into water-soluble groups, and organosoluble groups such as phenols, dihydrodiols, hydroxymethyl derivatives, quinones, and epoxides (USEPA 1980). In the case of benzo[*a*]pyrene, the diol epoxides are usually considered as the ultimate carcinogens. Other microsomal enzymes convert epoxide metabolites to easily excreted water soluble compounds, with excretion primarily through feces and the hepatobiliary system (USEPA 1980). Interspecies differences in sensitivity to PAH-induced carcinogenesis are due largely to differences in levels of fixed function oxidase activities, and these will directly affect rates at which active metabolites are converted to less-active products (Neff 1979).

Investigators (Neff 1979; USEPA 1980; Dipple 1985) agree that:

- Unsubstituted aromatic PAHs with fewer than 4 condensed rings have not shown tumorigenic activity
- That many, but not all, four-, five-, and six-ring PAH compounds are carcinogenic
- That only a few unsubstituted hydrocarbons with seven rings or more are tumorigenic or carcinogenic

Many PAH compounds containing four and five rings, and some containing six or more rings, provoke local tumors after repeated application to the dorsal skin of mice; the tumor incidence exhibited a significant dose-response relationship (Grimmer et al. 1985). Among unsubstituted PAHs containing a nonaromatic ring (e.g., cholanthrene and acenaphthanthracene), all active carcinogens retained an intact phenanthrene segment (USEPA 1980). The addition of alkyl substituents in certain positions in the ring system of a fully aromatic PAH will often confer carcinogenic activity or dramatically enhance existing carcinogenic potency. For example, monomethyl substitution of benz[*a*]anthracene can lead to strong carcinogenicity in mice, with potency depending on the position of substitution in the order $7 > 6 > 8 = 12 > 9$; a further enhancement of carcinogenic activity is produced by appropriate dimethyl substitution, with 7,12-dimethylbenz[*a*]anthracene among the most potent PAH carcinogens known. Alkyl substitution of partially aromatic condensed ring systems may also add considerable carcinogenic activity as is the case with 3-methylcholanthrene. With alkyl substitutes longer than methyl, carcinogenicity levels decrease, possibly due to a decrease in transport through cell membranes (USEPA 1980).

A good correlation exists between skin tumor-initiating activities of various benzo[*a*]pyrene metabolites and their mutagenic activity in mammalian cell mutagenesis systems (Slaga et al. 1978), although variations in chromosome number and structure may accompany tumors induced by various carcinogenic PAHs in rats, mice, and hamsters (Bayer 1978; USEPA 1980). Active PAH metabolites (e.g., dihydrodiols or diol epoxides) can produce sister chromatid exchanges in Chinese hamster ovary cells (Bayer 1978; USEPA 1980; Pal 1984). When exchanges were induced by the diol epoxide, a close relationship exists between the frequency of sister chromatid exchanges and the levels of deoxyribonucleoside-diol-epoxide adduct formation (Pal 1984). In general, noncarcinogenic PAHs were not mutagenic (USEPA 1980). Laboratory studies with mice have shown that many carcinogenic PAHs adversely affect the immune system, thus directly impacting an organism's general health, although noncarcinogenic analogs had no immunosuppressive effect. Further, the more carcinogenic the PAH, the greater the immunosuppression (Ward et al. 1985). Destruction of

oocytes and follicles in mouse ovary is documented following intraperitoneal injection of benzo[*a*]pyrene, 3-methylcholanthrene, and 7,12-dimethylbenz[*a*]anthracene; the rate of destruction was proportional to the activity of the ovarian cytochrome P-450-dependent monooxygenase, as well as the carcinogenicity of the PAH (Mattison 1980). However, no information is presently available to indicate whether PAHs present a hazard to reproductive success. In those cases where teratogenic effects are clearly evident (e.g., 7,12-dimethylbenz[*a*]anthracene), the required doses were far in excess of realistic environmental exposures (Lee and Grant 1981). Numerous studies show that unsubstituted PAHs do not accumulate in mammalian adipose tissues despite their high lipid solubility, probably because they tend to be rapidly and extensively metabolized (USEPA 1980; Lee and Grant 1981).

The biological half-life (T_b 1/2) of PAHs is limited, as judged by rodent studies. In the case of oral doses of benzo[*a*]pyrene and rat blood and liver, T_b 1/2 values of 5 to 10 min were recorded; the initial rapid elimination phase was followed by a slower disappearance phase lasting 6 h or more (USEPA 1980). The T_b 1/2 value of benzo[*a*]pyrene from blood of rats given 15 mg/kg BW by intravenous injection was 400 min (Moir et al. 1998). In that study, adipose and lung tissues had comparatively high concentrations of benzo[*a*]pyrene 32 h after dosing, and fecal excretion was the dominant route of BaP loss, being 4 to 10 times higher than urinary excretion (Moir et al. 1998). T_b 1/2 values from the site of subcutaneous injection in mice were 1.75 weeks for benzo[*a*]pyrene, 3.5 weeks for 3-methylcholanthrene, and 12 weeks for dibenz[*a,h*]anthracene; the relative carcinogenicity of each compound was directly proportional to the time of retention at the injection site (Pucknat 1981).

Many chemicals are known to modify the action of carcinogenic PAHs in experimental animals, including other PAHs that are weakly carcinogenic or noncarcinogenic. The effects of these modifiers on PAH metabolism appear to fall into three major categories (DiGiovanni and Slaga 1981b):

- Those that alter the metabolism of the carcinogen, causing decreased activation or increased detoxification
- Those that scavenge active molecular species of carcinogens to prevent their reaching critical target sites in the cell
- Those that exhibit competitive antagonism

For example, pyrene given to rats by intravenous injection or orally at 20 mg/kg BW alone or in combination with other PAHs produce the following observations: bioavailability of pyrene is increased in combination with fluoranthene or benz[*a*]anthracene; pyrene enhances the carcinogenic effect of benzo[*a*]pyrene, and carcinogenicity of benzo[*a*]pyrene can be inhibited by pyrene, phenanthrene, or anthracene; and some PAHs present in the environment accelerate the clearance of pyrene but reduce the level of 1-hydroxypyrene in urine (Lipniak-Gawlik 1998). Benz[*a*]anthracene, a weak carcinogen when applied simultaneously with dibenz[*a,h*]anthracene, inhibits the carcinogenic action of the latter in mouse skin; a similar case is made for benzo[*e*]pyrene or dibenz[*a,c*]anthracene applied to mouse skin shortly prior to initiation with 7,12-dimethylbenz[*a*]anthracene, or 3-methylcholanthrene (DiGiovanni and Slaga 1981a). Benzo[*a*]pyrene, a known carcinogen, interacts synergistically with cyclopenta[*cd*]pyrene, a moderately strong carcinogen found in automobile exhausts, according to results of mouse skin carcinogenicity studies (Rogan et al. 1983). Other PAH combinations were cocarcinogenic, such as benzo[*e*]pyrene, pyrene, and fluoranthene applied repeatedly with benzo[*a*]pyrene to the skins of mice (DiGiovanni and Slaga 1981a). Effective inhibitors of PAH-induced tumor development include selenium, Vitamin E, ascorbic acid, butylated hydroxytoluene, and hydroxyanisole (USEPA 1980). In addition, protective effects against PAH-induced tumor formation have been reported for various naturally occurring compounds such as flavones, retinoids, and Vitamin A (USEPA 1980). Until these interaction effects are clarified, the results of single-substance laboratory studies may be extremely difficult to apply to field situations of suspected PAH contamination. Additional work is also needed on PAH dose-

response relationships, testing relevant environmental PAHs for carcinogenicity, and elucidating effects of PAH mixtures on tumor formation (Grimmer 1983).

25.5 RECOMMENDATIONS

No standards have been promulgated for PAHs by any regulatory agency for the protection of sensitive species of aquatic organisms or wildlife, although some criteria have been proposed for aquatic life protection ([Table 25.9](#)). This observation is not unexpected in view of several factors:

1. The paucity of data on PAH background concentrations in wildlife and other natural resources
2. The absence of information on results of chronic oral feeding studies of PAH mixtures and the lack of a representative PAH mixture for test purposes
3. The demonstrable — and as yet poorly understood — effects of biological modifiers, such as sex, age, and diet, and interaction effects of PAHs with inorganic and other organic compounds, including other PAHs.

Nevertheless, the growing database for aquatic life indicates a number of generalizations: (1) many PAHs are acutely toxic at concentrations between 50 and 1000 µg/L; (2) deleterious sublethal responses are sometimes observed at concentrations in the range of 0.1 to 5.0 µg/L; (3) uptake can be substantial, but depuration is usually rapid except in some species of invertebrates; and (4) whole-body burdens in excess of 300 µg benzo[*a*]pyrene/kg (and presumably other PAHs) in certain teleosts would be accompanied by a rise in the activity of detoxifying enzymes.

Aquatic research has focused on PAHs because of their known relationship with carcinogenesis and mutagenesis (Black et al. 1988; Hawkins et al. 1990; Steard et al. 1990, 1991; Collier and Varanasi 1991; Smolowitz et al. 1992; Fernandez and L'Haridon 1994). Many reports exist of high incidences of cancer-like growths and developmental anomalies in natural populations of aquatic animals and plants, but none conclusively demonstrate the induction of cancer by exposure of aquatic animals to environmentally realistic levels of carcinogenic PAHs in the water column, diet, or sediments (Neff 1982b, 1985). However, studies by Baumann, Malins, Black, Varanasi, and their co-workers, among others, have now established that sediments heavily contaminated with PAHs from industrial sources were the direct cause of elevated PAH body burdens and elevated frequencies of liver neoplasia in fishes from these locales. Only a few sites containing high PAH concentrations in sediments have been identified (Couch and Harshbarger 1985), suggesting a need to identify and to evaluate other PAH-contaminated aquatic sites. Most fishery products consumed by upper trophic levels, including humans, contain PAH concentrations similar to those in green vegetables and smoked and charcoal-broiled meats, and would probably represent a minor source of PAH toxicity; however, consumption of aquatic organisms, especially filter-feeding bivalve molluscs, from regions severely contaminated with petroleum or PAH-containing industrial wastes, should be avoided (Jackim and Lake 1978; Neff 1982b). Neff (1982b) has suggested that repeated consumption of PAH-contaminated shellfish may pose a cancer risk to humans, and Al-Yakoob et al. (1994) aver that consumption of PAH-contaminated fish from the Arabian Gulf poses a risk to human health. If true, this needs to be evaluated using seabirds, pinnipeds, and other wildlife groups which feed extensively on molluscs and teleosts that are capable of accumulating high burdens of carcinogenic PAHs, in order to determine if similar risks exist.

For avian wildlife, data are incomplete on PAH background concentrations and on acute and chronic toxicity. Studies with mallard embryos and PAHs applied to the egg surface showed toxic and adverse sublethal effects at concentrations between 0.036 and 0.18 µg PAH/kg whole egg (Hoffman and Gay 1981). Additional research is needed on petroleum-derived PAHs and their effects on developing embryos of seabirds and other waterfowl. There is an urgent need for specific avian biomarkers of PAH exposure (Murk et al. 1996).

PAH criteria for human health protection ([Table 25.9](#)) were derived from tests with small laboratory mammals, primarily rodents. Accordingly, these proposed criteria should become interim guidelines for protection of nonhuman mammalian resources pending acquisition of more definitive data. The proposed PAH criteria are controversial. Pucknat (1981) states that there was no way to quantify the potential human health risks incurred by the interaction of any PAH with other PAHs or with other agents in the environment, including tumor initiators, promoters, and inhibitors. The problem arises primarily from the diversity of test systems and bioassay conditions used for determining carcinogenic potential of individual PAHs in experimental animals, and is confounded by the lack of a representative PAH mixture for test purposes, the absence of data for animal and human chronic oral exposures to PAH mixtures, and the reliance on data derived from studies with benzo[*a*]pyrene to produce generalizations concerning environmental effects of PAHs — generalizations which may not be scientifically sound — according to Pucknat (1981). The USEPA (1980) emphasizes that only a small percentage of PAH compounds are known to be carcinogenic, and that measurements of total PAHs (i.e., the sum of all multiple fused-ring hydrocarbons having no heteroatoms) cannot be equated with carcinogenic potential. Furthermore, when the term “total PAHs” is used, the compounds being considered should be specified for each case. Lee and Grant (1981) state that an analysis of dose-response relationships for PAH-induced tumors in animals shows, in some cases, deviation from linearity in dose-response curves, especially at low doses, suggesting a two-stage model consistent with a linear nonthreshold pattern. Because overt tumor induction follows a dose-response relationship consistent with a multihit promotion process, the multihit component of carcinogenesis may be supplied by environmental stimuli not necessarily linked or related to PAH exposure.

The well-documented existence of carcinogenic and anticarcinogenic agents strongly suggests that a time assessment of carcinogenic risk for a particular PAH can be evaluated only through a multifactorial analysis (Lee and Grant 1981). One of the most toxicologically significant processes involved in the response to PAH absorption is the interaction with drug metabolizing enzyme systems. The induction of this enzyme activity in various body tissues by PAHs and other xenobiotics is probably critical to the generation of reactive PAH metabolites at the target site for tumor induction. At present, wide variations occur in human and animal carcinogen-metabolizing capacity. Moreover, it has not yet been possible to definitely correlate enzyme activity with susceptibility to carcinogenesis. The obligatory coupling of metabolic activation with PAH-induced neoplasia in animals indicates that the modulation of drug-metabolizing enzymes is central to carcinogenesis (Lee and Grant 1981).

PAHs from drinking water contribute only a small proportion of the average total human intake (Harrison et al. 1975). The drinking water quality criterion for carcinogenic PAH compounds is based on the assumption that each compound is as potent as benzo[*a*]pyrene and that the carcinogenic effect of the compounds is proportional to the sum of their concentrations (USEPA 1980). Based on an oral feeding study of benzo[*a*]pyrene in mice, the concentration of this compound estimated to result in additional risk of one additional case for every 100,000 individuals exposed (i.e., 10^{-5}) is 0.028 µg/L. Therefore, with this assumption, the sum of the concentrations of all carcinogenic PAH compounds should be less than 0.028 µg/L in order to keep the lifetime cancer risk below 10^{-4} (USEPA 1980). The corresponding recommended criteria which may result in an incremental cancer risk of 10^{-6} and 10^{-7} over the lifetime are 0.0028 and 0.00028 µg/L, respectively ([Table 25.9](#)). If the above estimates are made for consumption of aquatic organisms only, the levels are 0.311 (10^{-5}), 0.031(10^{-6}), and 0.003(10^{-7}) µg/kg, respectively (USEPA 1980). The use of contaminated water for irrigation can also spread PAHs into other vegetable foodstuffs (USEPA 1980). When vegetables grown in a PAH-polluted area are thoroughly washed and peeled, their contribution to total PAH intake in humans is not significant (Wang and Meresz 1982). Herbivorous wildlife, however, may ingest significant quantities of various PAHs from contaminated vegetables — but no data were available on this subject.

^a Total of 6 PAHs: fluoranthene, benzo[a]pyrene, benzo[g,h,i]perylene, benzo[b]fluoranthene, benzo[k]fluoranthene, and indeno[1,2,3-cd]pyrene.

^b Total of 3 PAHs: benzo[a]pyrene, benzo[j]fluoranthene, and indeno[1,2,3-cd]pyrene.

^c Based on all carcinogenic PAHs.

^d Assuming 1600 g food daily, 70-kg adult, 1–10 mg total PAHs/diet.

^e As above, except 0.1–1.0 mg benzo[a]pyrene/diet.

^f Assuming average of 15–23 m³ of air inhaled daily.

^g To derive PAH criteria, a safety factor of 0.1 was used with most chronic data, but ranged between 0.1 and 0.01 of the lowest observed effective concentration in freshwater and 0.1 and 0.5 in marine waters.

^h Total of 6 PAHs: benzo[a]pyrene, benzo[b]fluoranthene, benzo[a]fluoranthene, benzo[k]fluoranthene, fluoranthene, and indeno[1,2,3-cd]pyrene

ⁱ 1, As quoted in Eisler 1987; 2, Wang and Meresz 1982; 3, Nagpal 1994; 4, Hall 1993; 5, USPHS 1995.

PAHs are widely distributed in the environment as evidenced by their detection in sediments, soils, air, surface waters, and plant and animal tissues. However, the ecological impact of PAHs is uncertain. PAHs show little tendency for bioconcentration despite their high lipid solubility (Pucknat 1981), probably because most PAHs are rapidly metabolized. Sims and Overcash (1983) list a variety of research needs regarding PAHs in soil-plant systems. Specifically, research is needed to establish: the rates of PAH decomposition in soils; the soil PAH levels above which PAH constituents adversely affect the food chain; and enhancement factors that increase degradation rates of PAHs, especially PAHs with more than three rings. Once these factors have been determined, PAH disposal into soils may become feasible at environmentally nonhazardous levels.

Diet is the major source of PAHs to humans. Authorities agree that most foods contain 1 to 10 µg total PAHs/kg fresh weight, that smoking or barbecuing fish and meats increases total PAH content up to 100-fold, that contaminated molluscs and crustaceans may contribute significantly to PAH intake, and that PAH carcinogenic risk to humans has existed at least since man began to

cook his food (Barnett 1976; USEPA 1980; Lee and Grant 1981; Lawrence and Weber 1984a). A total of 22 PAHs has been identified in foods, of which 11 have been found to be carcinogenic in experimental animals. Of these, only 5 (benzo[*a*]pyrene, benz[*a*]anthracene, 3-methylcholanthrene, dibenz[*a,h*]anthracene, and 7,12-dimethylbenz[*a*]anthracene) have been demonstrated to induce tumors following oral administration to rats and mice, and only 3 of the 11 exhibited positive dose-response relationships in chronic studies with mice (Lo and Sandi 1978). There is no credible evidence that any of the 11 known carcinogenic PAHs or their combinations can cause cancer in human beings via the oral route, especially in quantities likely to be present in foods (Lo and Sandi 1978). There is, however, a need for a complete risk assessment to human health from consumption of PAH-contaminated foods, especially in areas of the Middle East where PAH concentrations for anthracene and pyrene in food items greatly exceed the carcinogenic and mutagenic risk based on benzo[*a*]pyrene equivalents (Al-Yakoob et al. 1994).

In view of the carcinogenic characteristics of many PAH compounds, their increasing concentrations in the environment should be considered alarming, and efforts should be made to reduce or eliminate them wherever possible (Suess 1976). Current research, not unexpectedly, has focused on PAH removal from contaminated environments and on bioindicators of PAH exposure. Fernandez and L'Haridon (1994) recommend irradiation (with UV light or daylight) of certain PAHs or hydrocarbon-rich mixtures prior to disposal into the environment to help reduce their harmful effects. Roy and Liu (1997) have successfully used flushing with anionic surfactants to remove anthracene from contaminated soils, and recommend surfactant soil flushing to remove PAHs as an alternative new technology to groundwater flushing with water. Biomarkers proposed as indicators of PAH exposure include elevated excretion rate of 1-OH pyrene in bile of eels from contaminated sites (van der Oost et al. 1994), intestinal P-450 activity as an indicator of dietary PAH exposure and liver P-450 activity as an indicator of sediment PAH concentrations in marine teleosts (Van Veld et al. 1990), loss rate of 5-methyl deoxycytidine from DNA (Shugart 1990), and elevated hepatic EROD activity and concentrations of biliary PAH metabolites (McDonald et al. 1995; Yu et al. 1995). However, levels of bile conjugates as a biomarker of PAH exposure should be interpreted with caution, particularly if some fish are known to have chronic liver disease (Smith et al. 1993). Synchronous fluorescent spectroscopy (SFS) has been used successfully to identify pyrene- and benzo[*a*]pyrene-type metabolites in bile of brown bullheads from Lake Erie tributaries in 1990/91 (Lin et al. 1994). SFS is recommended for screening large numbers of fish samples for evidence of PAH exposure. Increased benzo[*a*]pyrene monooxygenase activity was evident in several species of freshwater fishes exposed to benzo[*a*]pyrene, as reflected by measurement of bile fluorescence (Britvic et al. 1993). Finally, there is a need for additional PAH toxicokinetic models that emphasize uptake, retention, translocation, and biotransformation rates (Law et al. 1991).

25.6 SUMMARY

Polycyclic aromatic hydrocarbons (PAHs) consist of hydrogen and carbon arranged in the form of two or more fused benzene rings. There are thousands of PAH compounds, each differing in the number and position of aromatic rings, and in the position of substituents on the basic ring system. Environmental concern has focused on PAHs that range in molecular weight from 128.16 (naphthalene, 2-ring structure) to 300.36 (coronene, 7-ring structure). Unsubstituted lower-molecular-weight PAH compounds, containing two or three rings, exhibit significant acute toxicity and other adverse effects to some organisms, but are noncarcinogenic. The higher-molecular-weight PAHs, containing four to seven rings, are significantly less toxic, but many of these compounds are demonstrably carcinogenic, mutagenic, or teratogenic to a wide variety of organisms, including fish and other aquatic life, amphibians, birds, and mammals. In general, PAHs show little tendency to biomagnify in food chains, despite their high lipid solubility, probably because most PAHs are

rapidly metabolized. Inter- and intraspecies responses to individual PAHs are quite variable, and are significantly modified by many inorganic and organic compounds, including other PAHs. Until these interaction effects are clarified, the results of single-substance laboratory tests may be extremely difficult to apply to field situations of suspected PAH contamination.

PAHs are ubiquitous in nature — as evidenced by their detection in sediments, soils, air, surface waters, and plant and animal tissues — primarily as a result of natural processes such as forest fires, microbial synthesis, and volcanic activities. Anthropogenic activities associated with significant production of PAHs — leading, in some cases, to localized areas of high contamination — include high-temperature ($>700^{\circ}\text{C}$) pyrolysis of organic materials typical of some processes used in the iron and steel industry, heating and power generation, and petroleum refining. Aquatic environments may receive PAHs from accidental releases of petroleum and its products, from sewage effluents, and from other sources. Sediments heavily contaminated with industrial PAH wastes have directly caused elevated PAH body burdens and increased frequency of liver neoplasia in fishes. At present, no criteria or standards have been promulgated for PAHs by any regulatory agency for the protection of sensitive species of aquatic organisms or wildlife. This observation was not unexpected in view of the paucity of data on PAH background concentrations in wildlife and other natural resources, the absence of information on results of chronic oral feeding studies of PAH mixtures, the lack of a representative PAH mixture for test purposes, and the demonstrable — and, as yet, poorly understood — effects of biological and nonbiological modifiers on PAH toxicity and metabolism. By contrast, criteria for human health protection and total PAHs, carcinogenic PAHs, and benzo[a]pyrene have been proposed for drinking water and air, and for total PAHs and benzo[a]pyrene in food: drinking water, 0.01 to $<0.2\text{ }\mu\text{g}$ total PAHs/L, $<0.002\text{ }\mu\text{g}$ carcinogenic PAHs/L, and $<0.0006\text{ }\mu\text{g}$ benzo[a]pyrene/L; air, $<0.01\text{ }\mu\text{g}$ total PAHs/m³, $<0.002\text{ }\mu\text{g}$ carcinogenic PAHs/m³, and $<0.0005\text{ }\mu\text{g}$ benzo[a]pyrene/m³; food, 1.6 to $<16.0\text{ }\mu\text{g}$ total PAHs daily, and 0.16 to $<1.6\text{ }\mu\text{g}$ benzo[a]pyrene daily. In view of the carcinogenic characteristics of many PAH compounds and their increasing concentrations in the environment, it now seems prudent to reduce or eliminate them wherever possible, pending acquisition of more definitive ecotoxicological data.

CHAPTER 26

Sodium Monofluoroacetate (Compound 1080)

26.1 INTRODUCTION

Sodium monofluoroacetate (CH_2FCOONa), also known as 1080 or Compound 1080, belongs to a class of chemicals known as the fluoroacetates (Pattison 1959). It is a tasteless and odorless water-soluble poison of extraordinary potency that has been used widely against rodents and other mammalian pests (Anonymous 1946; Negherbon 1959; Rammell and Fleming 1978; McIlroy 1981a; Hornshaw et al. 1986; Aulerich et al. 1987; Connolly and Burns 1990; Eisler 1995). The widespread use of 1080 in pest control has resulted in accidental deaths of livestock, wildlife, pets (cats and dogs), and humans (Anonymous 1946; Chenoweth 1949; Sayama and Brunetti 1952; Negherbon 1959; U.S. Environmental Protection Agency [USEPA] 1976; McIlroy 1982a), and several suicides in Asia from drinking 1080 rat poison solutions (Howard 1983). There is no effective antidote to 1080 (Mead et al. 1991). When consumed, fluoroacetate is converted to fluorocitrate, inhibiting the enzymes aconitase and succinate dehydrogenase. The accumulated citrate interferes with energy production and cellular function (Aulerich et al. 1987).

Monofluoroacetic acid (CH_2FCOOH) was first synthesized in Belgium in 1896 but attracted little attention from chemists and pharmacologists at that time (Chenoweth 1949; Atzert 1971). In 1927, sodium monofluoroacetate was patented as a preservative against moths (Sayama and Brunetti 1952). The toxic nature of monofluoroacetate compounds was first noted in Germany in 1934 (Atzert 1971). In the late 1930s and early 1940s Polish scientists conducted additional research on the toxic properties of fluoroacetate compounds, especially on the methyl ester of fluoroacetic acid that they had synthesized (Anonymous 1946; Chenoweth 1949). In 1942, British scientists further refined this compound to the sodium salt, which became known as 1080 (Anonymous 1946). In 1944, potassium monofluoroacetate (CH_2FCOOK) was isolated from *Dichapetalum cymosum*, a South African plant, and was the first known example of a naturally occurring organic fluoride; the plant, known locally as Gifblaar, caused many livestock deaths (Chenoweth 1949) and was recognized by Europeans as poisonous as early as 1890 (Peacock 1964). Fluoroacetate compounds have since been isolated from poisonous plants in Australia (*Acacia georginae*, *Gastrolobium* spp.), Brazil (rat weed, *Palicourea marginata*), and Africa (*Dichapetalum* spp.) (Atzert 1971). Ratsbane (*Dichapetalum toxicarium*), a west African plant, was known to contain a poison — subsequently identified as a fluoroacetate — that was lethal to rats, livestock, and humans and reportedly used by African natives during the 1800s to poison the wells and water supplies of hostile tribes (Anonymous 1946).

During World War II (1939 to 1945), as a result of acute domestic shortages of common rodenticides, such as thallium, strichnine, and red squill, a testing program was initiated for

alternative chemicals (Anonymous 1946). In June 1944, the U.S. Office of Scientific Research and Development supplied the Patuxent Wildlife Research Center (PWRC) — then a U.S. Fish and Wildlife Service laboratory — with sodium monofluoroacetate and other chemicals for testing as rodenticides (Atzert 1971). Sodium monofluoroacetate received the PWRC acquisition number 1080, which subsequently was adopted as its name by the chemical's manufacturer. Samples of 1080 were also shipped to the Denver Wildlife Research Center, another former U.S. Fish and Wildlife Service laboratory, for testing on additional species. Results of these tests gave evidence of the value of 1080 as an effective method of controlling animal predators of livestock and other animal pests (Atzert 1971). During World War II, 1080 protected Allied troops in the Pacific theater against scrub typhus, also known as "tsut sugamushi," a louse-borne rickettsial disease with rodents as vectors (Peacock 1964). In the United States, 1080 was first used in 1945 to control rodents, and later coyotes (*Canis latrans*), rabbits, prairie dogs, and gophers (Hornshaw et al. 1986; Aulerich et al. 1987). Between 1946 and 1949, at least 12 humans died accidentally in the United States from 1080 poisoning when it was used as a rodenticide; a child became ill but recovered after eating the cooked flesh of a 1080-poisoned squirrel (USEPA 1976). Since 1955, 1080 has been used extensively in a variety of baits — especially in Australia and New Zealand — to control European rabbits (*Oryctolagus cuniculus*), dingoes (*Canis familiaris dingo*), feral pigs (*Sus scrofa*), brush-tailed possums (*Trichosurus vulpecula*), and various species of wallabies (McIlroy 1981a, 1981b, 1982a, 1984; Twigg and King 1991). In Australia, vegetable baits are sometimes eaten by nontarget herbivores, such as sheep (*Ovis aries*), cattle (*Bos taurus*), and various species of wildlife, causing both primary and secondary poisoning of nontarget animals (McIlroy 1982a). In the United States, most uses of 1080 were canceled in 1972 due, in part, to deaths of nontarget animals (Balcomb et al. 1983). At present, the use of 1080 in the United States is restricted to livestock protection collars on sheep and goats (*Capra hircus*) against predation by coyotes (Palmateer 1989, 1990). Useful reviews on ecotoxicological aspects of 1080 include those by Chenoweth (1949), Peacock (1964), Atzert (1971), Kun (1982), Twigg and King (1991), Seawright and Eason (1994), and Eisler (1995).

26.2 USES

The use of 1080 in the United States is now restricted to livestock collars on sheep and goats for protection against predation by coyotes. Other countries, most notably Australia and New Zealand, use 1080 extensively in a variety of baits to control many species of vertebrate pests.

26.2.1 Domestic Use

Compound 1080 is highly poisonous to all tested mammals as well as humans (Green 1946). There is no known antidote to 1080, and it has been impossible to resuscitate any animal or human poisoned with 1080 once final stages of poisoning have appeared (Kalbach 1945; Green 1946; Connolly 1989, 1993a). In 25 years of use in the United States, there have been four suicides and at least 12 accidental human deaths; between 1959 and 1969, 37 known incidents of domestic animal poisoning have resulted from federal use of 1080 (Atzert 1971). Compound 1080 is not recommended for use in residential areas or for distribution in places where the public might be exposed (Green 1946); only licensed pest control operators can use 1080 (Green 1946; Peacock 1964; USEPA 1985; Murphy 1986). Tull Chemical in Oxford, Alabama, is the sole domestic producer of 1080; none is imported (USEPA 1985). When handling 1080, human operators should wear protective clothing, including gloves and a respirator; extreme caution is recommended at all times (Green 1946). Each applicator must carry syrup of ipecac to induce vomiting in case of accidental 1080 poisoning when attaching, removing, or disposing of livestock protection collars (Connolly 1989, 1993a).

Compound 1080 was first used in the United States in the late 1940s to control gophers, ground squirrels, prairie dogs, field mice, commensal rodents, and coyotes (Chenoweth 1949; Fry et al. 1986). Coyote damage to livestock in California alone is estimated at \$75 million annually (Howard 1983). Yearly amounts of 1080 used in the United States for predator control were 23 kg in the early 1960s, 7727 kg in the late 1960s, and only 8 kg in 1971 (Connolly 1982). Total production of 1080 in the United States between 1968 and 1970 averaged about 1182 kg annually (Atzert 1971). In 1977, 277,545 kg of 1080-containing baits (272 kg of 1080) were used to control ground squirrels (76%), prairie dogs (7%), and mice, rats, chipmunks, and other rodents (17%); California used 83% of all 1080 baits, Colorado 12%, and Nevada and Oregon 5% (USEPA 1985). About 0.3 kg 1080 per year are used in the livestock protection collar, but only about 35 g per year is released into the environment (Connolly 1993b). In March 1972, the use of 1080 for predator control was prohibited on federal lands. Later that year, all uses of 1080 for predator control were banned in the United States because of adverse effects on nontarget organisms, including endangered species (Palmateer 1989, 1990). In the period since 1080 was banned, the number of grazing livestock reported lost to predation on western national forests has increased. Between 1960 and 1971, 1.42% (range 1.0 to 1.9%) of all sheep and goats grazed were lost to predators vs. 2.17% (1.7 to 2.5%) in 1970 to 1978 (Lynch and Nass 1981). Until it was banned in 1972, the use of 1080 as a predator control agent in the United States was strictly controlled. The chemical was registered under the Federal Insecticide, Fungicide and Rodenticide Act (61 Stat 163; 7 U.S.C. 135-135K) for use only by governmental agencies and experienced pest control operators (Atzert 1971). The use of 1080 as a rodenticide was disallowed in 1985 for three reasons:

1. Lack of emergency treatment, namely a viable medical antidote
2. High acute toxicity to nontarget mammals and birds
3. A significant reduction in populations of nontarget organisms and fatalities to endangered species (USEPA 1985)

In 1985, 1080 use was conditionally permitted in livestock protection collars and in single lethal dose baits; a registration for the livestock protection collar was issued to the U.S. Department of the Interior on July 18, 1985 (USEPA 1985). On February 21, 1989, the registration for 1080 was canceled, effectively prohibiting all uses. In June 1989, however, technical 1080 was conditionally approved for use only in the 1080 livestock protection collar. The 30-mL collar is registered for use by the U.S. Department of Agriculture; by the states of Montana, Wyoming, South Dakota, and New Mexico; and by Rancher's Supply, Alpine, Texas (Palmateer 1989, 1990).

Compound 1080 was highly effective against all species of rats, prairie dogs, and ground squirrels, and satisfactory for the control of mice (Peacock 1964). The chemical was formulated in grain baits or chopped greens for crop and range rodents, and in water bait stations to control rats (USEPA 1985). The concentration of 1080 in baits was lowered to 0.02% both in the range of the California condor (*Gymnogyps californianus*) and for prairie dog control because of possible impacts on the endangered black-footed ferret (*Mustela nigripes*) (USEPA 1985). Commercial 1080 was commonly colored with 0.5% nigrosine and sold as a compound containing >90% sodium monofluoroacetate, to be mixed with foods at 2226 mg/kg in preparing baits, or dissolved in water at 3756 mg/L for poisoning drinking water in indoor control of rodents (Anonymous 1946; Green 1946; Negherbon 1959). Bait acceptance by rats was not significantly reduced by the dye (Peacock 1964). Compound 1080 was adequately accepted by rats and mice when present in water; solid food baits poisoned with 1080 were not always accepted as readily and sometimes required special preparation to insure the ingestion of lethal amounts (Green 1946). A water solution of 1080 was the most effective rodenticide tested for rat control in southern states, and 1080-grain baits were the most effective field rodenticides against ground squirrels, prairie dogs, and mice in California, South Dakota, and Colorado (Kalmach 1945). Seeds and cereal grains were the most effective baits

for small rodents: 1 kg 1080 was sufficient to kill 3.96 million squirrels (Peacock 1964). Grain baits were colored brilliant yellow or green to heighten repellency to birds; coloring baits did not affect their acceptance by rodents (Peacock 1964; Atzert 1971). Rats did not develop any significant tolerance to 1080 from ingestion of sublethal doses, although rats that survived a poisoning incident may develop an aversion to 1080 (Green 1946; Peacock 1964).

To kill coyotes and wolves (*Canis lupus*) in the United States and Canada, meat baits containing 35 mg 1080/kg were recommended, usually by injecting a water solution of 1080 into horse meat baits; only 28 to 56 g of a poisoned bait was sufficient to kill (Peacock 1964). Meat baits were usually placed during the autumn in areas with maximum coyote use and minimum use by most nontarget carnivores (Atzert 1971). The most widely publicized technique for poisoning predators was the 1080 large bait station: a 22- to 45-kg livestock meat bait injected with 35 mg 1080/kg bait (Connolly 1982). The use of 1080 stations peaked in the early 1960s, at which time 15 to 16 thousand stations were placed each winter in the western United States. After 1964, the number of stations declined annually, to 7289 stations in 1971 (Connolly 1982). Against canine predators of livestock, 1080 was more selective and less hazardous to nontarget species than strichnine or traps (Peacock 1964). Meat baits used to control coyotes were seldom fatal to hawks, owls, and eagles, even when these raptors gorged themselves on the 1080-poisoned baits (Peacock 1964). In addition to the large bait stations, an unknown number of U.S. government hunters used 1080 in smaller baits at various stations (Connolly 1982).

The introduction of 1080-livestock protection collars to protect goats and sheep against coyote depredation was initiated in 1985. Its use was limited to certified applicators (Burns et al. 1991). The 1080-filled rubber collars are attached to the throats of sheep and goats; 1080 is released when coyotes attack collared livestock with characteristic bites to the throat (Walton 1990; Burns et al. 1991). The livestock protection collars contain 30 mL of a 1% 1080 solution (Walton 1990) and tartrazine (Burns and Savarie 1989; Connolly 1993a) as a marker. The livestock protection collar may not be used in areas known to be frequented by endangered species of wildlife, and this includes various geographic areas in California, Michigan, Minnesota, Montana, Washington, Wisconsin, and Wyoming (Connolly 1989, 1993a). Compound 1080 is reportedly more effective and safer in livestock protection collars than sodium cyanide, diphacinone, or methomyl (Connolly 1982). Pen tests with compound 1080 in livestock protection collars began in late 1976, and field tests in 1978 (Connolly and Burns 1990). Under field conditions, 1080 livestock protection collars on sheep seem to protect selectively against predation by coyotes; no adverse effects on humans, domestic animals, and nontarget wildlife were recorded (Connolly and Burns 1990). The decision to permit limited use of 1080 in livestock protection collars is now being contested by at least 14 conservation groups because of its alleged hazard to nontarget organisms (bears, badgers, dogs, eagles) and to human health, and to the availability of alternate and more successful methods of coyote control (Sibbison 1984). In Texas, for example, annual predation losses of sheep and goats to coyotes are estimated at \$5 million. But very few Texas ranchers have taken advantage of the opportunity to use livestock protection collars, and only 23 coyotes were killed in 1989 by the collars vs. 473 by cyanide, snares, aerial gunning, and other control measures (Walton 1990). Toxic livestock protection collars in full operation would probably kill <1000 coyotes annually vs. 1 million coyotes killed annually in sport hunting and other control measures (Sibbison 1984).

Compound 1080 was also effective against jackrabbits, foxes, and moles. Baits containing 0.05 to 0.1% 1080 on vegetables were used in California to kill jackrabbits (*Lepus* spp.) and various rodents (Schitoskey 1975). The Arctic fox (*Alopex lagopus*), intentionally introduced onto the Aleutian Islands in 1835 (Bailey 1993), almost eliminated the Aleutian Canada goose (*Branta canadensis leucoparlia*) by 1967. 1080-tallow baits were successfully used to control fox populations (Byrd et al. 1988; Tietjen et al. 1988; Bailey 1993). Earthworm baits are used to kill moles. The earthworms are soaked for 45 min in a 2.5% solution of 1080 and placed in mole burrows. The solution can be used several times for additional lots of worms; however, the use of the manure worm (*Eisenia foetida*) should be avoided because it is seldom eaten by moles (Peacock 1964).

Secondary poisoning of domestic cats and dogs from consumption of 1080-poisoned rodents was frequently noted (Anonymous 1946). Cats and dogs are highly susceptible to 1080 and may die after eating freshly poisoned rodents, dried carcasses, or 1080 baits, or after drinking 1080-poisoned water (Green 1946). All pets should be confined or removed from the area to be poisoned and released after the entire program has been completed. Pigs and carnivorous wildlife are also at risk from consumption of 1080-poisoned rodents (Peacock 1964). Secondary poisoning of kit foxes (*Vulpes* spp.) is theoretically possible after eating a single kangaroo rat (*Dipodomys* spp.) that had swallowed or stuffed its cheeks with 1 g of a 0.1% vegetable/cereal bait and contained a total whole-body burden of about 1 mg 1080 per rat (Schitoskey 1975). To prevent secondary poisoning, all uneaten baits and carcasses of poisoned rodents should be recovered and incinerated (Green 1946), and no 1080-contaminated animal should be eaten by humans or fed to animals (Connolly 1989, 1993a).

26.2.2 Nondomestic Use

Compound 1080 has had limited use as a vertebrate pesticide in Canada, India, Mexico, and South Africa, and extensive use in Australia (Calver et al. 1989b) and New Zealand (Rammell and Fleming 1978). In Canada, 1080 was first used in 1950 in British Columbia to control wolves and coyotes preying on livestock (Peacock 1964). Poisoned 1080 baits were used in India to control (67 to 100% effective) populations of the Indian crested porcupine (*Hystrix indica*) throughout its range because of porcupine-caused damage and losses to agriculture crops; however, 1080 baits were not as effective as fumigants in controlling this species (Khan et al. 1992). In Mexico, 1080 was used against rabid coyotes, although many domestic dogs were also killed (Peacock 1964). In South Africa, beginning in 1961, 1080 was used to control the black-backed jackal (*Canis mesomelas*) preying on livestock, and baboons (*Papio anubis*) and moles that consumed agricultural crops (Peacock 1964). Livestock protection collars containing 30 mL of a 1% 1080 solution are now used in South Africa to combat predation by the Asiatic jackal (*Canis aureus*) (Walton 1990).

Compound 1080 was first used in Australia in the 1950s to kill the introduced European rabbit (*Oryctolagus cuniculus*). Principal target species in Australia now include other introductions such as dingoes, foxes (*Vulpes vulpes*), feral pigs (*Sus scrofa*), feral cats (*Felis cattus*), as well as native brush-tailed possums (*Trichosurus vulpecula*), red-necked wallabies (*Macropus rufogriseus*), and pademelons (*Thylogale billardierii*) (McIlroy 1981a, 1981b, 1982, 1984; Calver et al. 1989a, 1989b; Wong et al. 1991). In Australia, different baits contained different concentrations of 1080; meat baits contained 144 mg/kg, grain baits 288 to 300 mg/kg, fruits and vegetables 330 mg/kg, and pellets 500 mg/kg (McIlroy 1983a).

One method of killing rabbits in many areas of Australia is to apply 1080-poisoned bait (carrots, oat grains, pellets of bran or pollard) to furrows made in the earth or broadcast across the area from the air or ground (McIlroy 1984; McIlroy and Gifford 1991). Aerial dropping of diced carrots treated with 1080 was found to be almost 100% effective for rabbits (Anonymous 1964). In Victoria, more than 6.5 million ha were treated with 1080-poisoned carrots. To attract rabbits to the kill area, nonpoisoned carrots were applied to rabbit trails at more than 8.3 kg/km; nonpoisoned baits were offered twice, 3 days apart, followed by 1080-poisoned carrots 1 week later (Woodfield et al. 1964). Bait avoidance is reported in some populations of European rabbits exposed repeatedly to 1080 baits through sustained control programs. Behavioral resistance may reduce the effectiveness of sustained control and should be considered in pest management plans (Hickling 1994). Individuals — but not populations — of some native species of Australian animals and birds face a greater risk of being poisoned by 1080 during rabbit-poisoning campaigns than rabbits, particularly herbivorous macropodids, rodents, and birds with no prior exposure history to naturally occurring fluoroacetates (McIlroy 1992). Foxes, dingoes, dogs, and cats seem to be at greater risk of secondary poisoning than native birds and mammals, particularly from eating muscle from poisoned rabbits that contained as much as 5 mg 1080 per rabbit (McIlroy 1992).

The injection method of fresh meat baits for use in control of dingoes produced baits more uniform with respect to the amount of 1080 in the bait when compared with mixed baits prepared by tumbling in 1080 solutions. Both techniques, however, produced baits containing variable quantities of 1080 (Kramer et al. 1987). Use of 1080-poisoned baits to control wild dogs (*Canis familiaris familiaris*) and dingoes was not as successful as traps: 22% control for 1080 vs. 56% control for traps. Factors that reduced the success of poisoned baits included rapid loss in toxicity of the baits after their distribution; the rapid rate at which they were removed by other animals, particularly foxes and birds; and the dogs' apparent preference for natural prey (McIlroy et al. 1986a).

Feral pigs in Australia damage crops, degrade pasture, kill and eat lambs, and are potential vectors and reservoirs of exotic pathogens (O'Brien et al. 1986; O'Brien 1988). Control of feral pigs with poisoned baits, including 1080 bait, is difficult because most pigs regurgitate these baits shortly after ingestion (O'Brien et al. 1986). The vomitus may cause secondary poisoning of nontarget species, and pigs surviving sublethal exposure to 1080 as a result of vomiting may develop an aversion to 1080, thus decreasing their susceptibility to subsequent poisoning programs. The incorporation of antiemetics into 1080 baits should reduce or prevent vomiting, but those tested were not completely successful (O'Brien et al. 1986). Feral cats have altered ecosystems and depleted populations of indigenous lizards and birds on Australia, New Zealand, and numerous island habitats throughout the world. Fresh fish baits injected with 2 mg 1080 per bait are used as a humane and lethal poison for feral cats (Eason and Frampton 1991).

The use of 1080 in New Zealand is restricted to licensed operators employed by pest destruction boards and government departments (Temple and Edwards 1985). In Australia, and other locations, the addition of dye to identify toxic baits is standard practice (Temple and Edwards 1985; Statham 1989). The main purpose of such addition is to reduce the unintentional poisoning of birds; birds eat significantly less blue- or green-dyed feed than undyed feed (Statham 1989). Although birds prefer undyed baits to those dyed green, Canada geese (*Branta canadensis*) when feeding at night are unable to distinguish between dyed and undyed baits and consume both with equal frequency (Temple and Edwards 1985). Carrots used as wallaby baits in New Zealand are dyed with special green or blue pigments; however, the red-necked wallaby (*Macropus rufogriseus*) accepted both dyed and undyed carrots equally (Statham 1989). Mice (*Mus* spp.) readily consumed dyed wheat (Twigg and Kay 1992). Compound 1080 is used in jam-type baits to control brush-tailed possums. These baits contained 1080 at concentrations as high as 1500 mg 1080/kg FW bait and were dyed green to protect birds. Cinnamon was added to mask the flavor of the 1080 poison, and 800 mg potassium sorbate/kg was added as an antifungal bait preservative (Goodwin and Ten Houten 1991).

The Norway rat (*Rattus norvegicus*) had a severe effect on island populations of New Zealand birds, reptiles, and invertebrates (Moors 1985). In one case, rats on Big South Island exterminated five species of native forest birds within 3 years, including the last known population of the bush wren (*Xenicus longipes*). A paste containing petroleum jelly, soya oil, sugar, green dye, and 800 mg 1080/kg remained toxic for 6 to 9 months to rats preying on grey-faced petrels (*Pterodroma macroura*) and other birds. Because 1080 produces a poison-shyness in any Norway rat that eats a sublethal dose, complete eradication of this species by 1080 is improbable (Moors 1985). The use of anticoagulants — such as warfarin (multiple doses needed), brodifacoum (single dose) or coumatetralyl — seems more promising than 1080 in rat control programs (Moors 1985), although secondary poisoning of owls and hawks may occur (Hegdal and Colvin 1988).

In New Zealand, compound 1080 in a gel carrier is sometimes applied to the leaves of broadleaf (*Griselinia littoralis*) to poison red deer (*Cervus elephas*), feral goats, white-tailed deer (*Odocoileus virginianus*), and red-necked wallabies (Batcheler and Challies 1988). Use of 1080 gel baits reduced feral goat populations by 90% (Parkes 1983). Wallaby populations were reduced 87 to 91% using a 1080 gel applied to the foliage of palatable plants, and this compares favorably to reductions achieved using aerially sown baits (Warburton 1990). The gel carrier was an effective phytotoxin,

causing withering, death, or loss of chlorophyll from leaves within 10 days, and sometimes within 24 h (Parkes 1983).

Feral pigs are sometimes poisoned by inserting as many as 10 gelatin capsules (each containing 100 mg 1080) into carcass or offal baits. Poisoned carcasses may remain edible for more than 2 months during autumn and winter when poisoning campaigns are conducted. The 1080 is leached out when the carcass has disintegrated (McIlroy 1983a). Other techniques to control feral pigs include injection of 1080 gel into beef lung baits or insertion of capsules containing 1080 into apple, potato, or other fruit and vegetable baits. However, these techniques are potentially the most dangerous to applicators because 1080 powder, rather than a diluted solution, is used. Also, the baits are lethal to nontarget scavengers (McIlroy 1983a).

26.3 ENVIRONMENTAL CHEMISTRY

26.3.1 General

Sodium monofluoroacetate is a whitish powder, soluble in water to at least 263 mg/L but relatively insoluble in organic solvents. Some aqueous solutions of 1080 retain their rodenticidal properties for at least 12 months, but others lose as much as 54% of their toxicity after 24 days. Compound 1080 is unstable at $>110^{\circ}\text{C}$ and decomposes at $>200^{\circ}\text{C}$, although 1080 in baits or poisoned carcasses is comparatively stable. Losses of 1080 from meat baits are due primarily to microbial defluorination, and also to leaching from rainfall and consumption by maggots. Leachates from 1080 baits are not likely to be transported long distances by groundwater because they tend to be held in the upper soil layers. Compound 1080 can be measured in water at concentrations as low as 0.6 $\mu\text{g}/\text{L}$ and in biological samples at 10 to 15 $\mu\text{g}/\text{kg}$. As discussed later, 1080 is readily absorbed through the gastrointestinal tract, mucous membranes, and pulmonary epithelia. Once absorbed, it is uniformly distributed in the tissues. Metabolic conversion of high concentrations of fluoroacetate to fluorocitrate results in large accumulations of citrate in the tissues and eventual death from ventricular fibrillation or respiratory failure. Regardless of dose and in all tested species, no signs or symptoms of 1080 poisoning were evident during a latent period of 30 min to 2 h; however, death usually occurred within 24 h of exposure. Repeated sublethal doses of 1080 have increased the tolerance of some species of tested birds and mammals to lethal 1080 doses. Reptiles are more resistant to 1080 than mammals because of their low facility to convert fluoroacetate to fluorocitrate and their high defluorination capability. No effective antidote is now available to treat advanced cases of fluoroacetate poisoning; accidental poisoning of livestock and dogs by 1080 is likely to be fatal. Partial protection against 1080 poisoning in mammals has been demonstrated with glycerol monoacetate, a sodium acetate/ethanol mixture, and a calcium glutonate/sodium succinate mixture.

26.3.2 Chemical Properties

Some chemical and other properties of 1080 are summarized in [Table 26.1](#). In water, trace amounts (0.6 $\mu\text{g}/\text{L}$) of 1080 were detected using gas chromatography (GC) with electron capture detection; recoveries from environmental water spiked at 5 to 10 $\mu\text{g}/\text{L}$ ranged from 93 to 97% (Ozawa and Tsukioka 1987). Recent advances make it possible to measure 1080 in solutions at concentrations as low as 0.2 $\mu\text{g}/\text{L}$ (Kimball and Mishalanie 1993). In biological tissues, various methods have been used to determine fluoroacetic acid, including colorimetry, fluoride-ion electrodes, gas-liquid chromatography, and high-pressure chromatography. However, these methods involve lengthy extraction procedures, have low recoveries, or show lack of selectivity (Allender 1990). A sensitive gas chromatographic technique was developed and used successfully to determine

Table 26.1 Some Properties of Sodium Monofluoroacetate

Variable	Data
Alternate names	1080; Compound 1080; fratol; monosodium fluoroacetate; sodium fluoacetate; sodium fluoroacetate; ten-eighty
Chemical formula	CH_2FCOONa
Molecular weight	100.03
Physical state	White, odorless, almost tasteless, hygroscopic powdery salt, resembling powdered sugar or baking powder
Primary use	Rodenticide; mammal control agent
Purity	96.0–98.6%
Solubility	
Water	263 mg/L
Acetone, alcohol, animal and vegetable fats, kerosene, oils	Relatively insoluble
Stability	Unstable at >110°C and decomposes at >200°C. Hydrogen fluoride (20% by weight) is a decomposition product which readily reacts with metals or metal compounds to form stable inorganic fluoride compounds

^a Data from Chenoweth 1949; Negherbon 1959; Peacock 1964; Tucker and Crabtree 1970; Atzert 1971; Hudson et al. 1984.

fluoroacetate levels in organs from a magpie (*Gymnorhina tibicen*) that had ingested a bait containing 1080 poison. The procedure involved extraction of 1080 with acetone:water (8:1), followed by derivatization with pentafluorobenzyl bromide. Bait samples were initially screened by thin-layer chromatography, and identification of derivatized extracts was confirmed by gas chromatography–mass spectrometry GC–MS (Allender 1990). A new method for fluoroacetate determination in biological samples involves isolation of fluoroacetate as its potassium salt by ion-exchange chromatography and conversion to its dodecyl ester. The ester is quantified by capillary GC with a flame ionization detector for the range 1 to 10 mg/kg and by selected ion monitoring using GC–MS for the range 0.01 to 1.00 mg/kg (Burke et al. 1989). The detection limit for 1080 in tissues and baits is 15 µg/kg using a reaction-capillary GC procedure with photoionization detection; the detection limit is 100 µg/kg using flame ionization procedures. The detection limit using these procedures is less sensitive than GC–MS; however, GC–MS is not normally available in veterinary diagnostic laboratories (Hoogenboom and Rammell 1987).

26.3.3 Persistence

Significant water contamination is unlikely after aerial distribution of 1080 baits (Eason et al. 1993a). In one New Zealand field trial in which >20 metric tons of 1080 baits were aerially sown over a 2300-ha island to control brushtail possums (*Trichosurus vulpecula*) and rock wallabies (*Petrogale penicillata*), no 1080 was detected in surface or groundwater of the island for at least 6 months after baits were dropped. A similar case was made for streams and rivers after 100 metric tons of 1080 baits were sown by airplane over 17,000 ha of forest (Eason et al. 1992, 1993b). Laboratory studies on 1080 persistence in solutions suggest that degradation to nontoxic metabolites is most rapid at elevated temperatures and in biologically conditioned media, but is highly variable. In general, aqueous solutions of the salt or esters decrease in toxicity over time through spontaneous decarboxylation to sodium bicarbonate and to the highly volatile, relatively nontoxic, methyl fluoride. Solutions refrigerated at 5°C lost about 54% of their initial toxicity to laboratory rats after 24 days and about 40% after 7 days at room temperature, but 1080 solutions remained toxic to yeast for at least 1 month after storage at 3 to 5°C (Chenoweth 1949). In an aquarium containing plants and invertebrates and 0.1 mg 1080/L, water concentration of 1080 declined 70% in 24 h and was not detectable after 100 h; residues in plants were not detectable after 330 h (Eason et al.

1993b). In a distilled water aquarium without biota, 1080 residues declined only 16% in 170 h (Eason et al. 1993b). In another study, 1080 solutions prepared in distilled water and stored at room temperature for 10 years showed no significant breakdown; moreover, solutions of 1080 prepared in stagnant algal-laden water did not lose biocidal properties over a 12-month period (McIlroy 1981a). More research seems needed on 1080 persistence in aquatic environments.

In soils, 1080 is degraded to nontoxic metabolites by soil bacteria and fungi, usually through cleavage of the carbon–fluoride bond (Eason et al. 1991, 1993a). Soil microorganisms capable of defluorinating 1080 include *Aspergillus fumigatus*, *Fusarium oxysporum*, at least three species of *Pseudomonas*, *Nocardia* spp., and two species of *Penicillium* (Wong et al. 1992a). These microorganisms can defluorinate 1080 when grown in solution with 1080 as the sole carbon source, and also in autoclaved soil; the amount of defluorination ranged from 2 to 89% in soils and 2 to 85% in 1080 solutions. Some indigenous soil microflora were able to defluorinate 50 to 87% of the 1080 within 5 to 9 days in soil at 10% moisture at 15 to 28°C. The most effective defluorinators in solution and in soils were certain strains of *Pseudomonas*, *Fusarium*, and *Penicillium* (Wong et al. 1991, 1992a; Walker 1994). *Pseudomonas cepacia*, for example, isolated from the seeds of various fluoroacetate-accumulating plants can grow and degrade fluoroacetate in fluoroacetate concentrations as high as 10,000 mg/kg (Meyer 1994). Biodeflourination of 1080 by soil bacteria was maximal under conditions of neutral to alkaline pH, fluctuating temperatures between 11 and 24°C, and at soil moisture contents of 8 to 15%; biodeflourination of 1080 by soil fungi was maximal at pH 5 (Wong et al. 1992b).

Losses of 1080 from meat baits were most likely due to consumption of the bait by blowfly maggots, leaching by rainfall, defluorination by microorganisms, and leakage from baits during their decomposition (McIlroy et al. 1988). The 1080 in baits will persist under hot and dry conditions where leaching from rain is unlikely (Wong et al. 1992a). Baits remained toxic to dogs for over 32 days during winter when maggots were absent and 6 to 31 days during summer when maggots were present. Baits contained an average LD₅₀ dose to tiger quolls (*Dasyurus maculatus*) — a raccoon-like marsupial — for 4 to 15 days in winter and 2 to 4 days in summer (McIlroy et al. 1988). Meat baits that initially contained 4.6 mg 1080 retained 62% after 3 days, 29% after 6 days, and 28% after 8 days (McIlroy et al. 1986a). The persistence of 1080 in fatty meat baits for control of wild dogs in Australia was measured over a period of 226 days (Fleming and Parker 1991). Baits that initially contained 5.4 mg 1080 retained 73% at day 7, 64% at day 20, 25% at day 48, and 15% at day 226. These baits retained LD₅₀ kill values after 52 days to wild dogs, 93 days to cattle dogs, and 171 days to sheep dogs. In that study, loss of 1080 from the baits was not correlated with rainfall, temperature, or humidity. Losses were attributed to metabolism of 1080 bound to the fatty meat bait, leaching, consumption by maggots, and bacterial defluorination (Fleming and Parker 1991). When it is desirable for baits to remain toxic for long periods, the defluorination activity and microbial growth can be reduced significantly by incorporating bacteriostats and fungistats. Conversely, baits may be inoculated with suitable defluorinating microbes that rapidly detoxify 1080-poisoned baits (Wong et al. 1991).

Compound 1080 was found to be highly persistent in diets formulated for mink (*Mustela vison*). Mink diets analyzed 30 months after formulation lost 19 to 29% of the 1080 when the initial concentration ranged between 0.9 and 5.25 mg 1080/kg; loss was negligible at 0.5 mg 1080/kg ration (Hornshaw et al. 1986). A paste containing 0.08% 1080 plus petroleum jelly, soya oil, sugar, and green dye retained its rodenticidal properties for 6 to 9 months. But a rolled oats/cat food 1080 bait, because of its moistness, became fly-infested in warm weather, tended to rot, and lost its rodenticidal properties in a few days (Moors 1985). Gel baits set to kill deer were sampled after 45 days of weathering; only 10% of the 1080-treated leaves retained toxic gel after 45 days (Batcheler and Challies 1988). About 1.4% of 1080 was lost from the leaves per millimeter of rainfall; about 90% was lost in two trials in which 81 and 207 mm of rainfall were recorded. Compound 1080 decreased from 604 mg/bait at the start, to 76 mg/bait after 30 days, and to 5 mg/bait after 45 days. Significant losses of compound 1080 also resulted from biodegradation in

storage. *Penicillium* spp. from broadleaf samples degraded 1080 at pH 5.4 and 23°C and grew vigorously on 1080-poisoned gels; other species of microorganisms can also degrade 1080 (Batcheler and Challies 1988).

Leachates from 1080-poisoned baits are not likely to be transported long distances by the leaching water because they are held in the upper soil layers (Atzert 1971). This statement is predicated on the facts that: (1) salts of monofluoroacetic acid rapidly adsorb to plant tissues and other cellulosic materials; (2) some plants can decompose 29% of the adsorbed 1080 in 48 h; and (3) 1080 in soils is decomposed by soil microorganisms (Atzert 1971). The percent of 1080 defluorinated from various bait materials after 30 days as a result of microbial action ranged between 0.0 and 7.2% for cereals, eggs, horse meat, and beef; 14% for kangaroo meat; and 71% for oats (Wong et al. 1991). The defluorinating ability of fungi and bacteria was low when 1080 was the sole carbon source and high when alternative carbon sources such as peptone-meat extracts were present. The extent of defluorination varied among the different types of organisms associated with the baits. Microorganisms isolated from oats and kangaroo meat had the highest defluorinating activity, and those from cereals and eggs the lowest (Wong et al. 1991).

26.3.4 Metabolism

Sodium monofluoroacetate is absorbed through the gastrointestinal tract, open wounds, mucous membranes, and the pulmonary epithelium. It is not readily absorbed through intact skin (Negherbon 1959; Atzert 1971). Once absorbed, it seems to be uniformly distributed in the tissues, including the brain, heart, liver, and kidney (Peacock 1964). All tested routes of 1080 administration are equally toxic: there is no noteworthy difference in the acute toxicity of 1080 when administered orally, subcutaneously, intramuscularly, intraperitoneally, or intravenously (Chenoweth 1949; Peacock 1964; Atzert 1971). Moreover, the oral toxicity of 1080 is independent of the carrier, including water, meat, grain, oil, gum acacia suspension, or gelatin capsule carriers (Atzert 1971).

All students of the action of fluoroacetate have been impressed with the unusually long and variable latent period between administration and response. This latent period occurred in all species studied, regardless of route of administration (Chenoweth 1949; Negherbon 1959; Peacock 1964; Tucker and Crabtree 1970; Atzert 1971; Hudson et al. 1984). With few exceptions, the latent period ranges between 30 min and 2 h and massive doses — such as 50 times an LD₉₅ dose — do not elicit immediate responses. The time between 1080 treatment and death was relatively constant in all tested species, and usually ranged between 1 h and 1 day. The latent period associated with 1080 may result from three major factors: (1) the time required for hydrolysis of monofluoroacetate to monofluoroacetic acid, and its subsequent translocation and cell penetration; (2) the time required for biochemical synthesis of a lethal quantity of fluorocitrate; and (3) the time required for the fluorocitrate to disrupt intracellular functions on a large enough scale to induce gross signs of poisoning (Chenoweth 1949; Atzert 1971).

Many authorities agree that the toxicity of 1080 to mammals is due to its conversion to fluorocitrate, a fluorotricarboxylic acid (Gal et al. 1961; Atzert 1971; Roy et al. 1980; McIlroy 1981b; Kun 1982; Mead et al. 1985a, 1985b; Hornshaw et al. 1986; Twigg et al. 1986, 1988a, 1988b; Murphy 1986). These authorities concur that enzymatic conversion of fluoroacetate via fluoroacetyl coenzyme A plus oxalacetate in mitochondria is the metabolic pathway that converts the nontoxic fluoroacetate to fluorocitrate. Fluorocitrate blocks the Krebs cycle, also known as the tricarboxylic acid cycle, which is the major mechanism for realizing energy from food. Fluorocitrate inhibits the enzyme aconitase and thereby inhibits the conversion of citrate to isocitrate. Fluorocitrate also inhibits succinate dehydrogenase, which plays a key role in succinate metabolism. The inhibition of these two enzymes results in large accumulations of citrate in the tissues, blocking glucose metabolism through phosphofructokinase inhibition, and eventually destroying cellular permeability, cell function, and finally the cell itself. The classical explanation of fluorocitrate toxicity through aconitase inhibition has been questioned (Kun 1982; Savarie 1984). A more recent

explanation is that fluorocitrate binds with mitochondrial protein, thereby preventing citrate transport and its utilization by cells for energy production, although the underlying biochemical mechanisms are not completely understood (Kun 1982). Based on calculated metabolic rates of fluorocarboxylic acids, secondary poisoning of animals that have consumed 1080-poisoned prey is probably due to unmetabolized fluoroacetate rather than to fluorocitric acid (Kun 1982).

Dogs, rats, and rabbits metabolize fluoroacetate compounds to nontoxic metabolites and excrete fluoroacetate and fluorocitrate compounds; peak rate of excretion occurs during the first day after dosing and drops shortly thereafter. Rats dosed with radiolabeled 1080 at 5 mg/kg BW had seven different radioactive compounds in their urine. Monofluoroacetate comprised only 13% of the urinary radioactive material, fluorocitrate only 11%, and an unidentified toxic metabolite 3%; two nontoxic metabolites accounted for almost 73% of the urinary radioactivity (Atzert 1971). Animal muscle usually contained nondetectable residues of any 1080 component within 1 to 5 days of treatment (Marsh et al. 1987; Eason et al. 1993c). Defluorination occurred in the liver by way of an enzymic glutathione-dependent mechanism, which in the brush-tailed opossum resulted in the formation of S-carboxymethylcysteine and free fluoride ion (Twigg et al. 1986). A rapid rate of defluorination together with a low reliance on aerobic respiration favored detoxification of fluoroacetate rather than its conversion into fluorocitrate, and may account for the resistance of reptiles to 1080 when compared to mammals (Twigg et al. 1986).

Sublethal doses of 1080 have led to a tolerance to subsequent challenging doses in certain animals. In other species, however, repeated sublethal doses have resulted in accumulation of a lethal concentration (Atzert 1971). Repeated sublethal doses of 1080 have increased the tolerance of some eagles, rats, mice, and monkeys, but not dogs. Conversely, repeated sublethal doses of 1080 have accumulated to lethal levels in dogs, guinea pigs, rabbits, and mallards. Continued sublethal doses of 1080 to rats caused regressive changes in the germinal epithelium of the seminiferous tubules (Atzert 1971). Altered behavior in mice following high sublethal doses of 1080 probably resulted from neuronal damage caused by concurrent energy deficiency, further accentuated by the CNS stimulant action of fluoroacetate/fluorocitrate and the brain anoxia that occurred during 1080-induced intermittent convulsions. A similar pattern has been reported in two human patients (Omara and Sisodia 1990). Anuria in some 1080-dosed mice probably resulted from renal shutdown caused by hypocalcemic tension (Omara and Sisodia 1990). Tolerance to 1080 is a time-related phenomenon (Atzert 1971). Laboratory rats given 0.5 mg 1080/kg BW were more resistant to 5.0 mg/kg BW given >4 and <24 h later than nontested rats (Atzert 1971). Accumulation of 1080 is also a time-related phenomenon (Chenoweth 1949; Atzert 1971). Domestic dogs given 25 µg 1080/kg BW daily were unaffected until the fifth dose, when convulsions and death occurred. Also, larger sublethal doses could be administered to dogs on alternate days without adverse effects (Atzert 1971).

Fish, amphibians, and reptiles are usually less sensitive to 1080 than warm-blooded animals (Atzert 1971). Reptiles, for example, are more resistant to 1080 than mammals (Twigg et al. 1986). The relatively small elevation of plasma citrate levels in skinks (*Tiliqua rugosa*) given 100 mg 1080/kg BW reflects the exceptional tolerance of this lizard species. The minimal effect of fluoroacetate on aerobic respiration in *T. rugosa* could be explained by a low conversion of fluoroacetate into fluorocitrate or by a low susceptibility of aconitase to the fluorocitrate formed. Although defluorination in skinks helped to minimize the immediate effects of fluoroacetate in aerobic respiration, it resulted in rapid depletion of liver glutathione levels (Twigg et al. 1986).

The breakdown in intracellular processes caused by fluorocitrate or decreased energy production may result in death from gradual cardiac failure or ventricular fibrillation, death from progressive depression of the CNS with either cardiac or respiratory failure, or death from respiratory arrest following severe convulsions. Signs of 1080 intoxication included labored breathing, vomiting, lethargy, muscular incoordination, weakness, and tremors (Chenoweth 1949; Negherbon 1959; Tucker and Crabtree 1970; Atzert 1971; Hudson et al. 1984; Murphy 1986; Eason and Frampton 1991). Among herbivores, 1080-induced deaths were due primarily to cardiac disorders; among

carnivores, deaths were from CNS disorders; and among omnivores, deaths were from both cardiac and CNS disorders (Atzert 1971). Other signs of 1080 intoxication included kidney and testicular damage (Savarie 1984) and altered blood chemistry — specifically, elevated concentrations of citrate (Twigg et al. 1986), glucose, lactic acid, pyruvic acid, acetate, inorganic phosphate, potassium, and fluorine (Negherbon 1959). Some mammals additionally displayed parasympathetic nervous system effects, including increased salivation, urination, and defecation, with eventual cardiac failure (Hudson et al. 1984).

Vomiting probably evolved among carrion eaters as a natural protective mechanism, but it does not necessarily ensure survival from 1080 poisoning (McIlroy 1981b). For example, although 90% of eastern native quolls (*Dasyurus viverrinus*) and 95% of tasmanian devils (*Sarcophilus harrisii*) vomited within 26 to 55 min after ingesting 1080, this was still sufficient time for many to absorb a lethal dose. Loud sounds, sudden movements of an observer, or convulsions by another animal nearby sometimes stimulated convulsions. However, variability was great between species and among conspecifics. Signs preceding convulsions usually included restlessness; hyperexcitability or increased response to stimuli; trembling; rapid, shallow breathing; incontinence or diarrhea; excessive salivation; twitching of facial muscles; abnormal eye movements; incoordination; vocalization; and sudden bursts of violent activity. All affected animals subsequently fall to the ground in a tetanic seizure, with hind limbs or all four limbs and sometimes the tail extended rigidly from their arched bodies. This tonic phase is followed by a clonic phase in which the animals kick with the front legs, and eventually begin to relax. After this phase, animals either recover gradually, die shortly afterwards, experience additional seizures and then die or recover, or remain comatose until death up to 6 days later (McIlroy 1981b).

26.3.5 Antidotes

No highly effective treatment of well-established fluoroacetate poisoning is available (Chenoweth 1949; Peacock 1964; Atzert 1971), and accidental poisoning of livestock and domestic dogs is likely to be fatal (Mead et al. 1991). The following compounds were tested and had no effect on ameliorating 1080 intoxication: salts of fatty acids, anticonvulsants, vitamins, and metabolic intermediates (Chenoweth 1949); and nonphysiological sulfhydryl compounds, such as *N*-acetyl-cysteine and cysteamine (Mead et al. 1985a). As discussed later, sodium acetate/ethanol mixtures, barbiturates, glycerol monoacetate, calcium glutonate/sodium succinate mixtures, and 4-methyl-pyrazole offer partial protection to 1080-poisoned mammals, possibly because they compete with fluoroacetate in the Krebs cycle.

Sodium acetate partially protects mice against 1080, as does ethanol. Ethanol and sodium acetate administered together are twice as effective as either alone, suggesting a synergistic effect (Chenoweth 1949). Mixtures of acetate and ethanol reduced mortality of 1080-poisoned mice (given 2 times an LD₅₀ dose) from 80 to 30% (Tourtellotte and Coon 1950). Mice given 170 mg 1080/kg BW (about 10 times an LD₅₀ dose) plus an intraperitoneal injection of sodium acetate (2 to 3 g/kg BW) dissolved in ethanol (1.6 g/kg BW) reduced mortality by 90%. But the beneficial effect of the acetate/ethanol treatment to mice decreased rapidly with increasing time after the administration of 1080. Ethanol/acetate mixtures had some antidotal effect on 1080-poisoned dogs provided that treatment was administered within 30 min of poisoning (Tourtellotte and Coon 1950). A mixture of 2 g sodium acetate/kg BW plus 2 g ethanol/kg BW is recommended for treatment of 1080-poisoned monkeys (Peacock 1964).

Barbiturates were marginally effective in protecting domestic dogs against fluoroacetate poisoning, but not laboratory mice (Chenoweth 1949; Peacock 1964). Barbiturates administered to dogs within 30 min of 1080 poisoning (4 times an LD₅₀ dose) resulted in 80% survival; when therapy was given 3 h after poisoning, survival was 17% (Tourtellotte and Coon 1950). At higher

1080 doses (i.e., 6 times the LD₅₀ value), barbiturates were ineffective. Repeated intravenous injections of 20 mg pentobarbital/kg BW to a 1080-poisoned dog (0.3 mg 1080/kg BW) prevented death when administered within 8.5 h of poisoning (Tourtellotte and Coon 1950).

Glycerol monoacetate at 2 to 4 g/kg BW partially protects 1080-poisoned rats, rabbits, dogs, and rhesus monkeys (Chenoweth 1949; Peacock 1964; Murphy 1986). But its effectiveness is apparent only when administered intramuscularly in large amounts immediately after 1080 ingestion (Mead et al. 1991). A single dose of magnesium sulfate at 800 mg/kg BW given intramuscularly as a 50% solution shortly after 1080 exposure prevented death of rats dosed with marginally lethal amounts of 1080 (Peacock 1964).

A reduced level of blood calcium is one explanation for the toxic effects of fluoroacetate, and may account for the gap between chemical manifestations and the biochemistry of 1080 poisoning (Roy et al. 1980). Cats poisoned with 1080 showed a 27% drop in blood calcium levels within 40 min; intravenous administration of calcium chloride prolonged the life of treated cats from 94 min to 167 min (Roy et al. 1980). In a search for effective antidotes to fluoroacetate poisoning, calcium gluconate was chosen to antagonize hypocalcemia, and sodium alpha-ketoglutarate, and sodium succinate were selected to revive the TCA cycle (Omara and Sisodia 1990). Effectiveness of each of these antidotes individually and in certain combinations was tested in laboratory mice exposed to lethal doses (15 mg/kg BW, intraperitoneal injection) of 1080. Antidotal treatments were administered from 15 min to 36 h after dosing. All three antidotes alone, and a combination of calcium glutonate with sodium alpha-ketoglutarate, were ineffective in reducing mortality in treated mice. However, a combination of calcium glutonate (130 mg/kg BW) and sodium succinate (240 mg/kg BW) was effective if the two solutions were either injected at separate sites or mixed in the same syringe just prior to injection. Increasing the dose of sodium succinate to 360 or 480 mg/kg BW with calcium glutonate (130 mg/kg BW) was unrewarding. Additional studies are needed to confirm the efficacy and mechanisms of action of this combination (Omara and Sisodia 1990).

Intraperitoneal injection of 4-methylpyrazole to rats at 90 mg/kg BW, given 2 h prior to 1080 administration, offered partial protection against accumulations of citrate or fluorocitrate in the kidney (Feldwick et al. 1994). The antidotal effects of 4-methylpyrazole are attributed to its inhibition of NAD⁺-dependent alcohol dehydrogenase that converts 1,3-difluoro-2-propanol to difluoroacetone, an intermediate in the pathway of erythrofluorocitrate metabolism (Feldwick et al. 1994). A disadvantage of 4-methylpyrazole is that it needs to be administered before significant exposure to fluoroacetate.

First aid treatment for humans accidentally poisoned with 1080 includes immediate emesis and gastric lavage, followed by an oral dose of magnesium sulfate or sodium sulfate to remove the poison from the alimentary tract before absorption of lethal quantities can occur (Peacock 1964; Atzert 1971). When the stomach is emptied, oral administration of ethanol may be beneficial (Temple and Edwards 1985). The patient should be put at complete rest and given barbiturates having moderate duration of action, such as sodium amytole, to control convulsions (Anonymous 1964; Atzert 1971). Intramuscular injections of undiluted glycerol monoacetate at 0.5 mg/kg BW are recommended every 30 min for several hours and then at a reduced level for at least 12 h (Atzert 1971; Temple and Edwards 1985). If intramuscular administration is not feasible, a mixture of 100 mL undiluted glycerol monoacetate in 500 mL water can be given orally and repeated in an hour (Atzert 1971). If glycerol monoacetate is not available, acetamide or a combination of sodium acetate and ethanol may be given in the same dose (Atzert 1971). If ventricular fibrillation occurs, the heroic treatment of 5 mL 1% procaine hydrochloride via intracardiac puncture is justified (Anonymous 1964). Intravenous administration of procainamide is also effective in restoring normal rhythm in ventricular fibrillations (Atzert 1971). Symptoms of 1080 poisoning usually subside in 12 to 24 h, but the patient should be kept in bed for at least 3 days (Anonymous 1946).

26.4 LETHAL AND SUBLETHAL EFFECTS

26.4.1 General

Mammals were the least-resistant group tested against 1080. Individuals of sensitive species died after receiving a single dose of 0.05 to 0.2 mg/kg BW. As discussed later, adverse sublethal effects included testicular damage in rats (*Rattus* sp.) after drinking water containing 2.2 to 20.0 mg 1080/L for 7 days (0.07 to 0.71 mg/kg BW daily), impaired reproduction in mink fed diets containing 0.8 mg 1080/kg ration for 60 days, and altered blood chemistry in European ferrets given diets containing 1.1 mg 1080/kg feed for 28 days. Elevated fluoroacetate residues were measured in some 1080-poisoned mammals, notably European rabbits, of 34 mg/kg DW muscle and 423 mg/kg DW liver. Birds belonging to sensitive species died after a single 1080 dose of 0.6 to 2.5 mg/kg BW, daily doses of 0.5 mg/kg BW for 30 days, 47 mg/kg diet for 5 days, or 18 mg/L drinking water for 5 days. Accumulation and adverse sublethal effects in birds occurred at dietary loadings of 10 to 13 mg 1080/kg ration. The risk to human consumers of cooked meat from 1080-poisoned waterfowl seems negligible. Amphibians and reptiles were more resistant to 1080 than mammals and birds because of their greater ability to detoxify fluoroacetate by defluorination, a reduced ability to convert fluoroacetate to fluorocitrate, and an aconitase hydratase enzyme that is comparatively insensitive to fluorocitrate inhibition. LD₅₀ values for amphibians were >44 mg 1080/kg BW; for reptiles, this value was >54 mg 1080/kg BW. Other studies with 1080 and sensitive species showed death of mosquito larvae at water concentrations of 0.025 to 0.05 mg/L, death of terrestrial beetle and lepidopteran larvae at 1.1 to 3.9 mg/kg BW, no phytotoxicity to terrestrial flora at water concentrations of 10 mg/L, and — based on limited data — no adverse effects on freshwater fish at 370 mg/L.

26.4.2 Terrestrial Plants and Invertebrates

Fluoroacetate was first isolated in South Africa in 1944 from the gifblaar plant (*Dichapetalum cymosum*) (Negherbon 1959). Seeds of the South African *Dichapetalum braunii* may contain as much as 8000 mg fluoroacetate/kg DW (Meyer 1994). Several other species of *Dichapetalum* produce fluoroacetate, as well as *Palicourea marcgravii*, a South American species known to be poisonous (Twigg et al. 1986; Twigg and King 1991). In Australia, fluoroacetate occurs naturally in the leaves, flowers, and seeds of more than 35 species of leguminous plants of the genera *Gastrolobium* and *Acacia* (Mead et al. 1985; Twigg et al. 1986, 1988, 1990; Twigg and King 1991; McIlroy 1992). All but two of these species are confined to the southwest corner of western Australia; the other two species are found in northern and central Australia. Fluoroacetate concentrations varied regionally, seasonally, among species, and among parts of the plants. Fluoroacetate content of these plants is usually greatest in flowers, seeds, and young leaves, and this is consistent with chemically mediated defense strategies in which plants use poisonous compounds to protect those parts most essential to them (Twigg and King 1991). In Australia, the highest fluoroacetate concentrations measured were in air-dried leaves and seeds of two species from western Australia: concentrations reached 2650 mg/kg in leaves and 6500 mg/kg in seeds of *Gastrolobium* spp. Air-dried samples of the two species from northern and central Australia, *Acacia georginae* and *Gastrolobium grandiflorum*, contained as much as 25 mg fluoroacetate/kg leaf and 185 mg/kg seed (Twigg and King 1991).

Significant economic losses of domestic livestock have occurred in Africa and Australia after ingestion of fluoroacetate-bearing vegetation (Twigg and King 1991). Herbivores that have had evolutionary exposure to this vegetation are much less susceptible to fluoroacetate intoxication than geographically separate, unchallenged species (Mead et al. 1985; Twigg et al. 1986). The development of tolerance to fluoroacetate by insects, reptiles, birds, and mammals has evolved on at least three continents where indigenous plants produce fluoroacetate which protects them against herbivores

(Twigg and King 1991). In Australia, for example, animal populations that have coexisted with fluoroacetate-bearing vegetation for at least several thousands of years have developed varying degrees of tolerance to this potent toxin. Tolerance depends on their diet and habitat, size of their home range, mobility, and length of evolutionary exposure to fluoroacetate-bearing vegetation. Once developed, this tolerance is retained by animal populations even after isolation from the toxic vegetation for 70 to 100 centuries. Biochemical mechanisms responsible for the large toxicity differential between conspecifics with and without exposure to fluoroacetate-bearing vegetation are poorly understood (Twigg and King 1991).

Fluoroacetate and fluorocitrate have also been isolated from forage crops grown in an environment rich in atmospheric or inorganic fluoride (Lovelace et al. 1968; Ward and Huskisson 1969; Atzert 1971; Savarie 1984; Twigg and King 1991). For example, soybeans (*Glycine max*) can synthesize fluoroacetic acid when grown in an atmosphere containing elevated levels of hydrogen fluoride or in media containing high levels of sodium fluoride. Forage crops, including alfalfa (*Medicago sativa*) and crested wheat grass (*Agropyron cristatum*), found growing near a phosphate plant that discharged inorganic fluoride contained as much as 179 mg fluoroacetate/kg DW, 896 mg fluorocitrate/kg DW, and 1000 mg total fluoride/kg. The plants were not adversely affected, but horses (*Equus caballus*) grazing these crops showed signs of fluoride poisoning, suggesting that the toxic effect of inorganic fluoride adsorbed or absorbed by plants and not incorporated into monofluoroacetic acid was greater than the toxic effect of monofluoroacetic acid synthesized by the plants (Lovelace et al. 1968; Atzert 1971). Lettuce (*Lactuca sativa*) can absorb radiolabeled 1080 through its roots or leaves, resulting in elevated citrate concentrations and active retention of radioactivity when compared to controls (Ward and Huskisson 1969). Plants can degrade 1080 by cleaving the carbon–fluorine bond, as judged by studies with germinating seeds of the peanut, *Arachis hypogaea* (Atzert 1971).

Compound 1080 mixed with gel, paste, or grease carriers smeared on leaves of palatable plants has been used to control ungulate and marsupial pests in New Zealand, including feral goats (*Capra* sp.), red deer (*Cervus elephas*), and white-tailed deer (*Odocoileus virginianus*) (Parkes 1991). The effectiveness of 1080 in carbopol gel or petrolatum grease on leaves of the mahoe (*Melicytus ramiflorus*) was significantly modified by the phytotoxicity of these carriers. Both carriers caused baited leaves to abscise, and the rate of abscission increased when 1080 was included. Petrolatum was one third as phytotoxic as carbopol and retained 1080 for longer periods — at least 1 year. Carbopol lost about 95% of its 1080 after 64 days of exposure and 100 mm of rain vs. 22% loss in petrolatum under similar conditions. Carbopol with 1080 is recommended for use where its distribution is sufficient to place goats and other target species at immediate risk; petrolatum can be used in areas where a long-lasting bait is needed (Parkes 1991).

Compound 1080 has systemic insecticidal properties against insects feeding on treated plants. Cabbage (*Brassica oleracea capitata*) that had accumulated 1080 through its roots from solution or soil cultures, or following leaf application, was toxic by contact to eggs and larvae of the large white butterfly (*Pieris brassicae*), and various species of aphids (Negherbon 1959). Compound 1080 was not phytotoxic at 10 mg/L or several times the concentration necessary for insecticidal action, but its use as an insecticide is not recommended because of its high mammalian toxicity (Negherbon 1959; Spurr 1991).

At least nine groups of terrestrial invertebrates are adversely affected by eating 1080-poisoned baits, living in habitats contaminated by residues leaching from 1080 baits, or consuming animal by-products and carcasses contaminated with 1080 (Chenoweth 1949; Notman 1989). Lethal effects are reported in houseflies, moths, aphids, ants, bees, and mites that ate 1080-poisoned baits and in fleas that ate 1080-poisoned rats (Notman 1989). Cockroaches, collembolids, and slugs that ate poisoned baits experienced adverse effects. Egg production in wasps was disrupted after a single sublethal dose of 1080, and butterfly eggs treated with 1080 had 98% mortality of resultant larvae (Notman 1989). Harvester ants (*Pogono myrmex*) and darkling ground beetles (Tentyridae) removed and consumed 1080 bait, leaving bait and dead ants concentrated on the ground near the nest

(Hegdal et al. 1986). In a wasp control program, German wasps (*Vespula germanica*) and common wasps (*Vespula vulgaris*) fed 1080-poisoned canned sardines in aspic jelly were not affected at concentrations <100 mg 1080/kg bait (Spurr 1991). At 1000 mg/kg, however, wasp traffic at nest entrances was reduced 17%; at 5000 to 10,000 mg/kg, traffic was reduced 78 to 89%, and almost all wasps died within 100 m of bait stations after 6 h (Spurr 1991). Honeybees (*Apis mellifera*) feed readily on 1080 jam baits used to control opossums (*Trichosurus vulpecula*) in New Zealand (Goodwin and Ten Houten 1991). Bee kills have been documented in the vicinity of jam baits and dead bees contained 3.1 to 10.0 mg 1080/kg whole bee. The oral LD₅₀ for the honey bee is 0.8 µg/bee. Because no deaths occur within 2 h after feeding, poisoned bees may make several foraging trips before dying. Molasses or oxalic acid is now added to 1080 jam baits to repel bees (Goodwin and Ten Houten 1991). Poisoned insects may cause secondary poisoning of insectivores. Accordingly, 1080 should not be used in the vicinity of susceptible nontarget species of invertebrates or endangered insectivores (Notman 1989).

Tested insect larvae showed great variability in sensitivity to 1080 after abdominal injection (Twigg 1990). The LD₅₀ value, in mg 1080/kg BW — administered by way of fluoroacetate-bearing vegetation — was 1.05 for *Perga dorsalis* (Hymenoptera); for Lepidoptera, these values were 3.9 for *Mnesampla privata*, 42.7 for *Spilosoma* sp., and about 130.0 for *Ochrogaster lunifer*. For all species tested, death occurred within 2 to 48 h after injection, and total body citrate concentrations were significantly higher than that of unpoisoned conspecifics. Enhanced tolerance to 1080 was shown in larvae of Western Australian insects feeding on fluoroacetate-bearing vegetation (Twigg 1990).

Populations of terrestrial invertebrates were not adversely affected by 1080 poisoning operations to control brushtail possums in New Zealand, including populations of amphipods, ants, beetles, collembolids, millipedes, mites, weevils, slugs, spiders, and snails (Spurr 1994). Residues of 1080 in nontarget terrestrial invertebrates were low or negligible after an aerial poisoning campaign (Eason et al. 1993b). Residues of 1080 were measured in various species of terrestrial invertebrates in New Zealand before and after aerial application of possum baits containing 800 mg 1080/kg and sown at 5 kg/ha. No residues of 1080 were found in spiders, beetles, millipedes, centipedes, or earthworms at any stage. Residues of 1080 were detectable in some orthopteran insects (2 mg/kg FW) and cockroaches (4 mg/kg FW). Laboratory studies indicated that 90% of all 1080 was eliminated from insects within 4 to 6 days after dosing, suggesting low risk to insectivorous birds (Eason et al. 1993b).

26.4.3 Aquatic Organisms

Despite an intensive literature search, very little data were found on the toxicity of 1080 to aquatic life. King and Penfound (1946) report that fingerling bream and bass (species unidentified) tolerated 370 mg 1080/L for an indefinite period with no apparent discomfort. Deonier et al. (1946) aver that fourth instar larvae of the mosquito *Anopheles quadrimaculatus* were comparatively sensitive to 1080, and that 1080 was among the most toxic 3% of 6000 organic compounds screened against this life stage. In 48 h, concentrations of 0.025, 0.05, and 0.1 mg 1080/L were fatal to 15%, 40%, and 65% of these larvae, respectively. The common duckweed (*Spirodela oligorrhiza*) seems to be unusually sensitive to 1080. Growth inhibition of duckweed was recorded at 0.5 mg/L (Walker 1994), but this needs verification.

Recent unpublished data (as quoted in Fagerstone et al. 1994) on the acute toxicity of 1080 to rainbow trout (*Oncorhynchus mykiss*), bluegill (*Lepomis macrochirus*), and daphnid (*Daphnia magna*) suggest that these organisms are comparatively tolerant to 1080. For example, bluegills exposed to 970 mg 1080/L for 96 h showed no observable adverse effects. For rainbow trout, the no-observable-effect concentration during 96-h exposure was 13 mg 1080/L and the LC₅₀ (96 h) value was 54 mg/L with a 95% confidence interval of 39 to 74 mg/L. For *Daphnia*, no adverse

effects were noted at 130 mg 1080/L during exposure for 48 h, although 50% were immobilized at 350 mg/L in 48 h (Fagerstone et al. 1994). No data were available on effects of 1080 to aquatic biota during life-cycle or long-term exposures. Studies need to be initiated on effects of chronic exposure of 1080 to nontarget species of aquatic arthropods and macrophytes.

26.4.4 Amphibians and Reptiles

In general, the onset of action and time to death or recovery was slowest in amphibians and reptiles and they were among the most resistant to 1080 of all vertebrate animals tested (McIlroy et al. 1985; McIlroy 1986). LD₅₀ values for representative species of amphibians ranged from 54 to 2000 mg 1080/kg BW and for reptiles 44 to 800 mg/kg BW (Table 26.2). Frogs and lizards given a lethal oral dose of 1080 did not show signs of poisoning for 22 to 56 h and survived for 78 to 131 h (McIlroy et al. 1985). Frogs seem to be more sensitive to 1080 in summer than in winter (Chenowith 1949). Amphibians and reptiles possess an innate tolerance to 1080 when compared to mammals because of their greater ability to detoxify fluoroacetate by defluorination, a reduced ability to convert fluoroacetate to fluorocitrate, and an aconitase hydratase enzyme system that is less sensitive to inhibition by fluorocitrate (Twigg and Mead 1990).

One of the most tolerant reptiles tested against 1080 was the shingle-back lizard (*Tiliqua rugosa*) (McIlroy 1986), but populations of *T. rugosa* from western Australia that coexist with fluoroacetate-bearing vegetation were much less sensitive to 1080 intoxication than conspecifics from South Australia not exposed to the toxic plants (Table 26.2; McIlroy et al. 1985; Twigg et al. 1988a; Twigg and Mead 1990). The shingle-back lizard is an omnivore that feeds on flowers, leaves, and seeds, and probably evolved an increased tolerance to fluoroacetate through feeding on toxic plants such as *Gastrolobium* and *Oxylobium*, which are abundant in southwestern Australia (McIlroy et al. 1985).

Reptiles are unlikely to be affected by either primary or secondary poisoning during 1080-poisoning campaigns (McIlroy 1992). In Australia, 1080-poisoned baits contained 330 mg 1080/kg in carrot baits for rabbits and oat baits for pigs, 400 mg 1080/kg in oat baits for rabbits, 500 mg 1080/kg in pellet baits for rabbits and pigs, 14 mg 1080/kg in meat baits for dingos, and 144 mg/kg in meat baits for pigs (McIlroy et al. 1985). These data indicate that most species of reptiles tested would need to ingest unrealistic quantities of bait to be adversely affected by 1080. Most lizards, for example, would need to eat 43 to 172% of their body weight of poisoned rabbit baits, and 143 to 393% of their body weight of meat baits intended for pigs. However, Gould's monitor (*Varanus gouldi*) may ingest lethal amounts of meat baits intended for pigs after eating 31% of its body weight of poisoned baits. By comparison, a large pig (130 kg) needs to eat about 2 kg of meat bait (1.6% of its body weight) for an LD₉₉ dose (McIlroy et al. 1985).

Table 26.2 Effects of 1080 on Representative Amphibians and Reptiles

Group, Species, Dose, and Other Variables	Effect	Reference ^a
AMPHIBIANS		
Spotted grass frog, <i>Limnodynastes tasmaniensis</i> ; 60 mg/kg body weight (BW); single dose	LD ₅₀ , adults	1
Bullfrog, <i>Rana catesbeiana</i> ; 54.4 (95% confidence interval [=CI] of 25.6–115.0) mg/kg BW; single dose	LD ₅₀	2, 6
Frogs, various; 1000–2000 mg/kg BW; single dose	LD ₅₀	7, 8
Leopard frog, <i>Rana pipiens</i> ; 150 mg/kg BW; single dose	LD ₅₀	2, 9
South African clawed frog, <i>Xenopus laevis</i> ; >500 mg/kg BW; single dose	LD ₅₀	2, 9

Table 26.2 (continued) Effects of 1080 on Representative Amphibians and Reptiles

Group, Species, Dose, and Other Variables	Effect	Reference ^a
REPTILES		
Australian reptiles		
163 (44–336) mg/kg BW	LD50 mean and range for 5 species with no previous exposure to naturally occurring fluoroacetates	10
250 and 800 mg/kg BW	LD50 for 2 species with prior or continuing exposure to naturally occurring fluoroacetates	10
Gopher snake, <i>Pituophis catenifer</i> ; fed dead or moribund rodents poisoned with high concentrations of 1080	In 21 separate trials, 14 snakes regurgitated rodents and 7 had no significant effects within 5 days of ingestion	11
Bearded dragon, <i>Pogona barbatus</i> ; <110 mg/kg BW; single dose	LD50	1
Blotched blue-tongued lizard, <i>Tiliqua nigrolutea</i> ; 336 (95% CI of 232–487) mg/kg BW; single dose	LD50	1, 5
Shingle-back lizard, <i>Tiliqua rugosa</i> ; single dose 25 mg/kg BW	No effect on plasma testosterone concentration	3
100 mg/kg BW	Plasma testosterone concentration decreased 52%	3
100 mg/kg BW	Plasma citrate levels increased 3.4 times after 48 h	4
206 (95% CI of 147–289) mg/kg BW	LD50; nontolerant populations from South Australia	1, 5
300 mg/kg BW	Oxygen consumption reduced 2.5–11.0% over a 22-h postdosing observation period	4
525 (95% CI of 487–589 mg/kg BW)	LD50; tolerant populations from West Australia	1
Gould's monitor, <i>Varanus gouldi</i> ; 43.6 (95% CI of 27.5–69.2) mg/kg BW; single dose	LD50	1, 5
Lace monitor, <i>Varanus varius</i> ; <119 mg/kg BW; single dose	LD50	1

26.4.5 Birds

Laboratory studies with birds (Table 26.3) indicated several trends:

1. Death occurred in orally-dosed sensitive species after a single dose of 0.6 to 2.5 mg 1080/kg BW, daily doses of 0.5 mg 1080/kg BW for 30 days, 47 mg/kg diet for 5 days, or 18 mg/L drinking water for 5 days.
2. Single doses >10 mg/kg BW were usually fatal.
3. 1080 toxicity was enhanced at lower temperatures.
4. Younger birds were more sensitive than older birds.
5. Birds tended to avoid diets and drinking water containing high sublethal concentrations of 1080.
6. Accumulations and adverse effects were noted at dietary concentrations of 10 to 13 mg 1080/kg feed.
7. Birds with prior or continuing exposure to naturally occurring fluoroacetates were more resistant to 1080 than conspecifics lacking such exposure

Drinking water LC50 values were about 10 times higher (i.e., 10 times less toxic) than dietary LC50s for mallards (*Anas platyrhynchos*) and common bobwhites (*Colinus virginianus*). However, both species of birds consumed 5 to 10 times more water than food on a daily mg/kg BW basis

(Kononen et al. 1991). The minimum repeated daily oral dosage that was lethal to mallards in 30-day tests was 0.5 mg/kg BW, suggesting a high degree of cumulative action for this species (Tucker and Crabtree 1970). But European starlings (*Sturnus vulgaris*) tolerated 13.5 mg 1080/kg diet for extended periods without significant adverse effects (Balcomb et al. 1983). Studies with the galah (*Cacatua roseicapilla*) showed that 1080 lethality was not affected by the age or sex of the bird or the route of administration (McIlroy 1981a). But breeding adult female Pacific black ducks were more sensitive to 1080 than either males or nonbreeding females (McIlroy 1984).

The most common external signs of avian 1080 poisoning included depression, fluffed feathers, a reluctance to move, and convulsions (McIlroy 1984). Signs of 1080 poisoning first appeared 1 to 60 h after dosing, and deaths occurred 1 h to almost 11 days after dosing (McIlroy 1984). Death of 1080-poisoned California quail (*Callipepla californica*) usually occurred within 3 h, although birds were inactive within 2 h of dosing and comatose until death (Sayama and Brunetti 1952). The most common internal sign of 1080 poisoning was a dose-related increase in plasma citrate concentration, and this was a useful indicator of fluoroacetate sensitivity among birds of similar metabolic rates and phylogenetic affinities (Twigg and King 1989). Some birds poisoned with 1080 either vomited (little crow, *Corvus bennetti*; emu, *Dromaius novaehollandiae*; wedge-tailed eagle, *Aquila audax*; sulphur-crested cockatoo, *Cacatua galerita*) or had saliva or fluid dripping from their beaks (Pacific black duck, *Anas superciliosa*) (McIlroy 1984). Early signs of poisoning, such as vomiting, were seen at oral doses of 10 mg/kg BW in various raptors, including the rough-legged hawk (*Buteo lagopus*), the ferruginous rough-legged hawk (*Buteo regalis*), the northern harrier (*Circus cyaneus*), and the great horned owl (*Bubo virginianus*) (Atzert 1971). The onset of convulsions was preceded by rapid panting, squawking, shrieking or other vocalizations and then a brief period (5 to 120 s) of violent wing flapping, loss of balance, or paddling or running motions with the feet. Birds then fell to the ground while undergoing tetanic seizures, breathing slowly and laboriously, with wings and tail outstretched (McIlroy 1984). Turkey vultures (*Cathartes aura*) fatally poisoned by 1080 died 4 to 32 h after dosing; prior to death, birds displayed tremors, ataxia, lethargy, wing drooping, and emesis. Turkey vultures were more sensitive to 1080 at colder temperatures of 8 to 9°C than at 23 to 28°C; this may be due to inhibition by 1080 of mitochondrial oxidative phosphorylation at colder temperatures, making animals more sensitive at times of increased metabolic demand (Fry et al. 1986).

Some bird species probably developed a tolerance to 1080 from eating plants that contain fluoroacetate, or insects and other organisms that have fed on such plants (McIlroy 1984). Birds indigenous to geographic areas of Australia where fluoroacetate-bearing vegetation is abundant were more tolerant to 1080 than birds distributed outside the range of the toxic plants. Fluoroacetate tolerance in birds is postulated to increase with increasing evolutionary exposure to the toxic plants and decreasing mobility (Twigg and King 1989). In the low-nutrient environment of western Australia, fluoroacetate-tolerant herbivores clearly have a potential advantage over nontolerant herbivores in their broadened choice of fluoroacetate-bearing vegetation in the diet (Twigg et al. 1988b). The most sensitive Australian bird tested was the red-browed firetail (*Emblema temporalis*), with an LD₅₀ of 0.63 mg 1080/kg BW (0.007 mg/whole bird). The most resistant bird tested was the emu with an LD₅₀ of about 250 mg 1080/kg BW or about 8000 mg/whole bird (McIlroy 1983a, 1984, 1986). Emus in the southwest portion of Western Australia with evolutionary exposure to fluoroacetate-bearing vegetation have unusually high tolerance to 1080. Emu tolerance was attributed to: (1) their ability to detoxify fluoroacetate by defluorination; (2) a limited ability to convert fluoroacetate into fluorocitrate; and (3) possession of an aconitase hydratase enzyme that is relatively insensitive to fluorocitrate (Twigg et al. 1988b).

Deaths of nontarget species of birds after eating 1080-poisoned baits have been reported (Spurr 1979; McIlroy 1984; Fry et al. 1986; Hegdal et al. 1986; McIlroy et al. 1986a), although population effects have not yet been demonstrated. Birds of several species were found dead after 1080 baits were applied to kill California ground squirrels (*Spermophilus beecheyi*), but only Brewer's blackbird

(*Euphagus cyanocephalus*) contained measurable 1080 residues. Nontarget seed-eating birds that died after eating 1080-poisoned baits included sparrows, blackbirds, towhees (*Pipilo* spp.), horned larks (*Eremophila lepestris*), McCown's longspurs (*Calcarius mccownii*), chestnut-collared longspurs (*Calcarius ornatus*), and western meadowlarks (*Sturnella neglecta*) (Hegdal et al. 1986). Individuals of at least 20 species of Australian birds are at risk from dingo and pig poisoning campaigns that use meat baits containing 14 to 140 mg 1080/kg bait, and 39 species are at risk from rabbit and pig poisoning campaigns using vegetable baits that contain 330 to 500 mg 1080/kg bait. The extent of bird mortality and possible population effects depend on several factors (McIlroy 1984):

- Bait palatability to each species
- Availability of other foods
- Amount of 1080 ingested
- Number of birds in each population that consume baits before the target species or other nontarget groups
- Rate of 1080 leaching from baits by dew or rainfall

Birds seen feeding on 1080-poisoned baits for control of wild dogs included the pied currawong (*Strepera graculina*), the Australian raven (*Corvus coronoides*), the Australian magpie (*Gymnorhina tibicen*), and the wedge-tailed eagle (*Aquila audax*) (McIlroy 1981b; McIlroy et al. 1986a). Avian scavengers such as vultures, condors, hawks, and ravens are likely to find poisoned food items as they search for carcasses (Fry et al. 1986).

Secondary 1080 poisoning of birds is documented. Australian birds found dead after eating 1080-poisoned carcasses of pigs (*Sus* sp.) included kites (whistling kite, *Haliastur sphenurus*; black kite, *Milvus migrans*), eagles (Australian little eagle, *Hieraetus morphnoides*; wedge-tailed eagle), brown falcon (*Falco berigora*), Australian kestrel (*Falco cenchroides*), brown goshawk (*Accipiter fasciatus*), Australian magpie-lark (*Grallina cyanoleuca*), Australian raven, and crows (Australian crow, *Corvus orru*; little crow, *Corvus bennetti*) (McIlroy 1983a). Insectivorous birds that may have died after eating 1080-poisoned ants (*Veromessor andrei*, *Liometopum occidentale*) in the United States include acorn woodpeckers (*Melanerpes formicivorus*), the white-breasted nuthatch (*Sitta carolinensis*), and the ash-throated flycatcher (*Myiarchus cinerascens*) (Hegdal et al. 1986).

Little or no secondary hazards to raptors were evident — as judged by the absence of carcasses — from 1080 ground squirrel baiting operations among hawks, harriers, eagles, ravens, vultures, and condors. However, some species of owls were comparatively susceptible to 1080, including burrowing owls (*Athene cunicularia*) and barn owls (*Tyto alba*) (Hegdal et al. 1986). Raptors are less susceptible to secondary poisoning from 1080 than mammalian predators because birds have higher LD50 values, refuse to eat large amounts of 1080-poisoned meats, and sometimes regurgitate poisoned baits (Hegdal et al. 1986). The reduced hazard of acute 1080 poisoning via secondary sources for raptors is illustrated for the golden eagle (*Aquila chrysaetos*), a bird that normally consumes the internal organs of its prey before consuming other portions of the carcass (Atzert 1971). Golden eagles fed diets containing 7.7 mg 1080/kg diet — about 3 times the highest concentration of 1080 detected in carcasses of coyotes killed by 1080 livestock protection collars — all survived, although some eagles showed signs of 1080 intoxication, including loss of strength and coordination, lethargy, and tremors (Burns et al. 1991). For a 3.2-kg golden eagle to obtain an LD50 dose (1.25 to 5.00 mg 1080/kg BW), it would have to consume the internal organs of 7 to 30 coyotes killed by 1080, assuming that each coyote ingested 0.1 mg 1080/kg BW and did not excrete, detoxify, or regurgitate any of the toxicant and that, as in rats, about 40% of the dose is present in the internal organs at death (Atzert 1971). Since the internal organs of a coyote account for 20 to 25% of its live weight or 2.7 to 3.2 kg/coyote, and a golden eagle's daily consumption

of food is about 30% of its live weight or 0.9 kg (Atzert 1971), it seems unlikely for raptors to be at great risk from consuming coyotes killed by 1080 livestock protection collars (Burns et al. 1991).

Human consumers of meat from 1080-killed ducks would probably not be adversely affected after eating an average cooked portion (Temple and Edwards 1985). Moreover, oven-baking or grilling at temperatures >200°C will cause breakdown of 1080. For example, if a mallard received a triple lethal dose of 1080, then a 1-kg mallard would contain an estimated 14.4 mg of 1080. A 70-kg human would have to consume 25.4 kg of poisoned duck flesh to receive a lethal dose, as judged by LD₅₀ values of 4.8 mg/kg BW for mallards and 5 mg/kg BW for humans. Theoretically, consumption of only two whole ducks poisoned by 1080 may cause transient toxicity (Temple and Edwards 1985).

Avian populations that were reduced in numbers during 1080 poisoning for possum control usually recovered quickly if they had high potential for reproduction and dispersal (Spurr 1979). Birds from Australia or New Zealand with poor reproductive potential and poor dispersal had a high risk of nonrecovery; this group includes the three species of kiwi (*Apteryx* spp.), takake (*Notornis mantelli*), kakapo (*Strigops habroptilus*), laughing owl (*Sceloglaux albifacies*), bush wren (*Xenicus longipes*), rock wren (*Xenicus gilviventris*), fernbird (*Bowdleria punctata*), yellowhead (*Mohoua ochrocephala*), stitchbird (*Notiomystis cincta*), saddleback (*Philesturnus carunculatus*), kokako (*Callaeas cinerea*), and New Zealand thrush (*Turnagra capensis*) (Spurr 1979, 1993). Poison control programs against wild dogs, dingoes, and their hybrids using 1080 meat baits did not significantly affect nontarget populations of birds in the treated areas (McIlroy et al. 1986b). Baiting with 1080 to control rabbits and foxes in Australia usually had no significant permanent adverse effects on nontarget birds, although 15 of the 30 bird species in the treated areas during the poisoning campaign showed a temporary negative trend in abundance, especially welcome swallows (*Hirundo neoxena*), tree martins (*Hirundo nigricans*), and crimson rosellas (*Platycercus elegans*) (McIlroy and Gifford 1991). Aerial drops of 1080-laced pellets (11.8 kg/ha) to control brushtail possums and rock wallabies (*Petrogale penicillata*) on Rangitoto Island, New Zealand, had no observed effect on island bird populations over the next 12 months (Miller and Anderson 1992). No species of bird showed a population decline and several showed significant increases in numbers, including greenfinch (*Carduelis chloris*), Australian harrier hawk (*Circus approximans*), and tui (*Prosthemadera novae-seelandiae*). Increases were attributed to the reduction in numbers of mammalian browsers, which led to increased vegetation and improved habitat for nontarget bird species (Miller and Anderson 1992).

Mortality of nontarget birds in 1080 poisonings may be underreported because many die in their nests or roosts and are never found (Koenig and Reynolds 1987). Raptors of several species were found dead shortly after application of 1080 baits. However, no 1080 residues were detected in any of these birds and the cause of death was not established (Hegdal et al. 1986). Application of 1080 baits to control California ground squirrels was associated with deaths of yellow-billed magpies (*Pica nuttalli*) which contained about 1.02 mg 1080/kg FW of internal organs (Koenig and Reynolds 1987) vs. 0.6 to 0.7 mg 1080/kg FW in stomachs of black-billed magpies (*Pica*) treated with lethal doses of 1.6 to 3.2 mg 1080/kg BW (Okuno et al. 1984). It is not known if *P. nuttalli* ingested the 1080 bait directly, ate other poisoned animals, or both (Koenig and Reynolds 1987). Risks of 1080 poisoning to birds can be reduced by (McIlroy 1984; McIlroy et al. 1986a):

1. Setting meat baits out just before sunset and removing them early next morning
2. Burying baits for pigs below ground
3. Using baits that only the target animals prefer
4. Reducing the number of available small bait fragments
5. Masking the appearance of baits and enhancing their specificity by the use of dyes — although some birds in Australia seem to prefer green-dyed meat baits

Table 26.3 Effects of 1080 on Representative Birds

Species, Dose, and Other Variables	Effect	Reference^a
Chukar, <i>Alectoris graeca</i> ; 3.5 (95% confidence interval [=CI] of 2.6–4.8) mg/kg body weight (BW); single dose	LD50	1–4

26.4.6 Mammals

Studies with mammals (Table 26.4) showed several trends:

1. Individuals of sensitive species died after receiving a single dose between 0.05 and 0.2 mg/kg BW, including species of livestock, marsupials, canids, felids, rodents, and foxes.
2. Most individuals of tested species died after a single dose between 1 and 3 mg/kg BW.
3. A latent period was evident between exposure and signs of intoxication.
4. Mortality patterns usually stabilized within 24 h after exposure.
5. Species from fluoroacetate-bearing vegetation areas were more resistant than conspecifics from nonfluoroacetate vegetation areas.
6. Route of administration had little effect on survival patterns.
7. Younger animals were more sensitive than adults.
8. High residues were detected in some 1080-poisoned animals, notably rabbits with 34 mg/kg DW muscle and 423 mg/kg DW liver.
9. Secondary poisoning was evident among carnivores after eating 1080-poisoned mammals.
10. Sublethal effects included testicular damage in rats after drinking water containing 2.2 to 20.0 mg 1080/L for 7 days (0.07 to 0.71 mg/kg BW daily), impaired reproduction in mink fed diets containing 0.8 mg 1080/kg ration for 60 days, and altered blood chemistry in ferrets given diets containing 1.1 mg 1080/kg ration for 28 days.

The most sensitive mammal tested was the Texas pocket gopher (*Geomys personatus*), with an LD50 of <0.05 mg 1080/kg BW (McIlroy 1986). In general, carnivorous eutherian mammals were most sensitive to 1080 and amphibians most resistant; intermediate in sensitivity were herbivorous eutherian mammals and marsupials, carnivorous marsupials, herbivorous-granivorous rodents, omnivorous mammals, and birds — in that order (McIlroy 1992). Very young mammals seemed more sensitive to 1080 than other members of their populations (McIlroy 1981a); no other differences in sensitivity to 1080 were found that could be related to sex, age, or nutritional status

(McIlroy 1981a, 1981b; O'Brien 1988; O'Brien and Lukins 1988). Route of administration had little effect on 1080 toxicity. Oral dosages were as toxic as subcutaneous, intramuscular, intravenous, and intraperitoneal dosages (Negherbon 1959; McIlroy 1981a, 1983a). There are species differences, as yet unexplained, in fatal 1080 poisonings: dogs died of convulsions or respiratory paralysis, but monkeys, horses, rabbits, and humans died of ventricular fibrillations (Murphy 1986). Individuals of most species dosed with 1080 died within 7 days, but feral pigs and wedge-tailed eagles took longer (McIlroy 1981a). Ambient air temperatures in the range 4 to 33°C modified the sensitivity of small mammals to 1080. In mice (*Mus* spp.) and guinea pigs (*Cavia* spp.), sensitivity was greater at the extremes of the thermal regimes than at intermediate temperatures (McIlroy 1981b; Oliver and King 1983). Raccoons (*Procyon lotor*) and feral pigs were more sensitive at elevated ambient temperatures (Eastland and Beasom 1986b; O'Brien 1988), but opossums and domestic sheep were more sensitive at low temperatures (McIlroy 1982a; Eastland and Beasom 1986b). At elevated temperatures, 1080 was more toxic to feral pigs when administered via drinking water vs. oat baits, and in wheat baits vs. pellet baits (O'Brien 1988).

Warm-blooded species varied considerably in response to sodium fluoroacetate, with primates more resistant and rodents and carnivores more susceptible. Based on fatal or near-fatal cases of human poisonings, the dangerous dose for humans is 0.5 to 2.0 mg/kg BW (Negherbon 1959). Among the 171 species of mammals tested, for which there are data, there was considerable variability in the time until signs of poisoning became apparent (0.1 h to >7 days), the time to death (0.1 h to >21 days), and the time until animals began to show signs of recovery (2 h to 18 days) (McIlroy 1986). Signs of poisoning among herbivorous species of marsupials first appeared 1 to 39 h after dosing; death, followed 3 to 156 h after dosing (McIlroy 1982a). Australian carnivores did not show signs of 1080 poisoning for 0.6 to 4.8 h; first deaths occurred between 1.6 and 21 h and recovery in 0.4 to >26 h (McIlroy 1981b). Marsupial carnivores generally showed signs of 1080 poisoning earlier and died or recovered more quickly than did marsupial herbivores and placental mammals (McIlroy 1986). After the latent period, common signs of 1080 poisoning in caged mammals included hyperexcitation, rapid breathing, and trembling. Some animals then recovered, while others began to vomit, convulse, or both (McIlroy 1981b). The most common signs of 1080 poisoning in 14 species of Australian rodents were depression, hypersensitivity to stimuli, respiratory distress, and convulsions; signs usually appeared 0.4 to 38.1 h after dosing; deaths occurred 0.7 to 206 h after dosing. A few species were more tolerant, perhaps because of exposure to indigenous plants that contained fluoroacetate (McIlroy 1982b). Rabbits (*Oryctolagus* sp.) poisoned by 1080 showed increased sensitivity to noise or disturbance; those surviving high sublethal doses began recovering 5 to 23 h after dosing (McIlroy 1982a). Cows (*Bos* spp.) showed no signs of fatal 1080 poisoning until shortly before death; signs appeared in the following sequence: urination, staggering, falling down, slight spasms, and death 1.5 to 29 h after treatment (Robison 1970). Prairie dogs showed no signs of 1080 poisoning for several hours after consuming a fatal dose; death occurred 8 to 13 h after dosing and was preceded by a rapid respiratory rate, hyperactivity, and convulsions (Huggins et al. 1988). In feral pigs, signs of poisoning such as vomiting, increasing lethargy, and labored breathing appeared about 6.2 h after dosing (range 1.9 to 47.3 h), and death after 16.1 h (range 2.8 to 80 h) after dosing (McIlroy 1983a). Vomiting occurred in 98% of poisoned pigs, but was unrelated to dose (O'Brien 1988) or bait type (O'Brien et al. 1988). With some animals, particularly the eastern native cat (*Dasyurus viverrinus*), the tiger cat (*Dasyurus maculatus*), and the tasmanian devil, the first sign of 1080 poisoning is the sudden onset of vomiting. Vomiting was independent of dose ingested or mode of administration. Thereafter, animals may either recover or experience hyperexcitation, convulsions, and death (McIlroy 1981b).

Many 1080 control programs report high effectiveness without significant effect on nontarget species. Australian baits used to control various mammal pests usually contain 15 to 110 mg 1080/kg bait, although concentrations as high as 1200 mg/kg bait are documented (McIlroy 1981b). Baiting with 1080 to control European rabbits and red foxes (*Vulpes vulpes*) in New South Wales, Australia, caused a 90% reduction in numbers of rabbits and 75% of foxes; populations of both species began

to recover soon after the campaign ended, indicating the need for continued control measures. Populations of nontarget birds and mammals did not appear to be affected, and no dead birds or nontarget mammals were found (McIlroy and Gifford 1991). A similar case is reported for 1080 control programs in Australia against wild dogs, dingoes, and their hybrids (McIlroy et al. 1986b). In Tasmania, deliberate poisoning of forest-browsing pests with carrot baits containing 0.014% 1080 — the same concentration used elsewhere in Tasmania for rabbit control — resulted in 94% mortality of brushtail possum populations, 96% mortality of red-bellied pademelons, and 86% mortality of Bennett's wallabies (McIlroy 1982a). The use of 1080 to protect island-dwelling rare or endangered species of herbivorous marsupials — a comparatively tolerant group — to kill more sensitive introduced competitors or predators such as rabbits, foxes, and feral cats was suggested by McIlroy (1982a) as an interesting possibility.

Compound 1080 is highly toxic to some species of nontarget mammals, including domestic cats and dogs (Kalmbach 1945). Hazards to wildlife associated with 1080 baiting for California ground squirrels that reduced squirrel populations by 85% included some deaths of Heermann's kangaroo rats (*Dipodomys heermanni*), the little pocket mouse (*Perognathus longimembris*), the desert woodrat (*Neotoma lepida*), deer mice (*Peromyscus* spp.), and the western harvest mouse (*Reithrodontomys megalotis*). Poisoned rodents contained between 5.2 and 23.1 mg 1080/kg BW and 1080-poisoned desert cottontails (*Sylvilagus audubonii*) contained 8.2 mg 1080/kg stomach contents (Hegdal et al. 1986). Nontarget animals found dead in New South Wales state forest areas after 22 rabbit poisoning operations between 1971 and 1975 included, in decreasing order of frequency, foxes, wallabies, possums, gray kangaroos, wombats, rats, hares, birds, cats, sheep, and dogs. This pattern may reflect the relative abundance of each species in the areas involved, their access to and acceptance of baits, and their ease of detection after death by forestry personnel (McIlroy 1982a). In Australia, the animals alleged to be most at risk during rabbit- or pig-poisoning campaigns using pellet, grain, or carrot baits are the kangaroos, wallabies, and wombats. For example, common wombats (*Vombatus ursinus*) and hairy-nosed wombats (*Lasiorhinus latifrons*) need to consume only 10 to 16 g of pellet, grain, or carrot baits containing 0.33 to 0.5 mg of 1080 to receive an LD₅₀. Hairy-nosed wombats eat 120 to 570 g of food daily, and common wombats can eat over 500 g of unpoisoned carrots daily, indicating that both species could easily consume lethal quantities of bait. Livestock were next at theoretical risk, followed by brushtail possums, pigs, and various rodents and birds (McIlroy 1986). More data are needed on bait consumption rates of nontarget mammals if risk from 1080-poisoning campaigns is to be satisfactorily assessed.

Laboratory studies may overestimate the risk to nontarget species from 1080 baiting. The northern quoll (*Dasyurus hallucatus*), for example, was found to be at highest theoretical risk from aerial baiting programs, as judged by LD₅₀ laboratory studies with 15 species of rodents and dasyurids. But no quolls were found dead during aerial baiting to control dingoes, and all seemed to have normal movements as judged by radiotelemetry (King 1989). Alternatives to LD₅₀ testing now include tissue culture techniques, monitoring of metabolite levels in blood or tissues, and estimating the lowest dose likely to cause death (Calver et al. 1989a). Monitoring the level of citrate in blood plasma of animals that received a sublethal dose of 1080 has been used successfully with species large enough to provide adequate samples of blood plasma in several bleeds over a 24-h period, but these other alternatives have not been attempted on Australian fauna (Calver et al. 1989a).

Because 1080 acts as an emetic, especially on coyotes and feral pigs, there is a risk of primary poisoning to nontarget animals from eating the vomitus (Atzert 1971; McIlroy 1983a; Rathore 1985; O'Brien et al. 1986, 1988). Wild pigs poisoned by carrot baits placed for European rabbits were observed to leave trails of vomitus containing carrot and other ingested foods (Rathore 1985). The antiemetic compound metoclopramide (Maxolon®) prevents vomiting in pigs by blocking dopamine receptors in the chemoreceptor trigger zones. The addition of metoclopramide to 1080 poison baits for wild pigs reduces vomiting and thereby reduces the poisoning risk to nontarget species. The addition of metoclopramide improves the efficiency and percentage of the kill of wild pigs because they will not develop taste aversion to the baits. A similar case is made for dogs.

Baits containing this antiemetic at an effective concentration of 1 mg/kg BW shortened the median time for death for dogs from 151 min postdose for 1080 baits without metoclopramide to 132 min (Rathore 1985). At tested doses (1 to 16 mg/kg BW), metoclopramide did not decrease the frequency of vomiting by dogs, but did decrease the amount of vomitus (O'Brien et al. 1986).

Secondary poisoning is likely among carrion eaters feeding on rabbits and other herbivores poisoned with 1080-treated carrots, especially foxes and dingoes (secondary target species), and dogs and cats (McIlroy 1981b; McIlroy and Gifford 1992). Secondary poisoning was reported for dogs feeding on 1080-treated rodents and prairie dogs, and for cats feeding on treated rats and mice (Anonymous 1946). Some domestic dogs and cats were found dead within 450 m of a 1080-treatment area; signs of 1080 poisoning were evident but no 1080 residues were detected by chemical analyses (Hegdal et al. 1986). Ground squirrel control with 1080 baits caused secondary poisoning of dogs, cats, coyotes, bobcats (*Lynx rufus*), skunks, and kit foxes (Hegdal et al. 1986). The high susceptibility of threatened and endangered species of kit foxes to 1080 rodenticides, as judged by studies with nonthreatened species of kit foxes, suggests that 1080 could be a factor in their population decline (Schitoskey 1975). Sodium monofluoroacetate has a high degree of secondary toxicity in mammals, as evidenced by deaths of domestic ferrets that ate 1080-poisoned white-footed mice (*Peromyscus leucopus*) (Hudson et al. 1984). Similarly, coyotes died after ingestion of 1080-poisoned ground squirrels that contained 3 to 6 mg of 1080 equivalent to 0.24 to 0.63 mg/kg BW coyote (Casper et al. 1986; Marsh et al. 1987). Coyotes that ate a single 1080-poisoned squirrel daily for 5 days, for an estimated total dose of 0.12 to 0.27 mg/kg BW, usually survived, suggesting that there is little secondary hazard from multiple doses when they are small (Marsh et al. 1987). Carcasses and viscera from coyotes that died after ingesting 5 to 15 mg 1080 were fed for 14 to 35 days to other coyotes, domestic dogs, striped skunks (*Mephitis mephitis*), and black-billed magpies; no evidence of secondary poisoning was seen in any species tested. Maximum residues of 1080 in dead coyote tissues, in mg/kg FW, were 0.66 in muscle, 0.79 in small intestine, and 0.76 in stomach tissue (Burns et al. 1986). Tissues of 1080-poisoned coyotes did not produce secondary poisoning in opossums (*Didelphis virginiana*) (Eastland and Beason 1986a), striped skunks (Eastland and Beason 1986a; Burns et al. 1991), raccoons (Eastland and Beason 1986a; Hegdal et al. 1986), or badgers (*Taxidea taxus*) (Hegdal et al. 1986). The hazard of secondary poisoning to predators is minimal after consuming tissues of 1080-killed black-tailed prairie dogs (*Cynomys ludovicianus*), as their tissues contained <0.1 mg fluoroacetate/kg FW (Huggins et al. 1988). No mink died when fed 1080-poisoned rabbits at 40% of the total diet, provided that the rabbit gastrointestinal tract had been removed from the carcass. This suggests that secondary toxicity from 1080 is due primarily to consumption of the unmetabolized compound from the gut of prey species (Aulerich et al. 1987). The risk to different individuals or populations depends on the species' sensitivity to 1080, the number of poisoned animals consumed, and the amounts of different tissues or organs consumed (McIlroy and Gifford 1992).

Animals in Australia vary greatly in their sensitivity to 1080 poison, with known LD₅₀ values ranging from 0.11 to >800 mg/kg BW. Many native species, particularly in Western Australia have evolved tolerances to 1080 through ingestion of native plants that contain fluoroacetate or prey that consume these plants (McIlroy 1982a; McIlroy 1992). The degree to which this tolerance is developed depends on the extent of the toxic plants in the microhabitat, the need of each species to include those food species that contain fluoroacetate in its diet, and the length of evolutionary exposure to the toxic plants (Twigg et al. 1988b; King et al. 1989; Twigg and Mead 1990). This naturally occurring resistance to the toxins allows control programs that use 1080 to be more specific for introduced test species (Mead et al. 1985). Tolerance to fluoroacetate is present in insects, reptiles, mammals, and birds and is in the order of herbivores > omnivores > carnivores (Twigg and King 1991). Mammals with lower metabolic rates — such as marsupial carnivores — seem to be more tolerant to a metabolically interfering poison such as 1080 than mammals with a higher metabolism such as eutherian carnivores (McIlroy 1981a; 1981b). Tolerance to gradually increasing doses of fluoroacetate can be induced in the mouse, rat, and rhesus monkey, but not in

dog or rabbit; however, the protective effect of prior exposure to 1080 seldom persisted for more than 48 h (Chenoweth 1949). Laboratory white rats may acquire tolerance to 1080 by the ingestion of sublethal doses over a period of 5 to 14 days; cessation of dosing for 7 days caused a loss of tolerance (Kalmbach 1945). Some species acquired tolerance to 1080 after repeated sublethal doses and others accumulated the chemical until a lethal threshold was reached (McIlroy 1981a). Both phenomena were unpredictable if 1080 residues in the tissues remained between doses. Time required for complete elimination of 1080 from tissues varied among species: dogs required 2 to 3 days, rats 36 h, and sheep as long as 1 month (McIlroy 1981a).

Sublethal concentrations of 1080 may adversely affect reproduction, growth, and behavior. In rats (*Rattus* sp.), the organ most vulnerable to 1080 poisoning is the testes, and this is consistent with 1080-impaired energy production via blockage of the Krebs cycle and subsequent impairment of carbohydrate metabolism (Sullivan et al. 1979). Subacute dietary exposure to 1080 caused dose-dependent decreases in body weights and feed consumption in mink and European ferrets (Hornshaw et al. 1986). Toxic 1080 meat baits were usually avoided by the majority of tested nontarget dasyurids and rodents when alternative foods were available. Twelve of the 24 groups tested did not sample meat baits under these conditions (Calver et al. 1989a). Adult wild pigs given a sublethal dose of 1080 (0.5 mg/kg BW) in apple baits vomited within 30 min after eating the treated bait and avoided apple baits in future tests (Rathore 1985). Caged wild Norway rats (*Rattus norvegicus*) and black rats (*Rattus rattus*) developed a gradually increasing aversion to drinking water solutions of 1080, although this aversion was not sufficient to disrupt growth and reproduction (Kalmbach 1945).

Table 26.4 Effects of 1080 on Representative Mammals

Species, Dose, and Other Variables	Effect	Reference ^a
Arctic fox, <i>Alopex lagopus</i>		
Fed a single bait containing 4 mg 1080	Muscle contained 0.39 (0.24–0.65) mg 1080/kg fresh weight (FW)	1
Muscle from 66 foxes found dead on Kiska Island, Alaska, after 1080 poisoning; analysis 60 days after collection	Muscle from males contained 0.7 (0.12–2.2) mg 1080/kg FW; for females, it was 0.81 (0.09–2.8) mg/kg FW	1
Brown antechinus, <i>Antechinus stuartii</i>		
1.1–3.5 mg/kg body weight (BW)	LD50, from non-fluoroacetate-bearing vegetation area	2–4
11.0 mg/kg BW	LD50, from fluoroacetate vegetation area	4
Dusky antechinus, <i>Antechinus swainsonii</i> ; 3.2 (95% confidence interval [=CI] of 2.4–4.2) mg/kg BW	LD50	3
Black-handed spider monkey, <i>Ateles geoffroyi</i> ; 10.0–15.0 mg/kg BW	LD50	5–8
Australian mammals, various; 1.6–20.0 mg/kg BW	Lethal to 8 species of marsupials and 5 species of rodents	9
Australian rodents		
3.1 (0.7–9.0) mg/kg BW	LD50 mean (range) for 10 species with no known exposure to naturally occurring fluoroacetates	10
21.6 (3.5–80.0) mg/kg BW	LD50 mean (range) for 10 species with known past or continuing exposure to naturally occurring fluoroacetates	10
Burrowing bettong, <i>Bettongia lesueuer</i> ; 10–20 mg/kg BW	LD50	11
Cow, <i>Bos</i> spp.; single dose		
0.078 mg/kg BW	Not fatal to calves and adults	12
0.156 mg/kg BW	Not fatal to cows; LD20 for calves	12
0.22 (95% CI of 0.15–0.33) mg/kg BW	LD50 for steers and calves	5, 11, 12
0.312 mg/kg BW	LD67 for cows; LD80 for calves	12
0.39 (95% CI of 0.25–0.63) mg/kg BW	LD50 for Hereford cows	5, 11
0.624 mg/kg BW	LD100 for cows and calves	12

Table 26.4 (continued) Effects of 1080 on Representative Mammals

Species, Dose, and Other Variables	Effect	Reference^a
Canids, 6 species; 0.15 (95% CI of <0.1–0.3) mg/kg BW	LD50	13
Dog, <i>Canis familiaris</i>		
0.06 mg/kg BW, single oral dose	LD50; death in 5–9 h	6, 14
0.1–0.35 mg/kg BW, single oral dose	LD100; death in 4–6 h	6, 7, 14–16
Ingested about 1.96 mg of 1080 (56 g of a 1080-poisoned bait containing 35 mg 1080/kg horse meat)	Vomiting at 1.75 h post ingestion; seizure and a short yip 20 min later; seizures and exhaustion for the next 50 min; death at about 3 h after ingestion	16
Dingo, <i>Canis familiaris dingo</i>		
0.11 (95% CI of 0.09–0.15) mg/kg BW	LD50	3
0.123 (95% CI of 0.110–0.137) mg/kg BW	LD99	13
Coyote, <i>Canis latrans</i>		
Fed 1080-poisoned ground squirrels (<i>Spermophilus</i> sp.) that contained 0.01–0.09 mg fluoroacetate/kg FW	Maximum residues in dead coyotes, in mg 1080/kg FW, were 0.14 in large intestine, 0.09 in kidney, 0.07 in brain, 0.05 in stomach, and 0.03 in liver	17
0.1–0.2 mg/kg BW	LD50	5–8, 16
0.13–0.16 mg/kg BW by gavage	Muscle residues were 0.10–0.11 mg/kg FW	18
0.23–0.5 mg/kg BW; poisoned bait	Muscle residues of 0.08–0.15 mg/kg FW	18
0.5–1.0 mg/kg BW by gavage	Muscle residue of 0.08–0.15 mg/kg FW	18
1 mg/kg BW; poisoned bait	Muscle residue of 0.21 mg/kg FW	18
Ingestion of bait containing 5 mg 1080 (about 2.28 mg 1080/kg BW)	Signs of poisoning noted in 17–18 min after bait ingestion; death in 243–313 min after ingestion	19
Single lethal oral dose of 5 mg/kg BW		
Nonrefrigerated muscle tissue	Muscle contained 2.3 mg/kg FW <3 h after death; 1.5 mg/kg FW at 7 days	18
Frozen muscle tissue	Residue of 2.3 mg/kg FW after 30 days, 2.1 mg/kg FW after 60 days	18
Room temperature, muscle tissue	Residues ranged from 1.8–2.0 mg/kg FW between <3 h and 28 days	18
<3 h after death	Residues, in mg/kg FW, were 11.0 in stomach; 2.1–2.4 in heart, muscle, kidney and intestine; and 1.2 in liver	18
30.0 mg/kg BW by gavage	19.5 mg/kg FW in muscle	18
In pen tests, 25 coyotes were offered lambs with collars containing 5 or 10 mg 1080/mL	A total of 23 coyotes attacked and 21 died after collars were punctured in their first (n = 17), second (n = 3), or fifth (n = 1) tests. The average time to death was 217 min (range 115–436 min)	20
Goat, <i>Capra</i> sp.		
0.1 mg/kg BW; single oral dose	Half-time persistence of 5.4 h in plasma	21
0.3–0.7 mg/kg BW	LD50	5–8, 11, 16
Guinea pig, <i>Cavia</i> spp.		
0.18 mg/kg BW	LD50 at 4°C	22
0.23 mg/kg BW	LD50 at 32°C	22
0.38 mg/kg BW	LD50 at 17°C	22
0.39 mg/kg BW	LD50 at 24°C	22
Ground squirrels, <i>Citellus</i> spp.; 0.3–0.9 mg/kg BW	LD50	5–7, 15, 16
Hamsters, <i>Cricetus</i> spp.; 3.0 mg/kg BW	LD50	6
Black-tailed prairie dog, <i>Cynomys ludovicianus</i>		
0.125 mg/kg BW	No deaths	7, 23
0.17–0.3 mg/kg BW	LD50	5, 8, 23, 50
0.4–2.5 mg/kg BW	LD50–LD100	15, 16, 50
Dasyurids, 11 species; 3–12 mg/kg BW	LD50	24
Kowari, <i>Dasyuroides byrnei</i> ; ~2.8 mg/kg BW	LD50	3

Table 26.4 (continued) Effects of 1080 on Representative Mammals

Species, Dose, and Other Variables	Effect	Reference^a
Northern native cat, <i>Dasyurus hallucatus</i> ; 5.7 (95% CI of 3.9–8.2) mg/kg BW	LD50	3
Tiger cat, <i>Dasyurus maculatus</i> ; 1.8 (95% CI of 1.3–2.7) mg/kg BW	LD50	3
Quolls, <i>Dasyurus</i> spp.		
1.5 mg/kg BW	LD50, nontolerant population from southeastern Australia	4
7.5 mg/kg BW	LD50, tolerant populations from Western Australia	4
Eastern native cat, <i>Dasyurus viverrinus</i> ; 3.7 (95% CI of 3.2–4.4) mg/kg BW	LD50	3
Opossum, <i>Didelphis marsupialis</i> ; 60.0 mg/kg BW	LD50	5
Kangaroo rats, <i>Dipodomys</i> spp.		
0.1–0.2 mg/kg BW	LD47–LD85	5, 6, 16
0.2–1.0 mg/kg BW	LD100	16
Mule, <i>Equus asinus</i> X <i>E. caballus</i> ; 0.22–0.44 mg/kg BW	LD50	5, 11, 25
Horse, <i>Equus caballus</i> ; 0.32–1.00 mg/kg BW	LD50	5–8, 11, 12, 16, 25
North American porcupine, <i>Erethizon dorsatum</i> ; ~1.0 mg/kg BW	LD50	5
Eutherian mammals, Australia		
0.36 (95% CI of 0.04–3.5) mg/kg BW	LD50, 13 species of carnivores	13
0.44 (95% CI of 0.21–0.60) mg/kg BW	LD50, 7 species of herbivores	13
Feral cat, <i>Felis cattus</i>		
0.1–0.19 mg/kg BW	No deaths using poisoned fish baits	26
0.2–0.3 mg/kg BW	LD50, intravenous injection	26
0.28 (95% CI of 0.07–0.49) mg/kg BW	LD50, poisoned fish baits	26
0.35 mg/kg BW	LD50, acute oral route	26
0.35 mg/kg BW	LD90, poisoned fish baits	26
0.4 (95% CI of 0.31–0.52) mg/kg BW	LD50, oral intubation	3
1.3 mg/kg BW	All dead within 24 h when ingested as a fish bait	26
Domestic cat, <i>Felis domesticus</i>		
0.2–0.3 mg/kg BW	LD50	5–8, 16
0.5 mg/kg BW	LD100	16
Breviceps pocket gopher, <i>Geomys breviceps</i>		
<0.05 mg/kg BW	LD50	5, 6
0.05 mg/kg BW	LD100	16
Tuza pocket gopher, <i>Geomys floridanus</i>		
0.2 mg/kg BW	LD50	5, 6
0.25–0.5 mg/kg BW	LD60–LD100	16
Human, <i>Homo sapiens</i>		
0.7–2.1 mg/kg BW	LD50 (estimated)	5
2.0 mg/kg BW	LD100 (estimated) for children	16
2.0–10.0 mg/kg BW	LD50 (estimated) for adults	6, 27
Water-rat, <i>Hydromys chrysogaster</i> ; 2.9 mg/kg BW	LD50	28, 29
Golden bandicoot, <i>Isoodon auratus barrowensis</i> ; 8.9 (95% CI of 7.2–11.0) mg/kg BW	LD50	30
Northern brown bandicoot, <i>Isoodon macrourus</i> ; 3.5 mg/kg BW	LD50	30, 31
Southern brown bandicoot, <i>Isoodon obesulus</i>		
7.0–8.0 mg/kg BW	LD50; maximum latent period, 183 h; time until death, 7–206 h; time for survivors to recover, 27 h	30, 31

Table 26.4 (continued) Effects of 1080 on Representative Mammals

Species, Dose, and Other Variables	Effect	Reference^a
20.0 mg/kg BW; from area of fluoroacetate-bearing vegetation	Tolerated	30
Southern hairy-nosed wombat, <i>Lasiorhinus latifrons</i> ; 0.21 (95% CI of 0.15–0.29) mg/kg BW	LD50	11
Black-tailed jack rabbit, <i>Lepus californicus</i> ; 5.6 mg/kg BW	LD50	5, 11
Bobcat, <i>Lynx rufus</i> ; 0.67 mg/kg BW	LD50–LD100	7, 8, 16
Rhesus monkey, <i>Macaca mulatta</i> ; 4–12 mg/kg BW	LD50	5–7, 16
Macropodids, 7 species; 0.23 (95% CI of 0.1–0.6) mg/kg BW	LD50	13
Agile wallaby, <i>Macropus agilis</i> ; 0.22 mg/kg BW	LD50	11
Tammar wallaby, <i>Macropus eugenii</i>		
0.15 mg/kg BW	LD50, pouch young	11
0.27 mg/kg BW vs. 2.0–10.0 mg/kg BW	LD50, adults from nonfluoroacetate- vs. fluoroacetate-vegetation areas	11
Gel containing 12.5 mg 1080 applied to a single leaf of edible foliage	Population reduced 91% in North Island, New Zealand field trial	32
Marsupials		
Various species; fatally poisoned with 1080 under laboratory conditions	Mean residue concentrations, in mg 1080/kg FW, were 0.2 in muscle, 6.1 in viscera, and 29.7 in stomach and contents	33
0.25 (95% CI of 0.1–0.7) mg/kg BW; 10 species of herbivores	LD50, eastern Australia (nonfluoroacetate-vegetation area)	10, 13
2.6 (95% CI of 0.9–7.6) mg/kg BW; 9 species of carnivores	LD50	13
24.2–42.0 (95% CI of 1.5–389.4) mg/kg BW; 10 species of herbivores	LD50, Western Australia (fluoroacetate-vegetation area)	10, 13
From area of fluoroacetate-bearing vegetation		
Red kangaroo, <i>Macropus rufus</i> ; 2.0–4.4 mg/kg BW	LD50	11
Western brush wallaby, <i>Macropus irma</i> ; 5–10 mg/kg BW	LD50	11
Western gray kangaroo, <i>Macropus fuliginosus</i> ; 40–60 mg/kg BW	LD50	11
Brush-tailed bettong, <i>Bettongia penicillata</i> and banded hare-wallaby, <i>Lagostrophus fasciatus</i> ; 100–200 mg/kg BW	LD50	11
Eastern gray kangaroo, <i>Macropus giganteus</i> ; 0.1–0.4 mg/kg BW	LD50	11
Bennett's wallaby, <i>Macropus rufogriseus</i>		
0.2 mg/kg BW	LD50	11
Gel containing about 25 mg 1080 applied to single leaf of edible foliage	Population reduced 87% in South Island, New Zealand, field trial	32
Greater bilby (bandicoot), <i>Macrotis lagotis</i> ; 15 mg/kg BW; from area of fluoroacetate-bearing vegetation	Tolerated	30
Marten, <i>Martes marten</i> ; ~1.0 mg/kg BW	LD50	5
Grassland melomys rat, <i>Melomys burtoni</i> ; 2.6 (95% CI of 2.2–3.1) mg/kg BW	LD50	28
Striped skunk, <i>Mephitis mephitis</i>		
Diet		
Fed diet containing 4.1 mg 1080/kg ration for 5 days (about 2 times level found in 1080-poisoned coyotes)	No deaths or signs of poisoning other than reduced feeding and loss in body weight	35

Table 26.4 (continued) Effects of 1080 on Representative Mammals

Species, Dose, and Other Variables	Effect	Reference ^a
Fed coyote muscle for 14–35 days; coyote had been poisoned with massive (400 mg) dose of 1080	Fatal to all 3 skunks tested	19
Single dose		
0.125 mg/kg BW	No deaths in 7 days	34
0.25 mg/kg BW	LD40	34
0.35 (95% CI of 0.21–0.54) mg/kg BW	LD50	34
0.75 mg/kg BW	LD100	34
Tristram jird, <i>Meriones tristrami</i> ; fed wheat grain baits		
0.38–0.47 mg/kg BW	50% dead in 3 days	36
1.7–2.5 mg/kg BW	All dead within 24 h	36
Levant vole, <i>Microtus guentheri</i> ; fed wheat grain baits		
0.24–0.43 mg/kg BW	LD50	36
0.44 mg/kg BW	LD73	36
0.2–2.5 mg/kg BW	All dead within 24 h	36
Meadow mouse, <i>Microtus haydeni</i> ; 0.3–0.5 mg/kg BW	LD33–LD100	16
Meadow vole, <i>Microtus pennsylvanicus</i> ; 0.92 mg/kg BW	LD50	5
House mouse, <i>Mus musculus</i>		
2.6 mg/kg BW	LD50 at 12.2°C	22
4.5 mg/kg BW	LD50 at 33°C	22
5.8 mg/kg BW	LD50 at 17.9°C	22
7.4 mg/kg BW	LD50 at 30°C	22
8.3 (95% CI of 6.3–11.0) mg/kg BW	LD50	28
10.0 mg/kg BW	LD66	16
12.8 mg/kg BW	LD50 at 24°C	22
Mice, <i>Mus</i> spp.		
5.0–19.3 mg/kg BW	LD50	6, 14
13.5 (95% CI of 11.0–16.6) mg/kg BW	LD50; survivors exhibited persistent abnormal behavior, ranging from circling to resting with their heads tucked under the abdomen or brisket	37
15 mg 1080/kg BW alone, or followed by intraperitoneal injection of mixture of 130 mg calcium glutonate/kg BW plus 240 mg sodium succinate/kg BW	Alone, 1080 resulted in 80% dead in 48 h and 100% in 120 h. If antidote is administered within 15 min of 1080 exposure, survival increased to 70% at 48 h and 50% at 120 h after 1080 treatment; antidote survivors recovered much earlier and resumed feeding within 3 days of 1080 injection	37
150 mg 1080/kg bait	In pen tests, population numbers were reduced 88% in 20 days	38
Domestic ferret, <i>Mustela putorius</i>		
1.41 (95% CI of 1.00–2.00) mg/kg BW	LD50	39
Fed one 1080-poisoned white-footed mouse (<i>Peromyscus leucopus</i>) equivalent to 1, 2, 4, or 8 mg/kg BW ferret	All died at all doses except 1 ferret at 2 mg/kg BW	39
European ferret, <i>Mustela putorius furo</i>		
Fed internal organs for 3 days of 1080-killed black-tailed prairie dogs	1 of 10 ferrets died and 5 others showed signs of 1080 poisoning; all affected ferrets recovered 24–48 h after exposure	50
Fed ground whole carcasses (less skin, skull, and feet) of black-tailed prairie dogs that died of 1080 poisoning. Carcasses contained 0.05–0.1 mg fluoracetate/kg FW and composed 90% of diet	No adverse effects after 28 days	23

Table 26.4 (continued) Effects of 1080 on Representative Mammals

Species, Dose, and Other Variables	Effect	Reference^a
1.1 mg/kg diet for 28 days	Reduction in red and white blood cell numbers	40
1.2–1.4 mg/kg BW, single dose	LD50	5, 25, 40, 50
9.4 mg/kg diet for 28 days	LD50	40
Mink, <i>Mustela vison</i>		
0.1 mg/kg BW	No deaths in 3 days	40
0.25 mg/kg BW	50% dead in 3 days	40
0.5 mg/kg BW	2.5–2.8 h to death	40
0.8 mg/kg diet for 2 months prior to breeding	Impaired reproduction	40
1.0 mg/kg BW	1.5 h to death	40
2.9 mg/kg diet for 28 days	40% dead	40
3.2 (95% CI of 2.4–4.5) mg/kg diet for 28 days	50% dead	40
5.25 mg/kg diet for 28 days	Partial paralysis of hind limbs and reduced feed intake by day 5; 90% dead at 28 days	40
Nutria, <i>Myocaster coypus</i> ; 0.6 mg/kg BW	LD50	5
White-throated wood rat, <i>Neotoma albigula</i>		
<0.8 mg/kg BW	LD50	5
0.8 mg/kg BW	LD100	16
Wood rat, <i>Neotoma intermedia</i>		
1.0 mg/kg BW	LD20	16
1.5 mg/kg BW	LD50	5
2.0 mg/kg BW	LD100	16
Spinifex hopping-mouse, <i>Notomys alexis</i> ; 32.7 (95% CI of 27.4–39.3) mg/kg BW	LD50	28
Mitchell's hopping mouse, <i>Notomys mitchelli</i> ; 19.4 (95% CI of 15.8–23.9) mg/kg BW	LD50	28
Mule deer, <i>Odocoileus hemionus hemionus</i> ; 0.3–1.0 mg/kg BW	LD50, 8–11 months of age	5, 11, 25, 39
European rabbit, <i>Oryctolagus cuniculus</i>		
Found dead after consuming 1080-treated carrots; New South Wales, Australia; February 1986	Maximum concentrations of 1080, in mg/kg DW, were 263 in kidney, 423 in liver, 151 in heart, 34 in muscle, 136 in stomach, and 243 in stomach contents. Total 1080 content was 7.04 mg whole body and 4.87 mg in whole body less stomach and contents	33
0.36 (95% CI of 0.30–0.42) mg/kg BW	LD50, immatures	11
0.42 (95% CI of 0.26–0.58) mg/kg BW	LD50, adults	11
0.51 (95% CI of 0.44–0.58) mg/kg BW	LD90	11
Fed pellets containing 10 mg 1080/kg pellet	All dead within 6 h	41
Sheep, <i>Ovis aries</i>		
0.1 mg/kg BW; single oral dose	Residues after 2.5 h, in mg/kg, were 0.1 in plasma and 0.02–0.06 in other tissues; after 96 h, the maximum value in any tissue was 0.003 mg/kg. Half-time persistence of 1080 in plasma was 10.8 h	21
0.25–0.64 mg/kg BW	LD50	5, 11

26.5 RECOMMENDATIONS

It is emphasized that 1080 is a restricted pesticide that can only be used by certified applicators who have received special training (Green 1946; Negherbon 1959; USEPA 1985; Connolly 1993a), and that carcasses of all organisms found dead from 1080 poisoning must be buried or incinerated (USEPA 1985). Some authorities aver that continued use of 1080 is justified and desirable, and that risk is minimal to nontarget organisms. As discussed earlier, 1080 is a natural plant product, is generally highly toxic to most pests at low concentrations, is readily lost from baits following heavy dews or rainfall, is biodegraded by fungi and bacteria, and does not persist in soil or water. In New Zealand, 1080 has been used since 1954 and is still considered an essential pesticide for limiting forest and crop damage and for containing the spread of tuberculosis to livestock by brush-tailed possums (Eason et al. 1993b). It has been used to control isolated island populations of mammals that prey on endangered or threatened species of birds, as was the case for Arctic foxes preying on Aleutian Canada geese in the Aleutian Islands (Tietjen et al. 1988; Bailey 1993). In Australia and New Zealand, results of field studies suggest that 1080-poisoning campaigns had no significant effect on almost all populations of common nontarget species (McIlroy 1982a, 1992; McIlroy et al. 1986b; McIlroy and Gifford 1991; Spurr 1994), although more studies are recommended on vulnerable, rare, endangered, or uncommon species (McIlroy 1992).

There is, however, a growing body of information on 1080 that questions its usefulness in the United States. This database includes adverse effects on some nontarget organisms and endangered species; the confounding effects of the latent period, behavioral alterations, and application routes; and the development of suitable alternative chemicals. On the basis of acute oral toxicity tests, it is likely that sensitive nontarget mammals and birds will consume lethal quantities of 1080 from poisoned baits or from consumption of organisms fatally poisoned with 1080 (USEPA 1985). Field studies record deaths among sensitive nontarget species that ate 1080 baits, including bees (Goodwin

and Ten Houten 1991), insectivorous birds, (McIlroy 1982a; Hegdal et al. 1986), rabbits, rodents (Hegdal et al. 1986), cats, dogs (Kalmbach 1945; Green 1946; Hegdal et al. 1986), and livestock (McIlroy 1982a, 1986). Secondary poisoning is reported for carrion eaters and mammalian predators — especially canids and felines — after feeding on 1080-poisoned prey (Hegdal et al. 1986; McIlroy and Gifford 1992). Sublethal effects of 1080 on growth of ferrets and reproduction of mink are reported (Hudson et al. 1984; Hornshaw et al. 1986). Some endangered species are at risk from direct consumption of the 1080 baits or from secondary poisoning (USEPA 1985). In general, the use of 1080 within the geographic range of any endangered species is discouraged, or disallowed outright in the case of the California condor, the San Joaquin kit fox (*Vulpes macrotis mutica*), the Aleutian Canada goose, the Morrow Bay kangaroo rat (*Dipodomys heermanni morroensis*), and the salt marsh harvest mouse (*Reithrodontomys raviventris*). When exceptions are made, or when 1080 use is permitted in an area known to be frequented by an endangered species, restrictions are placed on the maximum concentration of 1080 in the baits (USEPA 1985).

It is unlikely that human consumers of meat from 1080-killed ducks would be adversely affected after eating an average cooked portion (Temple and Edwards 1985). The risk to humans is minimal to low from eating meat of domestic animals accidentally poisoned with high sublethal concentrations of 1080 because it is cleared rapidly from domestic animals, usually within a few days (Eason et al. 1994). In the absence of additional data, it seems prudent to postpone for at least 3 weeks the slaughter or marketing of livestock that survived 1080 exposure. No livestock in the United States contaminated with 1080 are marketed (Connolly 1993a).

No effective antidote to 1080 is currently available, and accidental poisoning of livestock and dogs is likely to be fatal (Green 1946; Chenoweth 1949; Peacock 1964; Atzert 1971; Mead et al. 1991). The lack of emergency human treatment in cases of 1080 poisoning, coupled with the observation that monoacetin — potentially the most effective medication for compound 1080 poisoning — is not available in a pharmaceutical grade (USEPA 1985), strongly indicates the need for a viable 1080 antidote. The search for an effective 1080 antidote is ongoing, and some candidate compounds offer partial protection, including mixtures of sodium acetate and ethanol, barbiturates (Tourtellotte and Coon 1950; Peacock 1964), glycerol monoacetate (Peacock 1964; Murphy 1986), a mixture of calcium glutonate and sodium succinate (Roy et al. 1980; Omara and Sisodia 1990), and 4-methylpyrazole (Feldwick et al. 1994). The development and availability of an effective 1080 antidote should constitute a high research priority. Until such time when this antidote is distributed, it seems reasonable to use 1080 in the United States only after other alternatives have been considered.

The interval between 1080 dosage and signs of intoxication is at least 30 min, regardless of dose or species tested, and needs to be considered when evaluating the efficacy of 1080. Coyotes, for example, may continue to kill livestock after receiving a lethal dose (Connolly and Burns 1990). And coyotes may travel some distance from their prey prior to incapacitation, making carcass recovery and program evaluation difficult, as was the case for 1080-poisoned quolls in Australia (King 1989). Similarly, many 1080-poisoned nontarget animals may have left the treated area before succumbing, thus leading to underestimation of mortality among this group (Collins 1965). Tolerance to fluoroacetates and avoidance of 1080 baits should also be considered in future 1080 poisoning campaigns by wildlife managers and animal damage control operators. Avoidance of 1080 toxic baits by target mammals is documented when alternative foods are available (Calver et al. 1989a), and among pigs and rats surviving sublethal exposures (Kalmbach 1945; Rathore 1985). Indigenous populations of mammals, birds, and reptiles that coexist with fluoroacetate-bearing vegetation are much less sensitive to 1080 poisoning, perhaps by as much as 2 orders of magnitude, than conspecifics lacking such exposure (Twigg et al. 1988; King et al. 1989; Twigg and Mean 1990).

The timing of application of 1080 baits is critical. In one mishap, baits were dropped aerially while many ground squirrels — the targeted species — were still in hibernation underground for the winter and had not emerged (Collins 1965). Aerial application of 1080 baits in a ground squirrel

control program in California, although effective in controlling the squirrels, resulted in great overuse of the baits. As many as 70 to 77% of the poisoned baits were not eaten by the squirrels and were not recovered. Also, the yellow dye used to color the baits — as a deterrent to birds — faded rapidly (Collins 1964, 1965). To protect migratory waterfowl, 1080 baits should not be applied immediately preceding or during the main waterfowl hunting season or whenever birds are abundant (Temple and Edwards 1985). To protect honeybees, 1080-poisoned jam baits should be deposited >400 m from apiary sites. If 1080 baits are dispersed <400 m from apiary sites, then beekeepers should remove their hives to a more distant site (Goodwin and Ten Houten 1991). The 1080 toxicity database for aquatic organisms is insufficient for practicable formulation of criteria to protect this ecosystem. This seems to be a high priority research need in geographic areas of intensive 1080 application.

Potential replacement chemicals for 1080 include PAPP (*para*-aminopropiophenone), DFP (1,3-difluoro-2-propanol), and various anticoagulant and nonanticoagulant toxins. PAPP is highly toxic to coyotes and domestic cats (each with LD50s of 5.6 mg/kg BW) and lethal to rats and mice (LD50s of 177 and 233 mg/kg BW, respectively); intermediate in sensitivity were bobcats (10.0), and kit foxes (14.1 mg/kg BW) (Savarie et al. 1983). DFP is under investigation in Australia as an alternative to 1080 in faunal management programs because it has a mode of action similar to that of 1080 and has an antidote in pyrazole (Mead et al. 1991). DFP is the major ingredient of the pesticide glifor used in Russia to control rodents, particularly voles of the genus *Microtus*. Also deserving of evaluation are 4-methylpyrazole and related compounds to function as antidotes to DFP intoxication (Mead et al. 1991). In New Zealand, alternatives to 1080 under evaluation include several nonanticoagulant toxins (glifor, cholecalciferol, calciferol, alpha-chloralase, nicotine, malathion) and anticoagulants, including brodifacoum and pindone (Eason et al. 1993a).

26.6 SUMMARY

Sodium monofluoroacetate (CH_2FCOONa), also known as 1080, was first used in the United States to control gophers, squirrels, prairie dogs, rodents, and coyotes (*Canis latrans*); 1080 domestic use is currently restricted to livestock protection collars on sheep and goats to selectively kill depredating coyotes. However, Australia, New Zealand, and some other nations continue to use 1080 to control rabbits, possums, deer, foxes, feral pigs and cats, wild dogs, wallabies, rodents, and other mammals. The chemical is readily absorbed by ingestion or inhalation. At lethal doses, metabolic conversion of fluoroacetate to fluorocitrate results in the accumulation of citrate in the tissues and death within 24 h from ventricular fibrillation or respiratory failure; no antidote is available. At sublethal doses, the toxic effects of 1080 are reversible. Primary and secondary poisoning of nontarget vertebrates may accompany use of 1080. Sensitive mammals died after receiving a single dose of 0.05 to 0.2 mg 1080/kg body weight (BW), including representative species of livestock, marsupials, canids, felids, rodents, and foxes. Most tested species died after a single dose of 1 to 3 mg/kg BW. High residues were measured in some 1080-poisoned target mammals and this contributed to secondary poisoning of carnivores ingesting 1080-poisoned prey organisms. Sublethal effects occurred in sensitive mammals at >2.2 mg 1080/L drinking water or 0.8 to 1.1 mg 1080/kg diet. Sensitive species of birds died after a single 1080 dose of 0.6 to 2.5 mg/kg BW, daily doses of 0.5 mg/kg BW for 30 days, 47 mg/kg in diets for 5 days, or 18 mg/L in drinking water for 5 days. Adverse effects occurred in birds at dietary loadings as low as 10 to 13 mg 1080/kg ration. Amphibians and reptiles were more resistant to 1080 than birds and mammals. LD50 values were >44 mg/kg BW for tested amphibians and >54 mg/kg BW for tested reptiles; resistance to 1080 was attributed to their reduced ability to convert fluoroacetate to fluorocitrate and their increased ability to detoxify fluoroacetate by defluorination. Mosquito larvae reportedly died at 0.025 to 0.05 mg 1080/L but fish seemed unaffected at 13 mg/L. However, data on 1080 in aquatic ecosystems are incomplete. Acute LD50 values for terrestrial insects ranged from 1.1 to

3.9 mg/kg BW to 130.0 mg/kg BW for larvae feeding on fluoroacetate-bearing vegetation. Residues of 1080 in exposed insects were usually low (<4 mg 1080/kg fresh weight) or negligible, and were usually eliminated completely within 6 days, suggesting low risk to insectivorous birds. Loss of 1080 from baits occurs primarily due to microbial defluorination and secondarily to leaching by rainfall and consumption by insect larvae; leachates from 1080 baits are likely to be held in the upper soil layers. The use of 1080 seems warranted in the absence of suitable alternative control methods.

CHAPTER 27

Toxaphene

27.1 INTRODUCTION

Toxaphene is a complex mixture of chlorinated bornanes and bornenes containing as many as 670 individual compounds. Heavy past usage, environmental persistence, and long-range atmospheric transport caused ecosystem-wide toxaphene contamination of biota from regions with little or no historical toxaphene application — including Arctic invertebrates, fishes, and mammals, Baltic seals and whales, and the atmosphere of the Great Lakes (Kucklick et al. 1993; Vetter et al. 1996). Environmental hazards and increasing public concerns associated with toxaphene (chlorinated camphene, 67 to 69% chlorine) are documented in a series of useful review articles (Pollock and Kilgore 1978; U.S. Environmental Protection Agency [USEPA] 1979, 1980a; Cohen et al. 1982; Rice and Evans 1984; Eisler and Jacknow 1985; Sullivan and Armstrong 1985; Saleh 1991; Bidleman and Muir 1993; U.S. Public Health Service [USPHS] 1994).

Toxaphene was introduced in the mid-1940s as a new insecticide, but only a few years elapsed before it was being used commercially on a large scale to effectively control a variety of pests — especially pests of cotton, corn, fruits, vegetables, grains, soybeans, and ectoparasites of livestock (USPHS 1994). Toxaphene solutions were often mixed with other pesticides, including methyl and ethyl parathion, DDT, and lindane (USPHS 1994). In the mid-1950s, toxaphene was first used in ponds, lakes, and streams as a piscicide. By 1966, toxaphene was the chemical of choice in fish eradication programs in Canada and second in the United States after rotenone (Lennon et al. 1970). Its use for this purpose was discontinued in the 1960s due to its lengthy persistence in water, high acute toxicity to aquatic biota, and significant bioaccumulation and biomagnification in various environmental compartments. By 1974, cumulative world use of toxaphene, mainly against insect pests of cotton, was estimated at 450,000 metric tons. Production of toxaphene declined from 1973 to 1980; however, annual consumption in 1980 was estimated at 105,000 tons, thus qualifying toxaphene as one of the most heavily utilized agricultural chemicals worldwide. In the early 1980s, toxaphene was extensively applied in California to control fruitworms on tomatoes, bollworm on cotton, and a wide range of pestiferous insects that infested alfalfa, broccoli, celery, beans, clover, lettuce, cauliflower, and pears. In time, toxaphene-resistant strains of cotton pests, including bollworm and lygus bug, appeared in California, Texas, Egypt, and India (USEPA 1979; USPHS 1994).

In November 1982, most registered uses of toxaphene were canceled by the U.S. Environmental Protection Agency, although existing available stocks could be used through 1986 (USEPA 1982). Prior to the USEPA action, similar actions that banned or restricted toxaphene use had been implemented in a number of countries, including Canada, England, Sweden, Finland, Denmark, France, Switzerland, Hungary, Italy, Egypt, and Algeria (Cohen et al. 1982; Swackhamer et al. 1993; Wideqvist et al. 1993). In 1990, the USEPA banned all uses of toxaphene in the United States or any of its territories because of adverse effects on human and animal health (USPHS 1994). In

1993, the USEPA banned the importation of food containing toxaphene residues in the United States or any of its territories. And on September 1, 1993, all tolerances, interim tolerances, and food additive regulations for toxaphene on all agricultural commodities were revoked (USPHS 1994). However, toxaphene-like pesticides are currently produced and used in many countries, including India, many South and Central American countries, Eastern bloc countries in the former Soviet Union, and many African countries (Kucklick et al. 1993; Voldner and Li 1993; USPHS 1994).

27.2 ENVIRONMENTAL CHEMISTRY

The commercial production of toxaphene involves the reaction of camphene, chlorine activated by ultraviolet radiation, and certain catalysts to yield chlorinated camphene with a chlorine content of 67 to 69% by weight. This product is a relatively stable material composed of at least 177 — as many as 670 are predicted — chlorinated bornanes and bornenes (Saleh 1991; McConnell et al. 1993). Of these components, 26 have been isolated and 10 identified; these 26 components comprise 40% of the toxaphene. Information on chemical properties and the fate and effects of the remaining components is missing or incomplete (Cohen et al. 1982). Several components that have been tested are more toxic to houseflies than the technical mixture, especially di-, tri-, and tetrachlorobornane compounds (Pollock and Kilgore 1978). Technical toxaphene is a yellow, waxy solid of empirical formula $C_{10}H_{10}Cl_8$ and an average molecular weight of 414. It melts at 65 to 99°C. Toxaphene is soluble in water to 3 mg/L and is readily soluble in fats and organic solvents, based on its high partition coefficient of 10 to the power 3.3 to 6.4. Toxaphene has a tendency to adsorb on sediments and to bioaccumulate in aquatic organisms (USEPA 1979; USPHS 1994).

Because toxaphene consists of numerous compounds, it seems inappropriate and misleading to continue using the name toxaphene to describe this insecticide. It is known that chemical properties, such as solubility, toxicity, volatility, and other properties, are the sum of the individual contribution of many different compounds in differing relative amounts. A 50-fold difference between toxicities of toxaphene components can occur, and, with a wide range in the polarity of different fractions, there probably are also significant solubility differences. In addition, the composition of toxaphene changes with time, and residues in fat are not of the same composition as parent toxaphene (Pollock and Kilgore 1978). The metabolism of toxaphene has been an area of limited research activity, owing to the analytical difficulties involved in detecting a multicomponent substance (Pollock and Kilgore 1978). However, toxaphene has been reported more often in biological samples in recent years. This increased recognition is probably due to better analytical methods for toxaphene analysis (Ribick et al. 1982), especially electron capture negative ion mass spectrometry (Muir and de Boer 1993), greater awareness by analysts, and the continuing use of toxaphene, while use of potentially interfering organochlorine insecticides has slowly decreased. Toxaphene was available as an emulsifiable concentrate, wettable powder, or dust. The commercial product is relatively stable but may decay upon prolonged exposure to sunlight, alkalis, or temperatures above 120°C. Toxaphene is also known as Agracide Maggot Killer, CAS 8001-35-2, Camphofene Huilex, Motox, Toxafeed, (USPHS 1994), chlorinated camphene, Synthetic 3956, Octachlorocamphene, Alltox, Geniphene, Toxakil (Negherbon 1959), polychlorocamphene, camphechlor, Clor Chem T-590, Cristoxo, Moto, Phenacide, Phenatox, Strobane-T, Toxon 63, and Vapotone (Johnson and Finley 1980). Chemically, it is known as a mixture of various chlorinated camphenes (Tucker and Crabtree 1970). The actual global production of toxaphene between 1950 and 1993 is unknown, but estimates range as high as 1.3 million metric tons (McConnell et al. 1993; Voldner and Li 1993).

Toxaphene partitions to the atmosphere, surface and groundwaters, soil and sediment particulates, and adipose tissue. As a result of its volatility and resistance to photolytic transformation, toxaphene has been transported over long distances in the atmosphere (USPHS 1994). Toxaphene residues have been detected in various environmental compartments hundreds of kilometers distant

from known applications of this insecticide. Prevailing winds, rainfall, and sediment runoff probably account for substantial portions of this transport (Kucklick et al. 1993; USPHS 1994). Rainfall, for example, has been implicated as a significant toxaphene vector in South Carolina estuaries (Harder et al. 1980). During and immediately after the summer use season, toxaphene levels in rain exceeded, by several times, the concentrations reported to produce bone damage in fish under controlled laboratory conditions. Toxaphene becomes sorbed to soils when it is used in agriculture. Therefore, a major mode of toxaphene transport in areas planted continuously in cotton is through sediment loss in runoff (McDowell et al. 1981). In soils, toxaphene is relatively immobile. Under anaerobic conditions, toxaphene is rapidly biotransformed in soils and sediments with a half-time persistence of 2 to 4 months. However, under aerobic conditions, toxaphene may persist for years — Tb 1/2 of 11 years — in aerated surface soils and sediments (USPHS 1994). Measurements indicated a linear relation between toxaphene yield and sediment yield in runoff water. Atmospheric transport of toxaphene is well documented. Air samples from the western North Atlantic contained measurable levels of toxaphene at distances up to 1200 km from the nearest point source of application on land (Bidleman and Olney 1975). Similarly, nationwide monitoring of toxaphene in fish showed increases during 1970 to 1974 (Schmitt et al. 1981), especially in areas where the insecticide was not used, suggesting that atmospheric transport is essential to widespread distribution. Airborne toxaphene is resistant to photodecomposition; however, selective volatilization of toxaphene components is a major cause of degradation, resulting in an estimated half-time of 15 days while in the atmosphere (Cohen et al. 1982).

Toxaphene degrades more rapidly in most environmental compartments than other chlorinated pesticides, such as DDT and dieldrin (Matsumura 1978). The major metabolic degradation mechanisms for toxaphene in all organisms from bacteria to primates are now believed to be the reductive dechlorination, reductive dehydrochlorination, and in some cases oxidative dechlorination to produce hydroxyl derivatives, acids, or ketones (Saleh 1991). Toxaphene persistence and degradation in soil, water, and biota are modified by numerous and disparate biological and abiotic factors. Under laboratory conditions, toxaphene in water has a half-time persistence of more than 10 years under conditions of high oxygen content, 25°C, and pH 5 to 8 (USPHS 1994). In lakes, toxaphene persistence was significantly related to lake depth, stratification, and turnover, but not related to surface area, pH, temperature, sunlight, and oxygen (Cohen et al. 1982). Data from studies where toxaphene was used to control nongame fish in lakes suggest that it may persist in water from several months to more than 9 years. For example, two mountain lakes in Oregon that were treated with toxaphene in fish eradication programs remained toxic for 1 to 6 years (Terrierre et al. 1966). Davis Lake, a shallow lake rich in aquatic life, which was treated with 88 µg toxaphene/L, could be restocked with rainbow trout (*Oncorhynchus mykiss*) within 1 year when water toxaphene levels were 0.63 µg/L. Trout grew rapidly, although whole-body burdens up to 24 mg/kg were recorded. Miller Lake, a deep, biologically sparse lake, was treated with 40 µg/L toxaphene; trout could not be restocked for 6 years until water levels had dropped to 0.8 µg toxaphene/L. Toxaphene at 50 µg/L was used to eradicate fish from Clayton Lake, New Mexico (Kallman et al. 1962). Water concentrations of 1.0 µg/L were measured 250 days posttreatment, but the lake remained toxic for 9 months, with restocking possible only after 12 months. Residues in fish surviving treatment were 3.5 mg/kg whole-body wet weight shortly after exposure, and 0.3 mg/kg about 5 months postapplication. Some lakes treated with toxaphene to kill fish have remained toxic for 3 to 4 years (Webb 1980). In another study (Johnson et al. 1966), lake water that contained 1.0 µg toxaphene/L (9 years after toxaphene treatment) supported healthy fish populations. In this lake, particulate matter contained 70 µg toxaphene/kg, and plankton contained 15,000 µg/kg. However, there were changes in gas chromatographic profiles of toxaphene residues taken from the lakes, suggesting that the parent toxaphene had been altered or degraded into compounds with lower environmental hazards to biota. Clearly, this subject area merits additional research effort.

In soils, toxaphene can persist for lengthy periods, with microbial degradation occurring under aerobic and anaerobic conditions (Cohen et al. 1982). Pimentel (1971) reported that toxaphene,

applied at 140 mg/kg soil, persisted for more than 6 years; when applied at 50 mg/kg, half the toxaphene was measurable after 11 years. Further, in sandy loam soils, 45% of the toxaphene remained 14 years after initial application of 100 mg/kg. Some investigators suggest that toxaphene degradation is more rapid under anaerobic conditions (Pollock and Kilgore 1978). Thus, toxaphene in anaerobic salt marsh sediments generally degraded within a few days to shorter-lived components (Williams and Bidleman 1978). Toxaphene accumulated only slightly in anaerobic marsh soils not flooded daily by tides (Gallagher et al. 1979), and the highest pesticide concentrations were associated with roots of dead plants.

Degradation of toxaphene in plant, air, and soil samples was evident following toxaphene application of 9 kg/ha to a San Joaquin Valley, California, cotton field (Seiber et al. 1979). Cotton leaves contained 661 mg toxaphene/kg immediately after application and 135 mg toxaphene/kg after 58 days, with the greatest loss attributed to components of highest volatility. Air samples were essentially the same at 2 and 14 days postapplication (1.8 to 1.9 $\mu\text{g}/\text{m}^3$). This was attributed to a corresponding enrichment of volatile components. Topsoil samples immediately after application and 58 days later contained 13.1 and 6.4 mg/kg, respectively; loss was primarily via vaporization, but at least one component was significantly degraded. One year later, soil cores and irrigation ditch samples showed extensive toxaphene degradation resulting in a selective decline of some components; anaerobic reduction occurred in these environmental compartments.

Toxaphene elimination rates vary between species. In rats, the half-time persistence of toxaphene (time to 50% excretion = $T_{1/2}$) was 1 to 3 days (USEPA 1980a). If the trend persisted, virtually all toxaphene would be eliminated in five half-lives. Elevated blood toxaphene levels in a human subject who had eaten catfish fillets containing 52 mg of toxaphene/kg dropped 67% in 11 days. By 14 days after the initial measurement, toxaphene blood levels were below analytical detection limits (USEPA 1980a). Persistence seems to be longer in some fishes. Lake trout (*Salvelinus namaycush*) given a single intraperitoneal injection of 7 mg toxaphene/kg BW had a $T_{1/2}$ of 322 days; for white suckers (*Catostomus commersoni*), this value was 524 days (Delorme et al. 1993).

27.3 CONCENTRATIONS IN FIELD POPULATIONS

Long-range atmospheric transport of toxaphene has resulted in measurable toxaphene residues in tissues of fishes from remote lakes in northern Canada; fishes from pristine areas of the North Atlantic, North Pacific, and Antarctic Oceans; and fishes, birds, and seals from the western North Atlantic Ocean, Arctic Ocean, Greenland, Sweden, Canada, and the drainage basin of Chesapeake Bay (Table 27.1) (Saleh 1991; USPHS 1994). In Lake Baikal, Russia, the toxaphene congener pattern in water was similar to that in the air, indicating the importance of atmospheric deposition processes to this water body (McConnell et al. 1993). Atmospheric toxaphene concentrations vary markedly with season, being lower in winter and higher in summer (Barrie et al. 1993).

National contaminant monitoring surveys, conducted in the period 1974 to 1976, show that toxaphene was detected in about 6% of all fish sampled. This is a higher percentage than recorded in fruits, vegetables, poultry, and meat (Ludke and Schmitt 1980). Fish collected nationwide at 109 stations between 1976 and 1979 had measurable toxaphene residues at about 60% of all stations sampled; concentrations in fish from the Great Lakes stations exceeded those in fish from most of the rest of the United States, including locations within the cotton-growing areas (Schmitt et al. 1983). Lake trout (*Salvelinus namaycush*) from Lake Michigan typically contained 5 to 10 mg of toxaphene/kg whole body on a wet weight basis; lake trout from Lake Huron contained 9 mg/kg. These residues are considered harmful to various sensitive species of freshwater teleosts (Schmitt et al. 1983). Since relatively little toxaphene has been used in the Great Lakes region when compared to cotton-growing areas in the mid-South, Northeast, and Southeast, it is postulated that atmospheric transport from areas to the south and southwest are the sources of toxaphene contamination in the

Great Lakes (Schmitt et al. 1983). Between 1976 and 1984, mean toxaphene concentrations in whole fish collected nationwide declined significantly from 0.34 mg/kg FW, maximum 12.7 mg/kg FW in 1976/77 to 0.14 mg/kg FW, maximum 8.2 mg/kg FW, in 1984 (Schmitt et al. 1990). Declines in toxaphene concentrations were also recorded in eggs of the guillemot (*Cephus* sp.) population from the Baltic Sea between 1974 and 1989 (Wideqvist et al. 1993) (Table 27.1).

Freshwater fishes of the Arroyo Colorado, a major waterway traversing the lower Rio Grande Valley in southern Texas, were highly contaminated with toxaphene and DDE residues when compared to fish collected elsewhere in the Valley; toxaphene concentrations ranged up to 31.5 mg/kg wet weight in whole-fish composite samples (Table 27.1). These values were within or above the range producing adverse effects in sensitive species of fish. In addition, toxaphene residues in carcasses of fish-eating birds contained up to 3 mg toxaphene/kg (Table 27.1). Unlike fishes, avian species readily metabolize and excrete toxaphene, so that little accumulation occurs in tissues. In any event, these levels of toxaphene in carcasses of piscivorous birds are probably biologically insignificant (White et al. 1983). In the Arroyo Colorado area, toxaphene was being used, to some extent, on crops such as cotton, not only as an insecticide, but as a carrier for more effective chemicals. Another possible source of contamination is a former pesticide plant at Mission, Texas, near the headwaters of the Arroyo Colorado. Soil at this site contained high concentrations of various pesticides, including toxaphene. Contaminant-laden runoff from this site could eventually reach the Arroyo from storm sewers and other water diversion facilities. The contaminated Arroyo Colorado, in turn, empties into the Laguna Madre, one of the more important breeding and nursery grounds for fish and wildlife in the United States. The Texas Department of Health, in an advisory to consumers, has stated that consumption of fishes from the Arroyo Colorado, especially blue catfish (*Ictalurus furcatus*) and gizzard shad (*Dorosoma cepedianum*), is not advised (White et al. 1983).

Birds, unlike fish, generally contained low or nondetectable levels of toxaphene, and the frequency of occurrence was relatively low when compared with that of other organochlorine pesticides (Table 27.1). This generalization held for eggs of the osprey (*Pandion haliaetus*) collected in southern New Jersey in 1974 (Wiemeyer et al. 1978); carcasses of 103 skinned shorebirds from Corpus Christi, Texas, during winter 1976/77 (White et al. 1980); eggs of the brown pelican (*Pelecanus occidentalis*) from 1971 to 1976 in Louisiana (Blus (et al. 1979); eggs of clapper rails (*Rallus longirostris*), purple gallinules (*Porphyrrula martinica*), and limpkins (*Aramus guarauna*) from the Southeast in 1972 to 1974 (Klass et al. 1980); and all avian tissues in Texas between 1965 and 1988 (Mora 1995). Among 105 herons found dead nationwide since 1976, only nine contained measurable quantities of toxaphene; for DDE, PCBs, dieldrin, and DDD, these frequencies were 96, 90, 37 and 35, respectively (Ohlendorf et al. 1981). Levels of toxaphene and other organochlorines in canvasbacks (*Aythya valisineria*) from Chesapeake Bay, Maryland, during 1973 to 1976 were below the levels known to cause problems in other species (White et al. 1979). However, adipose tissues from 55 male wild turkeys (*Meleagris gallopavo*) killed during the 1974 hunting season in southern Illinois contained 0.2 to 0.9 mg/kg of toxaphene (Bridges and Andrews 1977), suggesting that certain species of birds may selectively accumulate low concentrations of toxaphene.

Two bird kills reported in California have been attributed to toxaphene poisoning (Pollock and Kilgore 1978). In one case, the apparent route of exposure was from contaminated fish, with bird poisoning the result of toxaphene biomagnification in the food chain. In that case, algae contained 0.1 to 0.3 mg toxaphene/kg wet weight, snails and daphnids 0.2, fish 3 to 8, and fish-eating birds 39 mg/kg. The last value is substantially in excess of 3 mg/kg, a concentration considered biologically insignificant to fish-eating birds (White et al. 1983). The second incident involved some birds that were apparently killed by toxaphene when it was used to control grasshoppers on a shortgrass range. At 2 to 3 weeks postspray, bird carcasses contained 0.1 to 9.6 mg toxaphene/kg.

Toxaphene accumulates in tissues of many aquatic species, especially in lipid-rich tissues of polar fish and marine mammals (Swackhamer and McConnell 1993). Toxaphene concentrations in livers of Arctic fishes of 2.9 mg/kg FW and in Canadian cod liver oil of 28 mg/kg FW are recorded

(de Boer and Wester 1993). Toxaphene concentrations — up to 39.7 mg/kg FW blubber — in marine mammals from Newfoundland were higher than other groups of organochlorines measured and were probably due to elevated toxaphene concentrations in their diet of Atlantic cod (*Gadus morhua*) and herring (*Clupea harengus harengus*) (Muir et al. 1988). Only a few of the many polychlorobornane congeners accumulate in liver and blubber of marine mammals, perhaps because some of the higher chlorinated compounds with more than six chlorine atoms remain unmetabolized or are highly accumulated (Vetter et al. 1992). The two main toxaphene congeners identified in fish liver, dolphin blubber, and human milk were 2-exo, 3-endo, 5-exo, 6-endo, 8,8,9,10,10-nonachlorobornane, and 2-exo, 3-endo, 5-exo, 6-endo, 8,8,10,10-octachlorobornane (de Boer and Wester 1993). The three main congeners found in blubber (two octa- and one nonachloro compound) accounted for about 30 to 40% of the total toxaphene burden (Oehme et al. 1996). The major peak in the Baikal seal chromatogram was an 8-chlorinated bornane similar to that of ringed seals from the Canadian Arctic (Kucklick et al. 1993). But cod liver oils contained up to 10 major congeners and exceeded the maximum acceptable concentration for food in Germany of 0.1 to 0.4 mg total toxaphenes/kg lipid weight (de Boer and Wester 1993; Oehme et al. 1996). The octachlorobornane and nonachlorobornane congeners that dominated in Arctic amphipods, fishes, and marine mammals (narwhals and belugas) comprised only 8 to 11% in the ringed seal (*Phoca hispida*)–polar bear (*Ursus maritimus*) food chain (Zhu and Norstrom 1993).

Toxaphene is biomagnified through the food web by marine mammals, with factors ranging from about 40 to 100 for dolphins and porpoises (de Boer and Wester 1993). In Lake Michigan, toxaphene was biomagnified in aquatic food webs by about 5 from plankton to fish (sculpin, *Myoxocephalus* sp.) and 14 from mysids to fish (Evans et al. 1991). Biomagnification of toxaphene through food webs was clearly demonstrated in 16 species of organisms collected from oxbow lakes in northeastern Louisiana during 1980 (Neithammer et al. 1984). Without exception, residues were highest (3.6 mg/kg whole-body wet weight, range 1.7 to 5.5) in tertiary consumers, such as green-backed heron (*Butorides striatus*), various species of snakes, spotted gar (*Lepisosteus osseus*), and largemouth bass (*Micropterus salmoides*). Secondary consumers, such as bluegill (*Lepomis macrochirus*), blacktail shiner (*Notropis venustus*), and yellow-crowned night-heron (*Nycticorax violaceus*), contained lower residues (0.9 mg/kg wet weight, range 0.1 to 1.2). Primary consumers, including crayfish (*Procambarus* spp.) and threadfin shad (*Dorosoma petenense*), contained the lowest levels (0.8 mg/kg wet weight, range 0.6 to 1.0) of all consumer groups. Toxaphene levels were not detectable in water and sediments from these oxbow lakes (Neithammer et al. 1984). Variability in tissue toxaphene concentrations of fishes from Canadian Yukon lakes are related, in part, to differences in the food chains of the lakes (Kidd et al. 1993), with emphasis on prey lipid content (Hargrove et al. 1993).

27.4 LETHAL EFFECTS

Toxaphene is extremely toxic to freshwater and marine biota. In laboratory tests of 96-h duration, 50% mortality was recorded for the most sensitive species of freshwater and marine teleosts, marine crustaceans, and freshwater insects at nominal water concentrations of less than 10 µg/L of toxaphene, and, in several cases, less than 1 µg/L (Table 27.2). Bioassays of longer duration, based on exposure of aquatic organisms for the entire or most of the life cycle, produced significant adverse effects on growth, survival, and reproduction at toxaphene concentrations between 0.025 and 1.0 µg/L (Table 27.3). Toxaphene was most toxic to freshwater fishes in soft water at elevated temperatures (Saleh 1991). Based on its high toxicity and extensive use, it is not surprising that toxaphene was considered a major cause of nationwide fish kills in 1977 (USEPA 1980b).

Warm-blooded organisms are relatively resistant to toxaphene, as determined from results of short-term tests involving oral, dermal, and dietary routes of administration. In acute oral toxicity tests with birds and mammals, LD50 values ranged between 10 and 160 mg/kg body weight (Table 27.4). The dietary LC50 values for four species of birds ranged between 538 and 828 mg toxaphene/kg ration (Saleh 1991). The acute oral toxicities of toxaphene to rats, mice, dogs, guinea

Guinea pig, <i>Cavia</i> sp.	270

Note: Concentrations shown are in milligrams of toxaphene ingested per kilogram body weight (BW) fatal to 50% of test animals. A single dose was administered orally and survival data gathered over a 14-day posttreatment observation period.

Data from Tucker and Crabtree 1970; Hudson et al. 1984; Saleh 1991.

pigs, cats, rabbits, cattle, goats, and sheep extended from 25 to 270 mg/kg body weight (Pollock and Kilgore 1978; USEPA 1980a). These values are in good agreement with those shown in [Table 27.4](#). For reasons unknown, pregnant rodents were 5 to 10 times more resistant to oral toxaphene than were nonpregnant rodents (USPHS 1994). Dermal toxicities of toxaphene ranged from 250 mg/kg body weight for rabbits and 930 mg/kg for rats, to 25,000 mg/kg for cattle (Pollock and Kilgore 1978). As was true for acute oral and dermal toxicity data, comparatively high levels of dietary toxaphene were required (i.e., 538 to 828 mg/kg diet) to produce significant death rates in various species of birds (Heath et al. 1972). In their study on four species of gamebirds, each aged 2 weeks, Heath et al. (1972) fed them diets containing graded concentrations of toxaphene for 5 days, followed by 3 days of untreated food. LD₅₀ values at the end of day 8 were 828 mg toxaphene/kg diet for northern bobwhite, 686 for Japanese quail (*Coturnix coturnix japonica*), 542 for ring-necked pheasant (*Phasianus colchicus*), and 538 for mallard (*Anas platyrhynchos*). It appears that toxaphene is not a major hazard to bird survival at previously recommended field application rates (Hoffman and Albers 1984). However, at toxaphene levels not considered life-threatening to birds and mammals, fetotoxic effects have been recorded. For example, ring-necked pheasants fed 100 mg/kg dietary toxaphene produced eggs with significantly reduced hatch over controls. Similarly, toxaphene administered orally to pregnant rats and mice during organogenesis caused fetal toxicity at 15 mg/kg body weight (Pollock and Kilgore 1978).

Some human deaths, especially those of children, have been reported following the ingestion of toxaphene-contaminated foods (USEPA 1980a). Known toxaphene residues in food items of victims ranged from 9.7 to 47 mg/kg; a total dose of 2 to 7 g of toxaphene is considered acutely toxic to a 70-kg adult. For comparison purposes, a 4.5-kg bird would probably die after consumption of 45 to 450 mg toxaphene (USEPA 1980a).

27.5 SUBLETHAL EFFECTS

Among sensitive species of marine and freshwater fish and invertebrates, water concentrations of 0.054 to 0.299 µg/L of toxaphene were associated with growth inhibition, reduced reproduction, backbone abnormalities, or histopathology ([Table 27.5](#)). Aquatic biota are capable of spectacular accumulations of toxaphene from the medium; bioconcentration factors ranged between 1270 and 52,000 those of water under laboratory conditions ([Table 27.6](#)). A similar pattern was observed in Big Bear Lake, California, where toxaphene was applied at 200 µg/L to eradicate goldfish (Pimentel 1971). Biomagnification factors of 365 were calculated for plankton, 1000 for goldfish, and 8500 in pelican fat, representing residues of 73 mg toxaphene/kg in phytoplankton, 200 in goldfish, and 1700 in pelican fat. Accumulation of toxaphene by various species of fish food organisms is dependent on exposure time and concentration. For example, insect nymphs subjected to 20 µg/L of toxaphene for less than 24 h did not accumulate doses lethal to fish. However, algae, diatoms, and protozoan ciliates held for 24 h in 20 µg toxaphene/L solutions, and *Daphnia magna* held 120 h in 10 µg/L, were lethal when fed to fish (Schoettger and Olive 1961).

Fish accumulated part-per-million (mg/kg) toxaphene concentrations in various tissues within a few days when placed in toxaphene-treated lakes that contained less than 1.0 µg/L (Cohen et al. 1982). Freshwater teleosts experienced acute and chronic effects when whole-body levels were in excess of 0.4 mg/kg but less than 5 mg/kg (this latter value being the Food and Drug Administration “action level” for human consumption) (Cohen et al. 1982). Thus, groups of brook trout eggs containing 900 µg toxaphene/kg had drastically reduced survival when compared to controls (Cohen et al. 1982), and brook trout tissue residues exceeding 400 µg toxaphene/kg were associated with reductions in growth, abnormal bone development, and reduced fecundity (Mayer and Mehrle 1977). Fathead minnows containing more than 400 µg toxaphene/kg grew more slowly than controls (Mayer and Mehrle 1977); similar results were reported in channel catfish fry containing 600 to 3400 µg toxaphene/kg (Mayer and Mehrle 1977). Toxaphene retention by aquatic organisms is

^a 1, Sanders 1980; 2, Pollock and Kilgore 1978; 3, Mayer et al. 1975; 4, Mayer et al. 1977; 5, USEPA 1980a.

relatively lengthy when compared to mammals. In one case, American oysters (*Crassostrea virginica*) held for 24 weeks in 10 µg/L toxaphene solutions contained 32.4 mg/kg in soft tissues; after 16 weeks in noncontaminated seawater, oysters still contained 3.0 mg/kg (Pollock and Kilgore 1978).

Sublethal effects of toxaphene observed in mammals (Table 27.7), small laboratory animals, and birds were similar to those recorded for aquatic organisms. However, there was general agreement that effects were induced at much higher concentrations. In domestic white leghorn chickens, for example, toxaphene at 100 mg/kg in the diet for 30 weeks did not significantly alter egg production, hatchability, or fertility, although some bone deformation and kidney lesions were recorded (Bush et al. 1977). The highest dietary dose of toxaphene fed to chickens in lifetime exposure studies, which produced no effect on any parameter measured, ranged between 3.8 and 5 mg/kg (Bush et al. 1977). Several studies with the American black duck (*Anas rubripes*) produced effects similar to those recorded in chickens. In one study, ducklings fed diets containing 10 or 50 mg toxaphene/kg for 90 days had reduced growth and impaired backbone development (Mehrle et al. 1979). Collagen, the organic matrix of bone, was significantly decreased in cervical vertebrae of ducklings fed the diet containing 50 mg toxaphene/kg ration. Calcium concentrations increased in vertebrae of ducklings fed either 10 or 50 mg/kg dietary toxaphene; effects were observed only in female ducklings. In a long-term feeding study lasting 19 months, which included two breeding seasons, American black ducks, fed 10 or 50 mg toxaphene/kg in a dry mash diet, showed no significant differences when compared to control birds in survival, egg production, fertility, hatchability, eggshell thickness, or growth and survival of young (Haseltine et al. 1980). The only negative effects recorded included weight loss among treated males during summer and a slight delay in the number of days required to complete a clutch. Carcass toxaphene residues, which seldom exceeded 0.5 mg/kg, were found in only one duck fed the 50 mg/kg diet (Haseltine et al. 1980),

suggesting low body accumulations in American black duck. However, toxaphene residues were present in the liver of all birds fed toxaphene. At dietary concentrations of 10 or 50 mg/kg, there was no change in avoidance behavior of young American black ducks (Heinz and Finley 1978), which, if interrupted, is considered life-threatening.

Ring-necked pheasants (*Phasianus colchicus*) fed diets containing 300 mg toxaphene/kg showed decreases in egg deposition, egg hatch, food intake, and weight gain. At 100 mg/kg, all of these parameters, except reduced hatch, were the same as controls (Pollock and Kilgore 1978). In a field study, aerial applications of a DDT/toxaphene mixture in southwestern Idaho during 1970, at recommended concentrations to control pests, had no major impact on penned or feral ring-necked pheasants (Messick et al. 1974), suggesting that conformance with recommended application rates should be endorsed whenever possible. However, it is emphasized that recommended toxaphene application rates varied widely and depended, in part, on the pest species to be controlled, the number and type of other pesticides applied jointly, and climatic conditions. Laboratory studies with mallard eggs suggest that recommended toxaphene application rates in excess of 1.12 kg/ha, which is generally exceeded in most cases, may produce severe embryotoxic effects, including dislocated joints and poor growth (Hoffman and Eastin 1982).

Northern bobwhite fed 5 mg/kg dietary toxaphene for 4 months showed thyroid hypertrophy (Pollock and Kilgore 1978) and interference with the ability of bobwhites to discriminate patterns (Kreitzer 1980). In the latter investigation, Kreitzer fed 10 or 50 mg/kg dietary toxaphene to 3-day-old bobwhites for 20 weeks and found that toxaphene-treated birds made 50% more errors than

controls on initial testing. These effects appeared as early as 30 days after toxaphene exposure. In a second test, there was no difference between experimentals and controls, indicating that the ability to learn these tasks was not permanently impaired.

Rats, mice, dogs, deer, sheep, and cattle are all relatively resistant to toxaphene. No-effect levels of 20 to 25 mg/kg dietary toxaphene were documented during multigeneration exposure of rats and during 2-year feeding studies with mice and dogs (USEPA 1980a). No effects were observed in monkeys over a 2-year period during which they were fed diets containing 0.7 ppm toxaphene (Pollock and Kilgore 1978). Toxaphene is carcinogenic in rodents, inducing malignant neoplasms of the liver and other sites (Saleh 1991). Cancers were induced in mice and rats by toxaphene when residues in the diet exceeded 50 mg/kg during lifetime exposure (USEPA 1980a). Toxaphene increases the frequency of sister chromatid exchanges of chromosomes in a human lymphoid cell culture line (USPHS 1994). These results, together with the positive mutagenic response (to *Salmonella* bacteria), constitute substantial evidence that toxaphene is likely to be a human carcinogen (USEPA 1979, 1980a). Penned and wild deer fed toxaphene at 1000 mg/kg appeared normal but showed a decreased digestion rate, which was attributed to a decrease in rumen bacteria (Schwartz and Nagy 1974). Steers fed alfalfa hay containing 306 mg toxaphene/kg for 19 weeks stored 772 mg/kg in abdominal fat and 27 mg/kg in lean meat without apparent ill effects, demonstrating the lipophilicity of toxaphene and the relatively low accumulation rates. For sheep under an identical regimen, these values were 317 mg/kg in fat and 36 mg/kg in meat (Pollock and Kilgore 1978). Milk from dairy cows had measurable concentrations of toxaphene after the cows had been sprayed with emulsions, suspensions, or oil solutions of toxaphene at entomologically effective doses; toxaphene residues in milk were highest on days 1 and 2 postexposure (0.7 to 0.8 mg/L) and declined to control values of 0.06 to 0.08 mg/L by days 14 to 21 (Claborn et al. 1963).

Table 27.7 Sublethal Effects of Toxaphene on Selected Mammals

Organism	Effect	Reference ^a
COW, <i>Bos</i> sp.		
Fed diets containing 20, 60, 100, or 140 mg toxaphene/kg ration for 8 weeks followed by 21-day postexposure observation period. Milk analyzed periodically	Toxaphene concentrations in milk, in mg/L, after 8 weeks of exposure (21 days postexposure) were 0.23 (0.02) in the 20 mg/kg group, 0.48 (0.07) in the 60 mg/kg group, 0.91 (0.12) in the 100 mg/kg group, and 1.82 (0.20) in the 140 mg/kg group	1
Oral exposure to single dose of 50, 100, or 150 mg/kg of ¹⁴ C-labeled toxaphene	Toxaphene residues in tissues 7 days later were dose dependent and ranged, in mg/kg fresh weight (FW), from 2.9–22.3 in liver, 3.5–5.5 in kidney, and 2.7–3.9 in brain	2
GUINEA PIG, <i>Cavia</i> sp.		
2 or 5 mg/kg BW daily via oral route for 60 days	Histopathology of brain, liver, and kidney	3
DOG, <i>Canis familiaris</i>		
Given oral doses of 0.0, 0.2, 2, or 5 mg toxaphene/kg body weight (BW) daily for 13 weeks	Food consumption, growth, and survival normal in all groups. No adverse effects in 0.2 mg/kg group. Mild to moderate dose-dependent histological changes in liver and thyroid in high-dose groups. After 13 weeks, toxaphene residues, in mg/kg FW, increased in a dose-dependent manner in liver from 0.8 (0.2 mg/kg group) to 8.5 (5 mg/kg group), and in fat from 4 (0.2 mg/kg) to 92–105 (5 mg/kg BW daily)	4
HUMAN, <i>Homo sapiens</i>		
Inhalation, 500 mg/m ³ , 30 min daily for 10 days	No toxic effects	2

Table 27.7 (continued) Sublethal Effects of Toxaphene on Selected Mammals

Organism	Effect	Reference ^a
LABORATORY WHITE RAT, <i>Rattus</i> sp.		
Fed diets containing 0, 4, 20, 100, or 500 mg toxaphene/kg ration for 13 weeks	Growth, food consumption, and survival normal in all groups. No adverse effects at 4 mg/kg ration, equivalent to 0.35 mg/kg BW daily. Adverse effects in the high-dose group (500 mg toxaphene/kg ration) included enlarged liver, increased hepatic microsomal enzyme activities, and kidney damage; toxaphene residues in this group after 13 weeks, in mg/kg FW, were 7–10 in liver and 57–103 in fat	4
Weanlings were fed diets containing 0, 4, 20, 100, or 500 mg toxaphene/kg ration for 1 generation and 2 litters	No adverse effects on litter size, pup weight, fertility, gestation, or survival. Toxic effects — mostly associated only with the 500-mg/kg group — included depressed weight gain, elevated serum cholesterol, increased liver and kidney weight, and increased hepatic microsomal enzyme activities. Treatment-related changes in liver, kidney, and thyroid of adult rats were observed at diets as low as 20 mg/kg ration	6
Fed diets of >100 or >1000 mg toxaphene/kg ration for 12 weeks Given 0.05–15 mg/kg BW daily, chronic exposure	Liver pathology at >100 mg/kg ration and central nervous system effects at >1000 mg/kg diet Offspring showed behavioral effects at all doses; at 15 mg/kg BW daily, reproduction was inhibited and offspring showed immunosuppression	7 2
Pregnant females given toxaphene on days 6–15 of gestation at 32 mg/kg BW daily	Maternal survival was 87% on day 8 and 50% on day 16. Survivors had weight loss in whole body, thymus, and spleen. Adverse developmental effect (supernumerary ribs) in litters	5
Inhalation of 40 mg toxaphene dust/m ³ for 3 months	Slight hepatocellular necrosis	2

27.6 RECOMMENDATIONS

In November 1982, the U.S. Environmental Protection Agency canceled the registration of toxaphene for most uses and, thus, joined a growing number of nations in Western Europe, Scandinavia, North America, and North Africa that had previously initiated similar actions. With some restrictions, toxaphene was used domestically through the mid-1980s for treatment of scabies in cattle and sheep; controlling sporadic infestations of armyworms, cutworms, and grasshoppers on cotton, corn, and small grains; and, in Puerto Rico and the Virgin Islands, to control mealy bugs, pineapple gummosis moths, and banana weevils. Existing stocks of toxaphene were used through 1986 for control of sicklepod in soybeans and peanuts, for insects in corn cultivated without tillage, and for pests of dry and southern peas (USEPA 1982). In 1993, all uses and manufacture of toxaphene were banned in the United States (USPHS 1994). To understand the potential global budget of toxaphene, it is now necessary to obtain information on the present and historical uses in third world and former Eastern bloc countries (Swackhamer and McConnell 1993).

Although toxaphene is not markedly hazardous to most wildlife species for which data were available, the decision to withdraw or curtail agricultural uses of toxaphene was popular with most natural resource managers. Their concerns, apparently shared by others, were based, in part, on the following observations:

- Toxaphene causes death and deleterious effects to nontarget aquatic biota at extremely low concentrations (i.e., <1.0 µg/L).
- Toxaphene is persistent in soils, water, and other environmental compartments, with residence times measured in years.
- Toxaphene accumulates in aquatic organisms and biomagnifies through food chains.
- Toxaphene is widely distributed, even when the initial application point is hundreds of kilometers distant; transport is presumably by atmospheric and other vectors.
- Technical difficulties continue to exist in the chemical analysis of toxaphene, a compound with at least 177 isomers.
- There is an imperfect understanding of the fate and effects of individual toxaphene components.
- There is inadequate knowledge of interaction effects of toxaphene with other agricultural chemicals (especially when mixtures are applied simultaneously) and with other persistent compounds in aquatic ecosystems, such as PCBs, DDT and its isomers, and petroleum.
- There is the perception that suitable alternative pesticidal chemicals are available, including some carbamates, organophosphorus compounds, and synthetic pyrethroids.

At present, large but unknown quantities of toxaphene that were discharged into the environment over the past several decades remain undegraded and potentially bioavailable. Also, knowledge of toxaphene ecotoxicology is incomplete or inadequate. Limits for toxaphene residues in air, water, biota, and other environmental compartments for the protection of fish, livestock, and human health vary considerably ([Table 27.8](#)). The concentration of toxaphene in seawater considered safe for marine life protection is 0.07 µg/L; for sensitive freshwater species, this lies between 0.008 and 0.013 µg/L. This contrasts sharply with some recommended drinking water criteria for human health protection of 5.0 to 8.8 µg/L. Other existing criteria for human health protection, which range in various foods from 0.1 to 7.0 mg/kg, appear adequate at this time to protect sensitive wildlife species. It is emphasized that these values, and others shown in [Table 27.8](#), are considered criteria and not administratively legislated standards.

No standard reference materials have been certified for analysis of chlorobornanes, although several may be suitable — including fish oils and whale blubber. Analytical standards for several chlorobornanes are now available, but there is a need to identify other remaining environmentally significant congeners (Muir and de Boer 1993). More research is now recommended in the following areas:

- Partitioning between air/water (including snow), air/plant, and air/soil interfaces (Swackhamer and McConnell 1993)
- Processes that control degradation in soils and sediments and transformations during atmospheric transport (Swackhamer and McConnell 1993)
- Effects of inhalation and dermal exposure to toxaphene, especially studies of an intermediate or chronic exposure (USPHS 1994)
- Toxicities of specific toxaphene congeners and their chemical analysis (USPHS 1994)
- Bioconcentration and biomagnification of individual congeners in terrestrial food chains (Swackhamer and McConnell 1993)
- Acute management of toxaphene-induced seizures in humans with anticonvulsants, especially diazepam, phenobarbital, and phenytoin (USPHS 1994).

27.7 SUMMARY

Toxaphene (chlorinated camphene, 67 to 69% chlorine) is a broad-spectrum insecticide, which was formerly one of the most heavily used agricultural chemicals on a global scale, especially

Table 27.8 Proposed Toxaphene Criteria for Protection of Natural Resources and Human Health

Compartment	Allowable Concentration
AQUATIC LIFE PROTECTION	
Freshwater ^a	0.013 µg/L (24-h average); 1.6 µg/L maximum at any time (USEPA 1980a)
Freshwater Most states Acute Chronic	0.073 µg/L (USPHS 1994) 0.0002 µg/L (USPHS 1994)
Wisconsin Acute, Great Lakes Acute, cold water Acute, warm water Chronic; Great Lakes, cold water, warm water	0.61 µg/L (USPHS 1994) 0.81 µg/L (USPHS 1994) 0.61 µg/L (USPHS 1994) 0.01 µg/L (USPHS 1994)
Marine	0.07 µg/L maximum at any time (USEPA 1980a)
Marine Most states Acute Chronic	0.21 µg/L (USPHS 1994) 0.0002 µg/L (USPHS 1994)
Residues in fish tissues	5.0 mg/kg maximum, wet weight basis USEPA 1980a); 0.4–0.6 µg/kg maximum, wet weight basis (Mayer and Mehrle 1977)
LABORATORY WHITE RAT	
Diet No adverse effect level	4.0 mg/kg ration, equivalent to 0.29–0.38 mg toxaphene/kg body weight daily (Chu et al. 1988)
Lowest adverse effect level (histological damage)	20.0 mg/kg ration (Chu et al. 1988)
HUMAN HEALTH	
Minimum risk level, oral	5 µg/kg body weight daily for acute duration oral exposure of 14 days or less ^b ; 1 µg/kg BW daily for intermediate duration exposure of 15–364 days (USPHS 1994)
Safe daily dose	3.4 µg/kg body weight (USEPA 1980a)
Acceptable daily intake	1.25 µg/kg body weight (USEPA 1980a)
Air Arizona 1-h average 24-h average	3.7 µg/m ³ (USPHS 1994) 1.5 µg/m ³ (USPHS 1994)
New York, 1-year average	1.67 µg/m ³ (USPHS 1994)
Oklahoma, 24-h average	5.0 µg/m ³ (USPHS 1994)
Texas, 30-min average	0.5 µg/m ³ (USPHS 1994)
Daily intake	0.00018 µg/kg body weight (USEPA 1980a)
Immediately hazardous	200 mg/m ³ (USPHS 1994)
Drinking water California Maryland Missouri	5 µg/L; maximum of 500 µg/L for 1 day or 40 µg/L for 10 days (USPHS 1994) 0.21 µg/L (USPHS 1994) 5 µg/L (USPHS 1994) 0.000071 µg/L (USPHS 1994)
Diet Fish consumption Germany U.S.	0.4 mg/kg lipid weight (de Boer and Wester 1993) 5.0 mg/kg fresh weight (de Boer and Wester 1993)
Fat of meat from livestock	7.0 mg/kg (USEPA 1980a)
Milk and milk products, fat weight basis	0.5 mg/kg (USEPA 1980a)
Soybean oil	6 mg/L (USPHS 1994)
Sunflower seeds	0.1 mg/kg wet weight basis (USEPA 1980a)

Table 27.8 (continued) Proposed Toxaphene Criteria for Protection of Natural Resources and Human**Compartment****Allowable Concentration**

Citrus fruits	5.0–7.0 mg/kg wet weight basis (Canada); 0.4 mg/kg wet weight (W. Germany, Netherlands) (USEPA 1980a)
Groundwater	5 µg/L (USPHS 1994)
WILDLIFE PROPAGATION	
Nevada	
Irrigation	5 µg/L (USPHS 1994)
Watering of livestock	0.01 µg/L (USPHS 1994)

^a The International Joint Commission of the United States and Canada recommend a water quality standard of 0.008 µg/L for the protection of freshwater aquatic life. This standard is based on the study by Mayer et al. (1975), who found that toxaphene at 0.039 µg/L in water caused a significant increase in mortality and a significant decrease in growth of surviving brook trout fry over a 90-day period. The standard of 0.008 µg/L is obtained by applying an uncertainty value of 5.

^b Based on a LOAEL of 5.0 mg/kg BW daily for decreased hepatic biliary function in rats treated with toxaphene in the diet for 8 days and an uncertainty factor of 1000.

against pests of cotton. In 1982, the U.S. Environmental Protection Agency canceled the registrations of toxaphene for most uses; stocks of toxaphene could be used, with some restrictions, through 1986. Considerable, but unknown, quantities of toxaphene previously discharged into the environment over the past several decades may remain undegraded and potentially available to living resources. Since 1993, all domestic uses and manufacture of toxaphene were prohibited; however, toxaphene use in other countries is continuing.

Toxaphene is extremely persistent in soil and water, with documented half-times of 9 to 11 years. However, in air and in warm-blooded organisms, toxaphene degradation is rapid with half-times of 15 and 3 days, respectively. Toxaphene is especially hazardous to nontarget marine and freshwater organisms, with death recorded at ambient water concentrations substantially below 10 µg/L, and adverse effects observed on growth, reproduction, and metabolism at water concentrations between 0.05 and 0.3 µg/L. Aquatic organisms readily accumulate toxaphene from the ambient medium and diet, sometimes spectacularly, retain it for lengthy periods, and biomagnify the chemical through food chains. These phenomena could account for the numerous fish kills recorded after toxaphene application, as well as the high residues measured in fish from the Rio Grande Valley in southern Texas and other locations of former high agricultural use of toxaphene. Atmospheric vectors, including prevailing winds and rainfall, may transport toxaphene hundreds of kilometers from known point sources of application. This, in part, would explain the levels of 5 to 10 mg/kg whole-body wet weight recorded in various species of fish from the Great Lakes.

Based on estimated environmental exposure levels, toxaphene does not appear to constitute a major threat to warm-blooded animals, including migratory birds and other wildlife, domestic poultry and livestock, small laboratory mammals, and humans. Wildlife typically contain low or nondetectable levels of toxaphene, except for some species of fish-eating raptors, and the frequency of occurrence is low when compared with that of other organochlorine agricultural compounds. However, toxaphene has been implicated as a human carcinogen and mutagen at relatively high test dosages and was associated with some bird kills following aerial applications.

In water, the concentration of toxaphene considered safe for protection of freshwater life is conservatively estimated to lie between 0.008 and 0.013 µg/L; for marine life, it is 0.07 µg/L. This is in sharp contrast to the current recommended drinking water criterion for human health protection of 5.0 to 8.8 µg/L. Similarly, residues in fish tissue in excess of 0.4 to 0.6 mg/kg wet weight may be hazardous to fish health and should be considered as presumptive evidence of significant environmental contamination, although fish may contain up to 5.0 mg/kg before they are considered hazardous to human consumers. Toxaphene criteria for human health protection — which range in various foods from 0.1 mg/kg for sunflower seeds to 7.0 mg/kg in meat, fats, and citrus fruits — also appear adequate to safeguard sensitive species of wildlife.

CHAPTER 28

Arsenic

28.1 INTRODUCTION

Anxiety over arsenic (As) is understandable and frequently justifiable. Arsenic compounds were the preferred homicidal and suicidal agents during the Middle Ages, and arsenicals have been regarded largely in terms of their poisonous characteristics in the nonscientific literature (National Academy of Sciences [NAS] 1977). Acute arsenic poisoning was reported in the 1800s in horses, cows, deer, and foxes as a result of emissions from metal smelters (Ismail and Roberts 1992). In 1885, arsenic accounted for nearly one third of the homicide poisonings in France (North et al. 1997). Data collected on animals, including humans, indicated that inorganic arsenic can cross the placenta and produce mutagenic, teratogenic, and carcinogenic effects in offspring (Nagymajtenyi et al. 1985; Agency for Toxic Substances and Disease Registry [ATSDR] 1992). Correlations between elevated atmospheric arsenic levels and mortalities from cancer, bronchitis, and pneumonia were established in an epidemiological study in England and Wales, where deaths from respiratory cancer were increased at air concentrations $>3 \mu\text{g As/m}^3$ (National Research Council of Canada [NRCC] 1978). Chronic arsenical poisoning, including skin cancer and a gangrenous condition of the hands and feet called Blackfoot's disease, has occurred in people from several communities in Europe, South America, and Taiwan who were exposed to elevated concentrations of arsenic in drinking water (U.S. Environmental Protection Agency [USEPA] 1980; Lin et al. 1998). Inorganic arsenic in dietary staples such as yams and rice may have contributed substantially to exposure and adverse health effects observed in an endemic Taiwanese population historically exposed to arsenic in drinking water (Schoof et al. 1998). Severe health effects, including cancer and death, have recently been documented in Mongolia (Luo et al. 1997; Ma et al. 1998), Bangladesh (Biswas et al. 1998), Chile (Smith et al. 1998), and India (Chowdhury et al. 1997) from ingestion of naturally elevated levels of arsenic in the drinking water, and in Thailand from the use of traditional arsenic-containing medicines and arsenical wastes from mining activities (Choprapawon and Rodcline 1997). In Japan, about 12,000 infants were poisoned (128 deaths) after consuming dry milk containing 15 to 24 mg inorganic As/kg, which originated from contaminated sodium phosphate used as a milk stabilizer. Fifteen years after exposure, the survivors sustained an elevated frequency of severe hearing loss and brain-wave abnormalities (Pershagen and Vahter 1979).

Many reviews on ecotoxicological aspects of arsenic in the environment are available, including those by Woolson (1975), NAS (1977), NRCC (1978), Pershagen and Vahter (1979), USEPA (1980, 1985), Hood (1985), Andreae (1986), Sorensen (1987), Eisler (1988, 1994), Phillips (1990), ATSDR (1992), Abernathy et al. (1997), Society for Environmental Geochemistry and Health [SEGH] (1998) and the U.S. Public Health Service [USPHS] (1998). These authorities agree on six points:

1. Arsenic is a relatively common element and is present in air, water, soil, plants, and in all living tissues.
2. Arsenicals have been used in medicine as chemotherapeutics since 400 BCE, and organoarsenicals were used extensively for this purpose until about 1945, with no serious effects when judiciously administered.
3. Large quantities of arsenicals are released into the environment as a result of industrial and especially agricultural activities, and these may pose potent ecological dangers.
4. Exposure of humans and wildlife to arsenic may occur through air (emissions from smelters, coal-fired power plants, herbicide sprays), water (mine tailings runoff, smelter wastes, natural mineralization), and food (especially seafoods).
5. Chronic exposure to arsenicals by way of the air, diet, and other routes has been associated with liver, kidney, and heart damage, hearing loss, brain-wave abnormalities, and impaired resistance to viral infections.
6. Exposure to arsenic has been associated with different types of human cancers such as respiratory cancers and epidermoid carcinomas of the skin, as well as precancerous dermal keratosis. The epidemiological evidence of human carcinogenicity is supported by carcinogenesis in experimental animals (Deknudt et al. 1986).

28.2 SOURCES, FATE, AND USES

Global production of arsenic is estimated to be 75,000 to 100,000 tons annually, of which the United States produces about 21,000 tons and uses about 44,000 tons. Major quantities are imported from Sweden, the world's leading producer (NAS 1977; USEPA 1980). Imports of arsenic trioxide (As_2O_3) to the United States have increased from about 16 million kg in 1985 to about 30 million kg in 1989; imports of elemental arsenic have increased from about 0.45 million kg in 1985/88 to 1.2 million kg in 1989 (ATSDR 1992). The United States exports about 0.3 million kg arsenic compounds annually, mainly as arsenic acid, sodium arsenate, and lead arsenate (ATSDR 1992). Almost all (97%) of the arsenic made worldwide enters end-product manufacture in the form of arsenic trioxide, and the rest is used as additives in producing special lead and copper alloys (NAS 1977). About 74% of the total arsenic trioxide is in products used for wood preservation (ATSDR 1992). Most of the rest (about 19%) is used in production of agricultural chemicals, such as insecticides, herbicides, fungicides, algicides, and growth stimulants for plants and animals (ATSDR 1992). Smaller amounts are used in the production of glass, in the electronic industry, dyestuffs, and in veterinary and human medicines, including medicines for the eradication of tapeworm in sheep and cattle (NAS 1977; ATSDR 1992; Eisler 1994). The sole producer and refiner of As_2O_3 in the United States is a copper smelter in Tacoma, Washington (NAS 1977).

Arsenic naturally occurs as sulfides and as complex sulfides of iron, nickel, and cobalt (Woolson 1975). In one form or another, arsenic is present in rocks, soils, water, and living organisms at concentrations of parts per billion to parts per million (NAS 1977). Soil arsenic levels are normally elevated near arseniferous deposits and in mineralized zones containing gold, silver, and sulfides of lead and zinc (Dudas 1984; Thornton and Farago 1997). Secondary iron oxides formed from the weathering of pyrite act as scavengers of arsenic (Dudas 1984). Pyrite is a known carrier of arsenic and may contain up to 5600 mg/kg. For example, total arsenic is 10 times above normal background levels in soils derived from pyritic shale (Dudas 1984). Natural weathering of rocks and soils adds about 40,000 tons of arsenic to the oceans yearly, accounting for <0.01 mg/L input to water on a global basis (NRCC 1978). Many species of marine plants and animals often contain naturally high concentrations of arsenic (NAS 1977), but it is usually present in a harmless organic form (Woolson 1975). Anthropogenic input of arsenic to the environment is substantial and exceeds that contributed by natural weathering processes by a factor of about 3 (NRCC 1978).

The most important concept with respect to arsenic cycling in the environment is constant change. Arsenic is ubiquitous in living tissue and is constantly being oxidized, reduced, or otherwise

metabolized. In soils, insoluble or slightly soluble arsenic compounds are constantly being resolubilized, and the arsenic is being presented for plant uptake or reduction by organisms and chemical processes. Humans reportedly modify the arsenic cycle only by causing localized high concentrations (NAS 1977). The speciation of arsenic in the environment is affected partly by indiscriminate biological uptake, which consumes about 20% of the dissolved arsenate pool and results in measurable concentrations of reduced and methylated arsenic species. The overall arsenic cycle is similar to the phosphate cycle; however, regeneration time for arsenic is much slower — on the order of several months (Sanders 1980). The ubiquity of arsenic in the environment is evidence of the redistribution processes that have been operating since early geologic time (Woolson 1975). A prehuman steady-state solution to the global arsenic cycle (Austin and Millward 1984) indicates that major reservoirs of arsenic (in kilotons) are magma (50 billion), sediments (25 billion), oceanic deep waters (1.56 million), land (1.4 million), and ocean mixed layers (270,000); minor amounts occur in ocean particulates (100), and in continental (2.5) and marine tropospheres (0.069). Arsenic is significantly mobilized from the land to the troposphere by both natural and anthropogenic processes. Industrial emissions account for about 30% of the present-day burden of arsenic in the troposphere (Austin and Millward 1984). Agronomic ecosystems, for example, may receive arsenic from agricultural sources such as organic herbicides, irrigation waters, and fertilizers, and from such nonagricultural sources as fossil fuels and industrial and municipal wastes (Woolson 1975). Arsenic is mobile and nonaccumulative in air, plant, and water phases of agronomic ecosystems; arsenicals sometimes accumulate in soils, but redistribution mechanisms usually preclude hazardous accumulations (Woolson 1975).

Arsenic compounds have been used in medicine since the time of Hippocrates, ca. 400 BCE (Woolson 1975). Inorganic arsenicals have been used for centuries, and organoarsenicals for at least a century in the treatment of syphilis, yaws, amoebic dysentery, and trypanosomiasis (NAS 1977). During the period 1200 to 1650, however, arsenic was used extensively in homicides (NRCC 1978). In 1815, the first accidental death was reported from arsine (AsH_3) poisoning; and between 1900 and 1903, accidental poisonings from consumption of arsenic-contaminated beer were widely reported (NRCC 1978). In 1938, it was established that arsenic can counteract selenium toxicity (NRCC 1978; ATSDR 1992). The introduction of arsphenamine, an organoarsenical, to control venereal disease earlier this century gave rise to intensive research by organic chemists, which resulted in the synthesis of at least 32,000 arsenic compounds. But the advent of penicillin and other newer drugs nearly eliminated the use of organic arsenicals as human therapeutic agents (USEPA 1980). Arsenical drugs are still used in treating certain tropical diseases, such as African sleeping sickness and amoebic dysentery, and are used in veterinary medicine to treat parasitic diseases, including filariasis in dogs (*Canis familiaris*) and blackhead in turkeys (*Meleagris gallopavo*) and chickens, *Gallus* spp. (NAS 1977). Today, abnormal sources of arsenic that can enter the food chain from plants or animals include arsenical pesticides such as lead arsenate; arsenic acid, HAsO_3 ; sodium arsenite, NaAsO_2 ; sodium arsenate, Na_2AsO_4 ; and cacodylic acid, $(\text{CH}_3)_2\text{As}(\text{OH})$ (NAS 1977).

The major uses of arsenic are in the production of herbicides, insecticides, desiccants, growth stimulants for plants and animals, and especially wood preservatives. Much smaller amounts are used in the manufacture of glass (nearly all of which contains 0.2% to 1.0% arsenic as an additive — primarily as a decolorizing agent) and textiles, and in medical and veterinary applications (NAS 1977; USEPA 1980; Hamasaki et al. 1995). Arsenic is also an ingredient in lewisite, a blistering poison gas developed (but not used) during World War I, and in various police riot-control agents (NAS 1977). The availability of arsenic in certain local areas has been increased by various human activities:

- Smelting and refining of gold, silver, copper, zinc, uranium, and lead ores
- Combustion of fossil fuels, such as coal and gasoline
- Burning of vegetation from cotton gins treated with arsenical pesticides
- Careless or extensive use of arsenical herbicides, pesticides, and defoliants

- Dumping of land wastes and sewage sludge (1.1 mg/L) in areas that allow leaching into groundwater
- Use of domestic detergents in wash water (2.5 to 1000 mg As/L)
- Manufacture of glass
- Sinking of drinking water wells into naturally arseniferous rock (NRCC 1978; USEPA 1980).

There are several major anthropogenic sources of environmental arsenic contamination: industrial smelters — the effluent from a copper smelter in Tacoma, Washington, contained up to 70 tons arsenic discharged yearly into nearby Puget Sound (NRCC 1978); coal-fired power plants, which collectively emit about 3000 tons arsenic annually in the United States (USEPA 1980); and production and use of arsenical pesticides, coupled with careless disposal of used pesticide containers (NAS 1977). Elevated levels of arsenic have been reported in soils near smelters, in acid mine spoils, and in orchards receiving heavy applications of lead arsenate (NAS 1977; Dudas 1984). Air concentrations of arsenic are elevated near metal smelters, near sources of coal burning, and wherever arsenical pesticides are applied (NAS 1977). Atmospheric deposition of arsenic has steadily increased for at least 30 years, as judged by sedimentary evidence from lakes in upstate New York (Smith et al. 1987). Arsenic is introduced into the aquatic environment through atmospheric deposition of combustion products and through runoff from flyash storage areas near power plants and nonferrous smelters (Smith et al. 1987). Elevated arsenic concentrations in water were recorded near mining operations and from mineral springs and other natural waters — usually alkaline and with high sodium and bicarbonate contents (NAS 1977). In the United States, the most widespread and frequent increases in dissolved arsenic concentrations in river waters were in the northern Midwest. All evidence suggests that increased atmospheric deposition of fossil fuel combustion products was the predominant cause of the trend (Smith et al. 1987).

Agricultural applications provide the largest anthropogenic source of arsenic in the environment (Woolson 1975). Inorganic arsenicals (arsenic trioxide; arsenic acid; arsenates of calcium, copper, lead, and sodium; and arsenites of sodium and potassium) have been used widely for centuries as insecticides, herbicides, algicides, and desiccants. Paris green (cuprous arsenite) was successfully used in 1867 to control the Colorado potato beetle (*Leptinotarsa decemlineata*) in the eastern United States. Arsenic trioxide has been applied widely as a soil sterilant. Sodium arsenite has been used for aquatic weed control, as a defoliant to kill potato vines before tuber harvest, as a weed killer along roadsides and railroad rights-of-way, and for control of crabgrass (*Digitaria sanguinalis*). Calcium arsenates have been applied to cotton and tobacco fields to protect against the boll weevil (*Anthonomus grandis*) and other insects. Lead arsenate has been used to control insect pests of fruit trees, and for many years was the only insecticide that controlled the codling moth (*Carpocapsa pomonella*) in apple orchards and the horn worm larva (Sphingidae) on tobacco. Much smaller quantities of lead arsenate are now used in orchards because fruit growers rely primarily on carbamate and organophosphorus compounds to control insect pests; however, lead arsenate is still being used by some growers to protect orchards from certain chewing insects. The use of inorganic arsenicals has decreased due to the banning of sodium arsenite and some other arsenicals for most purposes, although they continue to be used on golf greens and fairways in certain areas to control annual bluegrass (*Poa annua*). In recent decades, inorganic arsenicals have been replaced by organoarsenicals for herbicidal application, and by carbamate and organophosphorus compounds for insect control (Woolson 1975). By the mid-1950s, organoarsenicals were used extensively as desiccants, defoliants, and herbicides (NRCC 1978). Organoarsenicals marketed in agriculture today, which are used primarily for herbicidal application, include cacodylic acid (also known as dimethylarsinic acid) and its salts — monosodium and disodium methanearsonate (Woolson 1975; NAS 1977). Organoarsenicals are used as selective herbicides for weedy grasses in turf, and around cotton and noncrop areas for weed control. At least 1.8 million ha (4.4 million acres) have been treated with more than 8000 tons of organoarsenicals (NAS 1977). In 1945, it was discovered that one organoarsenical (3-nitro-4-hydroxyphenyl arsonic acid) controlled coccidiosis and promoted growth in domestic chicken (Woolson 1975). Since that time, other substituted phenylarsonic acids

have been shown to have both therapeutic and growth-promoting properties as feed additives for poultry and swine (*Sus* spp.), and are used for this purpose today under existing regulations (Woolson 1975; NAS 1977) — although the use of arsenicals in poultry food was banned in France in 1959 (NRCC 1978).

28.3 CHEMICAL AND BIOCHEMICAL PROPERTIES

Elemental arsenic is a gray, crystalline material characterized by atomic number 33, atomic weight of 74.92, density of 5.727, melting point of 817°C, sublimation at 613°C, and chemical properties similar to those of phosphorus (Woolson 1975; NAS 1977; NRCC 1978; USEPA 1980, 1985; ATSDR 1992). Arsenic has four valence states: -3, 0, +3, and +5. Arsines and methylarsines, which are characteristic of arsenic in the -3 oxidation state, are generally unstable in air. Elemental arsenic, As⁰ is formed by the reduction of arsenic oxides. Arsenic trioxide (As⁺³) is a product of smelting operations and is the material used in synthesizing most arsenicals. It is oxidized catalytically or by bacteria to arsenic pentoxide (As⁺⁵) or orthoarsenic acid (H₃AsO₄). Arsenic in nature is rarely in its free state. Usually, it is a component of sulfidic ores, occurring as arsenides and arsenates, along with arsenic trioxide, which is a weathering product of arsenides. Most arsenicals degrade or weather to form arsenate, although arsenite may form under anaerobic conditions. Biotransformations may occur, resulting in volatile arsenicals that normally are returned to the land where soil adsorption, plant uptake, erosion, leaching, reduction to arsines, and other processes occur. This natural arsenic cycle reflects a constant shifting of arsenic between environmental compartments. Atomic absorption spectrometry is the most common procedure for measuring arsenic in biological materials, although other methods are used, including neutron activation (ATSDR 1992). A variety of sensitive techniques have been used to obtain speciation data for the forms of arsenic at trace levels (Hamasaki et al. 1995; Crecelius et al. 1998).

Arsenic species in flooded soils and water are subject to chemically and microbiologically mediated oxidation or reduction and methylation reactions (Tamaki and Frankenberger 1992; Hamasaki et al. 1995). At high Eh values (i.e., high oxidation-reduction potential) typical of those encountered in oxygenated waters, pentavalent As⁺⁵ tends to exist as H₃AsO₄, H₂AsO₄, HAsO₂, and AsO₄⁻³. At lower Eh, the corresponding trivalent arsenic species can be present, as well as AsS₂ (Thanabalasingam and Pickering 1986). In aerobic soils, the dominant arsenic species is As⁺⁵, and small quantities of arsenite and monomethylarsonic acid are present in mineralized areas. In anaerobic soils, As⁺³ is the major soluble species (Haswell et al. 1985). Inorganic arsenic is more mobile than organic arsenic, and thus poses greater problems by leaching into surface waters and groundwater (NRCC 1978). The trivalent arsenic species are generally considered to be more toxic, more soluble, and more mobile than As⁺⁵ species (Thanabalasingam and Pickering 1986). Soil microorganisms metabolize arsenic into volatile arsine derivatives. Depending on conditions, 17% to 60% of the total arsenic present in soil may be volatilized (NRCC 1978). Estimates of the half-life of arsenic in soil vary from 6.5 years for arsenic trioxide to 16 years for lead arsenate (NRCC 1978).

In water, arsenic occurs in both inorganic and organic forms, and in dissolved and gaseous states (USEPA 1980). The form of arsenic in water depends on Eh, pH, organic content, suspended solids, dissolved oxygen, and other variables (USEPA 1985). Arsenic in water exists primarily as a dissolved ionic species; particulates account for less than 1% of the total measurable arsenic (Maher 1985a). Arsenic is rarely found in water in the elemental state (0) and is found in the -3 state only at extremely low Eh values (Lima et al. 1984). Common forms of arsenic encountered in water are arsenate, arsenite, methanearsonic acid, and dimethylarsinic acid (USEPA 1985). The formation of inorganic pentavalent arsenic, the most common species in water, is favored under conditions of high dissolved oxygen, basic pH, high Eh, and reduced content of organic material; reverse conditions usually favor the formation of arsenites and arsenic sulfides (NRCC 1978;

Pershagen and Vahter 1979; USEPA 1980), although some arsenite is attributed to biological activity (Maher 1985a). Water temperature seems to affect arsenic species composition in the estuary of the River Beaulieu in the United Kingdom, where reduced and methylated species predominate during warmer months and inorganic As⁺⁵ predominates during the colder months. The appearance of methylated arsenicals during the warmer months is attributed both to bacterial and abiotic release from decaying plankton and to grazing by zooplankton (Howard et al. 1984). Also contributing to higher water or mobile levels are the natural levels of polyvalent anions, especially phosphate species. Phosphate, for example, displaces arsenic held by humic acids, and it sorbs strongly to the hydrous oxides of arsenates (Thanabalingam and Pickering 1986).

Marine algae transform arsenate into nonvolatile methylated arsenic compounds such as methanearsonic and dimethylarsinic acids (Tamaki and Frankenberger 1992). Freshwater algae and macrophytes, like marine algae, synthesize lipid-soluble arsenic compounds and do not produce volatile methylarsines. Terrestrial plants preferentially accumulate arsenate over arsenite by a factor of about 4. Phosphate inhibits arsenate uptake by plants, but not the reverse. The mode of toxicity of arsenate in plants is to partially block protein synthesis and interfere with protein phosphorylation — a process that is prevented by phosphate (Tamaki and Frankenberger 1992).

Physical processes play a key role in governing arsenic bioavailability in aquatic environments. For example, arsenates are readily sorbed by colloidal humic material under conditions of high organic content, low pH, low phosphate, and low mineral content (USEPA 1980; Thanabalingam and Pickering 1986). Arsenates also coprecipitate with, or adsorb on, hydrous iron oxides and form insoluble precipitates with calcium, sulfur, aluminum, and barium compounds (USEPA 1980). Removal of arsenic from seawater by iron hydroxide scavenging seems to be a predominant factor in certain estuaries. The process involves both As⁺³ and As⁺⁵ and results in a measurable increase in arsenic levels in particulate matter, especially at low salinities (Sloot et al. 1985; Tremblay and Gobeil 1990). Arsenic sulfides are comparatively insoluble under conditions prevalent in anaerobic aqueous and sedimentary media containing hydrogen sulfide. Accordingly, these compounds may accumulate as precipitates and thus remove arsenic from the aqueous environment. In the absence of hydrogen sulfide, these sulfides decompose within several days to form arsenic oxides, sulfur, and hydrogen sulfide (NAS 1977).

In reduced environments, such as sediments, arsenate is reduced to arsenite and methylated to methylarsinic acid or dimethylarsenic acids: these compounds may be further methylated to trimethylarsine or reduced to dimethylarsine, and may volatilize to the atmosphere where oxidation reactions result in the formation of dimethylarsinic acid (Woolson 1975). Arsenates are more strongly adsorbed to sediments than are other arsenic forms, the adsorption processes depending strongly on arsenic concentration, sediment characteristics, pH, and ionic concentration of other compounds (USEPA 1980). An important mechanism of arsenic adsorption onto lake sediments involves the interaction of anionic arsenates and hydrous iron oxides. Evidence suggests that arsenic is incorporated into sediments at the time of hydrous oxide formation, rather than by adsorption onto existing surfaces (Aggett and Roberts 1986). Arsenic concentrations in lake sediments are also correlated with manganese; hydrous manganese oxides — positively charged for the adsorption of Mn⁺² ions — play a significant role in arsenic adsorption onto the surface of lake sediments (Takamatsu et al. 1985). The mobility of arsenic in lake sediments and its release to the overlying water is related partly to seasonal changes. In areas that become stratified in summer, arsenic released from sediments accumulates in the hypolimnion until turnover, when it is mixed with epilimnetic waters. This mixing may result in a 10 to 20% increase in arsenic concentration (Aggett and O'Brien 1985). Microorganisms (including four species of fungi) in lake sediments oxidized inorganic As⁺³ to As⁺⁵ and reduced inorganic As⁺⁵ to As⁺³ under aerobic conditions; under anaerobic conditions, only reduction was observed (Freeman et al. 1986). Inorganic arsenic can be converted to organic alkyl arsenic acids and methylated arsines under anaerobic conditions by fungi, yeasts, and bacteria — although biomethylation may also occur under aerobic conditions (USEPA 1980).

Most arsenic investigators now agree on the following points:

1. Arsenic may be absorbed by ingestion, inhalation, or through permeation of the skin or mucous membranes.
2. Cells accumulate arsenic using an active transport system normally used in phosphate transport.
3. Arsenicals are readily absorbed after ingestion, most being rapidly excreted in the urine during the first few days, or at most a week (the effects seen after long-term exposure are probably a result of continuous daily exposure, rather than of accumulation).
4. The toxicity of arsenicals conforms to the following order, from greatest to least toxicity: arsines > inorganic arsenites > organic trivalent compounds (arsenoxides) > inorganic arsenates > organic pentavalent compounds > arsonium compounds > elemental arsenic.
5. Solubility in water and body fluids appears to be directly related to toxicity (the low toxicity of elemental arsenic is attributed to its virtual insolubility in water and body fluids, whereas the highly toxic arsenic trioxide, for example, is soluble in water to 12.0 g/L at 0°C, 21.0 g/L at 25°C, and 56.0 g/L at 75°C).
6. The mechanisms of arsenical toxicity differ considerably among arsenic species, although signs of poisoning appear similar for all arsenicals (Woolson 1975; NRCC 1978; Pershagen and Vahter 1979; Eisler 1988, 1994; ATSDR 1992; Abernathy et al. 1997; SEGH 1998).

The primary toxicity mode of inorganic As⁺³ is through reaction with sulfhydryl groups of proteins and subsequent enzyme inhibition; inorganic pentavalent arsenate does not react as readily as As⁺³ with sulfhydryl groups, but may uncouple oxidative phosphorylation (Howard et al. 1984; USEPA 1985). Inorganic As⁺³ interrupts oxidative metabolic pathways and sometimes causes morphological changes in liver mitochondria. Arsenite *in vitro* reacts with protein-SH groups to inactivate enzymes such as dihydrolipoyle dehydrogenase and thiolase, producing inhibited oxidation of pyruvate and beta-oxidation of fatty acids (Belton et al. 1985). Inorganic As⁺³ may also exert toxic effects by the reaction of arsenous acid (HAsO) with the sulfhydryl (SH) groups of enzymes. In the first reaction, arsenous acid is reduced to arsionous acid (AsOH₂), which then condenses to either monothiols or dithiols to yield dithioesters of arsionous acid. Arsionous acid may then condense with enzyme SH groups to form a binary complex (Knowles and Benson 1984a, 1984b).

Methylation to methylarsonic acid [(CH₃)₂AsO₃H₂] and dimethylarsinic acid [(CH₃)₂AsO₂H] is usually the major detoxification mechanism for inorganic pentavalent arsenates and trivalent arsenites in mammals. Methylated arsenicals rapidly clear from all tissues, except perhaps the thyroid (Marafante et al. 1985; Vahter and Marafante 1985; Yamauchi et al. 1986). Methylated arsenicals are probably common in nature. Methylation of arsenic (unlike methylation of mercury) greatly reduces toxicity and is a true detoxification process (Woolson 1975; Hamasaki et al. 1995; Aposhian et al. 1997). Before methylation (which occurs largely in the liver), As⁺⁵ is reduced to As⁺³ — the kidney being an important site for this transformation (Belton et al. 1985). Arsenate reduction and subsequent methylation are rapid: both arsenite and dimethylarsinate were present in hamster (*Cricetus* sp.) plasma only 12 min postinjection of inorganic As⁺⁵ (Hanlon and Ferm 1986c). Demethylation of methylated arsenicals formed *in vivo* has not yet been reported (USEPA 1980). Although terrestrial biota usually contain much lower total concentrations of arsenic than marine biota, metabolism of arsenic is similar in marine and terrestrial systems (Irgolic et al. 1998).

Toxic effects of organoarsenicals are exerted by initial metabolism to the trivalent arsenoxide form, and then by reaction with sulfhydryl groups of tissue proteins and enzymes to form an arylbis (organylthio) arsine (NAS 1977). This form, in turn, inhibits oxidative degradation of carbohydrates and decreases cellular ATP, the energy-storage molecule of the cell (NRCC 1978). Among the organoarsenicals, those physiologically most injurious are methylarsonous acid [CH₃As(OH)₂] and dimethylarsinous acid [(CH₃)₂AsOH] (Knowles and Benson 1984b). The enzyme inhibitory forms of organoarsenicals (arsionous acid) are formed from arsenous acid and the corresponding arsonic acids by a wide variety of enzymes and subcellular particles (Knowles and Benson 1984a). Organoarsenicals used as growth promoters and drugs are converted to more easily excreted (and sometimes more toxic) substances, although most organoarsenicals are eliminated without being

converted to inorganic arsenic or to demethylarsinic acids (Pershagen and Vahter 1979; Edmonds et al. 1993).

28.4 ESSENTIALITY, SYNERGISM, AND ANTAGONISM

Limited data are available on the beneficial, protective, and essential properties of arsenic and on its interactions with other chemicals. Arsenic apparently behaves more like an environmental contaminant than as a nutritionally essential mineral (NAS 1977). Nevertheless, low doses (<2 µg/day) of arsenic stimulated growth and metamorphosis in tadpoles and increased viability and cocoon yield in silkworm caterpillars (NAS 1977). Arsenic deficiency has been observed in rats: signs include rough haircoat, low growth rate, decreased hematocrit, increased fragility of red cells, and enlarged spleen (NAS 1977). Similar results have been documented in goats and pigs fed diets containing less than 0.05 mg As/kg (NAS 1977). In these animals, reproductive performance was impaired, neonatal mortality was increased, birth weight was lower, and weight gains in second-generation animals were decreased. These effects were not evident in animals fed diets containing 0.35 mg As/kg (NAS 1977; ATSDR 1992).

The use of phenylarsonic feed additives to promote growth in poultry and swine and to treat specific diseases does not seem to constitute a hazard to the animal or to its consumers. Animal deaths and elevated tissue arsenic residues occur only when the arsenicals are fed at excessive dosages for long periods (NAS 1977). Arsenic can be detected at low levels in tissues of animals fed organoarsenicals, but it is rapidly eliminated when the arsenicals are removed from the feed for the required 5-day period before marketing (Woolson 1975).

Selenium and arsenic are antagonists in several animal species. Dietary arsenic, as arsenate, alleviates the toxic effects of selenium, as seleno-DL-methionine, on mallard (*Anas platyrhynchos*) reproduction and duckling growth and survival (Stanley et al. 1994). Mallard ducklings fed arsenate in the diet at 200 mg As/kg ration were protected against the toxic effects of 60 mg Se/kg ration as selenomethionine, including selenium-induced mortality, impaired growth, hepatic lesions, and enzyme disruptions (Hoffman et al. 1992). In rats, dogs, swine, cattle, and poultry, the arsenic protects against selenium poisoning if arsenic is administered in the drinking water and selenium through the diet (NAS 1977; NRCC 1978; Pershagen and Vahter 1979). Inorganic arsenic compounds decrease the toxicity of inorganic selenium compounds by increasing biliary excretion (NRCC 1978). However, in contrast to antagonism shown by inorganic arsenic/inorganic selenium mixtures, the toxic effects of naturally methylated selenium compounds (trimethylselenonium chloride and dimethyl selenide) are markedly enhanced by inorganic arsenicals (NRCC 1978).

The toxic effects of arsenic can be counteracted with:

1. Saline purgatives
2. Various demulcents that coat irritated gastrointestinal mucous membranes
3. Sodium thiosulfate (NAS 1977)
4. Mono- and dithiol-containing compounds and 2,3-dimercaptopropanol (Pershagen and Vahter 1979)

Arsenic uptake in rabbit intestine is inhibited by phosphate, casein, and various metal-chelating agents (USEPA 1980). Mice and rabbits are significantly protected against sodium arsenite intoxication by *N*-(2,3-dimercaptopropyl)phthalimidic acid (Stine et al. 1984). Conversely, the toxic effects of arsenite are potentiated by excess dithiols, cadmium, and lead, as evidenced by reduced food efficiency and disrupted blood chemistry in rodents (Pershagen and Vahter 1979).

Arsenic effectively controls filariasis in cattle; new protective uses are under investigation. The control of parasitic nematodes (*Parafilaria bovicola*) in cattle was successful after 30 weekly treatments in plunge dips containing 1600 mg As₂O₃/L. However, the muscle of treated cattle

contained up to 1.3 mg As/kg, or 12 times the amount in controls (Nevill 1985). Existing anionic organic arsenicals used to control tropical nematode infections in humans have sporadic and unacceptable lethal side effects. Cationic derivatives have been synthesized in an attempt to avoid the side effects and have been examined for effects on adult nematodes (*Brugia pahangi*) in gerbils (*Meriones unguiculatus*). All arsenicals were potent filaricides; the most effective compounds tested killed 95% of adult *B. pahangi* after five daily subcutaneous injections of 3.1 mg As/kg body weight (Denham et al. 1986).

Animals previously exposed to sublethal levels of arsenic may develop tolerance to arsenic on reexposure. Although the mechanism of this process is not fully understood, it probably includes the efficiency of *in vivo* methylation processes (USEPA 1980). For example, resistance to toxic doses of As⁺³ or As⁺⁵ increases in mouse fibroblast cells pretreated with a low As⁺³ concentration (Fischer et al. 1985). Also, growth is better in arsenic-conditioned mouse cells in the presence of arsenic than in previously unexposed cells, and inorganic arsenic is more efficiently methylated. *In vivo* biotransformation and excretion of inorganic arsenic as monomethylarsonic acid (MMA) and dimethylarsinic acid (DMA) have been demonstrated in a number of mammalian species, including humans. It seems that cells may adapt to arsenic by increasing the biotransformation rate of the element to methylated forms, such as MMA and DMA (Fischer et al. 1985). Pretreatment of Chinese hamster (*Cricetus* spp.) ovary cells with sodium arsenite provided partial protection against adverse effects of methyl methanesulfonate (MMS) and may even benefit the MMS-treated cells. However, posttreatment dramatically increases the cytotoxic, clastogenic, and mitotic effects induced by MMS (Lee et al. 1986b).

Although arsenic is not an essential plant nutrient, small yield increases have sometimes been observed at low soil arsenic levels, especially for tolerant crops such as potatoes, corn, rye, and wheat (Woolson 1975). Arsenic phytotoxicity of soils is reduced with increasing lime, organic matter, iron, zinc, and phosphates (NRCC 1978). In most soil systems, the chemistry of As becomes the chemistry of arsenate; the estimated half-time of arsenic in soils is about 6.5 years, although losses of 60% in 3 years and 67% in 7 years have been reported (Woolson 1975). Additional research is warranted on the role of arsenic in crop production, and in nutrition, with special reference to essentiality for aquatic and terrestrial wildlife.

28.5 CONCENTRATIONS IN FIELD COLLECTIONS

28.5.1 General

In abundance, arsenic ranks 20th among the elements in the earth's crust (1.5 to 2 mg/kg), 14th in seawater, and 12th in the human body (Woolson 1975). It occurs in various forms, including inorganic and organic compounds and trivalent and pentavalent states (Pershagen and Vahter 1979). In aquatic environments, higher arsenic concentrations are reported in hot springs, in groundwaters from areas of thermal activity or in areas containing rocks with high arsenic content, and in some waters with high dissolved salt content (NAS 1977). Most of the other elevated values reported in lakes, rivers, and sediments are probably due to anthropogenic sources, which include smelting and mining operations; combustion of fossil fuel; arsenical grasshopper baits; synthetic detergent and sewage sludge wastes; and arsenical defoliants, herbicides, and pesticides (NAS 1977). Most living organisms normally contain measurable concentrations of arsenic, but except for marine biota, these are usually less than 1 mg/kg fresh weight. Marine organisms, especially crustaceans, may contain more than 100 mg As/kg dry weight, usually as arsenobetaine, a water-soluble organoarsenical that poses little risk to the organism or its consumer. Plants and animals collected from naturally arseniferous areas or near anthropogenic sources may contain significantly elevated tissue residues of arsenic. Additional and more detailed information on background concentrations

of arsenic in abiotic and living resources has been given by NAS (1977), Hall et al. (1978), NRCC (1978), USEPA (1980), Jenkins (1980), Eisler (1981, 1994), and Phillips (1990).

28.5.2 Nonbiological Samples

Arsenic is a major constituent of at least 245 mineral species, of which arsenopyrite is the most common (NAS 1977). In general, background concentrations of arsenic are 0.2 to 15 mg/kg in the lithosphere, 0.005 to 0.1 µg/m³ in air, <10 µg/L in water, and <15 mg/kg in soil (NRCC 1978; ATSDR 1992). The commercial use and production of arsenic compounds have raised local concentrations in the environment far above the natural background concentrations ([Table 28.1](#)).

Weathering of rocks and soils adds about 45,000 tons of arsenic to the oceans annually, accounting for less than 0.01 mg/L on a global basis (NRCC 1978). However, arsenic inputs to oceans have increased during the past century, both from natural sources and as a result of industrial use, agricultural and deforestation activities, emissions from coal and oil combustion, and loss during mining of metal ores. If present activities continue, arsenic concentrations in oceanic surface waters will have increased overall by about 2% by the year 2000, with most of the increased burden in estuaries and coastal oceans (e.g., Puget Sound, Washington; the Tamar, England; and the Tejo, Portugal) (Sanders 1985). Estimates of the residence times of arsenic are 60,000 years in the ocean and 45 years in a freshwater lake (NRCC 1978). In the hydrosphere, inorganic arsenic occurs predominantly as As⁺⁵ in surface water, and significantly as As⁺³ in groundwater containing high levels of total arsenic. The main organic species in freshwater are methylarsonic acid and dimethylarsinic acid, and these are usually present in lower concentrations than inorganic arsenites and arsenates (Pershagen and Vahter 1979). Total arsenic concentrations in surface water and groundwater are usually <10 µg/L. In certain areas, however, levels above 1 mg/L have been recorded (Pershagen and Vahter 1979).

In air, most arsenic particulates consist of inorganic arsenic compounds, often as As⁺³. Burning of coal and arsenic-treated wood, and smelting of metals are major sources of atmospheric arsenic contamination (i.e., >1 µg/m³). In general, atmospheric arsenic levels are higher in winter, due to increased use of coal for heating (Pershagen and Vahter 1979).

The main carrier of arsenic in rocks and in most types of mineral deposits is iron pyrite (FeS₂), which may contain >2000 mg As/kg (NRCC 1978). In localized areas, soils are contaminated by arsenic oxide fallout from smelting ores (especially sulfide ores) and combustion of arsenic-rich coal (Woolson 1975).

Arsenic in lacustrine sediment columns is subject to control by diagenetic processes and adsorption mechanisms, as well as anthropogenic influences (Farmer and Lovell 1986; Farag et al. 1995). For example, elevated levels of arsenic in surface or near-surface sediments may have several causes (Farmer and Lovell 1986), including natural processes (Loch Lomond, Scotland) and human activities such as smelting (Lake Washington, Washington; Kelly Lake, Ontario, Canada), manufacture of arsenical herbicides (Brown's Lake, Wisconsin), and mining operations (Northwest Territories, Canada; Clark Fork River, Montana). Elevated levels of arsenic in sediments of the Wailoa River, Hawaii, are the result of As₂O₃ applied as an anti-termite agent between 1932 and 1963. These elevated levels are found mainly in anaerobic sediment regions where the chemical has been relatively undisturbed by activity. Low levels of arsenic in the biota of the Wailoa River estuary suggest that arsenic is trapped in the anaerobic sediment layers (Hallacher et al. 1985).

Arsenic geochemistry in Chesapeake Bay, Maryland, depends on anthropogenic inputs and phytoplankton species composition (Sanders 1985). Inputs of anthropogenic arsenic into Chesapeake Bay are estimated at 100 kg daily, or 39 tons/year — probably from sources such as unreported industrial discharges, use of arsenical herbicides, and from wood preservatives (Sanders 1985). The chemical form of the arsenic in solution varies seasonally and along the axis of the bay. Arsenic is present only as arsenate in winter, but substantial quantities of reduced and methylated forms are present in summer in different areas. The forms and distribution patterns of arsenic

during the summer suggest that separate formation processes exist. Arsenite, present in low salinity regions, may have been formed by chemical reduction in anoxic, subsurface waters and then mixed into the surface layer. Methylated arsenicals are highly correlated with standing crops of algae. One particular form, methylarsonate, is significantly correlated with the dominant alga, *Chroomonas*. Since both arsenic reactivity and toxicity are altered by transformation of chemical form, the observed variations in arsenic speciation have considerable geochemical and ecological significance (Sanders 1985).

Table 28.1 Total Arsenic Concentrations in Selected Nonbiological Materials

Material and Units (in parentheses)	Concentration ^a	Reference ^b
AIR (µg/m³)		
Remote areas	<0.02	1
Urban areas	(0.0–0.16)	1
Near smelters

28.5.3 Biological Samples

Background arsenic concentrations in living organisms are usually <1 mg/kg fresh weight in terrestrial flora and fauna, birds, and freshwater biota. These levels are higher, sometimes markedly so, in biota collected from mine waste sites, arsenic-treated areas, near smelters and mining areas, near areas with high geothermal activity, and near manufacturers of arsenical defoliants and pesticides (Table 28.2). For example, bloater (*Coregonus hoyi*) collected in Lake Michigan near a facility that produced arsenical herbicides consistently had the highest (1.5 to 2.9 mg As/kg fresh weight whole body) arsenic concentrations measured in freshwater fishes in the United States between 1976 and 1984 (Schmitt and Brumbaugh 1990). Marine organisms normally contain arsenic residues of several to more than 100 mg/kg dry weight (Lunde 1977). However, as will be discussed later, these concentrations present little hazard to the organism or its consumers.

Arsenic concentrations in tissues of marine biota show a wide range of values, being highest in lipids, liver, and muscle tissues, and varying with the age of the organism, geographic locale, and proximity to anthropogenic activities (Table 28.2). In general, tissues with high lipid content contained high levels of arsenic. Crustacean tissues sold for human consumption and collected in U.S. coastal waters usually contained 3 to 10 mg As/kg fresh weight (Hall et al. 1978), or 1 to 100 mg/kg dry weight (Fowler and Unlu 1978), and were somewhat higher than those reported for finfish and molluscan tissues. Marine finfish tissues usually contained 2 to 5 mg As/kg fresh weight (Table 28.2). However, postmortem reduction of As⁺⁵ to As⁺³ occurs rapidly in fish tissues (Reinke et al. 1975), suggesting a need for additional research in this area. Maximum arsenic values recorded in elasmobranchs (mg/kg fresh weight) were 30 in the muscle of a shark (*Mustelus antarcticus*) and 16.2 in the muscle of a ray (*Raja* sp.) (Eisler 1981). The highest arsenic concentration recorded in a marine mammal, 2.8 mg As/kg fresh weight lipid, was from a whale (Eisler 1981).

Arsenic appears to be elevated in marine biota because of their ability to accumulate arsenic from seawater or food sources — and not because of localized pollution (Maher 1985b). The great majority of arsenic in marine organisms exists as water-soluble and lipid-soluble organoarsenicals that include arsenolipids, arenosugars, arsenocholine, arsenobetaine [(CH₃)₃AsCH₂COOH], monomethylarsonate [CH₃AsO(OH)₂], and demethylarsinate [(CH₃)₂AsO(OH)], as well as other forms (Edmonds et al. 1993). There is no convincing hypothesis to account for the existence of all the various forms of organoarsenicals found in marine organisms. One suggested hypothesis is that each form involves a single anabolic/catabolic pathway concerned with the synthesis and turnover of phosphatidylcholine (Phillips and Depledge 1986). Arenosugars (arsenobetaine precursors) are the dominant arsenic species in brown kelp (*Ecklonia radiata*), giant clam (*Tridacna maxima*), shrimp (*Pandalus borealis*), and ivory shell (*Buccinum striatum*) (Shiomii et al. 1984a, 1984b; Francesconi et al. 1985; Matsuto et al. 1986; Phillips and Depledge 1986). For most marine species, however, there is general agreement that arsenic exists primarily as arsenobetaine, a water-soluble organoarsenical that has been identified in tissues of western rock lobster (*Panulirus cygnus*),

American lobster (*Homarus americanus*), octopus (*Paroctopus* sp.), sea cucumber (*Stichopus japonicus*), blue shark (*Prionace glauca*), sole (*Limanda* sp.), squid (*Sepioteuthis australis*), prawn (*Penaeus latisulcatus*), scallop (*Pecten alba*), and many other species (including teleosts, molluscs, tunicates, and crustaceans) (Shiomii et al. 1984b; Francesconi et al. 1985; Hanaoka and Tagawa 1985a, 1985b; Maher 1985b; Norin et al. 1985; Matsuto et al. 1986; Ozretic et al. 1990; Phillips 1990; Kaise and Fukui 1992; Edmonds et al. 1993). Degradation of arsenobetaine in muscle and liver of the star spotted shark (*Mustelus manazo*) to inorganic arsenic occurs in a natural environment and suggests that arsenobetaine bioconverted from inorganic arsenic in seawater is degraded to original inorganic arsenic. About 13% of the arsenobetaine in shark muscle and 4% in liver was degraded to inorganic arsenic within 40 days (Hanaoka et al. 1993). The potential risks associated with consumption of seafoods containing arsenobetaine seem to be minor. The chemical was not mutagenic in the bacterial *Salmonella typhimurium* assay (Ames test), had no effect on metabolic inhibition of Chinese hamster ovary cells at 10,000 mg/L, and showed no synergism or antagonism on the action of other contaminants (Jongen et al. 1985). Arsenobetaine was not toxic to mice at oral doses of 10,000 mg/kg body weight during a 7-day observation period and was rapidly absorbed from the gastrointestinal tract and rapidly excreted in urine without metabolism, owing to its high polar and hydrophilic characteristics (Kaise et al. 1985; Kaise and Fukui 1992).

Shorebirds (seven species) wintering in the Corpus Christi, Texas, area contained an average of 0.3 mg As/kg fresh weight in livers (maximum of 1.5 mg/kg), despite the presence of smelters and the heavy use of arsenical herbicides and defoliants. These values probably reflect normal background concentrations (White et al. 1980). Similar arsenic levels were reported in livers of brown pelicans (*Pelecanus occidentalis*) collected from South Carolina (Blus et al. 1977). Bone arsenic concentrations in 23 species of birds collected in southwestern Russia during 1993 to 1995 ranged from 0.1 to 1.7 mg As/kg DW; arsenic concentrations were similar for terrestrial and aquatic birds, and for urban and rural environments (Lebedeva 1997). The highest arsenic concentration recorded in seemingly unstressed coastal birds was 13.2 mg/kg fresh weight lipids (Table 28.2). This tends to corroborate the findings of others that arsenic concentrates in lipid fractions of marine plants, invertebrates, and higher organisms. An abnormal concentration of 16.7 mg As/kg fresh weight was recorded in the liver of an osprey (*Pandion haliaetus*) from the Chesapeake Bay region (Wiemeyer et al. 1980). This bird was alive but weak, with serious histopathology including the absence of subcutaneous fat, presence of serous fluid in the pericardial sac, and disorders of the lung and kidney. The bird died shortly after collection. Arsenic concentrations in the livers of other ospreys collected in the same area were usually <1.5 mg As/kg fresh weight. Chicks of the avocet (*Recurvirostra americana*) reared from eggs taken near arsenic-contaminated ponds in California (127 to 1100 µg As/L) had reduced hatch, as well as impaired growth and immune function, when compared to chicks from a reference site (29 µg As/L). Other contaminants present included boron and selenium, although the authors concluded that arsenic played a significant role in observed effects (Fairbrother et al. 1994).

Arsenic concentrations in tissues of small mammals (field mouse, *Apodemus sylvaticus*; bank vole, *Clethrionomys glareolus*; field vole, *Microtus agrestis*; common shrew, *Sorex araneus*) from the vicinity of an English arsenic refinery were usually less than 1 mg/kg FW and did not reflect arsenic levels of the surrounding soil or vegetation (Ismail and Roberts 1992). In general, mean arsenic concentrations were highest in spleen, followed — in descending order — by bone, heart, kidney, brain, muscle, and liver (Ismail and Roberts 1992). For human adults, seafood contributes 74% to 96% of the total daily arsenic intake, and rice and rice cereals most of the remainder. For infants, 41% of the estimated total arsenic intakes arise from seafood and 34% from rice and rice cereals (Tao and Bolger 1998). Effective biomarkers of arsenic exposure in humans include elevated arsenic concentrations in hair, fingernails, and especially urine (Lin et al. 1998). In Taiwan, urinary levels of inorganic and organic arsenic metabolites are associated with previous exposure to high-arsenic artesian well water (Hsueh et al. 1998). Humans who had previously been exposed to high-arsenic drinking water and had switched to tap water containing <50 µg total As/L had — after 30 years — elevated levels of arsenic in urine, especially MMA and DMA (Hsueh et al. 1998).

Table 28.2 Arsenic Concentrations in Field Collections of Selected Species of Plants and Animals
 (Values listed are in mg As/kg fresh weight [FW] or dry weight [DW].)

Ecosystem, Species, and Other Variables	Concentration (mg/kg ^a)	Reference ^b
TERRESTRIAL PLANTS		
Colonial bentgrass, <i>Agrostis tenuis</i>		
On mine waste site	1480 DW; Max. 3470 DW	1
On low arsenic soil	(0.3–3) DW	1
Scotch heather, <i>Calluna vulgaris</i>		
On mine waste site	1260 DW	1
On low arsenic soil	0.3 DW	1
Coontail, <i>Ceratophyllum demersum</i>		
From geothermal area, New Zealand	(20–1060) DW	1
Cereal grains		
From arsenic treated areas	Usually <3 DW; Max. 252 DW	2
Nontreated areas	Usually <0.5 DW; Max. 5 DW	2
Grasses		
From arsenic treated areas	(0.5–60,000) DW	2
Nontreated areas	(0.1–0.9) DW	2
Apple, <i>Malus sylvestris</i>		
Fruit	<0.1 FW; <1.8 DW	1
Alfalfa, <i>Medicago sativa</i>		
U.S.	1.6 FW	1
Montana, smelter area	(0.4–5.7) FW	1
Mushrooms; Austria; 1995; near arsenic roasting facility in operation for about 500 years and closed for about 100 years; soil had 730 mg total As/kg DW		
<i>Collybia maculata</i>		
Total	30.0 DW	60
Arsenobetaine	>27.0 DW	60
<i>Collybia butyracea</i>		
Total	10.9 DW	60
Arsenobetaine	8.8 DW	60
Dimethylarsinic acid	1.9 DW	60
<i>Amantia muscaria</i>		
Total	21.9–22.0 DW	60, 61
Arsenate	Trace–0.3 DW	60, 61
Arsenite	Trace–0.4 DW	60, 61
Arsenobetaine	Max. 15.1 DW	60
Arsenocholine	2.5–2.7 DW	60, 61
Dimethylarsinic acid	Trace–0.7 DW	60, 61
Tetramethylarsonium salt	0.5–0.8 DW	60, 61
White spruce, <i>Picea alba</i>		
Arsenic-contaminated soil		
Branch	(2.8–14.3) DW	1
Leaf	(2.1–9.5)	1
Trunk	(0.3–55) DW	1
Root	(45–130) DW	1
Control site		
All samples	<2.4 DW	1
Pine, <i>Pinus silvestris</i> , needles		
Near U.S.S.R. metals smelter; soil levels 120.0 mg As/kg	22 FW	3
Peppers, <i>Piper spp.</i> ; China		
Fresh	<1 FW	56
Dried over arsenic-rich (35 g As/kg) coal fires	500 DW	56
Trees, nontreated areas	Usually <1 DW	2
Lowbush blueberry, <i>Vaccinium angustifolium</i>		
Maine, leaf		
Arsenic-treated soil	(6.8–15) DW	1

Table 28.2 (continued) Arsenic Concentrations in Field Collections of Selected Species of Plants and Animals (Values listed are in mg As/kg fresh weight [FW] or dry weight [DW].)

Ecosystem, Species, and Other Variables	Concentration (mg/kg ^a)	Reference ^b
Control	0.8 DW	1
Various species		
From uncontaminated soils	(<0.01–5) DW	2
From arsenic-impacted (80 mg/kg) soils	1.2 (<0.2–5.8) DW	4
Vegetables		
From arsenic-treated areas	Usually <3 DW; Max. 145 DW	2
Nontreated areas	Usually <1 DW; Max. 8 DW	2
Vegetation		
Near gold mine, Canada		
Air levels up to 3.9 mg As/m ³	Max. 11,438 DW	5
80 km distant	(12–20) DW	5
Near arsenic refinery (vs. control site), England	37 DW vs. 0.2 DW	54

FRESHWATER PLANTS

Aquatic Plants		
Arsenic-treated areas	(20–1450) DW	2
Untreated areas	(1.4–13) DW	2
Irish moss, <i>Chondrus crispus</i>		
Whole	(5–12) DW	1
Pondweeds, <i>Potamogeton</i> spp.		
Whole		
Near geothermal area	(11–436) DW	1
Control site	<6 DW	1
Widgeongrass, <i>Ruppia maritima</i>		
From Kern National Wildlife Refuge, California, contaminated by agricultural drainwater of 12–190 µg As/L	Max. 430 DW	32

FRESHWATER FISHES

Alewife, <i>Alosa pseudoharengus</i>		
Whole, Michigan	0.02 FW	1
Muscle, Wisconsin	0 FW	1
California; San Joaquin River; September–November 1986; whole fish

28.6 LETHAL AND SUBLETHAL EFFECTS

28.6.1 General

As will be discussed later, most authorities agree on ten points:

1. Inorganic arsenicals are more toxic than organic arsenicals, and trivalent forms are more toxic than pentavalent forms.
2. Episodes of arsenic poisoning are either acute or subacute; cases of chronic arsenosis are rarely encountered, except in humans.

3. Sensitivity to arsenic is greatest during the early developmental stages.
4. Arsenic can traverse placental barriers: as little as 1.7 mg As⁺⁵/kg body weight at critical stages of hamster embryogenesis, for example, can produce fetal death and malformation.
5. Biomethylation is the preferred detoxification mechanism for inorganic arsenicals.
6. Arsenic is bioconcentrated by organisms, but not biomagnified in the food chain.
7. In soils, depressed crop yields were recorded at 3 to 28 mg of water-soluble As/L, or about 25 to 85 mg total As/kg soil; adverse effects on vegetation were recorded at concentrations in air of >3.9 µg As/m³.
8. Some aquatic species were adversely affected at water concentrations of 19 to 48 µg As/L, or 120 mg As/kg in the diet, or tissue residue of 1.3 to 5 mg As/kg fresh weight.
9. Sensitive species of birds died following single oral doses of 17.4 to 47.6 mg As/kg body weight.
10. Adverse effects were noted in mammals at single oral doses of 2.5 to 33 mg As/kg body weight, at chronic oral doses of 1 to 10 mg As/kg body weight, and at feeding levels of 50 mg — and sometimes only 5 mg — As/kg in the diet.

The literature emphasizes that arsenic metabolism and toxicity vary greatly between species and that its effects are significantly altered by numerous physical, chemical, and biological modifiers. Adverse health effects, for example, may involve respiratory, gastrointestinal, cardiovascular, and hematopoietic systems, and may range from reversible effects to cancer and death, depending partly on the physical and chemical forms of arsenic tested, the route of administration, and the dose.

28.6.2 Carcinogenesis, Mutagenesis, and Teratogenesis

Inorganic arsenic is a known human carcinogen and has been assigned Group A classification by the U.S. Environmental Protection Agency, Group 1 classification by the International Agency for Research on Cancer, and been designated Category A1 by the American Conference of Governmental Industrial Hygienists (ATSDR 1992; USPHS 1998). Epidemiological studies show that an increased risk of cancers in the skin, lung, liver, and lymph and hematopoietic systems of humans is associated with exposure to inorganic arsenicals. These increased cancer risks are especially prevalent among smelter workers and in those engaged in the production and use of arsenical pesticides where atmospheric levels exceed 54.6 µg As/m³ (NRCC 1978; Belton et al. 1985; Pershagen and Bjorklund 1985). Skin tumors, mainly of low malignancy, have been reported after consumption of arsenic-rich drinking waters; a total dose of several grams, probably as As⁺³, is usually required for the development of skin tumors (Pershagen and Vahter 1979). High incidences of skin cancer and hyperpigmentation were noted among several population groups, especially Taiwanese and Chileans, consuming water containing more than 0.6 mg As/L. The frequency of cancer was highest among people over age 60 who demonstrated symptoms of chronic arsenic poisoning (NRCC 1978). In some areas of India, however, as many as 60% of the children between age 4 and 10 years had arsenical melanosis because of the exceptionally high levels of arsenic in the drinking water (Chowdhury et al. 1997). Elimination of arsenic in drinking water decreased the mortality incidence of arsenic-related cancers of the liver, lung, kidney, and skin in communities where blackfoot disease is endemic (Tsai et al. 1998).

Arsenic reportedly inhibits cancer formation in species having a high incidence of spontaneous cancers (NRCC 1978). In fact, arsenic may be the only chemical for which there is sufficient evidence for carcinogenicity in humans but not in other animals (Woolson 1975; Belton et al. 1985; Lee et al. 1985). In general, animal carcinogenicity tests with inorganic and organic arsenicals have been negative (Hood 1985), even when the chemicals were administered at or near the highest tolerated dosages for long periods (NAS 1977). Most studies of arsenic carcinogenesis in animals were presumably of insufficient duration to simulate conditions in long-lived species such as humans (NRCC 1978). However, mice developed leukemia and lymphoma after 20 subcutaneous injections of 0.5 mg As⁺⁵/kg body weight: 46% of the experimental group developed these signs vs. none of the controls (NRCC 1978). And mice given 500 µg As/L (as sodium arsenite) in the drinking water for lifetime exposures developed tumors in the lung, liver, and GI tract (Ng et al. 1998). Pulmonary

tumorigenicity has been demonstrated in hamsters administered calcium arsenate intratracheally (Pershagen and Bjorklund 1985). Inorganic arsenic interacts with benzo[a]pyrene in the induction of lung adenocarcinomas in hamsters (ATSDR 1992). Cacodylic acid and other organoarsenicals are not carcinogenic, but may be mutagenic at very high doses (Hood 1985). Monomethylarsonic acid (MMA) and dimethylarsinic acid (DMA) are primary metabolites of inorganic arsenic, a known human carcinogen. However, the rapid elimination ($T_{1/2} = 2$ h) and low retention (<2%) of MMA and DMA explain, in part, their low acute toxicity and cancer risk (Hughes and Kenyon 1998).

Several inorganic arsenic compounds are weak inducers of chromosomal aberrations, sister chromatid exchange, and *in vitro* transformation of mammalian and piscine cells. However, there is no conclusive evidence that arsenic causes point mutations in any cellular system (Pershagen and Vahter 1979; Belton et al. 1985; Lee et al. 1985; Deknudt et al. 1986; Manna and Mukherjee 1989). Studies with bacteria suggest that arsenite is a comutagen, or may inhibit DNA repair (Belton et al. 1985).

Arsenic is a known teratogen in several classes of vertebrates and has been implicated as a cause of birth defects in humans (Domingo 1994). Specific developmental malformations have been produced experimentally in mammals using inorganic As^{+3} or As^{+5} , either through a single dose or a continuous dose during embryogenesis (Hanlon and Ferm 1986b). Teratogenic effects are initiated no later than 4 h after administration of arsenic; fetal abnormalities are primarily neural tube defects (Hanlon and Ferm 1985c) but might also include protruding eyes, incomplete development of the skull, abnormally small jaws, and other skeletal anomalies (NRCC 1978). Inorganic As^{+3} and As^{+5} , but not organoarsenicals, cross placental barriers in many species of mammals and result in fetal deaths and malformations (NRCC 1978; USEPA 1980; Domingo 1994). Studies with hamsters, for example, showed that sodium arsenite can induce chromatid breaks and chromatid exchanges in Chinese hamster ovary cells in a dose-dependent manner (Lee et al. 1986b). In an earlier study (Lee et al. 1985), As^{+3} was about 10 times more potent than As^{+5} in causing transformations. The birth defects were most pronounced in golden hamsters exposed to As^{+5} during the 24-hr period of critical embryogenesis — day 8 of gestation (Ferm and Hanlon 1985) — when 1.7 mg As^{+5}/kg body weight induced neural tube defects in about 90% of the fetuses. Hanlon and Ferm (1986a) showed that hamsters exposed to As^{+5} and heat stress (39°C for 50 min) on day 8 of gestation produced a greater percentage of malformed offspring (18% to 39%) than did hamsters exposed to As^{+5} alone (4% to 8%).

28.6.3 Terrestrial Plants and Invertebrates

In general, arsenic availability to plants is highest in coarse-textured soils having little colloidal material and little ion exchange capacity, and lowest in fine-textured soils high in clay, organic material, iron, calcium, and phosphate (NRCC 1978). To be absorbed by plants, arsenic compounds must be in a mobile form in the soil solution. Except for locations where arsenic content is high (e.g., around smelters), the accumulated arsenic is distributed throughout the plant body in nontoxic amounts (NAS 1977). For most plants, a significant depression in crop yields was evident at soil arsenic concentrations of 3 to 28 mg/L of water-soluble arsenic and 25 to 85 mg/kg of total arsenic (NRCC 1978). Yields of peas (*Pisum sativum*), a sensitive species, were decreased at 1 mg/L of water-soluble arsenic or 25 mg/kg of total soil arsenic. Rice (*Oryza sativum*) yields were decreased 75% at 50 mg/L of disodium methylarsonate in silty loam, and soybeans (*Glycine max*) grew poorly when residues exceeded 1 mg As/kg (Table 28.3) (NRCC 1978). Forage plants grown in soils contaminated with up to 80 mg total As/kg from arsenical orchard sprays contained up to 5.8 mg As/kg dry weight; however, these plants were considered nonhazardous to grazing ruminants (Merry et al. 1986).

Attention focused on inorganic arsenical pesticides after accumulations of arsenic in soils eventually became toxic to several agricultural crops, especially in former orchards and cotton fields. Once toxicity is observed, it persists for several years even if no additional arsenic treatment is made (Woolson 1975). Poor crop growth was associated with bioavailability of arsenic in soils. For example, alfalfa (*Medicago sativa*) and barley (*Hordeum vulgare*) grew poorly in soils con-

taining only 3.4 to 9.5 mg As/kg, provided the soils were acidic, lightly textured, low in phosphorus and aluminum, high in iron and calcium, and contained excess moisture (Woolson 1975). Use of inorganic arsenical herbicides, such as calcium arsenate, to golf course turfs for control of fungal blight sometimes exacerbates the disease. The use of arsenicals on Kentucky bluegrass (*Poa pratensis*) is discouraged under conditions of high moisture and root stress induced by previous arsenical applications (Smiley et al. 1985).

Methylated arsenicals, whether herbicides or defoliants, are sprayed on plant surfaces. They can reach the soil during application or can be washed from the plants. Additional arsenic enters soils by exchange from the roots or when dead plant materials decay (Hood 1985). Cacodylic acid and sodium cacodylate are nonselective herbicides used in at least 82 products to eliminate weeds and grasses around trees and shrubs, and to eradicate vegetation from rights-of-way and other noncrop areas (Hood 1985). Normal application rates of various organoarsenicals for crop and noncrop purposes rarely exceed 5 kg/ha (Woolson 1975). At recommended treatment levels, organoarsenical soil residues are not toxic to crops, and those tested (soybean, beet, wheat) were more resistant to organoarsenicals than to comparable levels of inorganic arsenicals (Woolson 1975).

Air concentrations up to 3.9 µg As/m³ near gold mining operations were associated with adverse effects on vegetation. Higher concentrations of 19 to 69 µg As/m³, near a coal-fired power plant in Czechoslovakia, produced measurable contamination in soils and vegetation in a 6-km radius (NRCC 1978).

The phytotoxic actions of inorganic and organic arsenicals are different, and each is significantly modified by physical processes. The primary mode of action of arsenite in plants is inhibition of light activation, probably through interference with the pentose phosphate pathway (Marques and Anderson 1986). Arsenites penetrate the plant cuticle to a greater degree than arsenates (NAS 1977). One of the first indications of plant injury by sodium arsenite is wilting caused by loss of turgor, whereas stress due to sodium arsenate does not involve rapid loss of turgor (NAS 1977). Organoarsenicals, such as cacodylic acid, enter plants mostly by absorption of sprays; uptake from the soil contributes only a minor fraction (Hood 1985). The phytotoxicity of organoarsenical herbicides is characterized by chlorosis, cessation of growth, gradual browning, dehydration, and death (NAS 1977). In general, plants cease to grow and develop after the roots have absorbed much arsenic (NRCC 1978). Plants can absorb arsenic through the roots and foliage, although translocation is species dependent. Concentrations of arsenic in plants correlate highly and consistently with water-extractable soil arsenic, and usually poorly with total soil arsenic (NRCC 1978). For example, concentrations of arsenic in corn (*Zea mays*) grown in calcareous soils for 25 days were significantly correlated with the soil water-extractable arsenic fraction, but not other fractions. Extractable phosphorus was correlated positively to both arsenic in corn and to the water-soluble arsenic fraction (Sadiq 1986). In the moss *Hylocomium splendens*, arsenate accumulation from solution was through living shoots, optimum uptake being between pH 3 and 5 (Wells and Richardson 1985). Some plants, such as beets (*Beta vulgaris*), accumulated arsenic more readily at elevated temperatures, but the addition of phosphate fertilizers markedly depressed uptake (Merry et al. 1986).

Soils amended with arsenic-contaminated plant tissues were not measurably affected in CO₂ evolution and nitrification, suggesting that the effects of adding arsenic to soils does not influence the decomposition rate of plant tissues by soil microorganisms (Wang et al. 1984). The half-life of cacodylic acid is about 20 days in untreated soils and 31 days in arsenic-amended soils (Hood 1985). Estimates of the half-time of inorganic arsenicals in soils are much longer, ranging from 6.5 years for arsenic trioxide to 16 years for lead arsenate (NRCC 1978).

Data on arsenic effects to soil biota and insects are limited. In general, soil microorganisms are capable of tolerating and metabolizing relatively high concentrations of arsenic (Wang et al. 1984). This adaptation seems usually to be due to decreased permeability of the microorganism to arsenic (NAS 1977). Tolerant soil microbiota can withstand concentrations up to 1600 mg/kg; however, growth and metabolism were reduced in sensitive species at 375 mg As/kg and, at 150 to 165 mg As/kg, soils were devoid of earthworms and showed diminished quantities of bacteria and proto-

zoans (NRCC 1978). Earthworms (*Lumbricus terrestris*) held in soils containing 40 to 100 mg As⁺⁵/kg DW soil for 8 to 23 days had significantly reduced survival, especially among worms held in soils less than 70 mm in depth when compared to worms held at 500 to 700 mm. Survivors had negligible arsenic residues. Dead worms had higher concentrations, suggesting that arsenic homeostasis breaks down after death (Meharg et al. 1998). Honeybees (*Apis mellifera*) killed accidentally by sprayed As⁺³ contained 4 to 5 µg As per bee (NAS 1977), equivalent to 21 to 31 mg/kg body weight (Table 28.3). Larvae of the western spruce budworm (*Choristoneura occidentalis*) continued to feed on As⁺³-contaminated vegetation until a threshold level of about 2300 to 3300 mg As/kg dry weight whole larvae was reached; death then sometimes occurred (Table 28.3) (Robertson and McLean 1985). Larvae that had accumulated sufficient energy reserves completed the first stage of metamorphosis but developed into pupae of subnormal weight. Larvae containing <2600 mg As⁺³/kg ultimately developed into adults of less than normal weight, and some containing >2600 mg/kg dry weight died as pupae (Robertson and McLean 1985).

Table 28.3 Lethal and Sublethal Effects of Various Arsenic Compounds on Selected Species of Terrestrial Plants and Invertebrates

Ecosystem, Organism, and Other Variables	Arsenic Concentration and Effects	Reference ^a
TERRESTRIAL PLANTS		
Crops		
Total water soluble As in soils	Depressed crop yields at 3–28 mg/L	1
Total soil As concentrations	Depressed crop yields at 25–85 mg/kg	1
Common bermudagrass, <i>Cynodon dactylon</i>		
Arsenite	Plants grown on As-amended soils (up to 90 mg As ⁺³ /kg) contained up to 17 mg As/kg dry weight in stems, 20 in leaves, and 304 in roots	2
Fruit orchards		
Inorganic arsenites and arsenates	Soils contain 31–94 mg/kg dry weight (vs. 2.4 in untreated orchards); whole rodents contain <0.002 mg As/kg fresh weight (vs. ND in untreated orchards)	3
Soybean, <i>Glycine max</i>		
Total As	Toxic signs at plant residues >1 mg total As/kg	1
Grasslands		
Cacodylic acid	Kill of 75 to 90% of all species at 17 kg/ha; recovery modest	3
Rice, <i>Oryza sativum</i>		
Disodium methylarsonate	75% decrease in yield at soil (silty loam) concentrations of 50 mg/kg	1
Scots pine, <i>Pinus sylvestris</i>		
Inorganic As ⁺⁵	Seedlings die when soil (sandy) concentrations exceed 250 mg/kg DW. Maximum BCF factors low: 0.6 for roots; 0.1 for shoots. Residues >62 mg As/kg DW in shoots are toxic, and 3300 mg/kg DW is usually fatal	4
Pea, <i>Pisum sativum</i>		
Sodium arsenite	15 mg/L inhibits light activation and photosynthetic CO ₂ fixation in chloroplasts	5
Sandhill plant communities		
Cacodylic acid	No lasting effect at 2.25 kg/ha. Some species defoliated at 6.8 kg/ha. Significant effect, including 75% defoliation of oaks and death of all pine trees, at 34 kg/ha	3
Cowpea, <i>Vigna</i> sp.		
Total water soluble As in soils	Decreased yields at 1 mg/L	1
Total soil As concentrations (loamy sand)	Toxic at 25 mg/kg	1
Yeast		
Arsenate	At 75 mg/L, 60% reduction in phosphate transport and glucose metabolism in 30 min; at 375 mg/L, 100% reduction	1

Table 28.3 (continued) Lethal and Sublethal Effects of Various Arsenic Compounds on Selected Species of Terrestrial Plants and Invertebrates

Ecosystem, Organism, and Other Variables	Arsenic Concentration and Effects	Reference ^a
TERRESTRIAL INVERTEBRATES		
Honeybee, <i>Apis mellifera</i>		
Inorganic arsenite	Following arsenic spray dusting, dead bees contained 20.8–31.2 mg/kg FW (adults) or 5–13 mg/kg FW (larvae)	6
Beetles		
Cacodylic acid	Dietary levels of 100–1000 mg/kg fatal to certain pestiferous species	3
Western spruce budworm, <i>Christoneura occidentalis</i> , sixth instar stage		
Arsenic trioxide	Dietary levels of 99.5 mg/kg FW killed 10%, 2250 mg/kg killed 50%, and 65,300 mg/kg was fatal to 90%. Newly molted pupae and adults of As-exposed larvae had reduced weight. Regardless of dietary levels, concentrations of As ranged up to 2640 mg/kg DW in dead pupae, and 1708 mg/kg DW in adults	7
Earthworm, <i>Lumbricus terrestris</i>		
As ⁺⁵	Earthworms held in soils containing 40 mg As/kg DW for 23 days had no accumulations in first 12 days, with BCF of 3 by day 23	8
As ⁺⁵	100 mg As/kg DW soil was fatal to 50% in 8 days	8
As ⁺⁵	400 mg As/kg DW soil was fatal to 50% in 2 days	8

28.6.4 Aquatic Biota

Adverse effects of arsenicals on aquatic organisms have been reported at concentrations of 19 to 48 µg/L in water, 33 mg/kg in diets, and 1.3 to 5 mg/kg fresh weight in tissues (Table 28.4). The most sensitive of the aquatic species tested that showed adverse effects were three species of marine algae, which showed reduced growth in the range of 19 to 22 µg As⁺³/L; developing embryos of the narrow-mouthed toad (*Gastrophryne carolinensis*), of which 50% were dead or malformed in 7 days at 40 µg As⁺³/L; and a freshwater alga (*Scenedesmus obliquus*), in which growth was inhibited 50% in 14 days at 48 µg As⁺⁵/L (Table 28.4). Chronic studies with mass cultures of natural phytoplankton communities exposed to low levels of arsenate (1.0 to 15.2 µg/L) showed that As⁺⁵ differentially inhibits certain plants, causing a marked change in species composition, succession, and predator-prey relations. The significance of these changes on carbon transfer between trophic levels is unknown (Sanders and Cibik 1985; Sanders 1986). Adverse biological effects have also been documented at water concentrations of 75 to 100 µg As/L:

- At 75 µg As⁺⁵/L, growth and biomass in freshwater and marine algae was reduced.
- At 85 to 88 µg/L of As⁺⁵ or various methylated arsenicals, mortality was 10% to 32% in amphipods (*Gammarus pseudolimnaeus*) in 28 days.
- At 95 µg As⁺³/L, marine red alga failed to reproduce sexually.
- At 100 µg As⁺⁵/L, marine copepods died and goldfish behavior was impaired (Table 28.4).

Rainbow trout (*Oncorhynchus mykiss*) fed diets containing up to 90 mg As⁺⁵/kg were slightly affected, but those given diets containing >120 mg As/kg (as As⁺³ or As⁺⁵) grew poorly, avoided food, and failed to metabolize food efficiently. No toxic effects were reported over 8 weeks of exposure to diets containing 1600 mg/kg, as methylated arsenicals (Table 28.4). Dietary disodium

heptahydrate (DSA) is more toxic to juvenile rainbow trout than dietary arsenic trioxide, dimethylarsinic acid, or arsanilic acid (Cockell et al. 1991; Cockell and Bettger 1993). Diets containing 55 to 60 mg As⁺⁵/kg ration as DSA were associated with changes in the hepatobiliary system of juvenile rainbow trout after 12 weeks of feeding (Cockell et al. 1992). The most sensitive indicator of DSA insult in juvenile rainbow trout was chronic inflammation of the gallbladder wall, as found in 71% of trout exposed to 33 mg As/kg ration for 24 weeks and 100% of those exposed to 65 mg As/kg ration for 24 weeks. There was no damage at 13 mg/kg ration and lower in the 24-week study (Cockell et al. 1991). The whole-body arsenic concentrations in moribund rainbow trout poisoned by arsenate compounds in 11-week exposures ranged between 4 and 6 mg As/kg fresh weight (vs. 2.0 mg/kg fresh weight in controls) — and dead whole trout had 8 to 12 mg As/kg fresh weight — suggesting that a critical arsenic body concentration is reached before death or toxicant insult occurs (McGeachy and Dixon 1990). In bluegills (*Lepomis macrochirus*), tissue residues of 1.35 mg As/kg fresh weight in juveniles and 5 mg/kg in adults are considered elevated and potentially hazardous (NRCC 1978).

Toxic and other effects of arsenicals to aquatic life are significantly modified by numerous biological and abiotic factors (Woolson 1975; NAS 1977; NRCC 1978; USEPA 1980, 1985; Howard et al. 1984; Michnowicz and Weakley 1984; Bryant et al. 1985; Sanders 1986; Hamilton and Buhl 1990; McGeachy and Dixon 1990). The LC50 values, for example, are markedly affected by water temperature, pH, Eh, organic content, phosphate concentration, suspended solids, and presence of other substances and toxicants, as well as arsenic speciation, and duration of exposure. In general, inorganic arsenicals are more toxic than organoarsenicals to aquatic biota, and trivalent species are more toxic than pentavalent species. Early life stages are most sensitive, and large interspecies differences are recorded, even among species closely related taxonomically.

Arsenic is accumulated from the water by a variety of organisms. However, there is no evidence of magnification along the aquatic food chain (Woolson 1975; NAS 1977; NRCC 1978; Hallacher et al. 1985; Hood 1985; Lindsay and Sanders 1990; Woodward et al. 1995). In a marine ecosystem based on the alga *Fucus vesiculosus*, arsenate (7.5 µg As⁺⁵/L) was accumulated by all biota. After 3 months, arsenic was concentrated most efficiently by *Fucus* (120 mg/kg dry weight in apical fronds) and filamentous algal species (30 mg/kg dry weight); little or no bioaccumulation occurred in invertebrates, although arsenic seemed to be retained by gastropods and mussels (Rosemarin et al. 1985). In a simplified estuarine food chain, there was no significant increase in arsenic content of grass shrimp (*Palaemonetes pugio*) exposed to arsenate-contaminated food or to elevated water concentrations (Lindsay and Sanders 1990). In a freshwater food chain composed of algae, daphnids, and fish, water concentrations of 0.1 mg cacodylic acid/L produced residues (mg As/kg dry weight), after 48 h, of 4.5 in algae and 3.9 in daphnids, but only 0.09 in fish (NAS 1977). Microcosms of a Delaware cordgrass (*Spartina alterniflora*) salt marsh exposed to elevated levels of As⁺⁵ showed that virtually all arsenic was incorporated into plant tissue or strongly sorbed to cell surfaces (Sanders and Osman 1985). Studies with radioarsenic and mussels (*Mytilus galloprovincialis*) showed that accumulation varied with nominal arsenic concentrations, tissue, age of the mussel, and temperature and salinity of the medium (Unlu and Fowler 1979). Arsenate uptake increased with increasing arsenic concentration in the medium, but the response was not linear, accumulation being suppressed at higher external arsenic concentrations. Smaller mussels took up more arsenic than larger ones. In both size groups, arsenic was concentrated in the byssus and digestive gland. In general, arsenic uptake and loss increased at increasing temperatures. Uptake was significantly higher at 1.9% salinity than at 3.8%, but loss rate was about the same at both salinities. Radioarsenic loss followed a biphasic pattern; the biological half-life was 3 and 32 days for the fast and slow compartments, respectively; secretion of the byssal thread played a key role in elimination (Unlu and Fowler 1979). Factors known to modify rates of arsenic accumulation and retention in a marine shrimp (*Lysmata seticaudata*) include water temperature and salinity, arsenic concentration, age, and especially frequency of molting (Fowler and Unlu 1978).

Bioconcentration factors (BCF) experimentally determined for arsenic in aquatic organisms are, except for algae, relatively low. The BCF values for inorganic As⁺³ in most aquatic invertebrates and fish exposed for 21 to 30 days did not exceed 17 times; the maxima were 6 times for As⁺⁵, and 9 times for organoarsenicals (USEPA 1980, 1985). Significantly higher BCF values were recorded in other aquatic organisms (NRCC 1978), but they were based on mean arsenic concentrations in natural waters that seemed artificially high. A BCF of 350 times was reported for the American oyster (*Crassostrea virginica*) held in 5 µg As⁺⁵/L for 112 days (Zaroogian and Hoffman 1982). There was no relation between oyster body burdens of arsenic and exposure concentrations. However, diet seemed to contribute more to arsenic uptake than did seawater concentrations (Zaroogian and Hoffman 1982). An arsenic-tolerant strain of freshwater alga (*Chlorella vulgaris*) from an arsenic-polluted environment showed increasing growth up to 2000 mg As⁺⁵/L, and it could survive at 10,000 mg As⁺⁵/L (Maeda et al. 1985). Accumulations up to 50,000 mg As/kg dry weight were recorded (Maeda et al. 1985), suggesting a need for additional research on the extent of this phenomenon and its implications on food-web dynamics.

Some investigators have suggested that arsenic in the form of arsenite is preferentially utilized by marine algae and bacteria (Johnson 1972; Bottino et al. 1978; Johnson and Burke 1978). Arsenate reduction to arsenite in seawater depends on phosphorus in solution and available algal biomass (Johnson and Burke 1978). During algal growth, as phosphate is depleted and the P⁺⁵:As⁺⁵ ratio drops, the rate of As⁺⁵ reduction increases. The resultant As⁺³, after an initial peak, is rapidly oxidized to As⁺⁵, indicating the possibility of biological catalysis of oxidation as well as mediation of As⁺⁵ reduction. Researchers generally agree that As⁺³ is more toxic than arsenates to higher organisms; however, As⁺⁵ had a more profound effect on growth and morphology of marine algae than As⁺³. It is possible that marine algae erect a barrier against the absorption of As⁺³, but not against As⁺⁵. Within the cell, As⁺⁵ can then be reduced to the possibly more toxic As⁺³. For example, the culture of two species of marine algae (*Tetraselmis chui* and *Hymenomonas carterae*) in media containing various concentrations of As⁺⁵ or As⁺³ showed that arsenic effects varied with oxidation state, concentration, and light intensity. Arsenate was incorporated and later partly released by both species. Differences between rates of uptake and release suggest that arsenic undergoes chemical changes after incorporation into algal cells (Bottino et al. 1978). When bacterial cultures from the Sargasso Sea and from marine waters of Rhode Island were grown in As⁺³-enriched media, the bacteria reduced all available As⁺⁵ and utilized As⁺³ during the exponential growth phase, presumably as an essential trace nutrient. The arsenate reduction rate per cell was estimated to be 75×10^{-11} mg As/minute (Johnson 1972).

The ability of marine phytoplankton to accumulate high concentrations of inorganic arsenicals and transform them to methylated arsenicals that are later efficiently transferred in the food chain is well documented (Irgolic et al. 1977; Benson 1984; Matsuto et al. 1984; Freeman 1985; Froelich et al. 1985; Maeda et al. 1985; Norin et al. 1985; Sanders 1985; Yamaoka and Takimura 1986). Algae constitute an important source of organoarsenic compounds in marine food webs. In the food chain composed of the alga *Dunaliella marina*, the grazing shrimp *Artemia salina*, and the carnivorous shrimp *Lysmata seticaudata*, organic forms of arsenic were derived from *in vivo* synthesis by *Dunaliella* and efficiently transferred, without magnification, along the food chain (Wrench et al. 1979). Laboratory studies with five species of euryhaline algae grown in freshwater or seawater showed that all species synthesized fat-soluble and water-soluble arsено-organic compounds from inorganic As⁺³ and As⁺⁵. The BCF values in the five species examined ranged from 200 times to about 3000 times — accumulations being highest in lipid phases (Lunde 1973). In Charlotte Harbor, Florida, a region that has become phosphate enriched due to agricultural activity, virtually all of the arsenic taken up by phytoplankton was biomethylated and returned to the estuary, usually as monomethylarsonic and dimethylarsenic acids (Froelich et al. 1985). The ability of marine phytoplankton to methylate arsenic and release the products to a surrounding environment varies between species and even within a particular species in relation to their possession of necessary

methylating enzymes (Sanders 1985). The processes involved in detoxifying arsenate after its absorption by phytoplankton are not firmly established, but seem to be nearly identical in all plants, suggesting a similar evolutionary development. Like phosphates and sulfates, arsenate may be fixed with ADP, reduced to the arsonous level, and successfully methylated and adenosylated, ultimately producing the 5-dimethylarsenosoribosyl derivatives accumulating in algae (Benson 1984).

Sodium arsenite has been used extensively as an herbicide for control of mixed submerged aquatic vegetation in freshwater ponds and lakes. Concentrations of 1.5 to 3.8 mg As⁺³/L have usually been effective and are considered safe for fish (NAS 1977). However, As⁺³ concentrations considered effective for aquatic weed control may be harmful to several species of freshwater teleosts, including bluegills, flagfish (*Jordenella floridae*), fathead minnows (*Pimephales promelas*), and rainbow trout (*Oncorhynchus mykiss*) (Table 28.4). Fish exposed to 1 to 2 mg total As/L for 2 to 3 days may show one or more of several signs: hemorrhagic spheres on gills; fatty infiltration of liver; and necrosis of heart, liver, and ovarian tissues (NRCC 1978). In green sunfish (*Lepomis cyanellus*), hepatocyte changes parallel arsenic accumulations in the liver (Sorensen et al. 1985). Organoarsenicals are usually eliminated rapidly by fish and other aquatic fauna. Rainbow trout, for example, fed a marine diet containing 15 mg organic arsenic/kg had only negligible tissue residues 6 to 10 days later, although some enrichment was noted in the eyes, throat, gills, and pyloric caeca (Pershagen and Vahter 1979). Oral administration of sodium arsenate to estuary catfish (*Cnidoglanis macrocephalus*) and school whiting (*Sillago bassensis*) resulted in tissue accumulations of trimethylarsine oxide. Arsenobetaine levels, which occur naturally in these teleosts, were not affected by As⁺⁵ dosing. The toxicity of trimethylarsine oxide is unknown, but the ease with which it can be reduced to the highly toxic trimethylarsine is cause for concern (Edmonds and Francesconi 1987). Recent studies, however, suggest that humans are capable of metabolizing trimethylarsine to the comparatively innocuous arsenobetaine (Goessler et al. 1997).

Table 28.4 Lethal and Sublethal Effects of Various Arsenic Compounds on Selected Species of Aquatic Biota

Ecosystem, Species, Arsenic Compound ^a , and Other Variables	Arsenic Concentration (mg/L)	Effect	Reference ^b

- ^b 1, NRCC 1978; 2, USEPA 1980; 3, USEPA 1985; 4, Passino and Novak 1984; 5, Spehar et al. 1980; 6, Lima et al. 1984; 7, Johnson and Finley 1980; 8, NAS 1977; 9, Cockell and Hilton 1985; 10, Thursby and Steele 1984; 11, Bryant et al. 1985; 12, Sanders 1986; 13, Taylor et al. 1985; 14, Hood 1985; 15, Naqvi et al. 1990; 16, Naqvi and Flagge 1990; 17, Dyer et al. 1993; 18, McGeachy and Dixon 1992; 19, Cockell et al. 1991; 20, Cockell et al. 1992; 21, Hamilton and Buhl 1990; 22, Cockell and Bettger 1992; 23, Jensen-Eller and Crivello 1998.
- ^c Maximum acceptable toxicant concentration. Lower value in each pair indicates highest concentration tested producing no measurable effect on growth, survival, reproduction, or metabolism during chronic exposure; higher value indicates lowest concentration tested producing a measurable effect.

28.6.5 Birds

Signs of inorganic trivalent arsenite poisoning in birds (muscular incoordination, debility, slowness, jerkiness, falling, hyperactivity, fluffed feathers, drooped eyelid, huddled position, unkempt appearance, loss of righting reflex, immobility, seizures) were similar to those induced by many other toxicants and did not seem to be specific for arsenosis. Signs occurred within 1 h and deaths within 1 to 6 days postadministration; remission took up to 1 month (Hudson et al. 1984). Internal examination suggested that lethal effects of acute inorganic arsenic poisoning were due to the destruction of blood vessels lining the gut, which resulted in decreased blood pressure and subsequent shock (Nystrom 1984). *Coturnix* (*Coturnix coturnix*), for example, exposed to acute oral doses of As⁺³ showed hepatocyte damage (i.e., swelling of granular endoplasmic reticulum); these effects were attributed to osmotic imbalance, possibly induced by direct inhibition of the sodium pump by arsenic (Nystrom 1984).

Arsenic, as arsenate, in aquatic plants (up to 430 mg As/kg plant dry weight) from agricultural drainwater areas can impair normal development of mallard ducklings that consume these plants (Camardese et al. 1990) (Table 28.5). Pen studies with ducklings showed that a diet of 30 mg As/kg ration adversely affects growth and physiology, and a 300 mg As/kg diet alters brain biochemistry and nesting behavior. Decreased energy levels and altered behavior can further decrease duckling survival in a natural environment (Camardese et al. 1990).

Western grasshoppers (*Melanophis* spp.) poisoned by arsenic trioxide were fed, with essentially no deleterious effects, to nestling northern bobwhites (*Colinus virginianus*), mockingbirds (*Mimus polyglottos*), American robins (*Turdus migratorius*), and other songbirds (NAS 1977). Up to 134 poisoned grasshoppers, containing a total of about 40 mg As, were fed to individual nestlings with no apparent toxic effect. Species tested that were most sensitive to various arsenicals were the brown-headed cowbird (*Molothrus ater*) with an LD₅₀ (11-day) value of 99.8 mg copper acetoarsenite/kg diet; California quail (*Callipepla californica*) with an LD₅₀ single oral dose value of 47.6 mg sodium arsenite/kg body weight; and chicken with 33 and turkey with 17.4 mg/kg body weight of 3-nitro-4-hydroxy phenylarsonic acid as a single oral dose (Table 28.5).

Chickens rapidly excrete arsenicals; only 2% of dietary sodium arsenite remained after 60 h (NAS 1977), and arsanilic acid was excreted largely unchanged (Woolson 1975). Excretion of arsanilic acid by chickens was affected by uptake route: excretion was more rapid if administration was by intramuscular injection than if it was oral (NRCC 1978). Studies with inorganic As⁺⁵ and chickens indicated that (Fullmer and Wasserman 1986):

1. Arsenates rapidly penetrated mucosal and serosal surfaces of epithelial membranes.
2. As⁺⁵ intestinal absorption was essentially complete within 1 h at 370 mg As⁺⁵/kg BW, but only 50% complete at 3700 mg/kg BW.
3. Vitamin D₃ was effective in enhancing duodenal As⁺⁵ absorption in rachitic chicks.
4. As⁺⁵ and phosphate did not appear to share a common transport pathway in the avian duodenum.

Table 28.5 Lethal and Sublethal Effects of Various Arsenicals on Selected Species of Birds

Species and Arsenic Compound	Effect	Reference ^a
CHUKAR, <i>Alectoris chukar</i> Silvisar-510 (mixture of cacodylic acid and triethanolamine cacodylate)	Single oral LD50 dose of 2000 mg/kg body weight (BW); signs of poisoning evident within 10 min and mortalities within 1–2 days postadministration. Remission took up to 1 month	1
MALLARD, <i>Anas platyrhynchos</i> Sodium arsenate	Adult breeding pairs fed diets with 0, 25, 100, or 400 mg As/kg ration for up to 173 days. Ducklings produced were fed the same diet as their parents for 14 days. Dose-dependent increase in liver arsenic from 0.23 mg As/kg DW in controls to 6.6 in the 400-mg/kg group and in eggs from 0.23 in controls to 3.6 mg/kg DW in the 400-mg/kg group. Dose-dependent adverse effects on growth, onset of egg laying, and eggshell thinning. In ducklings, arsenic accumulated in the liver from 0.2 mg As/kg DW in controls to 33.0 in the 400-mg/kg group and caused dose-dependent decrease in whole-body and liver growth rate	9
Sodium arsenate	Ducklings were fed 30, 100, or 300 mg As/kg diet for 10 weeks. All treatment levels produced elevated hepatic glutathione and ATP concentrations and decreased overall weight gain and rate of growth in females. Arsenic concentrations were elevated in brain and liver of ducklings fed 100 or 300 mg/kg diets; at 300 mg/kg, all ducklings had altered behavior, i.e., increased resting time; males had reduced growth	6
Sodium arsenate	Day-old ducklings fed diets containing 200 mg As/kg ration for 4 weeks. When protein was adequate (22%), some growth reduction resulted. With only 7% protein in diet, growth and survival was reduced and frequency of liver histopathology increased	7
Sodium arsenate	Adult males fed diets containing 300 mg As/kg ration. Equilibrium reached in 10–30 days; 50% loss from liver in 1–3 days on transfer to uncontaminated diet	8
Sodium arsenite	323 mg/kg BW is LD50 acute oral value	1–3
Sodium arsenite	500 mg/kg diet is fatal to 50% in 32 days; 1000 mg/kg diet fatal to 50% in 6 days	2
Sodium cacodylate	1740–5000 mg/kg diet fatal to 50% in 5 days	4
Silvisar 510	Single oral LD50 >2400 mg/kg BW; regurgitation and excessive drinking noted	1
Lead arsenate	5000 mg/kg diet not fatal in 11 days	2
Copper acetoarsenite	5000 mg/kg diet fatal to 20% in 11 days	2
CALIFORNIA QUAIL, <i>Callipepla californica</i>	LD50 single oral dose of 47.6 mg/kg BW	1
COMMON BOBWHITE, <i>Colinus virginianus</i>	480 mg/kg in diet fatal to 50% in 11 days	2
Copper acetoarsenite	1740 mg/kg in diet for 5 days produced no effect on behavior, no signs of intoxication, and negative necropsy	4
Sodium cacodylate	Single oral LD50 dose of 3300 mg/kg BW	4
Monosodium methane-arsonate, $\text{CH}_4\text{AsNaO}_3$		
CHICKEN, <i>Gallus gallus</i>	Up to 34% dead embryos at dose range of 0.01–1 mg $\text{As}^{+3}/\text{embryo}$; threshold for malformations at dose range 0.03–0.3 mg/embryo	3
Inorganic trivalent arsenite	Up to 8% dead at dose range 0.01–1 mg $\text{As}^{+5}/\text{embryo}$; threshold for malformations at dose range 0.3–3 mg/embryo	3
Inorganic pentavalent arsenate	Teratogenic to embryos when injected at 1–2 mg/egg	3, 4
Disodium methyl arsenate	Developmental abnormalities at embryonic injected doses of 1–2 mg/egg	4
Sodium cacodylate	At dietary levels of 23.3 mg/kg, liver residues were 2.9 mg/kg FW at 9 weeks. No ill effects noted	5

Table 28.5 (continued) Lethal and Sublethal Effects of Various Arsenicals on Selected Species of Birds

Species and Arsenic Compound	Effect	Reference^a
3-Nitro-4-hydroxyphenyl-arsonic acid	At 18.7 mg/kg diet for 9 weeks, liver residues of 2.4 mg/kg FW. Those fed diets containing 187 mg/kg for 9 weeks had no ill effects; liver content of 7.5 mg/kg FW	5
3-Nitro-4-hydroxyphenyl-arsonic acid	LC50 dose of 33 mg/kg BW (single oral) or 9.7 mg/kg BW (intraperitoneal injection)	2
Arsanilic acid	Fed diets containing 45 mg/kg for 9 weeks; no effect except slightly elevated liver content of 1.2 mg/kg fresh weight. At dietary levels of 455 mg/kg, liver residues were 6.4 mg/kg FW after 9 weeks; no other effects evident	5
Cacodylic acid	Dosed orally without effect at 100 mg/kg BW daily for 10 days	4
CHICKENS, <i>Gallus</i> spp.		
Arsanilic acid	50% excreted in 36–38 h	3
Arsenate	50% excreted in 60–63 h	3
TURKEY, <i>Meleagris gallopavo</i>		
3-Nitro-4-hydroxyphenyl-arsonic acid	Single oral LD50 dose of 17.4 mg/kg BW	2
BROWN-HEADED COWBIRD, <i>Molothrus ater</i>		
Copper acetoarsenite	All survived 11 mg/kg diet for 6 months; maximum whole-body residue of 1.7 mg As/kg dry weight	2
Copper acetoarsenite	All survived 33 mg/kg diet for 6 months (whole-body content of 6.6 mg As/kg dry weight) or 7 months (8.6 DW)	2
Copper acetoarsenite	99.8 mg/kg in diet fatal to 50% in 11 days	2
Copper acetoarsenite	100 mg/kg in diet for 3 months fatal to 100%; tissue residues of 6.1 dry weight in brain, 40.6 in liver	2
GRAY PARTRIDGE, <i>Perdix perdix</i>		
Lead arsenate	300 mg/kg BW fatal in 52 h	2
RING-NECKED PHEASANT, <i>Phasianus colchicus</i>		
Sodium arsenite	Single oral dose of 386 mg/kg BW is LD50 value	1
Copper acetoarsenite	Single oral dose of 1403 mg/kg BW is LD50 value	3
Lead arsenate	4989 mg/kg in diet fatal	2

^a 1, Hudson et al. 1984; 2, NAS 1977; 3, NRCC 1978; 4, Hood 1985; 5, Woolson 1975; 6, Camardese et al. 1990; 7, Hoffman et al. 1992; 8, Pendleton et al. 1995; 9, Stanley et al. 1994.

28.6.6 Mammals

Mammals are exposed to arsenic primarily through the ingestion of naturally contaminated vegetation and water, or through human activity. In addition, feed additives containing arsanilic acid derivatives are often fed to domestic livestock to promote growth and retard disease. Some commercial pet foods contain up to 2.3 mg As/kg dry weight (NRCC 1978). Uptake may occur by ingestion (the most likely route), inhalation, and absorption through skin and mucous membranes. Soluble arsenicals are absorbed more rapidly and completely than are the sparingly soluble arsenicals, regardless of the route of administration (NRCC 1978). In humans, inorganic arsenic at high concentrations is associated with adverse reproductive outcomes, including increased rates of spontaneous abortion, low birth weight, congenital malformations, and death (Hopenhayn-Rich et al. 1998). However, at environmentally relevant levels and routes of exposure, humans are not at risk for birth defects due to arsenic (Holton et al. 1998). *In vitro* tests with human erythrocytes demonstrate that inorganic As⁺⁵ as sodium arsenite was up to 1000 times more effective than inorganic As⁺³ as sodium arsenite after exposure for 5 h to 750 mg As/L in causing death, morphologic changes, and ATP depletion (Winski and Carter 1998).

Acute episodes of poisoning in warm-blooded organisms by inorganic and organic arsenicals are usually characterized by high mortality and morbidity over a period of 2 to 3 days (NAS 1977;

Selby et al. 1977). General signs of arsenic toxicosis include intense abdominal pain, staggering gait, extreme weakness, trembling, salivation, vomiting, diarrhea, fast and feeble pulse, prostration, collapse, and death. Gross necropsy shows a reddening of gastric mucosa and intestinal mucosa, a soft yellow liver, and red edematous lungs. Histopathological findings show edema of gastrointestinal mucosa and submucosa, necrosis and sloughing of mucosal epithelium, renal tubular degeneration, hepatic fatty changes and necrosis, and capillary degeneration in the gastrointestinal tract, vascular beds, skin, and other organs. In subacute episodes, where animals live for several days, signs of arsenosis include depression, anorexia, increased urination, dehydration, thirst, partial paralysis of rear limbs, trembling, stupor, coldness of extremities, and subnormal body temperatures (NAS 1977; Selby et al. 1977; ATSDR 1992). In cases involving cutaneous exposure to arsenicals, a dry, cracked, leathery, and peeling skin may be a prominent feature (Selby et al. 1977). Nasal discharges and eye irritation were documented in rodents exposed to organoarsenicals in inhalation toxicity tests (Hood 1985). Subacute effects in humans and laboratory animals include peripheral nervous disturbances, melanosis, anemia, leukopenia, cardiac abnormalities, and liver changes. Most adverse signs rapidly disappear after exposure ceases (Pershagen and Vahter 1979).

Arsenic poisoning in most animals is usually manifested by acute or subacute signs; chronic poisoning is infrequently seen (NAS 1977). The probability of chronic arsenic poisoning from continuous ingestion of small doses is rare because detoxification and excretion are rapid (Woolson 1975). Chronic toxicity of inorganic arsenicals is associated with weakness, paralysis, conjunctivitis, dermatitis, decreased growth, and liver damage (NRCC 1978). Arsenosis, produced as a result of chronic exposure to organic arsenicals, was associated with demyelination of the optic and sciatic nerves, depressed growth, and decreased resistance to infection (NRCC 1978).

Research results on arsenic poisoning in mammals ([Table 28.6](#)) show general agreement on eight points:

1. Arsenic metabolism and effects are significantly influenced by the organism tested, the route of administration, the physical and chemical form of the arsenical, and the dose.
2. Inorganic arsenic compounds are more toxic than organic arsenic compounds, and trivalent species are more toxic than pentavalent species.
3. Inorganic arsenicals can cross the placenta in most species of mammals.
4. Early developmental stages are the most sensitive, and humans appear to be one of the more susceptible species.
5. Animal tissues usually contain low levels (<0.3 mg As/kg fresh weight) of arsenic. After the administration of arsenicals, these levels are elevated, especially in liver, kidney, spleen, and lung; and several weeks later, arsenic is translocated to ectodermal tissues (hair, nails) because of the high concentration of sulfur-containing proteins in these tissues.
6. Inorganic arsenicals are oxidized *in vivo*, biomethylated, and usually excreted rapidly in the urine, but organoarsenicals are usually not subject to similar transformations.
7. Acute or subacute arsenic exposure can lead to elevated tissue residues, appetite loss, reduced growth, loss of hearing, dermatitis, blindness, degenerative changes in liver and kidney, cancer, chromosomal damage, birth defects, and death.
8. Death or malformations have been documented at single oral doses of 2.5 to 33 mg As/kg body weight, at chronic doses of 1 to 10 mg As/kg body weight, and at dietary levels >5 and <50 mg As/kg diet.

Episodes of wildlife poisoning by arsenic are infrequent. White-tailed deer (*Odocoileus virginianus*) consumed, by licking, fatal amounts of sodium arsenite used to debark trees. The practice of debarking trees with arsenicals for commercial use has been almost completely replaced by mechanical debarking equipment (NAS 1977). In another incident, white-tailed deer were found dead of arsenic poisoning in a northern New York forest and had 102 mg As/kg fresh weight in liver and 56 mg As/kg FW in kidney. These tissue concentrations are 2 to 3 times higher than those in cattle that died of arsenic poisoning — estimated at 241 to 337 mg As/kg BW (Mathews and

Porter 1989). It is speculated that these deer licked trees injected with Silvisar 550, which contains monosodium methanearsonate, probably because of its salty taste (Mathews and Porter 1989). Snowshoe hares (*Lepus* sp.) appear to be especially sensitive to methylated arsenicals; hares died after consuming plants heavily contaminated with monosodium methanearsonate as a result of careless silviculture practices (Hood 1985).

Unlike wildlife, reports of arsenosis in domestic animals are common in bovines and felines, less common in ovines and equines, and rare in porcines and poultry (NAS 1977). In practice, the most dangerous arsenic preparations are dips, herbicides, and defoliants in which the arsenical is in a highly soluble trivalent form, usually as trioxide or arsenite (Selby et al. 1977). Accidental poisoning of cattle with arsenicals, for example, is well documented. In one instance, more than 100 cattle died after accidental overdosing with arsenic trioxide applied topically to control lice. On necropsy, there were subcutaneous edematous swellings and petechial hemorrhages in the area of application, and histopathology of the intestine, mucosa, kidney, and epidermis (Robertson et al. 1984). In Bangladesh, poisoned cattle showed depression, trembling, bloody diarrhea, restlessness, unsteady gait, stumbling, convulsions, groaning, shallow labored breathing, teeth grinding, and salivation (Samad and Chowdhury 1984). Cattle usually died 12 to 36 h after the onset of signs; necropsy showed extensive submucosal hemorrhages of the gastrointestinal tract (Samad and Chowdhury 1984) and tissue residues >10 mg/kg fresh weight in liver and kidney (Thatcher et al. 1985). It sometimes appears that animals, especially cattle, develop an increased preference for weeds sprayed with an arsenic weed killer, not because of a change in the palatability of the plant, but probably because arsenic compounds are salty and thus attractive to animals (Selby et al. 1977).

When extrapolating animal data from one species to another, the species tested must be considered. For example, the metabolism of arsenic in the rat (*Rattus* sp.) is unique and very different from that in man and other animals. Rats store arsenic in blood hemoglobin, excreting it very slowly — unlike most mammals which rapidly excrete ingested inorganic arsenic in the urine as methylated derivatives (NAS 1977). Blood arsenic, whether given as As^{+3} or As^{+5} , rapidly clears from humans, mice, rabbits, dogs, and primates; the half-life is 6 h for the fast phase and about 60 h for the slow phase (USEPA 1980). In the rat, however, blood arsenic is mostly retained in erythrocytes and clears slowly; the half-life is 60 to 90 days (USEPA 1980). In rats, the excretion of arsenic into bile is 40 times faster than in rabbits and up to 800 times faster than in dogs (Pershagen and Vähter 1979). Most researchers now agree that the rat is unsatisfactory for use in arsenic research (NAS 1977; NRCC 1978; Pershagen and Vähter 1979; USEPA 1980; Webb et al. 1986).

Dimethylarsinic acid is the major metabolite of orally administered arsenic trioxide, and is excreted rapidly in the urine (Yamauchi and Yamamura 1985). The methylation process is true detoxification, since methanearsonates and cacodylates are about 200 times less toxic than sodium arsenite (NAS 1977). The marmoset monkey (*Callithrix jacchus*), unlike all other animal species studied to date, was not able (for unknown reasons) to metabolize administered As^{+5} to dimethylarsinic acid; most was reduced to As^{+3} . Only 20% of the total dose was excreted in urine as unchanged As^{+5} , and another 20% as As^{+3} . The rest was bound to tissues, giving distribution patterns similar to arsenite (Vähter and Marafante 1985). Accordingly, the marmoset, like the rat, may be unsuitable for research with arsenicals.

Arsenicals were ineffective in controlling certain bacterial and viral infections. Mice experimentally infected with bacteria (*Klebsiella pneumoniae*) or viruses (pseudorabies, encephalitis, encephalomyocarditis) showed a significant increase in mortality when treated with large doses of arsenicals compared to nonarsenic-treated groups (NAS 1977; Aranyi et al. 1985).

It has been suggested, but not yet verified, that many small mammals avoid arsenic-supplemented feeds and consume other foods if given the choice (NAS 1977), and that cacodylic acid, which has negligible effects on wildlife, reduces species diversity due to selective destruction of vegetation (Hood 1985). Both topics merit more research.

Table 28.6 Lethal and Sublethal Effects of Various Arsenicals on Selected Species of Mammals

Organism and Arsenical	Effect	Reference ^a
COW, <i>Bos bovis</i>		
Arsenate	Cows fed 33 mg As ⁺⁵ daily per animal for 3 months had slightly elevated levels in muscle (0.02 mg/kg fresh weight vs. 0.005 in controls) and liver (0.03 vs. 0.012), but normal levels in milk and kidney	1
Arsenite	Cows fed 33 mg As ⁺³ daily per animal for 15–28 months had tissue levels, in mg/kg fresh weight, of 0.002 for milk (vs. <0.001 for controls), 0.03 for muscle (vs. 0.005), 0.1 for liver (vs. 0.012), and 0.16 for kidney (vs. 0.053)	1
CATTLE, <i>Bos</i> spp.		
Arsenic pentoxide (wood ashes treated with arsenic preservative)	Several deaths after eating ashes (780 mg/kg dry weight); tissue residues, in mg As/kg fresh weight, of 13.9 in liver, 23.7 in kidney, and 25.8 in rumen contents (vs. normal values of <0.5)	2
Arsenic trioxide	Single oral dose of 15–45 grams per animal is fatal	3
Arsenic trioxide	Toxic dose is 33–55 mg/kg body weight (BW), or 13.2–22 g for a 400-kg animal. Animals accidentally poisoned topically contained up to 15 mg As/kg fresh weight liver, 23 in kidney, and 45 in urine (vs. <1 for all normal tissues)	4
Cacodylic acid, (CH ₃) ₂ AsO(OH)	Calves were anorexic in 3–6 days when fed diets containing 4700 mg/kg. Adult oral dose of 10 mg/kg BW daily for 3 weeks, followed by 20 mg/kg BW daily for 5–6 weeks was lethal. Adverse effects at 25 mg/kg BW daily for 10 days	5
Methanearsonic acid	Calves were anorexic in 3–6 days when fed diets containing 4000 mg/kg	5
Monosodium methanearsonate	10 mg/kg BW daily for 10 days was fatal	3
Sodium arsenite	Single oral dose of 1–4 g fatal	3
DOG, <i>Canis familiaris</i>		
Cacodylic acid	Single oral LD ₅₀ value of 1000 mg/kg BW; diets containing 30 mg/kg for 90 days had no ill effects	5
Methanearsonic acid	Fed diets containing 30 mg/kg for 90 days with no ill effects	5
Sodium arsenite	50–150 mg fatal	3
DOMESTIC GOAT, <i>Capra</i> sp.		
Arsenic acid	Single oral dose of 2.5–7.5 mg/kg BW (50–150 mg) was acutely toxic	3
GUINEA PIG, <i>Cavia</i> sp.		
Arsenic acid	Dietary levels of 350 mg/kg resulted in blindness and optic disc atrophy in 25–30 days	6
Arsenic trioxide	Fed diets containing 50 mg/kg for 21 days; elevated As residues, in mg/kg fresh weight, of 4 in blood, 15 in heart (vs. <1 for all control tissues)	7
Sodium arsanilate	Subcutaneous injection of 70 mg/kg BW caused degeneration of sensory walls of inner ear; elevated As residues in cochlea	6
Sodium arsenate	Intraperitoneal injection of 0.2 mg/kg BW at age 2 months causes deafness	6
HAMSTER, <i>Cricetus</i> sp.		
Arsenate	Maternal dose of 5 mg As ⁺⁵ /kg BW caused some fetal mortality, but no malformations; higher dose of 20 mg/kg BW caused 54% fetal deaths and malformations	3
Calcium arsenate	Pulmonary tumorigenicity demonstrated 70 weeks after 15 intratracheal weekly injections of 3 mg/kg BW	8

Table 28.6 (continued) Lethal and Sublethal Effects of Various Arsenicals on Selected Species of Mammals

Organism and Arsenical	Effect	Reference^a
Dimethylarsinate	50% growth reduction in Chinese hamster ovary cells (CHOC) at 90–112 mg/L	9
Gallium arsenide	Single oral dose of 100 mg/kg BW mostly (85%) eliminated in 5 days, usually in form of organoarsenicals; all tissue levels <0.25 mg/kg	10
Sodium arsenate	Dosed intravenously on day 8 of gestation: 2 mg/kg BW had no measurable effect; 8 mg/kg produced increased incidence of malformation and resorption; 16 mg/kg BW killed all embryos	6
Sodium arsenate	50% growth reduction in CHOC at 2.25 mg/L	9
Sodium arsenite	Chinese hamster ovary cells (CHOC) show 50% growth reduction at 0.3 mg/L	9
Sodium cacodylate	Single intraperitoneal injection of 900–1000 mg/kg during midgestation results in some maternal deaths and increased incidences of fetal malformations	5
HORSE, <i>Equus caballus</i>		
Sodium arsenite	Daily doses of 2–6 mg/kg BW (1–3 grams) for 14 weeks is fatal	3
CAT, <i>Felis domesticus</i>		
Inorganic arsenate or arsenite	Chronic oral toxicity at 1.5 mg/kg BW	6
HUMAN, <i>Homo sapiens</i>		
Arsenic trioxide	Fatal at 70–189 mg, equivalent to about 1–2.6 mg As/kg BW	6
Arsenic trioxide	LD50 dose of 7 mg/kg BW	3
Cacodylic acid	LD50 of 1350 mg/kg BW	3
Lead arsenate	Some deaths at 7 mg/kg BW	3
Total arsenic	Accumulations of 1 mg/kg BW daily for 3 months in children, or 80 mg/kg BW daily for 3 years in adults produced symptoms of chronic arsenic poisoning	3
Total arsenic, daily oral dose	Prolonged dosages of 3–4 mg daily produced clinical symptoms of chronic arsenic intoxication	3
Total arsenic in drinking and cooking water	Prolonged use produced symptoms of chronic arsenic intoxication (0.6 mg/L) or skin cancer (0.29 mg/L)	3
Total arsenic, probably arsenate	12,000 Japanese infants poisoned (128 deaths) from consumption of dry milk contaminated with arsenic; average exposure of 3.5 mg As daily for 1 month. Severe hearing loss, brain wave abnormalities, and other CNS disturbances noted 15 years after exposure	6
Total inorganic arsenic	Daily dose of 3 mg for 2 weeks may cause severe poisoning in infants, and symptoms of toxicity in adults	6
CYNOMOLGUS MONKEY, <i>Macaca</i> sp.		
Fish-arsenic meal (witch flounder, <i>Glyptocephalus cynoglossus</i>) containing 77 mg total As/kg	Given a single meal at 1 mg/kg BW; tissue residues normal after 14 days	11
As above, except arsenic trioxide substituted for total As	As above	11
MAMMALS, many species		
Calcium arsenate	Single oral LD50 range of 35–100 mg/kg BW	3
Lead arsenate	Single oral LD50 range of 10–50 mg/kg BW	3
MAMMALS, most species		
Arsenic trioxide	3–250 mg/kg BW lethal	12
Sodium arsenite	1–25 mg/kg BW lethal	12

Table 28.6 (continued) Lethal and Sublethal Effects of Various Arsenicals on Selected Species of Mammals

Organism and Arsenical	Effect	Reference ^a
MOUSE, <i>Mus</i> spp.		
Arsenate	Maternal dose of 10 mg As ⁺⁵ /kg BW results in some fetal deaths and malformations	3
Arsenic trioxide	Single oral LD50 (96 h) value of 39.4 mg/kg BW; LD0 (96 h) of 10.4 mg/kg BW	12
Arsenic trioxide	"Adapted" group (50 mg As/L in drinking water for 3 months) had subcutaneous LD50 value of 14 mg/kg BW vs. 11 for nonadapted group	12
Arsenic trioxide	Air concentrations of 28.5 mg/m ³ for 4 h daily on days 9–12 of gestation caused fetotoxic effects and chromosomal damage to liver cells by day 18; effects included reduced survival, impaired growth, retarded limb ossification, and bone abnormalities. At 2.9 mg/m ³ , a 9.9% decrease in fetal weight was recorded; at 0.26 mg/m ³ , a 3.1% decrease was measured	13
Cacodylic acid	Oral dosages of 400–600 mg/kg BW on days 7–16 of gestation produces fetal malformations (cleft palate), delayed skeletal ossification, and fetal weight reduction	5
Dimethylarsinic acid	200–600 mg/kg BW daily for 10 days (DMA) produced fetal and maternal toxicity	25
Single oral dose		
Arsenous oxide	34 mg As/kg BW fatal to 50%	21
Tetramethylarsonium iodide	890 mg As/kg BW fatal to 50%	21
Dimethylarsinic acid	1200 mg As/kg BW fatal to 50%	21
Dimethylarsonic acid	1800 mg As/kg BW fatal to 50%	21
Arsenocholine	6500 mg As/kg BW fatal to 50%	21
Trimethylarsinoxide	10,600 mg As/kg BW fatal to 50%	21
Arsenobetaine	>100,000 mg As/kg BW fatal to 50%	21
Sodium arsenate	Maximum tolerated doses in terms of abortion or maternal death over 24 h in 18-day pregnant mice were 20 mg As ⁺⁵ /kg BW, intraperitoneal route, and 50 mg/kg BW when administered orally. Residue half-life was about 10 h, regardless of route of administration	14
Sodium arsenate	Given 500 µg As/L in drinking water for as long as 26 months, equivalent to 0.07–0.08 mg As/kg BW daily. No tumors in controls vs. 41.1% of mice in treated groups with 1 or more tumors — mostly of the lung, liver, and GI tract	22
Sodium arsenite	Fed 5 mg/kg diet for 3 generations: reduced litter size, but outwardly normal	6
Sodium arsenite	LD50 of 9.6 mg/kg BW, sc route; LD90 (7 days postadministration) of 11.3 mg/kg BW, sc route	15
Sodium arsenite	LD50 of 12 mg/kg BW intraperitoneal route. At 10 mg/kg BW, damage to bone marrow and sperm	16
Sodium cacodylate	Single intraperitoneal injection of 1200 mg/kg BW during midgestation results in increased rates of fetal skeletal malformations	5
MULE DEER, <i>Odocoileus hemionus hemionus</i>		
Silvisar-510 (mixture of cacodylic acid and triethanolamine cacodylate)	Single oral LD50 dose >320 mg/kg BW; appetite loss	17
WHITE-TAILED DEER, <i>Odocoileus virginianus</i>		
Sodium arsenite (used to debark trees)	Lethal dose of 923–2770 mg equivalent to about 34 mg/kg BW; liver residues of 40 mg/kg fresh weight	12
Arsenic acid (to control Johnson grass)	23 deer killed from apparent misuse. Arsenic levels, in mg/kg fresh weight, in deer found dead were 19 in liver, 18 in kidney, and 22.5 in rumen. Soils from area contained ~2.4 mg As/kg, and water 0.42 mg As/L	12

Table 28.6 (continued) Lethal and Sublethal Effects of Various Arsenicals on Selected Species of Mammals

Organism and Arsenical	Effect	Reference^a
RABBIT, <i>Oryctolagus</i> sp.		
Monomethylarsonic acid (MMA)	50 mg/kg ration for 7–12 weeks produces hepatotoxicity	25
DOMESTIC SHEEP, <i>Ovis aries</i>		
Arsanilic acid	One-year-old castrates fed diets with 273 mg As/kg for 28 days had 0.54 mg As/L in blood, 29 mg/kg dry weight in liver, 24 in kidney, and 1.2 in muscle (vs. <0.01 in all control tissues). After 6 days on an As-free diet, liver residues were <5 mg/kg DW. Maximum tissue levels in sheep fed diets containing 27 mg As/kg for 28 days were 3.2 mg/kg DW kidney; for a 144 mg/kg DW diet, the maximum tissue level was 27 mg/kg DW liver	7
Sodium arsenite	Single oral dose of 5–12 mg/kg BW (0.2–0.5 g) was acutely toxic	3
Soluble arsenic	Lambs fed supplemental arsenic for 3 months at 2 mg As/kg DW diet contained maximum concentrations of 2 mg/kg FW brain (vs. 1 in controls), 14 in muscle (2), 24 in liver (4), and 57 in kidney (10)	18
Total arsenic	Sheep fed diets containing lakeweed (<i>Lagarosiphon major</i>) (288 mg As/kg DW) at 58 mg total As/kg diet for 3 weeks without ill effect. Tissue residues increased during feeding, but rapidly declined when lakeweed was removed from diet	7
RAT, <i>Rattus</i> spp.		
Arsanilic acid	No teratogenesis observed in 7 generations at dietary level of 17.5 mg/kg; positive effect on litter size and survival	6
Arsenate	Fed diets containing 50 mg/kg for 10 weeks with no effect on serum uric acid levels	19
Arsenic trioxide	Single oral LD50 (96 h) value of 15.1 mg/kg BW	12
Arsenic trioxide	Single dose of 17 mg/kg BW administered intratracheally is maximally tolerated nonlethal dose; 2 weeks later, blood As elevated (36 mg/L) and lung histopathology evident	20
Arsenic trioxide	After 21 days on diet containing 50 mg/kg, tissue arsenic levels were elevated in blood (125 mg/L vs. 15 in controls), heart (43 mg/kg FW vs. 3.3), spleen (60 vs. <0.7), and kidney (25 vs. 1.5)	7
Arsenite	Oral administration of 1.2 mg/kg BW daily for 6 weeks reduced uric acid levels in plasma by 67%	19
Arsenite	10 mg As/L in drinking water for 7 months; urinary metabolites were mainly methylated arsenic metabolites with about 6% in inorganic form	24
Arsenobetaine	100 mg As/L in drinking water for 7 months; eliminated in urine unchanged without transformation	24
Cacodylic acid	Fetal and maternal deaths noted when pregnant rats dosed by gavage at 50–60 mg/kg BW daily during gestation days 6–13. Fetal abnormalities observed when dams given oral dosages of 40–60 mg/kg BW on days 7–16 of gestation	5
Dimethylarsinic acid (DMA)	Main metabolites in urine after 7 months of exposure to 100 mg As/L drinking water were DMA and trimethylarsin oxide (TMAO) with minute amounts of tetramethylarsonium (TMA)	24
Dimethylarsinic acid	40–60 mg/kg BW daily for 10 days associated with fetal and maternal toxicity	25
Monomethylarsonic acid (MMA)	100 mg As/L in drinking water for 7 months produced main products in urine of unchanged MMA and DMA, plus small amounts of TMA and TMAO	24
3-Nitro-4-hydroxyphenylarsonic acid	Single oral LD50 value of 44 mg/kg BW	12
Sodium arsenate	LD75 (48 h) value of 14–18 mg/kg BW (intraperitoneal route)	12

Table 28.6 (continued) Lethal and Sublethal Effects of Various Arsenicals on Selected Species of Mammals

Organism and Arsenical	Effect	Reference ^a
Sodium arsenite	Single intraperitoneal injection of 5–12 mg/kg on days 7–12 of gestation produced eye defects, exencephaly, and faulty development of kidney and gonads	6
Sodium arsenite	LD75 (48 h) value of 4.5 mg/kg BW (intraperitoneal injection)	12
Trimethylarsin oxide (TMAO)	100 mg As/L in drinking water for 7 months was excreted in urine mostly unchanged with some TMA	24
RODENTS, various species		
Cacodylic acid	LD50 (various routes) values range from 470–830 mg/kg BW	5
Sodium cacodylate	LD50 (various routes) values range from 600–2600 mg/kg BW	5
COTTON RAT, <i>Sigmodon hispidus</i>		
Sodium arsenite	Adult males given 0, 5, or 10 mg As ⁺³ /L drinking water for 6 weeks had dose-dependent decrease in daily food intake. Minimal effects on immune function, tissue weights, and blood chemistry	23
PIG, <i>Sus</i> sp.		
Sodium arsenite	Drinking water containing 500 mg/L lethal at 100–200 mg/kg BW	12
3-Nitro-4-hydroxyphenylarsonic acid	Arsenosis documented after 2 months on diets containing 100 mg/kg, or after 3–10 days on diets containing 250 mg/kg	12
RABBIT, <i>Sylvilagus</i> sp.		
Cacodylic acid	Adverse effects at dermal dosages equivalent to 4–6 g/kg BW	5
Calcium arsenate	Single oral dose of 23 mg/kg BW fatal in 3 days	12
Copper acetoarsenite	Single oral dose of 10.5 mg/kg BW fatal in 50 h	12
Inorganic arsenate	Single oral LD50 value of 8 mg/kg BW	3
Lead arsenate	Single oral dose of 40.4 mg/kg BW fatal in 52 h	12

^a 1, Vreman et al. 1986; 2, Thatcher et al. 1985; 3, NRCC 1978; 4, Robertson et al. 1884; 5, Hood 1985; 6, Pershagen and Vahter 1979; 7, Woolson 1975; 8, Pershagen and Bjorklund 1985; 9, Belton et al. 1985; 10, Yamauchi et al. 1986; 11, Charbonneau et al. 1978; 12, NAS 1977; 13, Nagymajtenyi et al. 1985; 14, Hood et al. 1987; 15, Stine et al. 1984; 16, Deknudt et al. 1986; 17, Hudson et al. 1984; 18, Veen and Vreman 1986; 19, Jauge and Del-Razo 1985; 20, Webb et al. 1986; 21, Hamasaki et al. 1995; 22, Ng et al. 1998; 23, Savabieasfahani et al. 1998; 24, Yoshida et al. 1998; 25, Hughes and Kenyon 1998.

28.7 RECOMMENDATIONS

Numerous criteria for arsenic have been proposed to protect natural resources and human health (Table 28.7). But many authorities recognize that these criteria are not sufficient for adequate or (in some cases) reasonable protection, and that many additional data are required if meaningful standards are to be promulgated (NAS 1977; NRCC 1978; Pershagen and Vahter 1979; USEPA 1980, 1985; Eisler 1994; Abernathy et al. 1997; SEGH 1998). Specifically, data are needed on the following subjects:

1. Cancer incidence and other abnormalities in natural resources from areas with elevated arsenic levels, and the relation to potential carcinogenicity of arsenic compounds
2. Interaction effects of arsenic with other carcinogens, cocarcinogens, promoting agents, inhibitors, and common environmental contaminants
3. Controlled studies with aquatic and terrestrial indicator organisms on physiological and biochemical effects of long-term, low-dose exposures to inorganic and organic arsenicals, including effects on reproduction and genetic makeup

4. Methodologies for establishing maximum permissible tissue concentrations for arsenic
5. Effects of arsenic in combination with infectious agents
6. Mechanisms of arsenical growth-promoting agents
7. Role of arsenic in nutrition
8. Extent of animal adaptation to arsenicals and the mechanisms of action
9. Identification and quantification of mineral and chemical forms of arsenic in rocks, soils, and sediments that constitute the natural forms of arsenic entering water and the food chain
10. Physicochemical processes influencing arsenic cycling.

In addition, the following techniques should be developed and implemented: (1) more sophisticated measurements of the chemical forms of arsenic in plant and animal tissues; (2) correlation of biologically observable effects with particular chemical forms of arsenic; and (3) management of arsenical wastes that accommodates recycling, reuse, and long-term storage.

Some proposed arsenic criteria merit additional comment, such as those on aquatic life protection, levels in seafoods and drinking water, and use in food-producing animals as growth stimulants or for disease prevention and treatment.

For saltwater life protection, the current water quality criterion of 36 µg As⁺³/L (USEPA 1985; [Table 28.7](#)) seems to offer a reasonable degree of safety. Only a few species of algae show adverse effects at <36 µg/L (e.g., reduced growth at 19 to 22 µg/L). In 1980, this criterion was 508 µg/L (USEPA 1980), about 14 times higher than the current criterion. The downward modification seems to be indicative of the increasingly stringent arsenic criteria formulated by regulatory agencies. The current criterion for freshwater-life protection of 190 µg As⁺³/L (USEPA 1985; [Table 28.7](#)), however, which is down from 440 µg As⁺³/L in 1980 (USEPA 1980), is unsatisfactory. Many species of freshwater biota are adversely affected at <190 µg/L of As⁺³, As⁺⁵, or various organoarsenicals ([Table 28.4](#)). These adverse effects include death and malformations of toad embryos at 40 µg/L, growth inhibition of algae at 48 to 75 µg/L, mortality of amphipods and gastropods at 85 to 88 µg/L, and behavioral impairment of goldfish (*Carassius auratus*) at 100 µg/L. A downward adjustment in the current freshwater aquatic-life protection criterion seems warranted.

In Hong Kong, permissible concentrations of arsenic in seafood destined for human consumption range from 6 to 10 mg/kg fresh weight ([Table 28.7](#)). However, these values are routinely exceeded in 22% of finfish, 20% of bivalve molluscs, 67% of gastropods, 29% of crabs, 21% of shrimp and prawns, and 100% of lobsters (Phillips et al. 1982). The highest arsenic concentrations recorded in Hong Kong seafood products were in gastropods (*Hemifusus* spp.), in which the concentrations of 152 to 176 mg/kg FW were among the highest recorded in any species to date (Phillips et al. 1982). A similar situation exists in Yugoslavia, where almost all seafoods exceed the upper limit prescribed by food quality regulations (Ozretic et al. 1990). Most of the arsenic in seafood products is usually arsenobetaine or some other comparatively harmless form. In effect, arsenic criteria for seafoods are neither enforced nor enforceable. Some toxicologists from the U.S. Food and Drug Administration believe that the average daily intake of arsenic in the different food commodities does not pose a hazard to the consumer (Jelinek and Corneliusen 1977). It is now clear that formulation of maximum permissible concentrations of arsenic in seafoods for health regulation purposes should recognize the chemical nature of arsenic (McGeachy and Dixon 1990; [Table 28.7](#)).

For maximum protection of human health from the potential carcinogenic effects of exposure to arsenic through drinking water or contaminated aquatic organisms, the ambient water concentration should be zero, based on the nonthreshold assumption for arsenic. But a zero level may not be attainable. Accordingly, the levels established are those that are estimated to increase cancer risk over a lifetime to only one additional case per 100,000 population. These values are estimated at 0.022 µg As/L for drinking water and 0.175 µg As/L for water containing edible aquatic resources (USEPA 1980; [Table 28.7](#)).

Various phenylarsonic acids — especially arsanilic acid, sodium arsanilate, and 3-nitro-4-hydroxyphenylarsonic acid — have been used as feed additives for disease control and for improvement of weight gain in swine and poultry for almost 40 years (NAS 1977). The arsenic is present as As⁺⁵

and is rapidly excreted; present regulations require withdrawal of arsenical feed additives 5 days before slaughter for satisfactory depuration (NAS 1977). Under these conditions, total arsenic residues in edible tissues do not exceed the maximum permissible limit of 2 mg/kg fresh weight (Jelinek and Corneliusen 1977). Organoarsenicals probably will continue to be used as feed additives unless new evidence indicates they should not be.

Table 28.7 Proposed Arsenic Criteria for the Protection of Selected Natural Resources and Human Health

Resource and Other Variables	Criterion or Effective Arsenic Concentration (Reference)
AQUATIC LIFE	
Freshwater biota: medium concentrations	4-day mean water concentration not to exceed 190 µg total recoverable inorganic As ⁺³ /L more than once every 3 years; 1-h mean not to exceed 360 µg inorganic As ⁺³ /L more than once every 3 years. Insufficient data for criteria formulation for inorganic As ⁺⁵ , or for any organoarsenical (USEPA 1985)
Freshwater biota: tissue residues	Diminished growth and survival reported in immature bluegills (<i>Lepomis macrochirus</i>) when total arsenic residues in muscle are >1.3 mg/kg fresh weight (FW) or >5 mg/kg in adults (NRCC 1978)
Saltwater biota: medium concentration	4-day average water concentration not to exceed 36 µg As ⁺³ /L more than once every 3 years; 1-h mean not to exceed 69 µg As ⁺³ /L more than once every 3 years. Insufficient data for criteria formulation for inorganic As ⁺⁵ , or for any organoarsenical (USEPA 1985)
Saltwater biota: tissue residues	Depending on chemical form of arsenic, certain marine teleosts may be unaffected at muscle total arsenic residues of 40 mg/kg FW (NRCC 1978)
BIRDS	
Tissue residues	Residues, in mg total As/kg FW, liver or kidney in 2–10 range are considered elevated; residues >10 mg/kg are indicative of arsenic poisoning (Goede 1985)
Mallard, <i>Anas platyrhynchos</i> Sodium arsenite in diet	Reduced growth in ducklings fed more than 30 mg As/kg diet (Camardese et al. 1990)
Turkey, <i>Meleagris gallopavo</i> Arsanilic acid in diet	Maximum dietary concentration for turkeys less than 28 days old is 300–400 mg/kg feed (NAS 1977) Maximum levels in diets, in mg/kg feed, are 50–100 for arsanilic acid, 25–188 for 3-nitro-4-hydroxy-phenylarsonic acid (for chickens and turkeys, not recommended for ducks and geese), and 180–370 for others (NAS 1977)
Phenylarsonic feed additives for disease control and improvement of weight gain in domestic poultry; safe dietary levels	
DOMESTIC LIVESTOCK	
Prescribed limits for arsenic in feedstuffs	
Straight feedstuffs, except those listed below	<2 mg total As/kg FW (Vreman et al. 1986)
Meals from grass, dried lucerne, or dried clover	<4 mg total As/kg FW (Vreman et al. 1986)
Phosphate mealstuffs	<10 mg total As/kg FW (Vreman et al. 1986)
Fish meals	<10 mg total As/kg FW (Vreman et al. 1986)
Tissue residues	
Poisoned	
Liver, kidney	5–>10 total As/kg FW (Thatcher et al. 1985; Vreman et al. 1986)
Normal, muscle	<0.3 mg total As/kg FW (Veen and Vreman 1986)
VEGETATION	
No observable effects	<1 mg total water-soluble soil As/L; <25 mg total As/kg soil; <3.9 µg As/m ³ air (NRCC 1978)

Table 28.7 (continued) Proposed Arsenic Criteria for the Protection of Selected Natural Resources and Human Health

Resource and Other Variables	Criterion or Effective Arsenic Concentration (Reference)
HUMAN HEALTH	
Diet	
Permissible levels	
Total diet	<0.5 mg As/kg dry weight diet (Sorensen et al. 1985); 0.0003–0.0008 mg/kg body weight (BW) daily (ATSDR 1992)
Fruits, vegetables	The tolerance for arsenic residues as As_2O_3 , resulting from pesticidal use of copper, magnesium, and sodium arsenates is 3.5 mg/kg (Jelinek and Corneliusen 1977)
Muscle of poultry and swine, eggs, swine edible by-products	<2 mg total As/kg FW (Jelinek and Corneliusen 1977)
Edible by-products of chickens and turkey, liver and kidney of swine	<2 mg total As/kg FW (Jelinek and Corneliusen 1977)
Seafood products	In Hong Kong, limited to <6 mg As^{+3}/kg FW for edible tissues of finfish and <10 mg As^{+3}/kg for molluscs and crustaceans (Phillips et al. 1982; Edmonds and Francesconi 1993); in Yugoslavia, these values are 2 for fish and 4 for molluscs and crustaceans (Ozretic et al. 1990); in Australia, <1 mg inorganic As/kg FW and in New Zealand <2 mg inorganic As/kg FW — there is no limit on organoarsenicals (Edmonds and Francesconi 1993). In the UK, seafood products should contain <1 mg As/kg FW contributed as a result of contamination (Edmonds and Francesconi 1993)
Adverse effects	
Consumption of aquatic organisms living in As-contaminated waters	
Cancer risk of	
10^{-5}	0.175 µg As/L (USEPA 1980)
10^{-6}	0.0175 µg As/L (USEPA 1980) ^a
10^{-7}	0.00175 µg As/L (USEPA 1980)
Drinking water	
Allowable concentrations	
Total arsenic	<10 µg/L (NAS 1977; Hering et al. 1997; Kurttio et al. 1998)
Total arsenic	<50 µg/L (Pershagen and Vahter 1979; USEPA 1980; Norin et al. 1985; ATSDR 1992; USPHS 1998)
Total arsenic, Maine	<30 µg/L (ATSDR 1992)
Adverse effects	
Cancer risk of	
10^{-5}	0.022 µg As/L (USEPA 1980)
10^{-6}	0.0022 µg As/L (USEPA 1980) ^a
10^{-7}	0.00022 µg As/L (USEPA 1980)
Symptoms of arsenic toxicity observed	9% incidence at 50 µg As/L, 16% at 50–100 µg/L, and 44% at >100 µg As/L (NRCC 1978)
Harmful after prolonged consumption “Cancer”	>50–960 µg As/L (NRCC 1978)
Skin cancer	In Chile, cancer rate estimated at 0.01% at 82 µg As/L, 0.17% at 600 µg As/L (NRCC 1978)
Total intake	0.26% frequency at 290 µg/L and 2.14% at 600 µg/L (USEPA 1980)
No observable effect	
North America	0.007–0.06 mg As daily (Pershagen and Vahter 1979); 2 µg/kg BW daily (ATSDR 1992)
Japan	0.07–0.17 mg As daily (Pershagen and Vahter 1979)
United States	
1960s	0.05–0.1 mg As daily (Pershagen and Vahter 1979)
1974	0.015 mg As daily (Pershagen and Vahter 1979)
1998	<0.021 mg As daily, based on <0.0003 mg/kg BW daily for 70-kg adult (USPHS 1998)
Canada	0.03 mg As daily (NRCC 1978)

Table 28.7 (continued) Proposed Arsenic Criteria for the Protection of Selected Natural Resources and Human Health

Resource and Other Variables	Criterion or Effective Arsenic Concentration (Reference)
Netherlands	
Acceptable	2 µg total inorganic As/kg body weight (BW) (about 0.14 mg daily for 70 kg adult); 0.094 mg daily through fishery products (Vos and Hovens 1986)
Adverse effects (prolonged exposure)	
Subclinical symptoms	0.15–0.6 mg As daily (NRCC 1978)
Intoxication	3–4 mg As daily (NRCC 1978)
Blackfoot disease	Total dose of 20 g over several years increases prevalence of disease by 3% Pershagen and Vahter 1979)
Mild chronic poisoning	0.15 mg As daily or about 2 µg/kg BW daily (NRCC 1978)
Chronic arsenic poisoning	Lifetime cumulative absorption of 1 g As, or intake of 0.7–2.6 g/year for several years (in medications) can produce symptoms after latent period of 4–24 years (NRCC 1978)
Tissue residues	
No observed effect levels	
Urine	<0.05 mg As/L (NRCC 1978)
Liver, kidney	<0.5 mg As/L (NRCC 1978)
Blood	<0.7 As/kg (NRCC 1978)
Hair ^b	<2 mg As/kg (NRCC 1978)
Fingernail	<5 mg As/kg (NRCC 1978)
Arsenic-poisoned	
Liver, kidney	2–100 mg As/kg FW; confirmatory tests >10 mg As/kg FW; residues in survivors several days later were 2–4 mg/kg FW (NAS 1977)
Whole body	In children, symptoms of chronic arsenicism evident at 1 mg As/kg BW, equivalent to intake of about 10 mg/month for 3 months; for adults, these values were 80 mg/kg BW, equivalent to about 2 g/year for 3 years (NRCC 1978)
Air	
Allowable concentrations	
Arsine	<200 µg/m ³ for U.S. industrial workers; proposed mean arsine limit of <4 µg/m ³ in 8-h period and <10 µg/m ³ maximum in 15 min (NAS 1977) <4 µg/m ³ (NRCC 1978)
Arsine	<2 µg/m ³ (ATSDR 1992)
Inorganic arsenic	<10 µg/m ³ (ATSDR 1992; USPHS 1998)
Occupational	<500 µg/m ³ (ATSDR 1992)
Residential	<3 µg/m ³ in U.S.S.R. and Czechoslovakia, <500 µg/m ³ for U.S. industrial workers (NAS 1977)
Organic arsenic	Proposed limit of <50 µg/m ³ , maximum of 2 µg/m ³ in 15 min, <10 µg airborne inorganic As/m ³ (USEPA 1980)
Total As	<0.3 µg/m ³ in U.S.S.R., <0.1 µg/m ³ in U.S. (Nagymajtenyi et al. 1985)
Total As (threshold limit value-time weighted mean:8 h/day, 40-h work week)	
Arsenic trioxide	
Adverse effects	
Increased mortality	Associated with daily time-weighted average arsenic exposure of >3 µg/m ³ for 1 year (NRCC 1978)
Respiratory cancer (increased risk)	Associated with chronic exposure >3 µg/m ³ , or occupational exposure (lifetime) of >54.6 µg As/m ³ (NRCC 1978)
Respiratory cancer (increased risk)	Exposure to 50 µg As/m ³ for more than 25 years associated with 3-fold increase (Pershagen and Vahter 1979)
Skin diseases	Associated with ambient air concentrations of 60–13,000 µg As/m ³ (NRCC 1978)
Dermatitis	Associated with ambient air concentrations of 300–81,500 µg As/m ³ (NRCC 1978)

^a One excess cancer per million population (10^{-6}) is estimated during lifetime exposure to 0.00022 µg arsenic per liter of drinking water, or to lifetime consumption of aquatic organisms residing in waters containing 0.0175 µg As/L (USEPA 1980).

^b Thai children, age 6–9 years from the Ronpiboon district with >5 mg As/kg DW hair had abnormally low IQs compared to those with 2.01–5 mg As/kg DW. Both groups had significantly lower IQs than controls (<1 mg As/kg DW hair), as measured by the Wechsler Intelligence Scale Test for Children (Unchalee et al. 1999). This study needs verification.

28.8 SUMMARY

Arsenic (As) is a relatively common element that occurs in air, water, soil, and all living tissues. It ranks 20th in abundance in Earth's crust, 14th in seawater, and 12th in the human body. Arsenic is a teratogen and carcinogen that can traverse placental barriers and produce fetal death and malformations in many species of mammals. Although it is carcinogenic in humans, evidence for arsenic-induced carcinogenicity in other mammals is scarce. Paradoxically, evidence is accumulating that arsenic is nutritionally essential or beneficial. Arsenic deficiency effects, such as poor growth, reduced survival, and inhibited reproduction, have been recorded in mammals fed diets containing <0.05 mg As/kg, but not in those fed diets with 0.35 mg As/kg. At comparatively low doses, arsenic stimulates growth and development in various species of plants and animals.

Most arsenic produced domestically is used in the manufacture of agricultural products such as insecticides, herbicides, fungicides, algicides, wood preservatives, and growth stimulants for plants and animals. Living resources are exposed to arsenic by way of atmospheric emissions from smelters, coal-fired power plants, and arsenical herbicide sprays; from water contaminated by mine tailings, smelter wastes, and natural mineralization; and from diet, especially from consumption of marine biota. Arsenic concentrations are usually low (<1.0 mg/kg fresh weight) in most living organisms, but they are elevated in marine biota (in which arsenic occurs as arsenobetaine and poses little risk to organisms or their consumers) and in plants and animals from areas that are naturally arseniferous or are near industrial manufacturers and agricultural users of arsenicals. Arsenic is bioconcentrated by organisms but is not biomagnified in the food chain.

Arsenic exists in four oxidation states, as inorganic or organic forms. Its bioavailability and toxic properties are significantly modified by numerous biological and abiotic factors, including the physical and chemical forms of arsenic tested, the route of administration, the dose, and the species of animal. In general, inorganic arsenic compounds are more toxic than organic compounds, and trivalent species are more toxic than pentavalent species. Arsenic may be absorbed by ingestion, inhalation, or through permeation of the skin or mucous membranes; cells take up arsenic through an active transport system normally used in phosphate transport. The mechanisms of arsenic toxicity differ greatly among chemical species, although all appear to cause similar signs of poisoning. Biomethylation is the preferred detoxification mechanism for absorbed inorganic arsenicals; methylated arsenicals usually clear from tissues within a few days.

Episodes of arsenic poisoning are either acute or subacute. Chronic cases of arsenosis are seldom encountered in any species except human beings. Single oral doses of arsenicals fatal to 50% of sensitive species tested ranged from 17 to 48 mg/kg body weight (BW) in birds and from 2.5 to 33 mg/kg BW in mammals. Susceptible species of mammals were adversely affected at chronic doses of 1 to 10 mg As/kg BW, or 50 mg As/kg diet. Sensitive aquatic species were damaged at water concentrations of 19 to 48 µg As/L (the U.S. Environmental Protection Agency drinking water criterion for human health protection is 50 µg/L), 120 mg As/kg diet, or (in the case of freshwater fish) tissue residues >1.3 mg/kg fresh weight. Adverse effects to crops and vegetation were recorded at 3 to 28 mg of water-soluble As/L (equivalent to about 25 to 85 mg total As/kg soil) and at atmospheric concentrations >3.9 µg As/m³.

Numerous and disparate arsenic criteria have been proposed for the protection of sensitive natural resources. However, the consensus is that many of these criteria are inadequate and that additional information is needed in at least five categories:

1. Developing standardized procedures to permit correlation of biologically observable effects with suitable chemical forms of arsenic
2. Conducting studies under controlled conditions with appropriate aquatic and terrestrial indicator organisms to determine the effects of chronic exposure to low doses of inorganic and organic arsenicals on reproduction, genetic makeup, adaptation, disease resistance, growth, and other variables

3. Measuring interaction effects of arsenic with other common environmental contaminants, including carcinogens, cocarcinogens, and promoting agents
4. Monitoring the incidence of cancer and other abnormalities in the natural resources of areas with relatively high arsenic levels, and correlating these with the possible carcinogenicity of arsenic compounds
5. Developing appropriate models of arsenic cycling and budgets in natural ecosystems.

CHAPTER 29

Boron

29.1 INTRODUCTION

Borax ($\text{Na}_2\text{B}_4\text{O}_7 \cdot 10\text{H}_2\text{O}$) was the first of the boron (B) minerals to be traded by the Babylonians more than 4000 years ago for use in the working and welding of gold (Greenwood and Thomas 1973). Borax has been known as a cleaning agent since the days of the ancient Greek and Roman empires and was used as a food preservative in Europe and America, although its use for the latter purpose has been discontinued (Weir and Fisher 1972). Boron and its compounds were used in the Egyptian and Roman eras to prepare borosilicate glass. Borax glazes were known from about the year 200; by 1556, borax was widely used throughout Europe as a flux (Greenwood and Thomas 1973). Boric acid (H_3BO_3) was first synthesized in 1707 (Greenwood and Thomas 1973). Boric acid and borates are the main boron compounds of ecological significance; other boron compounds usually degrade or are transformed to borates or boric acid (Sprague 1972).

Boron is an essential trace element for the growth and development of higher plants, although the range between insufficiency and excess is generally narrow, varying with the plant; boron is not required in fungi and animals (Sprague 1972; Weir and Fisher 1972; Birge and Black 1977; Goldbach and Amberger 1986; Stone 1990). In the southwestern United States, naturally elevated boron concentrations in surface waters used for irrigation may be sufficiently high to cause toxicity to plants of commercial importance (Benson et al. 1984). Another major source of boron entering ground and surface waters results from the use of borax-containing laundry products, coupled with ineffective removal of boron by conventional sewage processes (Benson et al. 1984). Agricultural drainwaters contaminated with boron are considered potentially hazardous to waterfowl and other wildlife populations throughout areas of the western United States (Smith and Anders 1989).

Medical and household uses of boric acid solutions as antiseptics have led to numerous accidental poisonings by ingestion or absorption through abraded skin, particularly in infants (U.S. Environmental Protection Agency [USEPA] 1975; Dixon et al. 1976; Landolph 1985; Siegel and Wason 1986). Poisonings have been reported in English children consuming milk containing 0.7 g boric acid/L, and in burn patients treated topically with saturated boric acid solutions (NAS 1980). In the 1940s, topical preparations of boric acid became a popular remedy for diaper rash in England. By 1953, at least 60 fatal cases of boric acid poisoning had been reported in English infants (O'Sullivan and Taylor 1983). Inhalation of boranes, especially diborane (B_2H_6), pentaborane (B_5H_9), and decaborane ($\text{B}_{10}\text{H}_{14}$) — which is used as a rocket propellant — is toxic to exposed workers (Dixon et al. 1976; NAS 1980). Boron compounds, especially boric acid, can also accumulate in animal tissues and produce a reduction in fertility, an increase in developmental abnormalities — especially those involving the skeletal system — stillbirth, and death (Weir and Fisher 1972; Lee et al. 1978; Landolph 1985). There seems to be a reasonable margin between a toxic dose in man and other vertebrates and in boron levels that may occur as incidental residues from

the use of borax and boric acid in agriculture and industry (Weir and Fisher 1972). Additional, and more extensive, information on ecological and toxicological aspects of boron in the environment is presented in reviews by Sprague (1972), USEPA (1975), NAS (1980), Anonymous (1983), Klasing and Pilch (1988), Butterwick et al. (1989), Eisler (1990), Stone (1990), U.S. Public Health Service [USPHS] (1991), and Culver et al. (1998).

29.2 ENVIRONMENTAL CHEMISTRY

29.2.1 General

The United States supplies about 70% of the global boron demand, and Turkey supplies 18%. Of the total annual U.S. production of about 500,000 tons, 45% is used in the manufacture of glass and glassware, 15% in laundry products, 10% in enamels and glazes, and 8% in agricultural chemicals. It is estimated that boron compounds enter the North American environment at a rate of 32,000 tons annually as a result of human activities, primarily from laundry products, irrigation drainwater, agricultural chemicals, coal combustion, and mining and processing. Boron compounds tend to accumulate in aquatic ecosystems because of the relatively high water solubility of these compounds.

The chemistry of boron is exceedingly complex and rivals that of carbon in its diversity. Most boron compounds, however, enter or degrade in the environment to borates (B-O compounds), such as borax and boric acid, and these are considered to be the most significant ecologically.

Toxicosis in animals has resulted from ingestion of boric acid or borax solutions, from topical applications of boric acid solutions to damaged skin, and from inhalation of boranes; the exact mechanisms of action are not understood. Boron and its compounds are potent teratogens when applied directly to the embryo, but there is no evidence of mutagenicity or carcinogenicity. Boron's unique affinity for cancerous tissues has been exploited in neutron capture radiation therapy of malignant human brain tumors.

29.2.2 Sources and Uses

Boron is a dark brown element that is widespread in the environment but occurs naturally only in combined form, usually as borax, colemanite ($\text{Ca}_2\text{B}_6\text{O}_{11} \cdot 5\text{H}_2\text{O}$), boronatrocacite ($\text{CaB}_4\text{O}_7\text{NaBO}_2 \cdot 8\text{H}_2\text{O}$), and boracite ($\text{Mg}_7\text{Cl}_2\text{B}_{16}\text{O}_{30}$) (USEPA 1975; NAS 1980). In the United States, boron deposits in the form of borax are concentrated in the desert areas of southern California, especially near Boron, California (USEPA 1975; USPHS 1991). Proven deposits of sodium tetraborates — from which borax is prepared and from which boron can be isolated — also exist in Nevada, Oregon, Turkey, Russia, and China (Sprague 1972; NAS 1980). About 300,000 metric tons of boron are removed from mined ore each year (Argust 1998). The United States supplies about 70% of the world boron demand, and Turkey supplies 18%; the most common commercial compounds are boric acid and borax (Sprague 1972; Butterwick et al. 1989; USPHS 1991).

In 1988, the United States produced 566,093 metric tons of boric oxide, imported an additional 60,000 metric tons of boron-containing minerals, and exported 589,680 metric tons of boric acid and borates (USPHS 1991). The majority of the boron produced annually at facilities in Oklahoma, New Jersey, Nevada, and Pennsylvania is in the form of sodium tetraborate compounds (USPHS 1991). Of the total production, about 42% occurs as anhydrous borax ($\text{Na}_2\text{B}_4\text{O}_7$), 29% as borax pentahydrate ($\text{Na}_2\text{B}_4\text{O}_7 \cdot 5\text{H}_2\text{O}$), 10% as borax decahydrate or borax, and 16% as boric acid or boric oxide (B_2O_3) (Sprague 1972; USEPA 1975). Boron and its compounds are used in the manufacture of glassware (40% to 45%); soaps and cleansers (15%); enamels, frits, and glazes (10%); fertilizers

(5%); and herbicides (2% to 3%); 22% to 28% goes for other uses including cosmetics, insecticides, antifreeze, as neutron absorbers in atomic reactors, and leather tanning (Sprague 1972; USEPA 1975; NAS 1980; USPHS 1991; Woods 1994; Argust 1998). Borates have some toxicity to insects and, in relatively high concentrations, can control cockroaches, woodboring insects, gypsy moths, and larvae of flies in manure piles and in dog runs (Sprague 1972; USEPA 1975). Some organoboron compounds are used to sterilize fuel distribution and storage systems against fungi and bacteria (Sprague 1972). Radioboron-10 is widely used in radiation therapy against brain tumors, especially in Japan (Hatanaka 1986). In medicine, certain amine-carboxyborane derivatives show promise in reducing serum cholesterol and triglyceride concentrations, in alleviating some forms of chronic arthritis, and as antineoplastic agents (Hall et al. 1994; Newnham 1994). Other boron compounds are used widely as thermal protection materials in space probes, in fireproofing of fabrics and wood, in leather manufacture, in numerous pharmaceuticals and hygiene products, in steel hardening, in deoxidation of bronze, as a high-energy fuel, as neutron-absorbing shielding near atomic reactors, and as water softeners, pH adjusters, emulsifiers, neutralizers, stabilizers, buffers, and viscosifiers (NAS 1980; Parry and Kodama 1980; Schillinger et al. 1982; Siegel and Wason 1986; USPHS 1991).

The major global environmental reservoirs of boron (metric tons) include continental and oceanic crusts (10^{15}), oceans (10^{12}), groundwater (10^8), ice (10^8), coal deposits (10^7), commercial borate deposits (10^7), biomass (10^7), and surface waters (10^5) (Argust 1998). The largest flows of boron in the environment arise from the movement of boron into the atmosphere from the oceans at 1.3 to 4.5×10^6 tons annually. Drainage from soil systems into groundwaters and surface waters accounts for 1.3×10^5 to 1.3×10^6 tons yearly. And boron mining and volcanic eruptions account for 4×10^5 and 2×10^5 tons of boron per annum, respectively (Argust 1998).

Boron enters the environment at about 32,000 metric tons annually in the United States (Table 29.1). Most ends up in the aquatic environment because of the relatively high water solubility of all boron compounds, especially boron-containing laundry products and sewage (USEPA 1975). Conventional sewage treatment removes little or no boron (USEPA 1975; Vengosh 1998). Studies of domestic wastewaters in California and Israel, using boron isotopic composition techniques, show that boron in sewage is derived from sodium borate components used in household detergents (Vengosh 1998). Of the total boron in coal, as much as 71% may be lost to the atmosphere upon combustion. More than 50% of the boron found in coal ash is readily water soluble (Pagenkopf and Connolly 1982). The release of boron from coal flyash to leachate water is dependent on the ash to water ratio: at 1 g ash/L, up to 90% of the boron is soluble; at 50 g/L, only 40% is released; at 100 g/L, less than 30% is released. Coating of coal ash with aluminum solution reduces boron solubility by about 90% due to the formation of an insoluble aluminum–borate complex (Pagenkopf and Connolly 1982).

Table 29.1 Environmental Sources of Domestic Boron

Source	Metric Tons, Annually
Laundry products	14,000
Agricultural chemicals and fertilizers	7000
Coal combustion	4000
Mining and processing	3000
Glass and ceramics	1500
Miscellaneous	2500
Total	32,000

Data from U.S. Environmental Protection Agency (USEPA). 1975. Preliminary Investigation of Effects on the Environment of Boron, Indium, Nickel, Selenium, Tin, Vanadium and Their Compounds. Vol. 1. Boron. U.S. Environ. Protection Agen. Rep. 56/2-75-005A. 111 pp.

Boron compounds listed in the “Commodity List of Explosives and Other Dangerous Articles” are boron trichloride (BCl_3), boron trifluoride (BF_3), decaborane ($\text{B}_{10}\text{H}_{14}$), and pentaborane (B_5H_9) (USEPA 1975). Boron trichloride is a corrosive liquid; the maximum quantity allowed in containers by rail is 1 L, and by air only one container is permitted per aircraft. Boron trifluoride is a nonflammable gas restricted to 140 kg in one outside container by rail, and to 140 kg in cargo planes only. Decaborane is a flammable solid, and transport by rail or air is limited to 12 kg. Pentaborane is a flammable liquid and is prohibited for transport by air or rail. Diborane (B_2H_6) and higher boranes are unstable and are classified as dangerous articles in transport; no more than 0.1 kg can be shipped in a cylinder (USEPA 1975). Organic boron–oxygen compounds readily hydrolyze and should be stored and transferred in an inert atmosphere; usually, glass containers are used for shipping small quantities, and steel containers or tank cars are used for bulk items. Hazardous atmospheric conditions resulting from high concentrations of boron compounds are localized and are not considered a serious environmental problem (USEPA 1975).

29.2.3 Chemical Properties

The element boron has an atomic number of 5, a molecular weight of 10.811, an oxidation state of 3 for simple compounds (but other oxidation states for carboranes and other polyhedral cage boron compounds), a specific gravity of 2.34, a melting point of 2300°C, sublimation at 2550°C, and is almost insoluble in water. Boron exists as B-10 (19.78%) and B-11 (80.22%) isotopes, and it contributes about 0.001% to Earth’s crust, although it does not occur free in nature (USEPA 1975; Smith 1985). The chemistry of boron is exceedingly complex and rivals that of carbon in diversity. Reviews on boron’s chemistry are especially abundant and include those by Steinberg and McCloskey (1964), Brotherton and Steinberg (1970a, 1970b), Greenwood and Thomas (1973), Grimes (1982), Evans and Sparks (1983), Smith (1985), Emin et al. (1986), Heller (1986), Niedenzu and Trofimenko (1986), Hermanek (1987), and USPHS (1991).

Most boron compounds degrade in the environment to B–O (borate) compounds, and these are the boron compounds of ecological significance — especially borax and boric acid (Sprague 1972; Antia and Cheng 1975; Thompson et al. 1976). Sodium tetraborate decahydrate (borax) has a melting point of 75°C, a boiling point of 320°C, and is soluble in water to 20 g/L at 0°C and to 1700 g/L at 100°C (USEPA 1975). Boric acid has a melting point of 169°C, a boiling point of 300°C and, like borax, is exceedingly soluble in water: 63.5 g/L at 30°C and 276 g/L at 100°C (USEPA 1975; USPHS 1991).

Boron exists in several forms in the soil (USEPA 1975); in soil solution, it exists largely as the undissociated weak monobasic acid that accepts hydroxyl groups (Gupta and Macleod 1982). Most plant-available boron in soils is associated with soil organic matter (Gupta and Macleod 1982), with the hot-water soluble boron fraction (Hingston 1986), and with soil solution pH ranges of 5.5 to 8.5 and 10 to 11.5 (Goldberg and Glaubig 1986). It is assumed that boron adsorbs to soil particles and aluminum and iron oxide minerals (Goldberg and Glaubig 1986). Boron mobility in soils is reduced under conditions of pH 7.5 to 9.0, and with high abundance of amorphous aluminum oxide, iron oxide, and organic content (USPHS 1991).

In water, boron readily hydrolyzes to form the electrically neutral, weak monobasic acid H_3BO_3 and the monovalent ion $\text{B}(\text{OH})_4^-$. Waterborne boron may be adsorbed by soils and sediments (USPHS 1991). The predominant boron species in seawater is boric acid (Thompson et al. 1976); concentrations are higher at higher salinities and in proximity to industrial waste discharges (Liddicoat et al. 1983; Narvekar et al. 1983). In seawater, borate or boric acid occurs naturally at 4.5 to 5.5 mg/L. About 76% of the total inorganic boron in seawater occurs as undissociated boric acid [$\text{B}(\text{OH})_3$], and the remainder is identified as the borate ion [$\text{B}(\text{OH})_4^-$]. Of the total borate ion, 44% appears to be complexed with sodium, magnesium, and calcium (Antia and Cheng 1975).

Other evidence suggests additional complexation of borate with ferric ions and polyhydroxylated organic compounds (Antia and Cheng 1975).

Atmospheric boron is in the form of particulates or aerosols of borides, boron oxide, borates, boranes, organoboron compounds, trihalide boron compounds, or borazines. The half-time persistence of airborne boron particles is short, usually on the order of days (USPHS 1991).

Despite the development of sophisticated instrumentation and techniques, the accurate determination of boron in biological materials is difficult at concentrations less than 1 mg B/kg (Downing et al. 1998). Problems associated with analysis of boron from biological sources include contamination from Teflon® vessels during microwave digestion; losses due to freeze drying; variations in boron isotope ratios, standards preparation, and reagent backgrounds; and instrumental interference (Downing et al. 1998). Inductively coupled plasma-mass spectrometry now allows quantitation of percutaneous absorption of ^{10}B in ^{10}B -enriched boric acid, borax, and disodium octaborate tetrahydrate in biological materials (Wester et al. 1998a), although absorption through intact human skin is significantly less than the mean daily dietary intake (Wester et al. 1998b).

29.2.4 Mode of Action

A proposed essential role for boron is as a regulator of enzymatic pathways closely involved with energy substrate metabolism, insulin release, and the immune system. Boron influences the activities of at least 26 enzymes — including reductases, transferases, hydrolases, and isomerases — examined in various biological systems by acting on the enzyme directly and binding to cofactors or substrates (Hunt 1998). The complexing ability of the boron atom is considered to be the key explanation of why it is essential to higher plants (USEPA 1975), although the exact mechanism of action is still unknown. In biological systems, boron probably is complexed with hydroxylated species, and inhibition or stimulation of enzymes and coenzymes is pivotal in its mode of action (Woods 1994). Boron interacts with substances of biological interest, including polysaccharides, pyridoxine, riboflavin, dehydroascorbic acid, and pyridine nucleotides (Sammam et al. 1998). Boron's complexing ability is thought to beneficially influence transport of sugars and other organic compounds, production of plant growth regulators, biosynthesis of nucleic acids and phenolic acid, carbohydrate metabolism, respiration, and pollen germination (USEPA 1975; Nielsen 1986).

Boron poisoning in animals is primarily an experimental phenomenon, although livestock in certain regions may be exposed to high concentrations in drinking water — up to 80 mg B/L — that have not been shown to be toxic (NAS 1980). Toxicosis in humans has resulted from ingestion of boric acid or borax solutions, topical applications of boric acid solutions to burn-damaged skin, and inhalation of boranes (NAS 1980). In mammals, boron is thought to regulate parathyroid function through metabolism of phosphorus, magnesium, and especially calcium. Boron has a close relationship with calcium metabolism, most likely at the cell membrane level (Nielsen 1986). The toxicological effects of boric acid and borax are similar for different species. Other inorganic borates that dissociate to boric acid display similar toxicity, whereas those that do not dissociate to boric acid may display a different toxicological profile (Hubbard 1998).

Dietary boron at nontoxic concentrations, as sodium borate or boric acid, is rapidly and almost completely absorbed from the gastrointestinal tract, does not seem to accumulate in healthy tissues, and is excreted largely in urine, usually within hours, but sometimes as long as 23 days. Similar patterns are evident for humans, dogs, cows, rabbits, rodents, and guinea pigs (NAS 1980; Benson et al. 1984; Nielsen 1986; Siegel and Wason 1986; USPHS 1991; Murray 1998). Urinary boron excretion changes rapidly with changes in boron intake, suggesting that the kidney is the site of homeostatic regulation (Sutherland et al. 1998). Boron does not seem to accumulate in soft tissues of animals, but does accumulate in bone; cessation of exposure to dietary boron resulted in a rapid drop in bone boron, usually within 24 h (Moseman 1994). Boric acid poisoning in animals,

regardless of route of administration, is characterized by the following signs: generalized erythema (boiled lobster appearance) starting in the axillary, inguinal, and face regions, eventually covering the entire body with conjunctival redness, followed by massive desquamation 2 to 3 days later; acute gastroenteritis, including nausea and vomiting; diarrhea; anorexia; cardiac weakness; excessive urinary excretion of riboflavin; decreased oxygen uptake by the brain; hypoacidity; altered enzyme activity levels; impaired growth and reproduction; and death from circulatory collapse and shock, usually within 5 days (Dani et al. 1971; Sprague 1972; USEPA 1975; NAS 1980; Schillinger et al. 1982; Settimi et al. 1982; Siegel and Wason 1986; USPHS 1991).

Boron hydrides or boranes, such as B_2H_6 , B_4H_{10} , and B_5H_9 , from chemical processes produce acute central nervous system (CNS) pulmonary damage and lung disease through inhalation (NAS 1980; Klaassen et al. 1986). Boranes produce toxic effects by creating embolisms of hydrogen gas as they react with tissue, and by depleting biogenic amines of the CNS and inhibiting aminotransferases and other pyridoxol-dependent enzymes (Korty and Scott 1970; USEPA 1975). Boranes produce similar effects in humans and animals, and these are generally ascribable to CNS depression and excitation (Naeger and Leibman 1972; Smith 1985). Symptoms of borane intoxication include pulmonary irritation, headache, chills, fatigue, muscular weakness and pain, cramps, dizziness, chest tightness, and pneumonia (NAS 1980). Boranes may adversely affect male reproductive capacity (Klaassen et al. 1986), but this requires verification. Decaborane ($B_{10}H_{14}$), as one example, is a highly lipid-soluble compound that can enter the body through inhalation, ingestion, or the skin. In water, decaborane is rapidly transformed into intermediate products that are eventually degraded to boric acid. The intermediate products, but not decaborane or boric acid, reduce phosphomolybdic acid and inhibit glutamic-oxaloacetic transaminase; treatment of intermediates with pyridoxol phosphate tends to reverse the inhibitory activity (Naeger and Leibman 1972). Low decaborane doses cause behavioral effects such as depression, catatonia, and convulsions (USEPA 1975).

Inorganic borates are comparatively toxic, apparently complexing hydroxy compounds and interfering with protein synthesis (USEPA 1975). Organoborate compounds exert physiological effects on the CNS and peripheral nervous system, acting as spasmolytics, sedatives, and convulsants, depending on their structure (USEPA 1975). Boron trihalides such as BBr_3 , BCl_3 , and BF_3 are corrosive to the eyes, skin, and mucous membranes, and will cause burns on the skin — apparently due to the hydrolysis of the trihalides to their halogen acids, and not to boron (USEPA 1975; Smith 1985).

Boron is a potent teratogen when applied directly to the embryo. Boric acid injected into chicken and amphibian embryos produced abnormal development of the neural tube, notochord, tail, and limbs, perhaps through complexing polyhydroxy compounds and interfering with riboflavin metabolism (Landauer 1952, 1953a, 1953b, 1953c; Landauer and Clark 1964; USEPA 1975; Settimi et al. 1982). Boron and its compounds, however, are neither mutagenic nor carcinogenic (Landolph 1985; Dieter 1994). Nonmutagenicity is based on results of the *Salmonella typhimurium*-mammalian microsome mutagenicity assay; boron neither enhances nor inhibits the activity of benzo[*a*]pyrene, a known mutagen (Anonymous 1983; Benson et al. 1984). There is no evidence that boron is a possible carcinogen, although long-term, selective uptake of boron by tumors has been reported (USEPA 1975).

Boron seems to have an affinity for cancerous tumors, and this property has been exploited in radiation therapy (Hamada et al. 1983; Hatanaka 1986). Boron-10 has been used in neutron capture therapy to cure malignant sarcomas implanted in the hind legs of mice, as well as spontaneous malignant melanomas in pigs (Slatkin et al. 1986). The sulfhydral borane monomer ($B_{12}H_{11}SH$)²⁻ is used as a B-10 carrier in neutron therapy of malignant human brain tumors and seems to be most effective at 30 µg B-10/kg tissue (Hatanaka 1986). Polyhedral boranes attached to monoclonal antibodies that are tumor specific may become useful in tumor therapy by neutron irradiation (Parry

and Kodama 1980). It is possible, however, that uptake of boron may be a nonspecific attribute of tumors and of a variety of normal tissues that lack a blood-brain barrier. Thus, the potential usefulness of selected B-10 carriers for treating extracranial neoplasms seems questionable at this time (Slatkin et al. 1986).

29.3 CONCENTRATIONS IN FIELD COLLECTIONS

29.3.1 General

Terrestrial plants are normally rich sources of boron. Levels in meat and fish are usually low. But these generalizations are based on limited data. Boron is ubiquitous in the environment as a result of natural weathering processes (Woods 1994). However, human activities such as mining, coal burning, and use of borax laundry detergents have resulted in elevated boron loadings in air, water, and soils (USPHS 1991). Comparatively high levels of boron occur in fish, aquatic plants, and insects at Kesterson National Wildlife Refuge that was contaminated by agricultural drainwater (Hothem and Ohlendorf 1989; Eisler 1990). The availability of inductively coupled plasma-mass spectrometry (ICP-MS) technology enables measurement of boron concentrations and isotope ratios in a large number of biological samples with minimal sample preparation at detection limits of 0.11 µg/L (Vanderpool et al. 1994).

29.3.2 Nonbiological Materials

Boron is distributed widely in the environment (Ahl and Jonsson 1972; USEPA 1975). Naturally elevated boron levels are usually associated with marine sediments, thermal springs, large deposits of boron minerals, seawater, and certain groundwaters ([Table 29.2](#)). Human activities, however, have resulted in elevated boron concentrations near coal-fired plants, in mine drainage waters, in municipal wastes, and in agricultural drainage waters. In one case, agricultural drainwater practices in western California produced boron concentrations in local rivers, groundwaters, and surface waters that exceeded the established limits for the protection of crops and aquatic life (Schuler 1987; Klasing and Pilch 1988; [Table 29.2](#)). Contamination of pristine groundwaters (<0.05 mg B/L) by domestic wastewater and agriculture-return flows (0.5 to 1.0 mg B/L) is documented by the isotopically distinguished signature of borate compounds. For example, in areas where calcium borates are applied as fertilizers, the B¹¹/B¹⁰ ratios of the soil water and leachates are expected to be low and can be used as diagnostic tools for tracing agriculture-return flows (Vengosh 1998).

Coal-fired power plants are major sources of atmospheric boron contamination. At least 30% of boron in coal is lost in this manner (Cox et al. 1978; Gladney et al. 1978). The apparently large amounts of boron lost to the environment through stack emissions may be directly related to the organic content of coal ([Table 29.2](#)) (Gladney et al. 1978). Also, disposal of B-laden drainage waters from boron mines is a major problem in certain geographic areas. In Turkey, for example, which possesses about 60% of the world's boron reserves — localized in a rectangular area about 100 × 200 km near the Simav River — drainage waters discharged from the mines as a result of borate production have elevated boron concentrations in the Simav River to levels unsuitable for crop irrigation purposes. About 68,000 ha of agricultural land irrigated by the Simav River is now threatened by boron pollution (Okay et al. 1985). In the United States, laundry detergents originating from household use may contribute as much as 50% of the boron loadings in effluents discharged into aquatic environments; lesser amounts are contributed by soil minerals, rainfall, and industry and sewage effluents (USEPA 1975).

29.3.3 Plants and Animals

Boron accumulates in both aquatic and terrestrial plants but it does not seem to biomagnify in the food chain (Howe 1998). Boron does not biomagnify in aquatic food chains and has low potential to accumulate in aquatic organisms, as judged by studies in the San Joaquin River, California, and its tributaries (Saiki et al. 1993). Marine and freshwater plants, fishes, and invertebrates concentrated boron from the medium by factors of less than 100, suggesting that biota is not a significant removal mechanism of boron from water (USPHS 1991). Boron concentrations in livers of birds collected from Baja California, Mexico, in 1986 were highest in the seed-eating mourning dove *Zenaida macroura* (maximum 28.5 mg B/kg FW) and lowest (maximum 8.7 mg B/kg FW) in fish-eating and omnivorous species (Mora and Anderson 1995).

Boron occurred at high concentrations in plants, insects, and fish at Kesterson National Wildlife Refuge in California — the recipient of contaminated agricultural drainwater — when compared to a nearby control area (Table 29.3) (Ohlendorf et al. 1986; Schuler 1987). The authors indicated that little is known about the effect of boron ingestion on bird reproduction, although both boric acid and borax produced mortality and teratogenic development when injected into eggs. Studies on the effects of boron on waterfowl growth, physiology (Hoffman et al. 1990), and reproduction (Smith and Anders 1989) are discussed later.

Terrestrial plants, especially nuts and some fruits and vegetables, are rich sources of boron (Table 29.3). Honey is another good source of boron, and concentrations up to 7.2 mg/kg dry weight have been reported (Nielsen 1986). Boron concentrations are also elevated in marine plants, zooplankton, and corals, but are low in fish and certain marine invertebrates (Table 29.3). No data were found on boron levels in terrestrial mammalian wildlife. The average daily intake of boron in humans ranges between 1 and 25 mg; however, populations residing in areas of the western

United States with natural boron-rich deposits may be exposed to higher-than-average levels of boron (USPHS 1991). Boron intake from drinking water is highly variable and dependent on the geographic source, the quantity of water consumed, and the water sources used to bottle other beverages (Coughlin 1998). Current estimates of boron in domestic diets for normal human adults is about 1 mg daily; however, toddlers age 2 years consumed 3.7 times more boron than mature males when adjusted for body weight (Meacham and Hunt 1998). There is great variability in the human diet, and people from different countries have different sources of dietary boron. In the United States, for example, major sources of dietary boron include coffee, milk, orange juice, peanut butter, wine, pinto beans, and other juices and fruits. By contrast, in Mexico and Kenya, major sources of dietary boron include corn, kidney beans, maguey (an alcoholic drink from fermented bananas), cactus, and mangoes (Rainey and Nyquist 1998). In rats, increasing concentrations of boron in drinking water were associated with increasing tissue boron concentrations, plasma testosterone, and Vitamin D, and a decrease in HDL cholesterol (Samman et al. 1998). Data for humans and domestic animals indicate that boron levels are elevated in bony tissues, but are always less than 0.6 mg B/kg fresh weight or 1.5 mg/kg dry weight in other tissues examined (Table 29.3).

29.4 EFFECTS

29.4.1 General

Boron is essential for the growth of higher plants and has been applied to boron-deficient soils for at least 50 years to improve yields of many crops. Phytotoxic levels of boron usually occur as a result of human activities, such as boron-contaminated irrigation waters and excess applications of boron-rich fertilizers, sewage sludges, and flyashes. Boron compounds at comparatively high concentrations are used to control pestiferous insects through direct biocidal action, enhancement of disease sensitivity, or use as a chemosterilant.

Representative species of aquatic plants, invertebrates, fishes, and amphibians can usually tolerate up to 10 mg B/L medium for extended periods without adverse effects, although it has been suggested that concentrations greater than 0.1 mg B/L may ultimately affect reproduction in rainbow trout (*Oncorhynchus mykiss*), and greater than 0.2 mg/L may impair survival of other fish species. In waterfowl, diets that contain 30 or 100 mg B/kg fresh weight adversely affect growth rate. Elevated tissue residues were recorded in ducks fed diets containing between 100 and 300 mg B/kg, and reduced survival occurred at dietary levels of 1000 mg B/kg. Boron is a potent avian teratogen when injected directly into embryos during the first 96 h of development. In mammals, the lethal dose of boron, as boric acid, varies according to species, and usually ranges between 210 and 603 mg B/kg body weight (BW); early development stages are especially sensitive. Excessive boron consumption adversely affects growth and reproduction in sensitive species of mammals (i.e., >1000 mg B/kg diet, >15 mg B/kg BW daily, >1.0 mg B/L drinking water, or >3 g B/kg BW single dose on the first day of pregnancy). Boron is not considered essential for mammalian growth but does protect against fluorosis and bone demineralization.

29.4.2 Terrestrial Plants

Boron was accepted as being an essential micronutrient for higher plants in 1923, with toxicity owing to excess boron much less common in the environment than boron deficiency (Howe 1998; Samman et al. 1998). The role of boron in nutrition and toxicity of terrestrial crops and forest trees has been reviewed extensively by Eaton (1944), USEPA (1975), Gupta (1979, 1983), Gupta and Macleod (1982), Pilbeam and Kirkby (1983), Gupta et al. (1985), Eisler (1990), and Stone (1990). It is generally agreed that boron is essential for the growth of higher plants and some species of fungi, bacteria, and algae, and that excess boron is phytotoxic. It is also agreed that plants vary greatly in their sensitivity to B toxicity (Boyd and Walley 1972; USEPA 1975; Birge and Black 1977; Goldberg and Glaubig 1986; Dear and Lipsett 1987; USPHS 1991). The exact mode of action of boron is unknown; however, its complexing ability facilitates the movement of sugars and other materials, and it is involved in cell wall bonding, conversion of glucose-1-phosphate to starch, and metabolism of nucleic acids (Sprague 1972; Gupta et al. 1985; Goldbach and Amberger 1986). Blevins and Lukaszewski (1994) suggest that boron toxicity to plants is attributed, in part, to interactions between borates and divalent cations like manganese, resulting in altered metabolic pathways of allantoate aminohydrolase in the case of manganese. The boron level in plants depends on the content and availability of soil boron, season, disease state, inherent species or variety

differences, and interactions with other substances (USEPA 1975; Gestring and Soltanpour 1987). Most of the plant-available boron comes from the decomposition of soil organic matter and from boron adsorbed and precipitated onto soil surface particles. However, soil solution boron is the most important form, and plants take it up directly from this source (Gupta et al. 1985). Boron availability to plants is strongly associated with the hot-water-soluble fraction. This usually ranges from 0.4 to 4.7% of the total boron. The highest percentage occurs in fine-textured soils, and the lowest occurs in coarse-textured soils (Gupta and Macleod 1982). Uptake of boron by plants is about 4 times higher at pH 4 than at pH 9, highest in the temperature range 10 to 30°C, and higher with increased light intensity (Sprague 1972).

For the past 60 years, boron has been applied to B-deficient soils to improve crop yields of grains, fruits, vegetables, legumes, pine trees, tobacco, cotton, sunflowers, and peanuts (USEPA 1975; Gupta 1979; Lipsett et al. 1979; Shorrocks and Nicholson 1980; Hopmans and Flinn 1984; Gupta and Cutcliffe 1985; Willett et al. 1985; Combrink and Davies 1987; Dear and Lipsett 1987; Mozafer 1987; Nuttall et al. 1987; Rerkasem et al. 1988; Stone 1990). Boron is unique among the essential micronutrients because it is the only element normally present in soil solution as a non-ionized molecule over the pH range suitable for plant growth (Gupta 1979). Boron deficiency in plants is widespread and has been reported in one or more crops in at least 43 states, almost all Canadian provinces, and many other countries (Gupta 1979). Boron deficiency in crops is more widespread than that of any other micronutrient (Gupta et al. 1985). It is more likely to occur in light-textured acid soils in humid regions because of boron's tendency to leach. However, deficiency may also occur in heavy-textured soils with high pH because boron is readily adsorbed under these conditions (Gupta et al. 1985). Deficiency signs include browning and spotting of leaves, chlorosis, abnormal thickening of cell walls, increased production of indoleacetic acid, accumulation of polyphenolic compounds, changes in membrane permeability, necrosis, and finally death (USEPA 1975; Gupta 1979). Visible signs of deficiency in corn are accentuated by calcium deficiency, and are least evident when calcium is added to excess. Under conditions of boron and calcium deficiency combined, yields are low, and starch phosphorylase activity in corn leaves increases markedly, as does that of ribonuclease and polyphenol oxidase (Chatterjee et al. 1987). Interaction effects were also measured between boron and potassium in alfalfa (Walker et al. 1987). Boron deficiency is usually corrected by application of 0.5 to 3 kg B/ha, depending on crop and formulation (Gupta 1979). Adding boron promotes translocation rate of photosynthetic products and increases CO₂ incorporation into free amino acids (Gupta 1979).

Boron toxicity has been reported in many species of grasses, fruits, vegetables, grains, trees, and other terrestrial plants (Gupta and Macleod 1982; Dye et al. 1983; Glaubig and Bingham 1985; Francois 1986; Nicholaichuk et al. 1988; Stone 1990) ([Table 29.4](#)). Toxic levels generally do not occur on agricultural lands unless boron compounds have been added in excessive quantities, such as with fertilizer materials, irrigation water, sewage sludge, or coal ash (Gupta and Macleod 1982; Gestring and Soltanpour 1987). Boron-contaminated irrigation water is one of the main causes of boron toxicity to plants. The continued use and concentration of boron in the soil due to evapotranspiration is the reason for eventual toxicity problems (Gupta et al. 1985). Borates have also been used as herbicides for complete kill of vegetation at application rates of 2244 kg/ha (equivalent to 2000 pounds/acre) (Sprague 1972). Borates are frequently applied at elevated concentrations (i.e., >2 g/kg soil) in combination with organic pesticides in order to produce bacteriostatic effects. The resultant B-produced reduction in microbial degradation of the pesticide effectively extends the pesticide's biocidal properties (Sprague 1972). In some cases, cooling tower drift from geothermal steam containing boron may cause foliar boron toxicity in the vicinity of generating units (Glaubig and Bingham 1985; Sage et al. 1989).

Boron poisoning in plants is characterized by stunted growth, leaf malformation, browning and yellowing, chlorosis, necrosis, increased sensitivity to mildew, wilting, and inhibition of pollen germination and pollen tube growth (USEPA 1975; Glaubig and Bingham 1985; Mitchell et al. 1987).

In barley (*Hordeum vulgare*), for example, excess boron caused decreased growth and grain yield, elevated residues in leaves, and increased rate of leaf senescence (Riley 1987; [Table 29.4](#)). Barley grown on zinc-deficient soils tended to accumulate boron up to 2.5 times within 7 days; a similar pattern was evident for excess phosphorus (Graham et al. 1987). Thus, under conditions of marginally high boron in the rooting zone, low zinc, and high phosphorus, boron may accumulate to toxic levels in plants (Graham et al. 1987). Toxic effects in plants — including leaf injury — were observed in 26% of plants at or below substrate concentrations that resulted in greatest growth, indicating considerable overlap between injurious and beneficial effects of boron in plants (Eaton 1944). In general, deficiency effects in plants were evident when boron concentrations in soil solution were <2 mg/L; optimal growth occurred at 2 to 5 mg/L; and toxic effects were evident at 5 to 12 mg B/L (Gupta et al. 1985). However, there is considerable variation in resistance to boron between species ([Table 29.5](#)). Sensitive species are known to include citrus, stone fruits, and nut trees; semitolerant species include cotton, tubers, cereals, grains, and olives; tolerant species usually include most vegetables (Gupta et al. 1985).

Table 29.4 Boron Toxicity to Some Terrestrial Plants

Species, Dose, and Other Variables	Effect (Reference ^a)
BIGLEAF MAPLE, <i>Acer macrophyllum</i> 0.9–5.4 mg B/L, in saturated soil extracts	Reduced growth; >25% foliar damage; leaf residues of 76–324 mg B/kg ash weight (1)
MADRONE, <i>Arbutus menziesii</i> 2.2–5.4 mg B/L, in saturated soil extracts	Growth inhibition; >25% foliar damage; leaf residues of 216–540 mg B/kg ash weight (1)
BEET, <i>Beta vulgaris</i> Soil B solutions 5 mg/L 15 mg/L	Optimal growth (2) Injury evident (2)
BROCCOLI, <i>Brassica oleracea italica</i> Grown in nutrient solutions containing 0.08 mg B/L 4.1 and 8.1 mg B/L	Chlorophyll levels and net photosynthetic rates were significantly lower than those grown in 0.41–0.81 mg B/L solutions (3) Leaf damage evident; lower chlorophyll levels and lower net photosynthetic rate than 0.4 and 0.8 mg B/L groups (3)
RHODES GRASS, <i>Chloris gayana</i> Grown in flyash containing 3 mg hot-water-soluble B/L	Toxic. Residues >149 mg/kg DW (4)
LEMON, <i>Citrus limonia osbeck</i> Soil B concentrations 0.03–0.04 mg/L 1 mg/L	Optimal growth (2) Injury evident (2)
SOYBEAN, <i>Glycine max</i> Grown in soils amended with scrubber sludge residues (4.1 g B/kg) from coal-fired power plant for 2–3 years	Higher sludge B levels of 2 mg B/kg soil surface at year 1, and 1.2 mg B/kg at year 2 produced signs of B toxicity, including decreased growth and elevated residues (>83 mg/kg DW) in leaf and (>47 mg/kg DW) in seeds (5)
SUNFLOWER, <i>Helianthus annuus</i> 50 mg B/L growth medium 10 mg B/L growth medium	Adversely affects phospholipid composition and synthesis in roots and microsomes from seedlings by inhibition of choline phosphotransferase (6) Tolerated level (6)
BARLEY, <i>Hordeum vulgare</i> Residues, in mg B/kg DW 0.5–1.0 in soil 30 in shoots 50–70 in shoots 60–80 in leaf 80–120 in shoots 120–130 in shoots	Residues of 46–100 mg/kg DW in leaves (7) Damage to older leaves (8) Reduction of 10% in dry weight of shoots (7) Toxicity evident (8) Toxic signs, but no yield reductions (8) Grain yield reduced 10% (8)

Table 29.4 (continued) Boron Toxicity to Some Terrestrial Plants

Species, Dose, and Other Variables	Effect (Reference^a)
ALFALFA, <i>Medicago sativa</i> 850–975 mg B/kg dry weight plant	Reduced yield (9)
RICE, <i>Oryza sativa</i> Whole plant B residues 38 mg/kg DW 43–55 mg/kg DW	No signs of toxicity (10) Signs of toxicity evident (10)
Soil waters 2.5–5 mg B/L	Toxic (10)
FRENCH BEAN, <i>Phaseolus vulgaris</i> Grown in flyash containing 3 mg hot-water-soluble B/L	Toxic. Residues >209 mg/kg DW (4)
Residues in whole plant, in mg B/kg dry weight 9–12 >125	Slow flowering and pod formation; general yellowing of tips (11) Reduced growth; burned older leaves dark brown (11)
DIGGER PINE, <i>Pinus sabiniana</i>, seedlings 13–17 mg B/L in saturated soil extracts	Growth reduction; foliar damage >25%; needle residues 1242–1512 mg B/kg ash weight (1)
PEAR, <i>Pyrus communis</i> 82–164 kg B/ha applied to soil around pear trees in a nonirrigated orchard over a 6-year period	Toxicity observed during application and during 4 years postapplication. Toxicity was associated with residues, in mg B/kg DW, of 90–115 in blossom clusters and 45–55 in fruit. Within 5 years postapplication, soil B levels were <2 mg/kg, and all visible signs of toxicity had disappeared (12)
VEGETATION, various species 2244 kg borates/ha (2000 lbs/acre)	Total kill of most species (2)
CORN, <i>Zea mays</i> Soil B concentrations 1 mg/L 5 mg/L	Optimal growth (2) Injury evident (2)
Plant residues >98 mg B/kg DW	Marginal burning and dark brown tips of older leaves (11)

^a 1, Glaubig and Bingham 1985; 2, Sprague 1972; 3, Petracek and Sams 1987; 4, Aitken and Bell 1985; 5, Ransome and Dowdy 1987; 6, Belver and Donaire 1987; 7, Riley 1987; 8, Kluge and Podlesak 1985; 9, Gestring and Soltanpour 1987; 10, Cayton 1985; 11, Gupta 1983; 12, Crandall et al. 1981.

Table 29.5 Boron Concentrations in Soil Water Associated with Optimal Growth and Plant Injury

Plant Category	Boron Concentration in Soil Water (mg/L)	
	Optimal Growth	Plant Injury
Sensitive species	Trace–1	Usually 1–5
Semitoriental species	Usually 1–5	Usually 5–15
Tolerant species	Usually 5–10	Usually 5–25

Data from Sprague, R.W. 1972. The ecological significance of boron. United States Borax and Chemical Corp., Los Angeles, 58 pp.

29.4.3 Terrestrial Invertebrates

Relatively high concentrations of boron compounds are used to control fruitflies, cockroaches, gypsy moth larvae, houseflies, and woodboring insects (Sprague 1972; USEPA 1975; Table 29.6). Boric acid is an effective stomach poison for several insect species, including German cockroaches (*Blattella germanica*), that are unable to detect the presence of boric acid (USEPA 1975). Insect infestation of wood and other substrates can be prevented by pretreatment with boric acid or borax at

Table 29.6 Lethal and Sublethal Effects of Boron on Terrestrial Invertebrates

Organism, Dose, and Other Variables	Effect (Reference ^a)
FRUITFLY, <i>Anastrepha ludens</i> Baits containing cottonseed hydrolysate and borax	Reduced infestation in oranges by 68%, and in mangoes by 98% (1)
HONEY BEE, <i>Apis mellifera</i> 8.7 mg B/L syrup (50 mg boric acid/L) 17.5 mg B/L syrup (100 mg boric acid/L)	No effect on survival (2) Fatal to about 50% (2)
GERMAN COCKROACH, <i>Blattella germanica</i> Baits containing 25% boric acid plus honey	Population reduction of 50% in about 5 days, 80% in 4 weeks, and 98% in 6–9 months (3)
Sugar diet containing 11% boric acid 25% boric acid 50% boric acid 100% boric acid	44% dead in 72 hours (1) 79% dead in 72 hours (1) 80% dead in 72 hours (1) 91% dead in 72 hours (1)
Baits containing 20% boric acid	88% population reduction in 2 weeks; 92 to 95% reduction in 4–12 weeks (4)
GYPSY MOTH, <i>Lymantria dispar</i>, larvae 0.25% boric acid solution (436 mg B/L) 0.5% boric acid 1% boric acid	No effect on gypsy moth nucleopolyhedrosis virus (NPV) (5) Enhanced NPV activity by 2-fold (5) Enhanced NPV activity by 11-fold (5)
HOUSEFLIES, <i>Musca domestica</i> 250–5000 mg B/kg diet, as boric acid Isobornyl thiocyanoacetate 27.3 µg/fly Aerosols, >2%	Inhibits reproduction (2) LD50 (1) 50% knockdown in 6 minutes (1)
AMERICAN COCKROACH, <i>Periplaneta americana</i> Baits containing 1.5% boric acid	All dead in 6 days (6)
WOODBORING INSECTS Common houseborer 430 mg boric acid/m ³ wood	Adequate wood protection (2)
Termites, 3 species >10,000 mg boric acid/m ³ wood	Required for wood protection (2)

^a 1, USEPA 1975; 2, Sprague 1972; 3, Gupta and Parrish 1984; 4, Wright and Dupree 1982; 5, Shapiro and Bell 1982; 6, Lizzio 1986.

doses of 0.25 to 0.55 kg/m³ of wood (USEPA 1975). Boric acid and other boron compounds are effective chemosterilants of the cotton boll weevil (*Anthonomus grandis*) and houseflies (USEPA 1975).

29.4.4 Aquatic Organisms

Boron effects on aquatic plants are highly species specific (Glandon and McNabb 1978; Rao 1981) (Table 29.7). Borate, like silicate, is an essential micronutrient for the growth of aquatic plants, such as diatoms, and it seems that a chemical combination of both nutrients in the form of silicoborate may be required by certain diatoms (Antia and Cheng 1975). In aquatic plants, boron affects nucleic acid metabolism, carbohydrate biosynthesis and transport, and membrane integrity, and it interacts with growth substances (Frick 1985). Diatoms (*Cylindrotheca fusiformis*) cultured under B-deficient conditions stop dividing and swell in size despite increased photosynthetic rates. Boron-deficient diatoms accumulate rubidium, phenolic compounds, nitrates, and phosphates, and they show increased activity of various enzymes, especially glucose-6-phosphate dehydrogenase. However, respiratory adjustment is negligible until nutrient stress becomes irreversible in about 48 h (Smyth and Dugger 1980, 1981). Boron, under conditions of excess, alleviates nutrient deficiency in some phytoplanktoners and can cause temporal variations of phytoplankton composition

in coastal waters (Rao 1981). Phytoplankton can tolerate up to 10 mg inorganic B/L in the absence of stress from pH adversity and nutrient deficiency, although higher borate concentrations up to 100 mg/L are expected to cause species redistribution by favoring the growth of some species and suppressing that of others (Antia and Cheng 1975; Table 29.7).

Available data for aquatic invertebrates and boron suggest that the no-observable-effect levels were 13.6 mg B/L for freshwater organisms and 37 mg B/L for marine biota (Table 29.7). Juvenile Pacific oysters (*Crassostrea gigas*) accumulated boron in relation to availability, but showed no prolonged retention following cessation of exposure (Thompson et al. 1976). At industrial discharge levels of about 1.0 mg B/L, no hazard is apparent to oysters and aquatic vertebrates (Thompson et al. 1976).

Boron may be an essential nutrient in several species of aquatic vertebrates. Insufficient boron (<3 µg B/L; 62 µg B/kg ration) interfered with the normal development of the South African clawed frog (*Xenopus laevis*) during organogenesis, and substantially impaired normal reproductive function in adult frogs (Fort et al. 1998). Impaired growth of rainbow trout (*Oncorhynchus mykiss*) embryos was documented at <90 µg B/L, and death of zebrafish (*Brachydanio rerio*) embryos at <2 µg B/L (Rowe et al. 1998).

The most sensitive aquatic vertebrates tested for which data are available were coho salmon (*Oncorhynchus kisutch*), with an LC50 (16-day) value of 12 mg B/L in seawater, and sockeye salmon (*O. nerka*), showing elevated tissue residues after exposure for 3 weeks in seawater containing 10 mg B/L (Table 29.7). Boron concentrations between 0.001 and 0.1 mg/L had little effect on survival of rainbow trout embryos after exposure for 28 days (Table 29.7). These low levels may represent a reduction in reproductive potential of rainbow trout, and concentrations more than 0.2 mg B/L may impair survival of other fish species, according to Birge and Black (1977). However, additional data are needed to verify these speculations. Birge and Black (1977) reported that concentrations of 100 to 300 mg B/L killed all species of aquatic vertebrates tested, that embryonic mortality and teratogenesis were greater in hard water than in soft water, but that larval mortality of fish and amphibians was higher in soft water than in hard water, and that boron compounds were more toxic to embryos and larvae than to adults. Moreover, they found no measurable effect on boron toxicity to aquatic vertebrates in water temperature in the range of 13 to 29°C, dissolved oxygen between 6.4 and 10.3 mg/L, and pH between 7.5 and 8.5. Elevated boron concentrations of 50 to 100 mg B/L adversely affects the development of amphibian embryos (Laposata and Dunson 1998). In central Pennsylvania ponds, embryos from two species of salamanders (spotted salamander, *Ambystoma maculatum*; Jefferson salamander, *Ambystoma jeffersonianum*), the wood frog (*Rana sylvatica*), and the American toad (*Bufo americanus*) were exposed to wastewater effluents of 0, 50, or 100 mg B/L. At 50 and 100 mg B/L, there were significant increases in the frequency of deformed larvae and reduced hatching success (Laposata and Dunson 1998).

Table 29.7 Lethal and Sublethal Effects of Boron on Aquatic Organisms

Taxonomic Group, Organism, Compound, Dose, and Other Variables	Effect	Reference ^a
AQUATIC PLANTS		
Blue-green alga, <i>Anacystis nidulans</i> , boric acid, H_3BO_3 0.01–4.0 mg B/L	Grows well in B-deficient media; growth neither stimulated nor inhibited at higher levels	1, 15
50 mg B/L	No effect on growth or organic constituents	2
75–100 mg B/L	Growth and chlorophyll content reduced; at 72 hours, photosynthetic pigments depleted	2
100 mg B/L	Decrease in protein content causing inhibition in nitrate uptake and nitrate reductase activity. Decreased chlorophyll content and photosynthesis inhibition within 72 h	2, 15

Table 29.7 (continued) Lethal and Sublethal Effects of Boron on Aquatic Organisms

Taxonomic Group, Organism, Compound, Dose, and Other Variables	Effect	Reference ^a
Green alga, <i>Chlorella pyrenoidosa</i> , boric acid 10 mg B/L	No effect on growth or cell composition. Bioconcentration factor (BCF) of 4 after 7 days	3
50 mg B/L	BCF of 5 after 7 days	3
50–100 mg B/L	Altered cell division and amino acid activity after 72 h; reversible photosynthesis inhibition. Giant cells formed with increased nitrate and protein	4
100 mg B/L	BCF of 4.8 after 7 days	3
>100 mg B/L	100% inhibitory for cell division and biomass synthesis in 72 h	4
Duckweed, <i>Lemna minor</i> , boric acid Control media, 10–20 mg B/L, pH 5.0	Normal growth	5
100 mg B/L, pH 5.0	Growth inhibited; recovery on transfer to control media	5
20 mg B/L, pH 4.0	Residues of 93 mg B/kg FW vs. 63 in controls	5
20 mg B/L, pH 7.0	Growth inhibited. Residues of 257 mg/kg FW vs. 49 in controls	5
Marine algae, 19 species, boric acid 5–10 mg B/L	No inhibitory effect on growth rate in 60 days; stimulatory to some species	6
10–50 mg B/L	Prolonged survival of peak populations of certain diatoms after growth cessation: <i>Bellerochea polymorpha</i> at 10 mg B/L, <i>Skeletonema costatum</i> at 50 mg B/L	6
50 mg B/L	Growth inhibition in 26% of species tested; adaptation and recovery by most species	6
100 mg B/L	Growth inhibition in 12 of 19 species tested; 8 species did not recover and died	6
Marine phytoplankton 30 mg B/L, high nitrates, phosphates, silicates, and low temperatures	Increased primary production and carbon assimilation	7
30 mg B/L, low nutrients, high temperatures	Photosynthesis inhibited up to 62%	7
30 mg B/L, unicellular cultures, 5-days-old	Photosynthesis inhibition	7
As above, 14-days-old	Enhanced photosynthesis in certain species	7
INVERTEBRATES		
Sea urchin, <i>Anthocidaris crassispina</i> , embryos, boric acid 37 mg B/L	Normal development	8
75 mg B/L	Fatal	8
Chironomid, <i>Chironomus decorus</i> , fourth instar 20 mg/L	Growth rate reduced in 96 h	21
1376 mg/L	LC50 (48 h)	21
Cladoceran, <i>Daphnia magna</i> 6.4 mg B/L	Highest concentration tested in 21-day exposure producing no measurable effect	9, 10
13.6 mg B/L	Lowest concentration tested in 21-day exposure causing reduction in number of broods, total young produced, mean brood size, and mean size	9, 10
27 mg B/L	LC14 (21 days)	10
53 mg B/L	LC50 (21 days)	10
54–200 mg B/L	No deaths in 48 h	9, 10
106 mg B/L	LC100 (21 days)	10

Table 29.7 (continued) Lethal and Sublethal Effects of Boron on Aquatic Organisms

Taxonomic Group, Organism, Compound, Dose, and Other Variables	Effect	Reference ^a
115–246 mg B/L	LC50 (48 h)	9, 10, 21
420 mg B/L	LC100 (48 h)	9
Mosquito larvae, 3 species, boric acid, mg/L		
250 (43.7 mg B/L)	LC97–LC99 through hatching	11
4000 (700 mg B/L)	LC100 (48 h), freshly-hatched	11
3000 (524 mg B/L)	LC100 (48 h), second instar	11
10,000 (1748 mg B/L)	LC100 (48 h), third instar	11
16,000 (2797 mg B/L)	LC100 (48 h), pupae	11
VERTEBRATES		
Amphibians; 3 species; eggs; exposed to 0, 50 or 100 mg B/L		
Jefferson salamander, <i>Ambystoma jeffersonianum</i> ; spotted salamander, <i>Ambystoma maculatum</i> ; wood frog, <i>Rana sylvatica</i>	At 50 and 100 mg B/L, there was a significant increase in frequency of deformed larvae	23
American toad, <i>Bufo americanus</i>	Reduced hatching success at 100 mg B/L	23
Zebrafish, <i>Brachydanio rerio</i> ; exposed for 6 months from embryos to adults		
0.002 mg/L	Embryonic death	25
>9.2 mg/L	Adult death	25
Fowler's toad, <i>Bufo fowleri</i> , embryos, through day 4 posthatch		
Boric acid		
Soft water, 50 mg CaCO ₃ /L		
25 mg B/L	LC1 (7.5 days)	12
145 mg B/L	LC50 (7.5 days)	12
Hard water, 200 mg CaCO ₃ /L		
5 mg B/L	LC1 (7.5 days)	12
123 mg B/L	LC50 (7.5 days)	12
Toad, <i>Bufo vulgaris</i> , embryos		
874 mg B/L, as boric acid. Exposure for 24 h from 2-cell stage to tailbud stage	Malformations included edema, microcephalia, short tail, and suppressed forebrain development	11
Goldfish, <i>Carassius auratus</i> , embryos, through day 4 posthatch		
Boric acid		
Soft water		
0.6 mg B/L	LC1 (7 days)	12
46 mg B/L	LC50 (7 days)	12
Hard water		
0.2 mg B/L	LC1 (7 days)	12
75 mg B/L	LC50 (7 days)	12
Borax, Na ₂ B ₄ O ₇ ·10H ₂ O		
Soft water		
1.4 mg B/L	LC1 (7 days)	12
65 mg B/L	LC50 (7 days)	12
Hard water		
0.9 mg B/L	LC1 (7 days)	12
59 mg B/L	LC50 (7 days)	12
Endangered fishes, three species, Green River, Utah; boron tested as boric acid		
Bonytail, <i>Gila elegans</i>		
280 (226–347) mg B/L	LC50 (96 h), fry	17
552 (452–707) mg B/L	LC50 (96 h), juveniles	17
Colorado squawfish, <i>Ptychocheilus lucius</i>		
279 (216–360) mg B/L	LC50 (96h), fry	17
527 (430–667) mg B/L	LC50 (96 h), juveniles	17

29.4.5 Birds

Boron stimulated growth in Vitamin D₃-deficient chicks. Supplemental dietary boron alleviated or corrected cholecalciferol deficiency-induced elevations in plasma glucose concentrations in chicks (Hunt 1994). There is no need to supplement the diets of laying hens with boron, provided that basal diets contained about 11 mg B/kg ration (Qin and Klandorf 1991).

Boron is a potent teratogen to domestic chicken embryos when injected into eggs. Injection of boron into the yolk sac of chicken embryos during the first 96 h of development with 1.0 to 2.5 mg of boric acid — equivalent to 3.2 to 8.0 mg B/kg fresh weight egg (55 g egg) — produced a wide range of developmental abnormalities (Table 29.8). Several compounds are known to counteract B-induced avian developmental abnormalities, or to reduce the frequency of malformations, although the mode of action is unclear. These compounds include sodium pyruvate, to counteract rumplessness (Landauer 1952); nicotinamide, to decrease frequency of facial defects (Landauer 1952) and melanin formation (Landauer 1953c); and riboflavin, which greatly reduced the teratogenic effects of boric acid (Landauer 1952, 1953a, 1953b; Landauer and Clark 1964). Other polyhydroxy compounds, such as D-ribose, pyridoxine hydrochloride, and D-sorbitol hydrate, also reduced or abolished boric acid-induced teratogenicity in chick embryos (Landauer 1953b).

High concentrations of boron have been found in the San Joaquin Valley of California in irrigation drainwater and in aquatic plants consumed by waterfowl. Measured boron concentrations in that locale exceeded 20 mg/L in subsurface agricultural drainage waters, 400 mg/kg dry weight in widgeongrass (*Ruppia maritima*) and algae, 150 mg/kg dry weight in aquatic insects, 1860 mg/kg dry weight in some aquatic plants, and up to 3390 mg/kg dry weight in seeds consumed by waterfowl (Schuler 1987; Klasing and Pilch 1988; Smith and Anders 1989; Hoffman et al. 1990). At present, only selenium has been implicated as the cause of abnormal development among waterfowl in western areas impacted by irrigation drainwaters (Ohlendorf et al. 1986; Hoffman et al. 1988, 1990). However, studies by Smith and Anders (1989) and Hoffman et al. (1990) with mallards demonstrate that dietary boron concentrations well below levels that can occur in the environment represent a toxicological hazard that has not been considered in the management of agricultural drainwater. For example, dietary concentrations of 300 to 400 mg B/kg of feed on a fresh weight basis — substantially lower than boron levels reported in the vicinity of some western wildlife refuges contaminated by agricultural drainwater — adversely affect mallard growth, behavior, and brain biochemistry and are often associated with elevated tissue boron levels (Table 29.8). Dietary levels

of 100 mg B/kg fresh weight result in reduced growth of female mallard ducklings (Hoffman et al. 1990), and diets containing as little as 30 mg B/kg fresh weight fed to mallard adults adversely affected the growth rate of their ducklings (Smith and Anders 1989). Resource managers must now consider boron, as well as selenium, and their possible interactions, as a toxic hazard to wildlife populations throughout areas of the western United States (Smith and Anders 1989).

Table 29.8 Lethal and Sublethal Effects of Boron on Birds

Species, Dose, and Other Variables	Effect (Reference ^a)
MALLARD, <i>Anas platyrhynchos</i>	
Adults fed diets containing various concentrations of B, as boric acid, for 3 weeks, then mated. Resultant ducklings continued on same diets for 21 days. Data collected on reproduction, survival, residues, and histopathology when ducklings were age 21 days.	
8 mg B/kg diet fresh weight (controls). Diets contained about 10% moisture	Boron residues in egg, liver, and brain of adults and ducklings were always <3 mg B/kg dry weight (8)
30 mg B/kg diet FW	Duckling weight gain reduced compared to controls. Residues in egg and duckling liver and brain about 3–4 mg B/kg DW; residues <3 in adult liver and brain (8)
300 mg B/kg diet FW	Duckling body weights at hatch significantly lower than controls; duckling weight gain reduced. Mean residues, in mg B/kg dry weight, were 13 in egg, 15 in adult liver (Max. 24), 17 in duckling liver (Max. 36), 14 in adult brain (Max. 24), and 19 in duckling brain (Max. 44) (8)
1000 mg B/kg diet FW	No observable effect on adults. No effect on egg fertility or shell thickness. Significantly reduced hatching success; duckling mortality through age 7 days significantly greater than controls, and body weight lower. Total number of 21-day-old ducklings produced per female and brain:body weight ratios were significantly higher than controls. Mean B residues, in mg/kg DW, were 49 in egg, 33 in adult liver (Max. 74), 51 in duckling liver (Max. 89), 41 in adult brain (Max. 89), and 66 in duckling brain (Max. 110). No histopathology evident in liver, brain, kidney, or heart (8)
Breeding adults fed diets containing 0, 450, or 900 mg B/kg ration as boric acid for as long as 24 weeks. Ducklings produced received the same treatment as their parents for 14 days, then killed	No histopathology and no adverse effects on survival. B residues in the 900 mg B/kg group, in mg/kg B/kg FW, were 11 in egg vs. 2 in controls, 8.5 in adult liver vs. 0.6 in controls, and 13 in duckling liver vs. 0.3 in controls; values for the 450 mg/kg group were intermediate. Adults in the high-dose group had weight loss and decreased hemoglobin; eggs produced were lower in weight and fertility than controls. Hatching success and duckling weight in the high-dose group were reduced; duckling growth was reduced; altered duckling liver biochemistry (14)
Adult males fed diet containing 1600 mg B/kg ration as boric acid for 32 days	Boron accumulated in blood, brain, and liver, reaching 30–67 mg B/kg DW in 2–15 days. Boron was eliminated rapidly, with few detectable residues after 1 day on a boron-free diet (12)
Ducklings, age 1 day, fed diets containing 0, 100, 400, or 1600 mg B/kg ration as boric acid for 9 weeks	Only the high-dose group had consistently altered activity schedules, including decreases in amount of time spent in alert behaviors and in the water. Overall feeding time was increased, but did not result in an increase in the amount of food consumed (13)
Ducklings, age 1 day, 2-week dietary exposure 1000 mg B/kg FW diet, as boric acid 5000 mg B/kg diet, as boric acid	Adverse effects on growth (9) Some deaths (9)
Ducklings, age 1 day, 4-week dietary exposure. Diets contained as much as 1000 mg B/kg ration as boric acid alone or in combination with 15 or 60 mg Se/kg ration as selenomethionine. Diets contained either 22% or 7% protein	Boron alone caused growth reduction, with effect exacerbated by selenium and low protein (11)

Table 29.8 (continued) Lethal and Sublethal Effects of Boron on Birds

Species, Dose, and Other Variables	Effect (Reference^a)
Ducklings age 1 day, 10-week dietary exposure to boric acid	
Controls, 13 mg B/kg FW diet. Diets contained 12% to 14% moisture	Brain B concentration of 2 mg/kg DW (9)
100 mg B/kg FW diet	Delayed growth of females, plasma triglyceride levels elevated, abnormal liver metabolism, brain residue of 4 mg/kg DW (9)
400 mg B/kg FW diet	Delayed growth of females, plasma triglyceride elevated, brain B residue of 5 mg/kg DW, decrease in brain ATP, altered duckling behavior in bathing and resting (9)
1600 mg B/kg FW diet	Some deaths (10%), delayed growth, decreased food consumption, plasma triglyceride elevated, brain B residue of 51 mg/kg DW (Max. 99), decrease in brain calcium and ATP, reduction in time spent bathing and standing, increase in time spent resting, increased serum calcium, lower hematocrit and hemoglobin; no histopathology of brain, liver, or kidney (9)
DOMESTIC CHICKEN, <i>Gallus domesticus</i>	
Embryo, yolk injection	
Boric acid	
0.01 mg B/kg body weight (BW)	LD1 (1)
1.0 mg B/kg BW	LD50 (1)
1.0 mg at age 28 h	Developmental abnormalities (2)
2.0 mg at 28 h of development	Malformations of nervous system, eyes, and spinal cord (3)
2.5 mg at 24 h of development	Rumplessness (7)
2.5 mg at 84 h of development	Foot defects (7)
2.5 mg at 96 h of development	Skeletal deformities, cleft palate, missing toes, eye deformities (4–6)
15.8 mg B/kg egg at 96 h of development	LD50 (96 h). Most (70 to 85%) of the survivors at age 18 days had edema, inhibited feather growth, pale body coloration, and reduced body weight (10)
Borax	
0.01 mg B/kg BW	LD1 (1)
0.5 mg B/kg BW	LD50 (1)
Embryo, chorioallantoic membrane injection on day 8 of incubation with 0.1, 0.5, or 1.0 mg B/egg as sodium tetraborate	Chicks had a dose-dependent decrease in bone organic matrix, hatchability, and bone growth (16)
Adult	
Basal diets (11 mg B/kg ration) supplemented with 100 mg B/kg ration for 2 weeks, then reduced to 60 mg B/kg ration for 3 additional weeks	Egg production reduced (15)
875 mg B/kg diet, as boric acid, for 6 days	Egg production ceased; production normal 14 days after B withdrawn (1)

^a 1, Birge and Black 1977; 2, Schowling and Cuevas 1975; 3, Schowling et al. 1976; 4, Landauer 1953a; 5, Landauer 1953b; 6, Landauer 1953c; 7, Landauer 1952; 8, Smith and Anders 1989; 9, Hoffman et al. 1990; 10, Ridgway and Karnofsky 1952; 11, Hoffman et al. 1991; 12, Pendleton et al. 1995; 13, Whitworth et al. 1991; 14, Stanley et al. 1996; 15, Qin and Klandorf 1991; 16, King et al. 1991.

29.4.6 Mammals

No requirement for boron in mammals is proven, although evidence is accumulating suggesting that boron may be an essential nutrient. Boron is related to normal energy utilization, immune function, and metabolism of bone, minerals, and lipids (Penland 1998). Boron deficiency (<0.04

mg B/kg ration of dams) impairs early embryonic development in rodents. These effects were not observed at 2 mg B/kg ration (Lanoue et al. 1998). Boron deprivation in animals and humans results in decreased brain electrical activity similar to that observed in nonspecific malnutrition, and reduced cognitive and psychomotor function (Penland 1998). Learning performance (manual dexterity, eye-hand coordination, memory, attention, perception) in humans was significantly higher when the daily boron ingestion rate was 3 mg vs. 0.23 mg (Penland 1994). Boron dietary supplements to postmenopausal women age 48 to 82 years induced changes consistent with the prevention of calcium loss and bone demineralization (Nielson et al. 1987; Nielsen 1994). In rats, adequate dietary boron protected against premature senescence (Massie 1994) and alleviated the signs of Vitamin D₃ deficiency through improved absorption and retention of calcium and phosphorus, and retention of femur magnesium (Hunt 1994). In cattle, increases in boron ingestion were associated with elevated boron levels in plasma and urine, increased boron excretion, decreased plasma phosphate concentrations, and increased renal and urinary clearance of phosphates (Weeth et al. 1981). Boron accumulations in rat testes were associated with progressive germ cell depletion that persisted long after toxic exposure to boron had occurred (Lee et al. 1978).

Boron effectively counteracts symptoms of fluoride intoxication in humans (Zhou et al. 1987) and in rabbits poisoned experimentally (Elsair et al. 1980a, 1980b, 1981). Humans suffering from skeletal fluorosis experienced 50 to 80% improvement after drinking solutions containing 300 to 1100 mg of borax per liter daily, 3 weeks a month for 3 months (Zhou et al. 1987). Boron enhances sequestration of fluoride from bone and excretion through kidneys and possibly the intestinal tract (Elsair et al. 1980a, 1981).

Inorganic borates, including boric acid, and sodium, ammonium, potassium, and zinc borates display low acute toxicity to mammals via oral, dermal, and inhalation routes of exposure. The critical effects in several species of mammals during chronic exposure to boron compounds are male reproductive toxicity and developmental abnormalities (Hubbard 1998). For example, prenatal exposure to elevated levels of boric acid causes reduced incidences of supernumerary ribs and a shortening or absence of the 13th rib in several species of laboratory animals (Narotsky et al. 1998). The doses that cause these effects are far higher than any levels to which human populations could be exposed. Humans would need to consume 3.3 g of boric acid or 5.0 g of borax to ingest the same dose level at the lowest animal NOAEL (Hubbard 1998). Boron has no measurable effect on human fertility or reproduction among workers exposed to borates or to populations exposed to high environmental borate levels (Hubbard 1998; Sayli 1998; Tuccar et al. 1998). Adult Turkish females, for example, residing in boron-rich areas (29 mg B/L drinking water) or boron-poor areas (0.3 to 0.5 mg B/L drinking water) did not differ in rate of spontaneous abortions, stillbirths, or congenital malformations (Tuccar et al. 1998).

Long-term exposure of humans to airborne boron dust may cause irritation of the nose, throat, and eyes, and large amounts of boron ingested over short periods of time can adversely affect the gastrointestinal tract, liver, kidney, and brain, and may lead to death (USPHS 1991). However, borax mean air exposures of 18 mg/m³ measured for high-exposure workers together with dietary boron, resulted in an estimated absorption of only 0.38 mg B/kg BW daily. At this level, there was no progressive accumulation across the work week (Culver et al. 1994). Epidemics and sporadic cases of oral intoxication in people are often due to inadvertent addition of boric acid to infant formulas (Siegel and Wason 1986). Five of 11 human infants died within 3 days of exposure after ingesting formula prepared with a 2.5% aqueous solution of boric acid, equivalent to 4.5 to 14.0 g of boron ingested. Prior to death, these infants were lethargic and vomiting; postmortem degenerative changes were observed in liver, kidney, and brain (USPHS 1991). Some products containing boron compounds, such as pacifiers, have been sold in Ireland despite a recommendation from the Pharmaceutical Society of Great Britain that they should not be sold because of hazards to infants (O'Sullivan and Taylor 1983). Fatal cases of boron poisoning have involved misuse of boron compounds in hospitals, either from accidental substitution of boric acid solution for water in infant formula or from accidental use of boric acid as a diapering powder (USEPA 1975). In an adult fatality, the victim died after inundation by borax solution (USEPA 1975). In one case, a 12-month-old girl developed violent vomiting, coughing, irritability, tremors, seizures, and a delirious reaction

after accidentally swallowing a mixture containing 3 g boric acid and 300 mg cinchocaine chloride prescribed due to a painful dental protrusion (Egfjord et al. 1988). Her plasma boric acid level 6 h later was 26 mg/L; the half-time persistence ($T_{1/2}$) for boric acid in plasma is about 7 h (Egfjord et al. 1988). The lethal dose of boric acid varies according to the species. In mammals, it ranges from 210 to 603 mg B/kg BW, and death is due to CNS paralysis and gastrointestinal irritation (Table 29.9; NAS 1980; USPHS 1991). Human newborns are especially sensitive, and accidental deaths have been recorded at doses between 50 and 140 mg B/kg BW (Table 29.9).

In mammals, excessive boron consumption results in a reduced growth rate and sometimes loss in body weight. These may not be due entirely to reduced feed and water consumption (Table 29.9; Seal and Weeth 1980). Growth retardation has been reported in cattle given 150 mg B/L drinking water (about 15 mg B/kg BW daily), in dogs consuming diets containing 1750 mg B/kg, in rabbits eating rations equivalent to >140 mg B/kg BW daily, and in rats given 150 mg B/L drinking water or 1060 mg B/kg diet (Table 29.9). In some cases, animals will avoid B-contaminated drinking water if given a choice. Rats, for example, will reject drinking water containing as little as 1.0 mg B/L (Dixon et al. 1976), and cattle will avoid water containing >29 mg B/L (Green and Weeth 1977).

Male workers engaged in boric acid production showed weakened sexual activity, decreased seminal volume, low sperm count and motility, and increased seminal fructose (USEPA 1975). Animal studies demonstrated that the testes atrophy or degenerate if large amounts of boron are eaten or drunk; these effects have not been reported in humans (USPHS 1991). Adverse effects on reproduction of laboratory animals have been reported in sensitive species fed diets containing more than 1000 mg B/kg, or given drinking water containing 1.0 mg B/L (equivalent to about 0.3 mg B/kg BW daily), or given a single oral dose of 3000 mg B/kg BW on the first day of pregnancy (Table 29.9). Boric acid caused developmental toxicity — including fetal weight reduction, prenatal mortality and malformations, decreased survival — in rats, mice, and rabbits in the range of 16 to 80 mg B/kg BW daily given either throughout gestation or only during major organogenesis (Heindel et al. 1994).

Volatile boron compounds, especially boranes, are usually more toxic than boric acid or soluble borates (Table 29.9) (NAS 1980). However, there is little commercial production of synthetic boranes, except for sodium borohydride — one of the least toxic boranes (Sprague 1972). Boron trifluoride is a gas used as a catalyst in several industrial systems, but on exposure to moisture in air, it reacts to form a stable dihydride (Rusch et al. 1986). For boric oxide dusts, occupational exposures to 4.1 mg/m³ (range 1.2 to 8.5) are associated with eye irritation; dryness of mouth, nose and throat; sore throat; and cough (Garabrant et al. 1984).

Table 29.9 Lethal and Sublethal Effects of Boron on Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect (Reference ^a)
CATTLE, <i>Bos</i> spp.	
Drinking water	
Supplemented with 15, 30, 60, or 120 mg B/L for 10 days	Boron levels in plasma rose from 2.7 mg/L in controls to 4.4 (15 mg/L group) to 5.3 (30 mg/L group) to 8.3 (60 mg/L group) to 13.4 mg/L in the 120 mg B/L drinking water supplement (5)
29 mg B/L, and higher	When given choice, cattle preferred tap water to drinking water supplemented with B compounds (1)
120 mg B/L, as borax, for 10 days	No effect on feed or water consumption; no overt signs of toxicosis (2)
150 mg B/L, as borax, for 30 days, equivalent to 15.3 mg B/kg BW daily	Decreased feed consumption, weight loss, edema, inflammation of legs, daily elevated plasma B levels of 1.2 mg/L vs. 0.5 in controls, abnormal blood chemistry (1–5)
Diet	
Consumed feed containing 157 mg B/kg, as borax, for 42 days	No adverse effects (3)

Table 29.9 (continued) Lethal and Sublethal Effects of Boron on Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect (Reference^a)
Fed 2–2.5 g boron daily as borax, for 40 days	No observable adverse effects; all B excreted, mostly in urine (6)
Fed 20 g borax daily	Milk B residues increased from <1.0 mg/L to >3 mg/L (5)
Ingested total dose of 100–300 g boron, equivalent to 200–600 mg B/kg BW	Toxic dose (7)
Found dead after consuming 1 kg borax, or about 250 g B	Residues, in mg B/kg FW, were 1300 in ruminal fluids, 1900 in abomasal fluids, 24 in liver, 19 in rumen, and 21 in abomasum (7)
DOG, <i>Canis familiaris</i>	
Diet	
350 mg B/kg feed, 2 years	Tolerated (8)
1540 mg borax/kg or 3000 mg boric acid/kg, chronic study (174–524 mg B/kg diet)	No adverse effects (6, 9)
1170 mg B/kg, 38 weeks	Testicular degeneration, spermatogenesis cessation (5, 8)
Inhalation	
92 mg pentaborane/m ³ for 15 min	LC50 (9)
GUINEA PIG, <i>Cavia</i> spp.	
Inhalation	
0.018 mg decaborane/m ³ , 6 h daily, 5–6 exposures	Eye inflammation, listlessness, emaciation, convulsions (3)
HUMAN, <i>Homo sapiens</i>	
Dermal	
7-month-old infant treated for dermatitis with 3% boric acid powder	Fatal. Boron concentrations elevated in bile, intestinal contents, and spleen (9)
Adult administered about 645 g of boric acid dermally	Toxicosis observed (10)
Inhalation	
Borax dust, 1.1–14.4 mg/m ³ , occupational exposure for at least 5 years	At 14.4 mg/m ³ , 33% of workers noted dryness of mouth, nose, or throat; 28% had eye irritation problems; 15% had nosebleeds and cough; 13% had sore throat or shortness of breath and chest tightness. At 4.0 and 1.1 mg/m ³ , no symptoms except eye irritation were noted by more than 5% and 3% of exposed participants (11) Irritation of nose, throat, and eyes (27) Pulmonary irritation, headache, nausea, fatigue, muscular weakness, liver and kidney pathology (3)
Boron dust, >4.1 mg/m ³ for 11 years	
Boranes, various	
Oral	
3 mg B daily for 119 days to diet containing 0.25 mg B	Reduction in urinary excretion of calcium and magnesium by postmenopausal women (12)
20 mg B daily	Normal adult intake (6)
Solutions >88 mg B/L or >500 mg boric acid/L	Fatal to infants (13)
895 mg B/kg BW; single attempted suicidal dose of a boric-acid-containing insecticide by adult female	Vomiting; hospitalized for 96h; asymptomatic after release (27)
1–3 g boric acid, or 0.3–0.8 g/kg BW	Lethal to newborns. (14, 27)
2–4.5 g boric acid or 0.5–1.2 g/kg BW	Nonfatal to infants, but serum levels elevated from 20–150 mg borate/L (14)
>3.5 g boric acid daily	Probably harmful or lethal to infants and newborns (10)
4 g boric acid or borates daily	No toxicosis in adults (6, 9)
4.5–15 g boric acid, equivalent to 1.25–4.2 g/kg BW, in accidentally contaminated formula in newborn nursery	Death preceded by severe symptomology; serum levels of 400–1000 mg borate/L (13, 14)
5–6 g of borates, or 0.7 g/kg BW	Fatal to infants (14, 15)
15–20 g of boric acid, equivalent to 0.25–0.3 g/kg BW	Fatal to adults (9, 14, 15, 27)

Table 29.9 (continued) Lethal and Sublethal Effects of Boron on Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect (Reference^a)
Infants, age 6–16 weeks, given pacifiers dipped in a proprietary borax (107 g/L) and honey compound. Dose during 1-month-exposure period estimated at 3–9 g borax	Some developed seizure disorders characterized by vomiting, loose stools, irritability, diarrhea; elevated blood B values of 2.6–8.5 mg B/L vs. <0.6 in controls. When preparation withheld, seizures stopped and children remained well for at least 5 years (13)
Injection, intravenous	
Adult males, age 22–28 years, given single infusion of 562–611 mg boric acid, equivalent to 8.0–8.7 mg B/kg BW	Tb 1/2 persistence of boric acid was 21 h. Most excreted in urine in 24 h, 94% in 96 h, and ~99% in 120 h; plasma boric acid concentrations after infusion was about 16 mg/L vs. 0.5 at start; no discomfort during or after infusion (16)
Adults given total dose of 20 g boric acid	No permanent adverse effects (9)
MONKEY, <i>Macaca</i> spp.	
Inhalation	
Pentaborane, 640 mg/m ³ , 2 min	LC50 (9)
Intraperitoneal injection	
Decaborane, 1 mg/kg BW daily, multiple injections	Altered brain wave activity (9)
Decaborane, 6 mg/kg BW, single injection	LC50 (9)
MICE, <i>Mus</i> sp.	
Drinking water	
5 mg B/L, lifetime exposure	No effect on growth, longevity, or tumor incidence (2, 5)
Ingestion	
3 g B/kg BW, first day of pregnancy	94% of embryos did not develop past blastocyst stage vs. 9% in controls (9)
Diet	
Equivalent to 27 mg B/kg BW daily	No adverse reproductive effects (33)
48 mg B/kg BW daily for 103 weeks	40% dead (27)
96 mg/kg BW daily for 103 weeks	Testicular atrophy (27)
Equivalent to 111 mg B/kg BW daily	Reduced fertility (33)
144 mg/kg BW daily for 13 weeks	Decreased survival (27)
288 mg/kg BW daily for 13 weeks	Testicular degeneration (27)
1500 mg boric acid/kg (262 mg B/kg) daily	All dead within 10 days (17)
Injection, intravenous	
1.32 g sodium borate per kg BW, single dose	LD50 (18)
Injection, intraperitoneal	
25.2 mg decaborane/kg BW, single dose	LD50 (9)
44.7 mg decaborane/kg BW, single dose, prior treatment for 8 days at 250 mg/kg BW with pyridoxine hydrochloride	LD50 (9)
2817 mg sodium borate/kg BW, single dose	LD50 (18)
Inhalation	
Pentaborane	
0.011 mg/m ³ for 4 h	LC50 (3)
50 mg/m ³ , 15 min	LC50 (9)
342 mg/m ³ , 2 min	LC50 (9)
1034 mg/m ³ , 30 seconds	LC50 (9)
RABBIT, <i>Oryctolagus</i> sp.	
Diet	
Equivalent to 800–1000 mg borates/kg BW daily for 4 days	Growth retardation (18)
Intragastric route	
Daily dose of 100 mg calcium borate for 4 months	Altered serum chemistry (9)
Intravenous injection	
Single dose of 800–900 mg boric acid/kg BW	LD50 (18)

Table 29.9 (continued) Lethal and Sublethal Effects of Boron on Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect (Reference ^a)
Intraperitoneal injection	
30 mg decaborane/kg BW	Death within 24 h (3)
Dermal	
25–200 mg boric acid/kg BW daily	Not irritating or toxic when applied to intact skin (18)
Sodium borate solutions of 50,000 or 100,000 mg borates/L applied to skin	Mildly or moderately irritating (18)
Boron oxide dust	Application to skin produced erythema that lasted 2–3 days; instillation in eyes produced immediate conjunctivitis as a result of exothermic hydration of boron oxide to boric acid (19)
Inhalation	
120–150 mg calcium borate/m ³ , 2 h daily, 10 weeks exposure	Respiratory tract pathology, growth inhibition, enlarged liver (9)
RAT, <i>Rattus</i> sp.	
Drinking water	
Free access for 90 days to drinking water containing 0.3, 1.0, or 6.0 mg B/L	Rats refused to drink water at 1.0 or 6.0 mg/L (15)
0.3 mg boric acid/L for 6 months	No effect on gonadotoxicity (20)
1.0 mg boric acid/L for 6 months, equivalent to 0.05 mg B/kg BW daily	Decreased spermatozoid count, reduction in spermatozoid activity (20)
6 mg B/L, 90 days	No toxic effect on male reproductive system, blood chemistry, or growth (5, 15)
6 mg B/L for 6 months, equivalent to 0.3 mg B/kg BW daily	Gonadotoxicity in male rats; altered enzyme activity levels in blood and liver (20, 21)
75 mg B/L, as borax, for 45 days	No effect on growth or reproduction (3)
100 mg B/L for 21 days	Tissue B levels in kidney, liver, brain, and blood increased for first 9 days but returned to normal by day 21 except for blood, which continued to rise (21)
150 mg B/L for 70 days, or 170 mg B/L for 25 days	Slight reduction in growth rate (5)
>150 mg B/L for extended periods	Adverse effects probable (5)
300 mg B/L for 49–70 days	Growth rate reduced 21%, but no change in food consumption; coarse coat; atrophied scrotal sacs (4)
440 mg B/L for 25 days	Growth inhibition (4)
880 mg B/L for 70 days	Inhibited sperm production (27)
3 g sodium tetraborate/L for 10–14 weeks	Increase in activity of cerebral succinic dehydrogenase and brain acid proteinase, and in brain RNA concentration; decrease in liver cytochrome P-450 activity (22)
Diet	
Females fed diets with 0.04 (low) or 2 (adequate) mg B/kg ration for 6 weeks before breeding and through pregnancy; reproductive outcome monitored on gestation day 20	Low dietary B significantly lowered maternal blood, liver, and bone B concentrations; however, it had no clear effects on fetal growth or development (35)
Day 10 embryos from dams fed either the low (0.04 mg/kg ration) or adequate (2 mg/kg ration) boron diets for at least 12 weeks were cultured in serum collected from male rats exposed to the low or adequate dietary B treatments	Dams fed the low B diet had a significant reduction in number of implantation sites when compared to dams fed the B-adequate diet; however, embryonic growth <i>in vitro</i> was not affected by B treatment (35)
Pregnant rats fed diets with boric acid equivalent to <0.35 (controls), 3, 6, 10, 13, or 25 mg B/kg BW daily from gestational days 0–20. About half the dams in each group were killed on gestational day 20 and blood and prenatal outcome evaluated. Remaining dams received a control diet beginning on gestational day 20 and their litters monitored throughout lactation	Maternal blood boron concentrations were elevated in all boron groups in a dose-dependent manner. On gestational day 20, blood B concentrations of 1.3 mg/kg FW were associated with the no-observed-adverse-effect level (NOAEL) and 1.53 mg/kg FW with the lowest-observed-adverse effect level (LOAEL), equivalent to dietary intakes of 10 and 13 mg B/kg BW daily, respectively, for developmental toxicity. Developmental toxicity persisted postnatally only at 25 mg B/kg BW daily, a dose associated with more than a 10-fold increase in maternal blood B (2.8 mg B/kg FW) vs. 0.23 mg/kg FW in controls (34)

Table 29.9 (continued) Lethal and Sublethal Effects of Boron on Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect (Reference^a)
Equivalent to 17.5 mg B/kg BW daily	No adverse reproductive effects (33)
Equivalent to 26 mg B/kg BW daily	Mild reversible inhibition of spermatiation (33)
Equivalent to 58.5 mg B/kg BW daily	Testicular atrophy; reduced fertility (33)
Fed diets containing 0, 200, 1000, 3000, or 9000 mg B/kg ration as boric acid for up to 12 weeks, equivalent to <0.2 (control), 1.7, 8.5, 26, or 68 mg B/kg BW daily; resistance to destructive testing was measured on femurs, tibias, and lumbar vertebrae	Vertebral resistance to a crushing force was increased by about 10% at all boron dose levels (200–9000 mg B/kg ration); no effect on femurs and tibias. Dietary loadings of 3000 and 9000 mg/kg were reproductively toxic to males and the developing fetus (31)
0.09–1.71 mg boric acid/kg BW daily for 6 months (0.015–0.3 mg B/kg BW daily)	Adverse changes in testes (18)
0.16 or 2.7 mg B/kg ration for 12 weeks to Vitamin D-deprived rats	Abnormal mineral balance in low-dose diet; normal calcium, magnesium, and phosphorus balance in 2.7 mg/kg supplement (28)
350 or 525 mg B/kg diet, as borax or boric acid, for 2 years	No observable adverse effects on fertility, lactation, litter size, weight, or appearance (6)
500, 1000, or 2000 mg B/kg diet, as borax, for 30–60 days, equivalent to 12, 25, or 50 mg B ingested daily	No adverse effects at 500 mg B/kg diet for 60 days. At 1000 and 2000 mg B/kg, adverse effects measured on male reproductive capacity, including germinal aplasia and infertility; effects persisted for at least 8 months following B exposure at highest dose (23)
525 mg B/kg diet for 90 days	Tolerated (8); testes damage (27)
1000 mg boric acid or borax/kg BW daily	Weight loss after 1 week on borax diet, or 2 weeks on boric acid diet; toxic signs after 3 weeks on both diets (24)
1050 mg B/kg diet, as borax or boric acid, for 2 years	Testicular degeneration (6)
1060 mg B/kg diet, as sodium borate, chronic exposure	Growth retardation and testicular atrophy (18)
1170 mg B/kg diet for 2 months	Coarse coat, scaly tails, hunched position, bloody discharge from eyes, depressed hemoglobin and hematocrit (5)
1170 mg B/kg diet, as borax or boric acid, 2 years	Sterility in males and females (6, 8)
1575 mg B/kg ration for 28 days as boric acid, adult males	Testicular lesions after 7 days, atrophy after 28 days (29); no return of spermatogenesis after resumption of normal diet for as long as 32 weeks (30)
1750 mg B/kg diet, 25 days	Reduction of 50% in growth rate (4)
1750 mg B/kg diet, as sodium borate, chronic	Severe testicular atrophy (18)
10,250 mg B/kg ration	Dead after 1 day (27)
Oral, single dose, except where noted	
450 mg B/kg BW	No effect on male fertility (15)
500 mg B/kg BW by gavage on gestation days 5–9, 6–9, 6–10, or on single days between gestation days 6 and 11	After multiday exposures, there was an increased frequency of malformations of the axial skeleton involving the head, sternum, ribs, and vertebrae. About 90% of the fetuses exposed on gestation day 9 had only 6 cervical vertebrae; 60% of the fetuses exposed on gestation day 10 had reduced survival and a reduction in the number of thoracic and lumbar vertebrae (32)
510–690 mg B/kg BW, as borax	LD50 (8, 9, 24)
550–710 mg B/kg BW, as boric acid	LD50 (8, 9, 24)
600 mg B/kg BW	LD50 (2)
3.45–5.14 g sodium borate/kg BW	LD50 (18)
5.1 g boric acid/kg BW	LD50 (6)
6.1 g borax/kg BW	LD50 (6)
Injection, subcutaneous	
1.4 g boric acid/kg BW	LD50 (18)
Injection, intravenous	
5–75 mg boric acid/kg BW	Slight reduction in arterial blood pressure (21)

Table 29.9 (continued) Lethal and Sublethal Effects of Boron on Mammals

Organism, Route of Administration, Dose, and Other Variables	Effect (Reference ^a)
Injection, intraperitoneal	
42 mg sodium borate/kg BW, single injection	Tissue residues after 30 min, in mg B/kg FW, were 25 in blood, 30 in liver, and 50 in kidney vs. <5 in all control tissues. After 3 months, residues were 20 mg B/kg FW in brain, 45 in heart, 60 in liver, and 75 in kidney (21)
Inhalation, boron trifluoride	
2, 6, or 17 mg BF ₃ /m ³ , 6 h daily, 5 days weekly, 13 weeks	At 17 mg/m ³ , altered proximal tubular epithelium of kidney and abnormal serum chemistry. At 6 mg/m ³ , elevated fluoride levels in urine, serum, and bone, but no toxic response. No difference from controls at 2 mg/m ³ (26)
24 or 66 mg/m ³ , 6 h daily, 9 days	Clinical signs of respiratory irritation, nasal discharge, weight loss, increased lung weight, depressed liver weight, kidney pathology at 66 but not 24 mg/m ³ (26)
55 mg/m ³ , 4–7 h daily, 5 days weekly, 6 weeks	Some deaths in rats and other rodent species tested, but no deaths in nonrodent species (26)
180 mg/m ³ , 6 hours daily, consecutive days	All dead prior to sixth exposure (26)
259 mg/m ³ , 4–7 h daily, 2 days	All dead. Mortality was lower for guinea pigs, dogs, rabbits, mice, and cats. Lung and kidney damage in all species (26)
1210 mg/m ³ , 4 h	50% dead (26)
Inhalation, boron oxide	
470 mg/m ³ , 10 weeks	Reddish exudates from nose, but no deaths or signs of lung damage (19)
470 mg/m ³ , 24 weeks	No signs of toxicosis (9)
Inhalation, decaborane	
20 mg/m ³ , 6 h daily, 5 days weekly	Tremors, convulsions, nervousness, restlessness, weight loss, belligerence (3)
36 mg/m ³ , 4 h	LC50 (3)
Inhalation, pentaborane	
3 mg/m ³ , 6 h daily, 5 days weekly	Extreme belligerence, tremors, weight loss (3)
18 mg/m ³ , 4 h	LC50 (3)

29.5 RECOMMENDATIONS

Many boron criteria have been proposed for the protection of crops, aquatic life, waterfowl, livestock, and human health (Table 29.10). The risk to aquatic ecosystems from boron is low (Howe 1998). Boron concentrations in contaminated industrial effluents seldom exceed 1.0 mg B/L, a level considered nonhazardous to aquatic life (Table 29.10) (Thompson et al. 1976). In a few boron-rich areas, natural levels will be higher, although organisms may adapt to local conditions (Howe 1998). However, future accumulations of boron in groundwater through wider uses of boron-containing cleansing agents may adversely affect aquatic organisms and other species of plants and animals, as now occurs in areas where natural boron deposits exist (USEPA 1975). Long-term monitoring of groundwaters and surface waters for boron levels seems warranted.

Results of chronic feeding studies using mallards demonstrate that diets containing 13 mg B/kg FW produce no adverse effects, but those containing 30 or 100 mg B/kg FW are associated with elevated tissue boron residues and growth reduction, and diets containing 1000 mg B/kg are fatal

(Table 29.10). More research is needed on the fate and effects of boron on waterfowl and raptors, especially in those areas where high dietary boron loadings are encountered as a result of agricultural drainwater disposal practices.

Minimum concentrations of dietary boron needed to maintain animal health are not known with certainty. However, diets containing <0.4 mg B/kg fresh weight may adversely affect metabolism of rats and chicks. Accordingly, animal diets should contain >0.3 mg B/kg fresh weight until necessary feeding data become available (Nielsen 1986). Also, the defensible boron maximum for livestock drinking water may be considerably higher than 5 mg/L (Table 29.10) because several “safe” water sources in Nevada exceeded this upper maximum and approached 80 mg B/L (Green and Weeth 1977). Data are unavailable on boron effects on terrestrial wildlife. Until these data become available, it seems reasonable to apply the same criteria proposed for livestock protection (Table 29.10) to mammalian wildlife, that is, diets should contain more than 0.4 mg B/kg DW but less than 100 mg/kg, and drinking water <5 mg/L.

Medicinal use of boric acid and borax for babies has resulted in anorexia, nausea, vomiting, diarrhea, marked cardiac weakness, a red eruption over the entire body, and (rarely) death (NAS 1980). The medical community has since abandoned the use of boric acid solutions as irrigants and antiseptics (Siegel and Wason 1986), abandoned all medical uses in Denmark (Egfjord et al. 1988), and severely limited availability (prescription only) in Ireland (O’Sullivan and Taylor 1983). Increased use of boric acid as a household pesticide should be viewed with concern, especially in households where children have access to non-safety-capped boric acid containers (Siegel and Wason 1986). However, the amine-carboxyborane derivatives show promise as therapeutic agents for a number of disease states. More research is needed on medical aspects of amine-carboxyborane compounds and their ability to reduce serum cholesterol and to relieve, through their anti-inflammatory properties, the effects of chronic arthritis (Hall et al. 1994; Newnham 1994). This group of compounds were effective antineoplastic agents with selective activity against single cell and solid tumors derived from human and rodent leukemias, lymphomas, sarcomas, and carcinomas (Hall et al. 1994). Health benefits of borates and boron compounds and their role in fertility and pregnancy merit additional investigation (Mastromatteo and Sullivan 1994). Boron, for example, may be essential to normal bone growth and composition and protect against bone loss associated with aging (McCoy et al. 1994).

The fact that boron is essential to plants is firmly established (NAS 1980; USPHS 1991). However, when boron concentrations in irrigation waters exceed 2 mg/L, extensive plant toxicity should be expected (Pagenkopf and Connolly 1982). High concentrations of boron in some potential irrigation waters in parts of the western United States at levels capable of causing crop damage have prompted implementation of boron criteria for irrigation waters (Table 29.10), although no legally enforceable boron standards have been promulgated (USEPA 1975). More information is needed on crop plants in the following subjects: interaction of boron with other elements in the soil and its effects on boron availability to plants, the role of boron on pollination as it affects seed yield and sugar content of crops, and distinguishing signs of boron deficiency in plants from similar signs of molybdenum deficiency (Gupta and Macleod 1982; Mastromatteo and Sullivan 1994).

More research is needed on the accurate measurement of boron in biological materials when the concentrations are <1.0 mg B/kg (Sullivan and Culver 1998). Standard biological reference materials with low boron levels need to be produced for use in interlaboratory comparisons. This becomes especially important in studies on boron-deficiency states and the ability of the organism to conserve boron at very low intakes (Sullivan and Culver 1998). More research is needed on homeostatic regulation of boron and functional markers of boron metabolism (Sutherland et al. 1998). Sullivan and Culver (1998) recommend additional studies to establish:

- The availability of boron from the diet and its distribution to the tissues
- Boron essentiality in higher organisms
- The beneficial effects of boron on health
- The role of borates in behavioral disorders and cognitive performance

New advances in boron nutrition research should include better characterization of the mechanisms through which boron modulates immune function and insulin release (Hunt 1998). Epidemiological studies should be initiated to identify health conditions associated with inadequate dietary boron (Sutherland et al. 1998). Finally, Dourson et al. (1998) recommend more research on uncertainty factors used in establishing tolerable daily intake values for the protection of human health, with emphasis on variations in interspecies and intraspecies differences in resistance to boron.

Table 29.10 Proposed Boron Criteria for the Protection of Natural Resources and Human Health

Resource and Other Variables	Criterion	Reference ^a
CROPS		
Irrigation waters		
Sensitive crops	0.3–<0.75 mg B/L	1–3, 19
Semitorient crops	0.67–2.5 mg B/L	1–3
Tolerant crops	1–4 mg B/L	1–3
Maximum safe concentration	4 mg B/L	2
Residues in crops		
Boron deficiency	<15 mg B/kg dry weight (DW) plant	4, 5
Toxicosis	>200 mg B/kg DW plant	4, 5
Soil concentrations		
Optimal growth of several species	>0.1–<0.5 mg B/kg DW soil	19
Deficiency, Bangladesh	<0.2 mg B/kg DW surface layer	26
FOREST TREES		
Conifers, sensitive species		
Deficient	<4 mg B/kg DW foliage	23
Low	>4–<8 mg B/kg DW foliage	23
Intermediate	13–20 mg B/kg DW foliage	23
Toxic	>75 mg B/kg DW foliage	23
Angiosperms, sensitive species		
Deficient	8–16 mg B/kg DW foliage	23
Toxic	>180 mg B/kg DW foliage	23
AQUATIC ORGANISMS		
Nonhazardous levels in water		
Fish, oysters	<1–5 mg B/L	2, 6, 25
Aquatic communities	1–2 mg/L	25
Aquatic plants	4 mg B/L	2
Aquatic invertebrates	6–10 mg B/L	25
“Safe” levels in water		
Largemouth bass, <i>Micropterus salmoides</i>	<30 mg B/L	1, 7
Bluegill, <i>Lepomis macrochirus</i>	<33 mg B/L	1, 7
Rainbow trout, <i>Oncorhynchus mykiss</i> , embryos and larvae	0.75–1.0 mg B/L	20
Adverse effects, sensitive species		
	10–12 mg B/L	6, 20
WATERFOWL		
Diet		
No observed adverse effect	<13 mg B/kg fresh weight (FW)	17
Adverse effects	30–100 mg B/kg FW	17, 18
Fatal	1000 mg B/kg FW	18
LABORATORY ANIMALS		
No observed adverse effect		
Rat	<15.6 mg/kg body weight (BW) daily during gestation	22
Rabbit	<25 mg B/kg BW daily	22

Table 29.10 (continued) Proposed Boron Criteria for the Protection of Natural Resources and Human Health

Resource and Other Variables	Criterion	Reference^a
Mouse	<50 mg B/kg BW daily	22
Adverse effect level		
Rat	>15.6 mg B/kg BW daily during gestation	22
Rabbit	>50 mg B/kg BW daily	22
Mouse	90 mg B/kg BW daily during gestation	22
LIVESTOCK		
Diet		
Boron deficiency	<0.4 mg B/kg DW	5
Toxic signs probable	>100 mg B/kg DW	5
Maximum tolerable level, as borax	150 mg B/kg DW	4, 5
Total dose, toxic	100–300 g of B (equivalent to 200–600 mg B/kg BW)	9
Drinking water		
Maximum allowable	5 mg B/L	4, 8, 10, 11
Maximum tolerated	40 mg B/L	10
“Safe”	40–150 mg B/L	11
Adverse effects	>150 mg B/L	5
PESTICIDE APPLICATIONS		
Boric acid, 99% powder	Effective for control of household cockroaches, ants, and fleas	2
Boric acid, 8% solution	Fungicide for vegetables, fruits, and trees	12
HUMAN HEALTH		
Air		
Threshold Limit Value (8 h daily, 5 days weekly)		
Pentaborane	0.01 mg/L	4
Diborane	0.1 mg/L	4
Decaborane	0.5 mg/L	4
Sodium borate	1–5 mg/m ³	16, 17
Boron trifluoride	<3 mg/m ³	19
Calcium borate	4–6 mg/m ³	3
Boron tribromide	10 mg/m ³	19
Boron oxide		
Total dust	10 mg/m ³	19
Respirable fraction	<5 mg/m ³	19
Sodium tetraborate	10 mg/m ³	19
Decahydrate	<5 mg/m ³	19
Anhydrous and pentahydrate	<1 mg/m ³	19
Borate dusts		
Safe	<1 mg B/m ³ daily	21
Infrequent effects	1.1 mg B/m ³ daily	21
Adverse effects	4–14.6 mg B/m ³ daily	21
Daily intake		
Total tolerable	0.4 mg/kg BW ^b	24
Worldwide	Range 0.3–41 mg B, means usually 10–20 mg B ^c	4, 5, 13
Finland	1.7 mg B	5
England	2.8 mg B	5
U.S.	3 mg B	4
No effect level	4 g boric acid	14
Adverse effect level		
Chronic intoxication	4–5 g boric acid	14
Lethal to infants and small children	5–6 g boric acid	14

Table 29.10 (continued) Proposed Boron Criteria for the Protection of Natural Resources and Human Health

Resource and Other Variables	Criterion	Reference ^a
Lethal to adults	18–20 g boric acid, single dose	14
Dermal, ocular		
Sodium borate and boric acid	Safe as cosmetic ingredients at <5% concentrations; not recommended on infant skin or injured skin	12, 16
Diet		
Citrus fruits	<8 mg B/kg FW	19
Cottonseed	<30 mg B/kg FW	19
Hop extracts	<310 mg B/kg FW	19
Minimal risk level	<3.2 mg B/kg ration FW	19
Adverse effects, including death	>4161 mg B/kg ration FW	19
Drinking water		
Recommended	<0.3 mg B/L	15
Former Soviet Union	<0.5 mg B/L	10
U.S.	<1.0 mg B/L	4, 11
"Safe"	<20 mg B/L	2, 10
No toxic effects	20–30 mg B/L	2
Tissue residues		
Blood, children and infants		
Normal	<1.25 mg B/L FW	19
Adverse systemic effects	20–150 mg B/L FW	19
Fatal	200–1600 mg B/L FW	19
Serum, adults		
No significant toxicity	<2320 mg B/L FW	19
Urine, adults		
Normal	0.7–1.5 mg B/L FW	19

^a 1, Sprague 1972; 2, Papachristou et al. 1987; 3, USEPA 1975; 4, NAS 1980; 5, Nielsen 1986; 6, Thompson et al. 1976; 7, Birge and Black 1977; 8, Weeth et al. 1981; 9, Brockman et al. 1985; 10, Seal and Weeth 1980; 11, Green and Weeth 1977; 12, Siegel and Wason 1986; 13, Benson et al. 1984; 14, Schillinger et al. 1982; 15, Krasovskii et al. 1976; 16, Anonymous 1983; 17, Hoffman et al. 1989; 18, Smith and Anders 1989; 19, USPHS 1991; 20, Black et al. 1993; 21, Wegman et al. 1994; 22, Heindel et al. 1994; 23, Stone 1990; 24, Becking and Chen 1998; 25, Howe 1998; 26, Miah 1999.

^b Based on NOAEL of 9.6 mg B/kg BW daily for reproductive effects in rats and an uncertainty factor of 25.

^c Becking and Chen (1998) estimate global mean daily intake of B by humans as 1.9 mg, mostly from food (65%) and drinking water (30%). For a 70-kg adult, this is equivalent to 0.027 mg B/kg BW daily.

29.6 SUMMARY

The United States is the major global producer of boron compounds and supplies about 70% of the annual demand. Although boron is ubiquitous in the environment, human activities such as mining, coal burning, drainwater disposal, and use of borax laundry detergents have resulted in elevated boron loadings in the atmosphere and in irrigation waters. The chemistry of boron is complex and rivals that of carbon in its diversity. However, most boron compounds enter or degrade in the environment to B–O compounds (borates) — such as borax and boric acid — and these are considered to be the most significant ecologically.

Boron is an essential trace element for the growth of terrestrial crop plants and for some species of fungi, bacteria, and algae, but excess boron is phytotoxic. Representative species of aquatic organisms, including plants, invertebrates, fishes, and amphibians, usually tolerated up to 10 mg B/L medium for extended periods without harm. In waterfowl, growth was adversely affected at dietary levels of 30 to 100 mg B/kg fresh weight, tissue boron concentrations were elevated at 100 to 300 mg B/kg diet, and survival was reduced at dietary levels of 1000 mg B/kg. All of these dietary levels currently exist near agricultural drainwater disposal sites in the western United States. Boron is not now considered essential in mammalian nutrition, although low dietary levels protect

against fluorosis and bone demineralization. Excessive consumption (i.e., >1000 mg B/kg diet, >15 mg B/kg body weight daily, >1.0 mg B/L drinking water, or >210 mg B/kg body weight in a single dose) adversely affects growth, survival, or reproduction in sensitive mammals. Boron and its compounds are potent teratogens when applied directly to the mammalian embryo, but there is no evidence of mutagenicity or carcinogenicity. Boron's unique affinity for cancerous tissues has been exploited in neutron capture radiation therapy of malignant human brain tumors.

Boron criteria recommended for the protection of sensitive species include:

- <0.3 mg B/L in water for irrigation of crops
- <1.0 mg B/L for aquatic life
- <5.0 mg B/L in livestock drinking waters
- <30 mg B/kg in diets of waterfowl
- <100 mg B/kg in diets of livestock.

CHAPTER 30

Molybdenum

30.1 INTRODUCTION

Molybdenum (Mo) is present in all plant, human, and animal tissues, and is considered an essential micronutrient for most life forms (Schroeder et al. 1970; Underwood 1971; Chappell and Peterson 1976; Chappell et al. 1979; Goyer 1986). The first indication of an essential role for molybdenum in animal nutrition came in 1953 when it was discovered that a flavoprotein enzyme, xanthine oxidase, was dependent on molybdenum for its activity (Underwood 1971). It was later determined that molybdenum is essential in the diet of lambs, chicks, and turkey poult (Underwood 1971). Molybdenum compounds are now routinely added to soils, plants, and waters to achieve various enrichment or balance effects (Friberg et al. 1975; Friberg and Lener 1986).

There are certain locations where plants will not grow optimally because of a deficiency in molybdenum, and other places where the levels of molybdenum in plants are toxic to livestock grazing on the plants (Chappell and Peterson 1976). Molybdenum poisoning in cattle was first diagnosed in England in 1938; molybdenosis was shown to be associated with consumption of herbage containing large amounts of this element, and to be controllable by treatment with copper sulfate (Underwood 1971). Molybdenum poisoning of ruminants, especially cattle, has been reported in at least 15 states, and in Canada, England, Australia, New Zealand, Ireland, the Netherlands, Japan, and Hungary. Molybdenosis was most pronounced in areas where soils were alkaline, high in molybdenum and low in copper, or near industrial point sources such as coal, aluminum, uranium, or molybdenum mines; steel alloy mills; or oil refineries (Dollahite et al. 1972; Alloway 1973; Kubota 1975; Buck 1978; Ward 1978; Chappell et al. 1979; Kincaid 1980; King et al. 1984; Kume et al. 1984; Sas 1987). All cattle are susceptible to molybdenosis, milking cows and young stock being the most sensitive (Underwood 1971). Industrial molybdenosis in domestic cattle and sheep, which usually involved a single farm or pasture, has been widely documented (Ward 1978):

- In Colorado in 1958 from contaminated river waters used in irrigation
- In Alabama in 1960 from mine spoil erosion
- In North Dakota in 1968 from flyash from a lignite burning plant
- In Missouri in 1970-1972 from clay pit erosion
- In Pennsylvania in 1971 from aerial contamination by a molybdenum smelter
- In South Dakota in 1975 from molybdenum-contaminated magnesium oxide
- In Texas in 1965-1972 from uranium mine waste leachate

In humans, a gout-like disease in two villages in Armenia was attributed to the ingestion of local foods high in molybdenum and grown in soils high in molybdenum (Friberg and Lener 1986).

Esophageal cancer was prevalent in various parts of southern Africa where food was grown in low molybdenum soils; it was reported in China in a low frequency rate that was significantly correlated with increasing molybdenum concentrations in cereals and drinking water (Luo et al. 1983). Additional and more extensive data on ecological and toxicological aspects of molybdenum in the environment were reviewed by Schroeder et al. (1970), Underwood (1971), Friberg et al. (1975), Chappell and Peterson (1976, 1977), Ward (1978), Chappell et al. (1979), Gupta and Lipsett (1981), Friberg and Lener (1986), and Eisler (1989).

30.2 ENVIRONMENTAL CHEMISTRY

30.2.1 General

Molybdenum is a comparatively rare element that is used primarily in the manufacture of steel alloys for the aircraft and weapons industries. Most of the global production of about 100,000 tons annually comes from the United States — primarily Colorado. Anthropogenic activities that have contributed to environmental molybdenum contamination include combustion of fossil fuels, and smelting, mining, and milling operations for steel, copper, and uranium, as well as for molybdenum. In general, the chemistry of molybdenum is complex and inadequately known. Its toxicological properties are governed to a remarkable extent by interactions with copper and sulfur, although other metals and compounds may confound this interrelation.

30.2.2 Sources and Uses

Molybdenum is used in the manufacture of high-strength, low-alloy steels and other steel alloys in the aircraft and weapons industries, and in the production of spark plugs, X-ray tubes and electrodes, catalysts, pigments, and chemical reagents (Friberg et al. 1975; Kummer 1980; Goyer 1986). The most important industrial compound is the trioxide, Mo_3O_8 , which is resistant to most acids and is oxidized in air at $>500^\circ\text{C}$ (Shamberger 1979).

Molybdenum, discovered about 200 years ago, entered the commercial market in the 1920s as a result of extensive metallurgical research into its alloying properties and to the finding at Climax, Colorado, of the largest proven reserves of molybdenum worldwide (King et al. 1973). Molybdenum does not occur free in nature and is found only in combination with sulfur, oxygen, tungsten, lead, uranium, iron, magnesium, cobalt, vanadium, bismuth, or calcium. The most economically important ores are molybdenite (MoS_2), jordisite (amorphous MoS_2), and ferrimolybdate ($\text{FeMoO}_3 \cdot \text{H}_2\text{O}$); less important are wulfenite (PbMoO_4), powellite (CaMoO_4), and ilsemannite (Mo_3O_8) (Friberg et al. 1975; Chappell et al. 1979; Friberg and Lener 1986; Goyer 1986).

World molybdenum production has increased from about 90 metric tons in 1900 — half from Australia and Norway, half from the United States — to 136 tons in 1906, 1364 in 1932 (an order of magnitude increase in 26 years), 10,909 in 1946, and 91,000 tons in 1973. Through the years, molybdenum has been produced in about 30 countries. In 1973, about 60% of the worldwide production was from the United States, 15% from Canada, 15% from the U.S.S.R. and China combined, and 10% from other nations — Chile, Japan, Korea, Norway, and Mexico (King et al. 1973). By 1979, the United States produced about 62% of the world production of 103,000 metric tons, and exported about half, chiefly to western Europe and Japan; other major producers in 1979 were Canada, Chile, and the U.S.S.R. (Kummer 1980). In the United States, only three mines in Colorado account for almost 70% of domestic production. Other active molybdenum mining sites in North America are in Arizona, Nevada, New Mexico, Utah, and California; molybdenum reserves have also been proven in Idaho, Alaska, Pennsylvania, and British Columbia (Kummer 1980). About 65% of domestic molybdenum is recovered from ores rich in molybdenum; the rest is a by-product from ores of copper, tungsten, and uranium (Chappell et al. 1979).

As a result of various human activities, molybdenum enters the environment from many sources (King et al. 1973; Friberg et al. 1975; Chappell et al. 1979). Coal combustion is the largest atmospheric source of molybdenum, contributing about 550 metric tons annually, or 61% of all atmospheric molybdenum worldwide that comes from anthropogenic sources. In Sweden alone, about 2.5 tons molybdenum are emitted into the atmosphere yearly from oil combustion (Friberg et al. 1975). Molybdenum mining and milling are the source of about 100 metric tons annually to aquatic systems. At the world's largest molybdenum mine in Climax, Colorado, where about 36,000 tons of tailings are generated daily, the operation releases up to 100 tons of molybdenum annually as aqueous effluent. Other sources are molybdenum smelting, uranium mining and milling, steel and copper milling, oil refining, shale oil production, and claypit mining.

30.2.3 Chemical Properties

Molybdenum, which can function both as a metal and metalloid, is an essential component in a large number of biochemical systems — including xanthine oxidase. At least four metalloenzymes are known to be molybdenum dependent, and all are molybdoflavoproteins (Schroeder et al. 1970). Molybdenum is characterized by the following physical and chemical properties: atomic number 42; atomic weight 95.94; density 10.2; melting point 2617°C; boiling point 4612°C; oxidation states 0, +2, +3, +4, +5, and +6; crystalline forms as gray-black powder, or silver-white metal; mass numbers (percent contribution of naturally occurring molybdenum) of 92 (15.86%), 94 (9.12%), 95 (15.7%), 96 (16.5%), 97 (9.45%), 98 (23.75%), and 100 (9.62.%); and radioactive isotopes of mass number 90, 91, 93, 99 (Tb 1/2 of 67 h, frequently used as a tracer), 101, 102, and 105 (Busev 1969; Schroeder et al. 1970; Shamberger 1979; Friberg and Lener 1986). In water at pH >7, molybdenum exists primarily as the molybdate ion, MoO_4^{2-} ; at pH <7, various polymeric compounds are formed, including the paramolybdate ion, $\text{Mo}_7\text{O}_{24}^{6-}$ (Busev 1969). In soils, molybdate was sorbed most readily to alkaline, high calcium, high chloride soils; retention was least in low pH, low sulfate soils (Smith et al. 1987). There is general agreement that molybdenum chemistry is complex and inadequately known. Additional and more extensive information on its properties was summarized in major reviews by Busev (1969), Boschke (1978), Brewer (1980), Coughlan (1980), Newton and Otsuka (1980), Parker (1983), and Mitchell and Sykes (1986).

30.2.4 Mode of Action

Interactions among some trace metals are so pervading and so biologically influential that the results of nutritional and toxicological studies conducted with a single element can be misleading unless the dietary and body tissue levels of interacting elements are clearly defined (Underwood 1979). For molybdenum, interactions are so dominant — especially in ruminant species — that a particular level of intake in the diet can lead to molybdenum deficiency or to molybdenum toxicity in the animal, depending on the relative intakes of copper and inorganic sulfate (Schroeder et al. 1970; Underwood 1971, 1979; Clawson et al. 1972; Suttle 1973, 1983a; Friberg et al. 1975; Buck 1978; Ward 1978; Chappell et al. 1979; Shamberger 1979; Van Ryssen and Stielau 1980; Gupta and Lipsett 1981; Ivan and Veira 1985; Friberg and Lener 1986; Goyer 1986; Kincaid et al. 1986; Osman and Sykes 1989).

The first indications of interaction between copper and molybdenum came more than 40 years ago from studies of grazing cattle in certain areas of England. Afflicted animals lost weight, developed severe diarrhea, and (in extreme cases) died. The disease is sometimes called teart (rhymes with heart) or molybdenosis, and is caused by eating herbage rich in molybdenum (i.e., 20 to 100 mg/kg dry weight diet compared to <5 mg/kg in nearby healthy pastures) and low or deficient in copper and inorganic sulfate (Underwood 1979). Molybdenosis is a copper deficiency

disease that occurs particularly in cattle and sheep and is usually caused by the depressing effect of molybdenum on the physiological availability of copper (Clawson et al. 1972; Dollahite et al. 1972; Alloway 1973; Erdman et al. 1978; Mills and Breamer 1980; Van Ryssen and Stielau 1980; Nederbragt 1982; Suttle 1983a; Goyer 1986; Osman and Sykes 1989). The disease was treated successfully with copper sulfate at 1 to 2 g daily in the diet, or 200 to 300 mg daily by intravenous injection (Buck 1978; Underwood 1979; Ivan and Veira 1985). When ruminant diets contained copper at 8 to 11 mg/kg weight — a normal range — cattle were poisoned at molybdenum levels of 5 to 6 mg/kg and sheep at 10 to 12 mg/kg. When dietary copper was low (i.e., <8 mg/kg) or sulfate ion level was high, molybdenum at 1 to 2 mg/kg ration was sometimes toxic to cattle. Increasing the copper in diets to 13 to 16 mg/kg protected cattle against concentrations up to 150 mg/kg of dietary molybdenum (Buck 1978). Studies of molybdenum metabolism are of limited value unless one knows the status in the diet of inorganic sulfate, which alleviates molybdenum toxicity in all known species by increasing urinary molybdenum excretion (Underwood 1971, 1979).

Copper prevents the accumulation of molybdenum in the liver and may antagonize the absorption of molybdenum from food. The antagonism of copper to molybdenum depends on sulfate, which may displace molybdate (Goyer 1986). In certain sheep pastures, for example, the herbage may contain up to 15 mg copper/kg dry weight and <0.2 mg Mo/kg dry weight — conditions favoring the development of a high copper status that may lead to copper poisoning. Treatment consists of providing molybdate salt licks, which are highly effective in reducing copper levels in grazing sheep (Buck 1978; Underwood 1979). A low copper:molybdenum ratio (i.e., <2), rather than the absolute dietary concentration of molybdenum, is the primary determinant of susceptibility to molybdenum poisoning; molybdenosis is not expected when this ratio is near 5 (Buck 1978; Ward 1978; Mills and Breamer 1980). Ratios of copper to molybdenum in sweet clover (*Melilotus* spp., a known molybdenum accumulator plant) growing in coal mine spoils in the Dakotas, Montana, and Wyoming ranged from 0.4 to 5, suggesting that molybdenosis can be expected to occur in cattle and sheep grazing in low Cu:Mo areas (Erdman et al. 1978). A similar situation existed in British Columbia, where 19% of all fodders and grains had a Cu:Mo ratio <2 (Underwood 1979).

There are several explanations for the high sensitivity of ruminants to increased dietary molybdenum and sulfur, the most plausible being the role of thiomolybdates (Penumarthy and Oehme 1978; Lamand et al. 1980; Nederbragt 1980, 1982; Suttle 1980, 1983b; Mills et al. 1981; Suttle and Field 1983; Weber et al. 1983; Hynes et al. 1985; Friberg and Lener 1986; Allen and Gawthorne 1987; Sas 1987; Strickland et al. 1987). Thiomolybdates are compounds formed by the progressive substitution for sulfur and oxygen in the molybdate (MoO_4^{2-}) anion when hydrogen sulfide and MoO_4^{2-} interact *in vitro* at neutral pH. Di-, tri-, and tetrathiomolybdates are formed, but only the last of these effectively impairs copper absorption. When sufficient tetrathiomolybdate (MoS_4) is formed in the rumen, it and copper in the gut combine and the resultant complex is bound strongly to proteins of high molecular weight. The molybdoproteins so formed are strong chelators of copper, and may be the agents responsible for copper deficiency through formation of biologically unavailable copper complexes in gut, blood, and tissues of animals that consume diets containing high concentrations of molybdenum. To confound matters, the complex molybdenum–copper–sulfur interrelationship can be modified, or disrupted entirely, by many compounds or mixtures. These include the salts of tungsten (Schroeder et al. 1970; Underwood 1971; Mills and Breamer 1980; Luo et al. 1983; Goyer 1986), zinc (Penumarthy and Oehme 1978; Parada 1981; Alary et al. 1983), lead and manganese (Underwood 1971), iron (Phillippo et al. 1987b), vanadium (Vaishampayan 1983), chromium (Vaishampayan 1983; Chung et al. 1985), phosphorus (Underwood 1971; Baldwin et al. 1981), cystine and methionine (Underwood 1971, 1979), fluoride (Goyer 1986), and proteins (Underwood 1971, 1979; Friberg and Lener 1986; Kincaid et al. 1986).

30.3 CONCENTRATIONS IN FIELD COLLECTIONS

30.3.1 General

Molybdenum levels tend to be elevated in nonbiological materials and in terrestrial flora in the vicinity of molybdenum mining and reclamation activities, fossil-fuel power plants, and disposal areas for molybdenum-contaminated sewage sludge, flyash, and irrigation waters. Concentrations of molybdenum in fish, wildlife, and invertebrates were low when compared to those in terrestrial plants, although certain aquatic invertebrates were capable of high bioconcentration. Concentrations of molybdenum alone, however, were not sufficient to diagnose molybdenum deficiency or toxicosis.

30.3.2 Nonbiological Samples

Elevated levels of molybdenum in nonbiological materials have been reported near certain mines, power plants, and oil shale deposits, as well as in various sewage sludges, fertilizers, and agricultural drainwaters ([Table 30.1](#)). Molybdenum is concentrated in coal and petroleum, and the burning of these fuels contributes heavily to atmospheric molybdenum (King et al. 1973). Combustion of fossil fuels contributes about 5000 metric tons of molybdenum annually to the atmosphere; atmospheric particulates contain about 0.001 µg Mo/m³ air (Goyer 1986).

Natural molybdenum concentrations in ground and surface waters rarely exceed 20 µg/L; significantly higher concentrations are probably due to industrial contamination. Existing wastewater and water treatment facilities remove less than 20% of the molybdenum; accordingly, drinking water concentrations are near those of the untreated source (Chappell et al. 1979). Molybdenum concentrations in saline waters appear to be directly related to salinity (Prange and Kremling 1985; Sloot et al. 1985). In the Wadden Sea, for example, molybdenum concentrations were 0.08, 0.4, and 1.0 µg/L at salinities of 0.07, 1.2, and 3.3%, respectively (Sloot et al. 1985).

The molybdenum content of soil may vary by more than an order of magnitude, causing both deficient and excessive concentrations for plants and ruminants in some parts of the world (Friberg et al. 1975). Native soils may contain enough molybdenum to cause molybdenosis in range livestock in some areas of the United States, particularly in Oregon, Nevada, and California (Kubota et al. 1967; Erdman et al. 1978). Elevated soil molybdenum levels can result from both natural and industrial sources. Usually when soil molybdenum levels exceed 5 mg/kg dry weight, a geological anomaly or industrial contamination is the likely explanation (Chappell et al. 1979). Molybdenum is more available biologically to herbage plants in alkaline soils than in neutral or acidic soils (Underwood 1971; Friberg et al. 1975; Shacklette et al. 1978; Wright and Hossner 1984). Liming of acidic soils or treatment with molybdenum-containing fertilizers can effectively raise the molybdenum content of herbage (Underwood 1971; Pierzynski and Jacobs 1986).

The disposal of sewage sludge, flyash from coal combustion, and molybdenum-contaminated irrigation waters to agricultural fields may result in the production of molybdenum-rich herbage. Sewage sludges rich in molybdenum and applied to agricultural soils resulted in elevated molybdenum content in corn and soybeans in a dose-dependent pattern (Pierzynski and Jacobs 1986). Similarly, flyash from coal combustion applied to pasture and croplands at rates sufficient to provide molybdenum at concentrations of 40 g/kg and higher resulted in potentially hazardous levels in vegetation to ruminant grazers. Molybdenum in flyash applied to soils remained biologically available for extended periods, especially in calcareous soils (Elseewi and Page 1984). Irrigation has also been proposed as a possible disposal method for large quantities of water having molybdenum concentrations of 5 to 100 mg/L that result from mining and reclamation activities. This method of disposal is not recommended unless all animals are kept off irrigated sites and the vegetation can be harvested and destroyed until molybdenum levels in the plants remain below 10 mg/kg dry weight (Smith et al. 1987).

30.3.3 Biological Samples

All plants contain molybdenum, and it is essential for the growth of all terrestrial flora (Schroeder et al. 1970). Molybdenum concentrations were elevated in terrestrial plants, especially in those collected from soils amended with flyash, liquid sludge, or molybdenum-contaminated irrigation waters, in naturally occurring teat pastures, and in the vicinity of molybdenum mining and ore processing activities, steelworks, and other metal processors. Molybdenum concentrations greater than 20 mg/kg dry weight were frequently documented in plants from contaminated areas (Table 30.2). Legumes, especially trefoil clovers (*Lotus* sp.) selectively accumulated molybdenum; concentrations of 5 to 30 mg/kg dry weight were common in molybdenum-contaminated areas (Friberg et al. 1975; Shacklette et al. 1978). The molybdenum levels were sometimes high and potentially toxic in legumes from

poorly drained acidic soils (Kubota et al. 1967; Underwood 1971). Some terrestrial grasses displayed copper:molybdenum ratios between 0.5 and 3.7. Since ratios greater than 2 were within the range where molybdenosis is likely, and since most of the molybdenum concentrations were greater than the maximum tolerable level of 6 mg/kg dry weight, hypocuprosis (molybdenosis) in cattle was expected (Schalscha et al. 1987). Major sources of molybdenum overload in fodder were in plants grown on high-molybdenum alkaline soils and from industrial contamination by coal and uranium mines and alloy mills (Sas 1987). Variations in molybdenum content of pasture species ranged from 0.1 to 200 mg/kg dry weight, and most variations were due to soil and species differences (Underwood 1971). Pasture plants collected from mountainous areas of southern Norway were usually deficient in copper, and low to partly deficient in molybdenum. As a result, the copper:molybdenum ratios were generally high and may explain the occurrence of chronic copper poisoning in grazing sheep in that region (Garmo et al. 1986).

Except in terrestrial plants, molybdenum concentrations were low in all groups examined; maximum concentrations reported from all sampling locales were about 6 mg/kg dry weight in aquatic plants, about 4 mg/kg fresh weight in aquatic invertebrates, 2 mg/kg fresh weight in fishes (except for rainbow trout liver and kidney — 26 to 43 mg/kg fresh weight — from fish collected near a molybdenum tailings outfall), 4 mg/kg dry weight in birds, 30 mg/kg dry weight in domestic ruminant liver, 85 mg/kg dry weight in the horse, and <4 mg/kg dry weight in mammalian wildlife and humans (Table 30.2).

No food chain biomagnification of molybdenum was found in 1987 in aquatic organisms from the San Joaquin River, California (Saiki et al. 1993). Maximum concentrations of molybdenum recorded in the San Joaquin River in 1987 were 10 µg/L in water, and — in mg/kg DW — 3.1 in detritus, 1.4 in algae, 0.54 in chironomid larvae, 0.64 in whole crustaceans, and 0.51 in bluegills (Saiki et al. 1993). Molybdenum did not biomagnify in the fish/crustacean/hump-backed dolphin (*Sousa chinensis*) food chain (Parsons 1998). Molybdenum concentrations from cetacean liver tissues were 4.1 times lower than those of whole prey organisms, i.e., 0.8 vs. 3.3 mg Mo/kg DW. Hump-backed dolphins from Hong Kong consume about 4.3 mg of molybdenum daily, equivalent to about 0.02 mg Mo/kg BW (Parsons 1998). Large interspecies differences were evident among aquatic organisms in their ability to accumulate molybdenum from the medium. Marine bivalve molluscs usually contained 30 to 90 times more molybdenum than the ambient seawater; however, some species from Greek waters had bioconcentration factors up to 1300 (Eisler 1981). Marine plankton accumulated molybdenum from seawater by factors up to 25 (Goyer 1986). But growth in aquatic phytoplankton populations was inhibited under conditions of low or missing molybdenum, nitrogen, and organic matter concentrations. The role of molybdenum in this process requires clarification (Paerl et al. 1987). In rainbow trout (*Oncorhynchus mykiss*), residues of molybdenum in tissues were affected only slightly by the concentrations in water; tissue residues ranged from 5 to 118 µg/kg fresh weight in water containing trace (<6 µg/L) concentrations; 10 to 146 µg/kg in water containing low (6 µg/L) concentrations; and from 13 to 322 µg/kg in water containing high (300 µg/L) concentrations (Ward 1973). A similar pattern was reported for kokanee salmon, *Oncorhynchus nerka* (Ward 1973). Rainbow trout held for 2 weeks in live traps 1.6 km downstream from a molybdenum mine tailings outfall survived, but liver and kidney had significantly elevated levels of molybdenum, calcium, manganese, iron, zinc, strontium, and zirconium, and 10% less potassium. The observed mineral changes may have been due to outfalls from nonmolybdenum mines discharged into the river system (Kienholz 1977).

In moles (*Talpa europaea*), adults had significantly higher concentrations of molybdenum in liver than did juveniles (Pankakoski et al. 1993). The significance of this observation is imperfectly understood. Molybdenum mining operations are not detrimental to mammalian wildlife, as judged by normal appearance and low molybdenum levels in liver and kidney of nine species — including deer, squirrel, chipmunk, badger, beaver, marmot, and pika — collected from areas with high environmental molybdenum levels (Kienholz 1977). It is emphasized that molybdenum concentrations in animal tissues give little indication of the dietary molybdenum status, and are of little diagnostic value for this purpose unless the sulfate, protein, and copper status of the diet are also known. This point is discussed in greater detail later.

Table 30.2 Molybdenum Concentrations in Field Collections of Selected Species of Animals and Plants (Values shown are in mg Mo/kg [ppm Mo] fresh weight [FW], dry weight [DW], or ash weight [AW].)

Taxonomic Group, Organism, Tissue, and Other Variables	Concentration ^a (mg/kg)	Reference ^b
TERRESTRIAL PLANTS

30.4 EFFECTS

30.4.1 General

Trace quantities of molybdenum are beneficial and perhaps essential for normal growth and development of plants and animals. In mammals, molybdenum can protect against poisoning by copper, mercury, and probably other metals, and may have anticarcinogenic properties. For all organisms, the interpretation of molybdenum residues depends on knowledge of molybdenum, copper, and inorganic sulfate concentrations in diet and in tissues. Some molybdenum compounds have insecticidal properties at low concentrations and have been proposed as selective termite control agents.

Aquatic flora and fauna seem to be comparatively resistant to molybdenum salts. Adverse effects on growth and survival were usually noted only at water concentrations of 50 mg Mo/L and higher. However, one study with newly fertilized eggs of rainbow trout produced an LC50 (28 day) value of 0.79 mg Mo/L compared to an LC50 (96 h) value of 500 mg/L for adults. Also, bioconcentration of molybdenum by selected species of algae and invertebrates (up to 20 g/kg dry weight) poses questions on risk to higher trophic level organisms.

In birds, adverse effects of molybdenum have been reported on growth at dietary concentrations of 200 to 300 mg/kg, on reproduction at 500 mg/kg, and on survival at 6000 mg/kg. In mammals, cattle are especially sensitive to molybdenum poisoning, followed by sheep, under conditions of copper and inorganic sulfate deficiency. Cattle were adversely affected when grazing pastures with a copper:molybdenum ratio <3, when fed low copper diets containing 2 to 20 mg Mo/kg diet, or when total daily intake approaches 141 mg molybdenum. Cattle usually die at doses of 10 mg Mo/kg body weight. Other mammals, including horses, pigs, rodents, and ruminant and nonruminant

nant wildlife, are comparatively tolerant to molybdenum. Deer, for example, are at least 10 times more resistant than domestic ruminants to molybdenum. No adverse effects in deer were noted at dietary levels of 1000 mg/kg after 8 days, slight effects at 2500 mg/kg after 25 days, and reduction in food intake and diarrhea at 5000 mg/kg diet after 15 days.

30.4.2 Terrestrial Plants

In a major literature review, Gupta and Lipsett (1981) concluded that molybdenum was essential for plant growth due to its role in the fixation of nitrogen by bacteria using the enzymes nitrogenase and nitrate reductase, and that plants readily accumulated MoO_4^{2-} except under conditions of low pH, high sulfate, and low phosphate, and in some highly organic soils. Molybdenum deficiency has been recorded in a variety of crops worldwide, but there is an extremely narrow range between adequacy and deficiency. In lettuce (*Lactuca sativa*), for example, adverse effects were noted at 0.06 mg/kg (dry weight) in plants, but sufficiency was attained at 0.08 to 0.14 mg/kg. A similar case is made for *Brassica* spp. (i.e., Brussels sprouts, cabbage, and cauliflower) (Gupta and Lipsett 1981). In certain species, such as beets (*Beta vulgaris*) and corn (*Zea mays*), the ratio between deficiency and sufficiency may differ by more than 10 times (Gupta and Lipsett 1981).

Okra (*Abelmoschus esculentus*), grown in soils supplemented with molybdenum at 1, 2, or 3 mg/kg, as sodium molybdate, showed increasing growth and yields when compared to nonsupplemented soils. Fruiting occurred earlier and persisted longer with increasing molybdenum concentration (Singh and Mourya 1983). The cashew (*Anacardium occidentale*) — one of the most valuable plantation crops in India — developed yellow-leaf spots accompanied by low molybdenum levels and excess manganese in low pH soils; in extreme cases the tree was defoliated (Subbaiah et al. 1986). The disorder was corrected by foliar spraying of molybdenum salts or by liming the soil. A similar case was reported for Florida citrus in the 1950s, which was shown to be due to molybdenum deficiency (Subbaiah et al. 1986).

Soils amended with sewage sludge containing 12 to 39 mg Mo/kg dry weight (soil contained 2 mg Mo/kg dry weight at start and 4.8 to 6 mg/kg after treatment) were planted with corn and bromegrass (*Bromus inermis*). A lime-treated sludge increased molybdenum concentrations in plant tissues after several years of sludge application; maximum values recorded were 1.9 mg Mo/kg dry weight in bromegrass and 3.7 in corn (Soon and Bates 1985). No toxicity of molybdenum has yet been observed in field-grown crops, although forages containing 10 to 20 mg/kg dry weight are considered toxic to cattle and sheep (Soon and Bates 1985).

30.4.3 Terrestrial Invertebrates

Sodium molybdate and other molybdenum compounds in toxic baits have potential for termite control (Brill et al. 1987). Baits containing 1000 mg Mo/kg were fatal to 99% of the termite *Reticulitermes flavipes* in 48 days. After 8 to 10 days, termites became steel-gray in color, but appeared otherwise normal. Mortality began only after day 16. Termites did not avoid the poisoned bait, even at concentrations of 5000 mg Mo/kg. Yoshimura et al. (1987) reported similar results with another species of termite; sodium molybdate killed 100% of the workers in a colony of *Copotermes formosanus* within 24 h after eating filter paper treated with a 5% solution. Some other species of insects — including fire ants (*Solenopsis* sp.) and various species of beetles and cockroaches — were not affected when exposed to baits containing 5000 mg Mo/kg for 48 days (Brill et al. 1987).

30.4.4 Aquatic Organisms

Aquatic plants are comparatively resistant to molybdenum. In sensitive species, adverse effects were evident on growth at 50 mg/L and on development at 108 mg/L (Table 30.3). Bioconcentration of molybdenum from the medium by certain freshwater algae can result in residues up to 20 g/kg

dry weight without apparent damage ([Table 30.3](#)). The implications of this phenomenon for waterfowl and other species that consume molybdenum-laden algae need to be explored.

Molybdenum is considered essential for aquatic plant growth, but the concentrations required are not known with certainty and are considered lower than those for any other essential element (Schroeder et al. 1970; Henry and Tundisi 1982). Molybdenum starvation restricts nitrogen fixation in algae, thereby limiting photosynthetic production during depleted conditions. Blue-green alga (*Anabaena oscillaroides*) cultured in molybdenum-deficient media containing 0.004 to 0.005 µg Mo/L rapidly depleted molybdenum in the medium; this ability was lost at higher concentrations of added molybdenum, when *Anabaena* began to accumulate the element (Steeg et al. 1986). The addition of tungstate to molybdenum-deficient media enhances dinitrogenase inactivation, resulting in inhibited algal growth. This process is reversed at molybdenum levels of 0.005 to 0.04 µg/L (Steeg et al. 1986). On the other hand, algal growth was significantly enhanced when vanadium (V) was present at 12.5 µg/L, although higher concentrations of V were growth inhibitory in 7 days (Vaishampayan 1983). Algal uptake of molybdenum is rapid during the first 2 h, and slower thereafter. The sequential biological reduction of hexavalent to pentavalent to trivalent molybdenum occurs intracellularly in green algae (Sakaguchi et al. 1981). Uptake is greater in freshwater than in seawater, greater at increased doses, and greater at reduced algal densities (Sakaguchi et al. 1981); it is also greater at elevated temperatures (Penot and Videau 1975).

Molybdenum occurs naturally in seawater as molybdate ion, MoO_4^{2-} , at about 10 µg/L (Abbott 1977). Despite the high concentrations of dissolved molybdenum in offshore seawater, phytoplankton from offshore locales contain extremely low molybdenum residues, almost typical of molybdenum-deficient terrestrial plants (Howarth and Cole 1985). This phenomenon is attributed to the high concentrations of sulfate in seawater; sulfate inhibits molybdate assimilation by phytoplankton, making it less available in seawater than in freshwater. As one result, nitrogen fixation and nitrate assimilation — processes that require molybdenum — may require greater energy expenditure in marine than in freshwaters and may explain, in part, why marine ecosystems are usually nitrogen-limited and lakes are not (Howarth and Cole 1985). Experimentally increasing the ratio of sulfate to molybdate inhibits molybdate uptake by marine algae, slows nitrogen fixation rates, and slows the growth of organisms that use nitrate as a nitrogen source (Howarth and Cole 1985).

Limited data suggested that aquatic invertebrates were very resistant to molybdenum. Adverse effects were observed on survival at >60 mg Mo/L and on growth at >1000 mg Mo/L ([Table 30.3](#)). Bioconcentration factors were low, but depending on initial dose, measured residues (mg/kg fresh weight) were as high as 16 in amphipods, and were 3 in clams, 18 in crayfish muscle, and 32 in crayfish carapace (Short et al. 1971). The host organisms seemed unaffected under these molybdenum burdens, but effects on upper trophic level consumers were not clear. Tailings from a pilot molybdenum mine on the North American Pacific coast were acutely lethal at concentrations of >61,000 mg tailings solids/L seawater to larvae of the mussel *Mytilus edulis*, and to adults of the amphipod *Rhepoxynius abronius* and the euphausiid *Euphausia pacifica*. Acute sublethal effects were observed at >277,000 mg/L (Mitchell et al. 1986). All species of invertebrates tested in this preliminary study were more sensitive than juvenile coho salmon, *Oncorhynchus kisutch* (Mitchell et al. 1986). In another study, zooplankton exposed to molybdenum mine tailings <8 µm in diameter at high sublethal concentrations ingested and excreted these particles (Anderson and Mackas 1986). The lowest tailing concentration tested at which a deleterious effect was observed was 100 mg/L for depression of respiration in the copepod *Calanus marshallae*, and 560 mg/L for increased mortality in copepods and the euphausiid *Euphausia pacifica*; concentrations of molybdenum mine tailings were always <15 mg/L at 0.5 km downstream from a molybdenum tailings outfall (Anderson and Mackas 1986).

Freshwater and marine fishes were — with one exception — extremely resistant to molybdenum. LC50 (96 h) values ranged between 70 mg/L and <3000 mg/L ([Table 30.3](#)). The exception was newly fertilized eggs of rainbow trout exposed for 28 days through day 4 posthatch; the LC50 (28 day) value was only 0.79 mg/L (Birge et al. 1980), suggesting that additional research is needed

on the sensitivity of early life stages to molybdenum. In general, molybdenum was more toxic to teleosts in freshwater than in seawater, and more toxic to younger fish than to older fish. In rainbow trout, it bioconcentrated up to 16 mg/kg fresh weight in liver, 18 in spleen, 7 in muscle, 6 in gill, and 2 in gastrointestinal tract (Table 30.3) (Short et al. 1971). Environmental levels of molybdenum as molybdate measured in the Mo mining areas of Colorado were not considered harmful to rainbow trout (McConnell 1977). Molybdenum enrichment of Castle Lake, California (a high mountain lake in which molybdenum was determined to be the limiting micronutrient), coupled with favorable environmental conditions, led to record high yields of trout. The addition of 16 kg sodium molybdate, or 6.4 kg molybdenum, to Castle Lake in July 1963 was followed by larger standing crops of zooplankton and bottom fauna, which probably promoted survival of the 1965 year class and resulted in record yields to the angler of rainbow trout and brook trout (*Salvelinus fontinalis*) in 1967 (Cordone and Nicola 1970). Enrichment of molybdenum-deficient waters to improve angler success merits additional research.

Table 30.3 Molybdenum Effects on Selected Species of Aquatic Organisms

Organism, Mo Concentration, and Other Variables	Effect	Reference ^a
AQUATIC PLANTS		
Blue-green alga, <i>Anabaena oscillarioides</i>		
0.005 µg/L	Bioconcentration factor (BCF) of 3300 in 60 min	1
0.073 µg/L	BCF of 550 in 60 min	1
25 µg/L	BCF of 7–24 in 60 min	1
Green alga, <i>Chlorella vulgaris</i>		
10 mg/L	Residues of about 20,000 mg/kg dry weight in 20 h. Dead (heat-killed) <i>Chlorella</i> contained 4902 mg/kg dry weight in 1 h vs. 3264 mg/kg in live cells	2
20 mg/L	Normal growth in 96 h	2
50 mg/L	Reduced growth in 96 h	2
Euglena, <i>Euglena gracilis</i>		
5.4 mg/L	Normal growth and reproduction	3
96 mg/L	No abnormal cells in 48 h	3
108 mg/L	Abnormal development, cells forming clusters. Culture is photosensitive with blue color	3
>960 mg/L	No growth	3
Freshwater alga, <i>Nitella flexilis</i>		
0.014 µg/L	BCF of 628 in 25 days	4
3.3 mg/L	BCF of 39 in 24 days; elevated residues of 130 mg/kg fresh weight	4
Blue-green alga, <i>Nostoc muscorum</i>		
17.7 µg/L	Required for growth	5
INVERTEBRATES		
Amphipod, <i>Allorchestes compressa</i>		
60 mg/L	No deaths (= LC0) in 96 h	6
247 mg/L	50% dead (= LC50) in 96 h	6
450 mg/L	97% dead (= LC97) in 96 h	6
Starfish, <i>Asterias rubens</i>		
127 mg/L	LC50 (24 h) at pH 5.8	7
254 mg/L	LC50 (24 h) at pH 8.2	7
Copepod, <i>Calanus marshallae</i>		
20 mg/L	Minor increase in oxygen consumption in 24 h	8
100 mg/L	Decreased oxygen consumption in 24 h	8
560 mg/L	LC50 (19 days)	8
Green crab, <i>Carcinus maenas</i>		
1018 mg/L	LC50 (48 h)	7

Table 30.3 (continued) Molybdenum Effects on Selected Species of Aquatic Organisms

Organism, Mo Concentration, and Other Variables	Effect	Reference ^a
American oyster, <i>Crassostrea virginica</i> 1375 mg/L	Reduction of 50% in shell growth in 96 h	9
Hermit crab, <i>Eupagurus bernhardus</i> 100 mg/L	LC0 (50 days)	7
222 mg/L	LC50 (48 h)	7
Euphausiid, <i>Euphausia pacifica</i> 560 mg/L	LC50 (112 h)	8
Amphipod, <i>Gammarus</i> sp. 3.3 mg/L	BCF of 4.8 in whole animal in 24 days	4
Lake periphyton 0.014 µg/L	BCF of 3570 in 24 days	4
Clam, <i>Margaretifera margaretifera</i> 3.3 mg/L	Maximum BCF values in 15–24 days were 1.8 in shell, 0.9 in soft parts, and 0.3 in muscle	4
Mysid shrimp, <i>Mysidopsis bahia</i> 1205 mg/L	LC50 (96 h)	9
Mussel, <i>Mytilus edulis</i> , larvae 147 mg/L	Development reduced 50% in 48 h, based on survival and abnormalities	10
Crayfish, <i>Pacifastacus leniusculus</i> 3.3 mg/L	BCF in 24 days of 5.7 for muscle and 9.8 for carapace	4
Pink shrimp, <i>Penaeus duorarum</i> 1909 mg/L	LC50 (96 h)	9
Pullet-shell (clam), <i>Venerupis pallustra</i> 381 mg/L	LC50 (24 h)	7
FISH		
Flannelmouth sucker, <i>Catostomus latipinnis</i> ; larvae; age 12–13 days; molybdenum as sodium molybdate >2800 mg Mo/L	LC50 (48 h)	15
1940 (95% CI = 1680–2370) mg Mo/L	LC50 (96 h)	15
Sheepshead minnow, <i>Cyprinodon variegatus</i> 3057 mg/L	LC50 (96 h)	9
Bluegill, <i>Lepomis macrochirus</i> 1320 mg/L	LC50 (96 h)	11
Rainbow trout, <i>Oncorhynchus mykiss</i> Embryos and larvae exposed for 28 days starting at fertilization through 4 days posthatch 28 µg/L	LC1 (28 days)	12
125 µg/L	LC10 (28 days)	12
790 (610–990) µg/L	LC50 (28 days)	12
17.0–18.5 mg/L, exposed continuously for 1 year from eyed eggs to juvenile stage	No significant effect on survival, growth, or blood hematocrit	10, 11
500 mg/L	LC25 (96 h), mean length 20 mm	11
800 mg/L	LC50 (96 h), mean length 20 mm	11
1320 mg/L	LC50 (96 h), mean length 55 mm	11
Steelhead trout, <i>Oncorhynchus mykiss</i> 0.014 µg/L	Max. BCF of 1143 in liver and gastrointestinal tract after chronic exposure	4
3.3 mg/L	Max. BCF in 24 days of 5.4 in spleen, 4.5 in liver, 2.3 in muscle, 1.8 in gill, and 0.6 in gastrointestinal tract	4
Coho salmon, <i>Oncorhynchus kisutch</i> >1000 mg/L	LC50 (96 h); fry	13

30.4.5 Birds

Data are missing on the effects of molybdenum on avian wildlife under controlled conditions. All studies conducted with birds have been restricted to domestic poultry. Signs of molybdenum deficiency in domestic chickens included loss of feathers, lowered tissue molybdenum concentrations, reduced xanthine dehydrogenase activity in various organs, decreased uric acid excretion, disorders in ossification of long bones, and changes in joint cartilage that led to complete immobility. Signs were eliminated when diets were supplemented with molybdenum at concentrations of 0.2 to 2.5 mg/kg (Reid et al. 1956; Friberg and Lener 1986). Efforts to produce a molybdenum deficiency syndrome in birds and mammals by feeding diets low in molybdenum have been unsuccessful (Friberg et al. 1975). Thus, it has been necessary to introduce a compound with a known property of inhibiting molybdenum, namely wolframate (Na_2WO_4), a tungsten compound. Wolframate increases molybdenum excretion, leading to molybdenum deficiency in rats and chickens. With this technique it has been possible to produce an assumed molybdenum deficiency in chicks consisting of reduced weight gain and sometimes death (Friberg et al. 1975). Dietary requirements to maintain normal growth in rats and chicks were probably less than 1 mg Mo/kg food, and thus substantially less than that of any other trace element recognized as essential (Mills and Breamer 1980). In fact, birds may require molybdenum at concentrations up to 6 mg/kg in their diets for optimal growth (Kienholz 1977). Dietary molybdenum counteracts adverse effects in chicks on growth and survival induced by hexavalent chromium. Chicks fed 900 mg chromium/kg ration for 4 weeks showed significantly depressed growth, 25% mortality, and elevated liver chromium. However, diet supplementation to 150 mg Mo/kg resulted in normal growth and liver chromium values, and no deaths (Chung et al. 1985).

Early studies with chicks and turkey poult showed that the addition of only 13 to 25 µg Mo/kg — as molybdate or molybdic acid — to basal diets containing 1.0 to 1.5 mg Mo/kg resulted in a growth advantage of 14 to 19% in 4 weeks over that in unsupplemented groups (Reid et al. 1956, 1957). Roosters given daily dietary supplements of 100 or 400 µg molybdenum per bird for 4 weeks to basal diets containing 0.51 mg Mo/kg had reduced serum uric acid values when compared to those of controls. The significance of this finding is not clear (Karring et al. 1981). Birds are relatively resistant to molybdenum. For example, day-old chicks fed diets containing 20% molybdenum mine tailings for 23 days were unaffected, and those fed diets containing 40% molybdenum mine tailings showed only a slight reduction in body weight during the same period (Kienholz 1977). Dietary levels of 200 mg Mo/kg ration results in minor growth inhibition of chicks; and at 300 mg/kg feed, the growth of turkey poult was reduced (Underwood 1971). Dietary supplements of 500 mg Mo/kg ration produced a slight decrease in growth rate of chicks after 4 weeks; hens, however, laid 15% fewer eggs than controls, and all eggs contained embryolethal concentrations of 16 to 20 mg Mo/kg (Friberg et al. 1975). At dietary supplements of 1000 mg

Mo/kg, egg production was reduced 50% in domestic chickens (Friberg et al. 1975). Dietary loadings of 2000 mg/kg induced severe growth depression and a 100-fold increase in molybdenum content in tibia (Underwood 1971) and an 80% reduction in egg production (Friberg et al. 1975). At 4000 mg/kg diet, severe anemia was reported in chickens (Underwood 1971). Mortality of chicks fed 6000 mg Mo/kg diet for 4 weeks was 33%; at 8000 mg Mo/kg diet for 4 weeks, 61% of the chicks died and survivors weighed only 16% as much as the controls (Friberg et al. 1975). Chicks, unlike mammals, did not experience molybdenum reduction in tissues after sulfate administration — although sulfate markedly reduced the signs of Mo toxicity (Underwood 1971).

30.4.6 Mammals

Almost all studies conducted to date on molybdenum effects under controlled conditions have been on livestock, especially cattle and sheep. Molybdenum is beneficial and perhaps essential to adequate mammalian nutrition. Moreover, it can protect against poisoning by copper or mercury, and may be useful in controlling cancer. Evidence of functional roles for molybdenum in the enzymes xanthine oxidase, aldehyde oxidase, and sulfite oxidase suggests that molybdenum is an essential trace nutrient for animals (Underwood 1971; Earl and Vish 1979; Mills and Breamer 1980). Signs of molybdenum deficiency include decreased intestinal and liver xanthine oxidase activity (Mills and Breamer 1980). Molybdenum prevents damage to the liver in sheep receiving excess copper; accumulations of copper and molybdenum in kidney were present in a biologically unavailable form and of negligible physiological significance (Van Ryssen et al. 1982). Dietary supplements of 70 mg molybdenum per day for a restricted period is recommended for reduction of liver Cu in sheep, provided dietary Cu levels are simultaneously reduced (Van Ryssen et al. 1986). Molybdenum, as sodium molybdate, protects against acute inorganic mercury toxicity in rats by altering the metabolism of cysteine-containing proteins in the cytoplasm of liver and kidney, resulting in lowered mercury content in these organs (Yamane and Koizumi 1982; Koizumi and Yamane 1984). Anticarcinogenic properties of molybdenum in rats have been reported, although the mechanisms of action are unknown. In one study, 2 or 20 mg Mo/L in drinking water significantly inhibited cancer of the esophagus and forestomach experimentally induced by *N*-nitrososarcosine ethyl ester (Luo et al. 1983). In another study with virgin female rats, 10 mg Mo/L in drinking water reduced by half the number of mammary carcinomas experimentally induced by *N*-nitroso-*N*-methylurea (Wei et al. 1985). Additional research seems warranted on the role of molybdenum in cancer inhibition.

Molybdenosis has been produced experimentally in many species of mammals, including cattle, sheep, rabbits, and guinea pigs (Friberg et al. 1975). Signs of molybdenum poisoning vary greatly among species, but generally include the following: copper deficiency, especially in serum; reduced food intake and growth rate; liver and kidney pathology; diarrhea and dark-colored feces; anemia; dull, wiry, and depigmented hair; reproductive impairment, including delayed puberty, female infertility, testicular degeneration, and abnormal or delayed estrus cycle; decreased milk production; joint and connective tissue lesions; bone abnormalities; and loosening and loss of teeth (Underwood 1971; Dollahite et al. 1972; Friberg et al. 1975; Erdman et al. 1978; Penumopathy and Oehme 1978; Ward 1978; Chappell et al. 1979; Mills and Breamer 1980; Alary et al. 1981; Baldwin et al. 1981; Friberg and Lener 1986; Van Ryssen et al. 1986; Phillippe et al. 1987a). These authorities also agree on three additional points:

- Early signs of molybdenosis are often irreversible, especially in young animals
- The severity of the signs depends on the level of molybdenum intake relative to that of copper and inorganic sulfate
- If afflicted animals are not removed promptly from molybdenum-contaminated diets and given copper sulfate therapy, death may result.

Molybdenum poisoning in ruminants, or teart disease, has been known since the mid-1800s and affects only ruminants of special pastures. Degree of teartness varies from field to field and season to season, and is usually proportional to the molybdenum content in herbage. Molybdenum levels in typical teart pastures range from 10 to 100 mg/kg dry weight compared to normal levels of 3 to 5 mg/kg (Friberg and Lener 1986). If herbage contains more than 12 mg Mo/kg dry weight, problems should be expected in cattle, and to a lesser extent in sheep (Friberg et al. 1975). In situations where cattle are accidentally exposed to high molybdenum levels, the administration of copper sulfate should result in molybdenum excretion, up to 50% in 10 days (Penumarthy and Oehme 1978). Aside from cattle and sheep, all evidence indicates that other mammals are comparatively tolerant of high dietary intakes of molybdenum, including horses, pigs, small laboratory animals, and mammalian wildlife (Underwood 1971; Buck 1978; Chappell et al. 1979; Friberg and Lener 1986; Osman and Sykes 1989; [Table 30.4](#)). Cattle excrete molybdenum primarily through feces, but other (more tolerant) species such as pigs, rats, and humans, rapidly excrete molybdenum through urine, and this may account, in part, for the comparative sensitivity of cattle to molybdenum (Underwood 1971). Cattle normally excrete about 67% of all administered MoO_3 in feces and urine in 7 days; guinea pigs excreted 100% in urine in 8 days; and swine excreted 75% in urine in 5 days (Penumarthy and Oehme 1978). Cattle are adversely affected when:

- They graze copper-deficient pastures containing 2 to 20 mg/kg molybdenum, and the copper to molybdenum ratio is less than 3
- They are fed low copper diets containing 5 mg (or more) Mo/kg dry weight
- The total daily intake approaches 141 mg molybdenum
- The body weight residues exceed (a fatal) 10 mg Mo/kg ([Table 30.4](#)).

It is clear that both the form of molybdenum administered and the route of exposure affect molybdenum metabolism and survival ([Table 30.4](#)). By comparison, adverse effects (some deaths) were noted at 250 mg Mo/kg body weight (BW) (in guinea pigs), at 50 mg/kg BW in domestic cats (central nervous system impairment), at 10 mg/L drinking water in mice (survival), at 10 to 15 mg total daily intake in humans (high incidence of gout-like disease), and at 3 mg/m³ air in humans for 5 years (respiratory difficulties), or 6 to 19 mg/m³ in humans for 4 years ([Table 30.4](#)).

In newborn lambs from ewes that consumed high-molybdenum diets during pregnancy, demyelination of the central nervous system was severe, accompanied by low copper contents in the liver (Earl and Vish 1979). Sheep are more tolerant than cattle to molybdenum poisoning due, in part, to a lower turnover of ceruloplasmin, a copper-transporting enzyme that is inhibited by molybdenum. However, this characteristic makes sheep more sensitive than cattle to copper poisoning (Ward 1978). For example, chronic copper poisoning in sheep in several districts in Norway is probably due to molybdenum-deficient forages rather than to excess copper intake (Froslie et al. 1983). Swayback is a spastic paralysis in lambs born of ewes that were copper deficient during pregnancy (Todd 1976). In northern Ireland, where cases have been reported, pastures were not copper deficient, and swayback was due to an imbalance of copper, molybdenum, and sulfur. Very severely affected lambs were paralyzed in all limbs and died shortly after birth because they were unable to stand and suckle. Lambs less severely affected developed signs in about 2 weeks, but usually only the hind limbs were affected. Brain and spinal cord lesions were present, resulting in demyelination of spinal cord and cavitation of brain tissues; lesions were irreversible, but death might have been avoided with adequate copper therapy (Todd 1976).

Horses are generally considered to be tolerant of dietary copper deficiencies and of copper and molybdenum excesses that affected ruminants. Yet molybdenum accumulated in equine liver and has been implicated as a possible contributory factor in bone disorders in foals and yearlings grazing pastures containing 5 to 25 mg Mo/kg (Cymbaluk et al. 1981; Strickland et al. 1987). Cattle and horses are highly susceptible to pyrrolizidine alkaloids, an ingredient in certain poisonous plants such as tansy ragwort (*Senecio jacobaea*). Signs of poisoning included elevated copper levels in

liver followed by fatal hemolytic crisis. Sheep are more resistant to alkaloids than equines or bovines, and sheep grazing has been recommended as a means of controlling tansy ragwort. However, dietary supplements of 10 mg Mo/kg increased the susceptibility of sheep to tansy ragwort intoxication, despite the observed increase in copper excretion (White et al. 1984).

In rodents, molybdenum is neither teratogenic nor embryocidal to golden hamsters at doses up to 100 mg/kg body weight, and has no measurable effect on fertility or gestation of female rats given similar high doses (Earl and Vlish 1979). Voluntary rejection of high-molybdenum diets by rats results in anorexia. This phenomenon implies sensory, probably olfactory, recognition of molybdate in combination with other dietary constituents to form compounds with a characteristic odor detectable by rats (Underwood 1971). The ability to reject high-molybdenum diets requires a learning or conditioning period because it is lacking or weak with freshly prepared diets and extends to a discrimination between a toxic (high molybdenum) and nontoxic (high molybdenum plus sulfate) diet. Rats may associate a gastrointestinal disturbance with a sensory attribute of diets containing toxic levels of molybdenum (Underwood 1971).

Data on molybdenum effects on mammalian wildlife are scarce, although those available strongly suggest that domestic livestock are at far greater risk (Osman and Sykes 1989) ([Table 30.4](#)). Studies with mule deer (*Odocoileus hemionus*) showed that this species was at least an order of magnitude more tolerant to high levels of dietary molybdenum than were domestic ruminants, and at least as resistant as swine, horses, and rabbits (Nagy et al. 1975; Ward and Nagy 1976; Ward 1978; Chappell et al. 1979). Female mule deer showed no visible effects after 33 days on diets containing up to 200 mg Mo/kg feed, or after 8 days at 1000 mg/kg. Only slight effects — some reduction in food intake and some animals with diarrhea — were observed at diets of 2500 mg/kg for 25 days. At feeding levels of 5000 and 7000 mg/kg for periods of 3 to 15 days, signs were more pronounced; however, recovery began almost immediately after transfer to uncontaminated feed. Signs of copper deficiency and of molybdenosis are very similar, and careful diagnosis is necessary to ensure use of the correct remedial action. For example, some populations of Alaskan moose (*Alces alces gigas*) showed faulty hoof keratinization and decreased reproductive rates, but this was attributed to copper-deficient browse growing on low copper soils, and not to increased molybdenum levels in herbage (Flynn et al. 1977). In another case, a high proportion of white-tailed deer (*Odocoileus virginianus*) feeding near uranium-mine spoil deposits in several Texas counties — areas in which extreme molybdenosis has been documented in grazing cattle — had antlers that were stunted, twisted, and broadened or knobby at the tips (King et al. 1984). However, the copper levels in liver of these deer were similar to those of deer in a control area — 16.7 mg/kg fresh weight vs. 18.0 — and only 1 of 19 deer examined from the mining district had a detectable molybdenum concentration in liver (0.7 mg/kg fresh weight) vs. none in any control sample. On the basis of low contents of copper in soils and vegetation, it was concluded that white-tailed deer examined were experiencing copper deficiency (hypocuprosis), with signs similar to molybdenosis (King et al. 1984).

In humans, molybdenum is low at birth, increases until age 20 years, and declines thereafter (Goyer 1986). Although conclusive evidence that molybdenum is required by humans is lacking, there is general agreement that it should be considered as one of the essential trace elements. The absence of any documented deficiencies in man indicates that the required level is much less than the average daily intake of 180 µg molybdenum in the United States (Chappell et al. 1979). Human discomfort has been reported in workers from copper–molybdenum mines, and in those eating food products containing 10 to 15 mg Mo/kg and <10 mg copper/kg and grown on soils containing elevated molybdenum of 77 mg/kg and 39 mg copper/kg. Symptoms included general weakness, fatigue, headache, irritability, lack of appetite, epigastric pain, pain in joints and muscles, weight loss, red and moist skin, tremors of the hands, sweating, dizziness (Friberg et al. 1975), renal xanthine calculi, uric acid disturbances (Schroeder et al. 1970), and increased serum ceruloplasmin (Friberg and Lener 1986). The typical human adult contains only 9 mg molybdenum, primarily in liver, kidney, adrenal, and omentum (Goyer 1986). Most of the ingested molybdenum is easily

absorbed from the GI tract and excreted within hours or days in urine, mostly as molybdate; excesses may be excreted also by the bile, particularly as hexavalent molybdenum (Friberg et al. 1975; Goyer 1986; Friberg and Lener 1986). At high dietary levels, molybdenum reportedly prevents dental caries (Schroeder et al. 1970), but this requires verification.

Table 30.4 Molybdenum Effects on Selected Species of Mammals

Species, Dose, and Other Variables	Effects (Reference) ^a
CATTLE, COWS, <i>Bos</i> spp.	
Near steelworks, 20 kg Mo as MoO_3 emitted daily in gaseous form; fallout deposits ~2 mg/m ² monthly, corresponding to a pasture Mo content from 2–20 mg Mo/kg dry weight (DW). Pasture had slight Cu deficiency of natural origin, with copper:Mo ratio in pastures <3	About 40% of 5000 grazing cows with signs of molybdenosis. No signs of poisoning before steelworks began operations. Signs evident almost immediately in first grazing season; most pronounced in younger animals closest to source. Remedial actions included copper glycine and installation of additional emission filters at the steel-works (1)
Low dietary Mo (<5 mg Mo/kg), adequate copper	Growth and fertilization rate normal; liver copper >70 mg/kg DW; 63% of embryos developed normally (2)
Fed diets containing 5 mg Mo/kg DW and 4 mg copper/kg DW for 84 weeks	Reduced food intake and efficiency of food use, altered iron metabolism, clinical signs of copper deficiency. Onset of puberty delayed 10 weeks, decreased conception rate (fertility 12–33% vs. 57–80% in controls), disrupted estrus cycle (67% were anestrus vs. 7% in controls), and other signs consistent with decreased releases of luteinizing hormones associated with altered ovarian secretion (3, 4)
High dietary Mo (15–20 mg Mo/kg), copper deficient	Growth and fertilization normal; liver copper 10 mg/kg DW; only 16% of embryos developed normally (2)
Fed diets of normal copper and high Mo (30 mg/kg feed)	Blood Mo level of 0.6–0.8 mg/L (5)
Diets containing 40 mg Mo/kg and 6 mg copper/kg fed to lactating cows for 9 weeks	Reduction of 30% in milk yield; rapid decline in plasma copper; milk Mo levels of 1.6 mg/L; growth reduction in nursing calves (6)
Fed diets of 60 mg Mo/kg DW	Low liver copper, intestinal disturbances, brittle bones prone to fracture (7)
Dairy herd fed pelleted feed containing 140 mg Mo/kg FW and up to 10 mg copper/kg FW	Molybdenosis. Contaminated magnesium oxide (12,200 mg Mo/kg) added to ration at 1% was the source of the excess Mo (8)
Drinking water with Mo as ammonium molybdate. Basal diet with 13 mg copper/kg and 2900 mg sulfur/kg	In 5-week-old calves, there was no effect on liver or plasma copper levels (9)
1 or 10 mg Mo/L in drinking water for 21 days	Copper liver burden reduced to 201 mg/kg DW vs. 346 in controls; copper in plasma elevated to 1100 µg/L vs. 690 in controls. No effect on growth, or food and water consumption (9)
50 mg Mo/L in drinking water for 21 days	Normal milk Mo level of 0.06 mg/L (5)
Total daily intake of 100 mg Mo	Anorexia, diarrhea, and weight loss in Swiss beef cattle (10)
Total daily intake of 141 mg Mo	Milk Mo level of 0.37 mg/L (5)
Total daily intake of 500 mg Mo	Signs of molybdenum poisoning (7)
Total daily intake of 1360 mg Mo daily as soluble molybdate	Lethal dose (11)
10 mg Mo/kg BW	
GUINEA PIG, <i>Cavia</i> sp.	
Chronic exposure, daily dose in mg Mo/animal	
25, as MoO_3	75% mortality (12)
200, as calcium molybdate	25% mortality (12)
Air concentrations of 28–285 mg Mo/m ³	Hexavalent Mo compounds absorbed appreciably, but not disulfide compounds (10, 13)
Dose, in mg Mo/kg BW, various administration routes	
80	LD0 (12)
250	Some deaths (11)
400	LD75 (4 days) (12)
800	LD100 (4 months) (12)

Table 30.4 (continued) Molybdenum Effects on Selected Species of Mammals

Species, Dose, and Other Variables	Effects (Reference)^a
DOMESTIC RUMINANTS	
Pastures containing 10–20 mg Mo/kg DW	“Risk” zone for molybdenosis (12)
Pastures containing 20–100 mg Mo/kg DW	“Teart” disease characterized by anemia, poor growth, diarrhea; prolonged exposure resulted in joint deformities and death (13)
HORSES, PONIES, <i>Equus</i> sp.	
Feeding on teart pastures with elevated Mo content	No effect (5)
Given single oral dose of radio Mo-99, as molybdate, or about 20–28 mg	Mo-99 appeared rapidly in plasma as molybdate, but quickly cleared with Tb 1/2 of 7–10 h (14)
Fed diets containing 20 mg Mo/kg DW for 4.5 months; diet supplemented with sulfur for 1 month at 1.2 g/kg feed	Animals remained healthy. No decline in total plasma copper or increase in plasma insoluble copper (14)
Fed diets containing up to 107 mg Mo/kg for 14 days	Increasing dietary Mo resulted in decreasing copper retention due to increasing excretion of copper in feces; up to 1.45 g Mo/kg BW absorbed and retained with no obvious adverse effects (15)
DOMESTIC CAT, <i>Felis domesticus</i>	
Intravenous injection, in mg Mo/kg BW	
25	Increased arterial blood pressure (12)
50	Central nervous system impairment (12)
HUMAN, <i>Homo sapiens</i>	
Drinking water, in µg/L	
50	No effect (11)
200	Increased urinary excretion, normal serum Mo levels, no change in copper metabolism (11)
Total intake, in mg Mo daily	
0.18	Average intake in U.S. (11)
0.5–1	Increased urinary copper excretion (11)
10	Increase in blood and urine Mo levels, increases in serum ceruloplasmin, increased xanthine oxidase activity (11)
10–15	Increased uric acid, decreased copper excretion, high incidence of gout-like disease (11)
Atmospheric concentrations, in mg Mo/m ³ air	
1–3; 5-year exposure	Respiratory difficulties (12)
6–19; 4-year exposure	Respiratory difficulties (12)
MOUSE, <i>Mus</i> spp.	
10 mg Mo/L in drinking water of breeding mice	Decrease in survival of F ₂ and F ₃ generations (16)
SHEEP, <i>Ovis</i> spp.	
Molybdenum-deficient diet of 0.03 mg/kg	High incidence of renal xanthine calculi (5)
Adequate diet of 0.4 mg Mo/kg, due to resowing of pasture and lime treatment	Zero incidence of renal calculi (5)
Content of pasture 0.4–1.5 mg Mo/kg DW	Mo concentrations, in mg/kg FW, were 0.0–0.03 in plasma, 2.0–2.4 in liver, and 0.4–0.5 in kidney. No lameness or connective tissue lesions (17)
2.4 mg Mo/kg diet in lambs	Significantly enhanced growth when compared to sheep fed 0.36 mg Mo/kg diet; growth associated with increased cellulose digestibility by rumen biota (5)
Grazing pastures treated 3 times with 420 g Mo/ha: at start, and weeks 45 and 72. Mo content of pasture usually 5.5–12.5 mg/kg DW	Mo concentrations, in mg/kg FW, were 1.7–2.4 in plasma, 6.0–6.4 in liver, and 6.9–8.1 in kidney. Lameness and connective tissue lesions in most sheep (17)

Table 30.4 (continued) Molybdenum Effects on Selected Species of Mammals

Species, Dose, and Other Variables	Effects (Reference)^a
Given diets of high copper (82 mg/kg) and sulfur (3.8 g/kg), and Mo at 20, 40, or 60 mg/kg for 193 days	Liver damage due to copper at low Mo (20 mg/kg) diets; at 40 and 60 mg Mo/kg, both metals accumulated in kidney cortex but no evidence of liver histopathology or kidney damage (18)
Breeding ewes fed diets of normal Cu, high Mo (30 mg/kg feed)	Blood Mo level of 2.4–3.4 mg/L (5)
Diets of 50 mg Mo/kg	Avoidance by lambs; may be learned olfactory recognition (19)
Lambs grazing on soils where copper:Mo ratio is <0.4	Swayback observed in 15–39% (10)
Ram lambs fed diets of adequate sulfate and copper (7.7 mg/kg DW). Copper to Mo ratios of 5.5, 5.3, 1.1, or 0.7 for 105 days	No significant measurable effects at ratios of 5.5 and 5.3. Secondary Cu deficiency (molybdenosis) at 1.1 ratio evident in blood and plasma, and in liver at 0.7 (20)
Lambs fed daily intake of 8 mg Mo, 36.3 mg Cu, and 3.7 g S for 125 days	No effect on growth of food intake; significant increases in levels of kidney cortex copper, liver Mo, and plasma copper; major differences in responses among breeds tested (21)
Total intake raised from 0.4 mg daily to 96 mg daily	Blood Mo level of 4.95 mg/L (5)
Fed 75 mg Cu daily for 50 days, followed by 140 mg Mo and 4 g S daily for 13 days with no added Cu	Molybdenosis within 8 days (22)
As above, but 70 mg Mo daily at day 13 for 34 days	40% reduction in liver copper (22)
WHITE RABBIT, <i>Oryctolagus</i> spp.	
Dietary Mo concentrations, in mg Mo/kg ration 100; lifetime exposure	Reduced growth, hair loss, dermatosis, anemia, skeletal and joint deformities, decreased thyroxin (11)
500; 12 weeks	No obvious effects (12)
1000; 12 weeks	Some growth retardation (12)
2000–4000	Many deaths of weanlings in about 37 days, and of adults in 53 days. Survivors were anorexic, diarrheic, anemic, and had front-leg abnormalities; successful recovery after copper therapy (12)
5000	Thyroid dysfunction (11)
RAT, <i>Rattus</i> spp.	
Drinking water, in mg Mo/L 10; exposure for 3 years	Disrupted calcium metabolism (29). Increased sensitivity to cold stress, elevated tissue residues of 50–60 mg Mo/kg DW (23, 24)
20; 30 weeks exposure	No effect on growth or organ histology (25)
50; lifetime exposure	Some growth retardation (11)
1000; lifetime exposure	No severe signs observed in breeding adults. Resultant pups, however, maintained on this regimen were stunted, rough haired, sterile (males), and hyperactive (11)
Dose, in mg Mo per animal daily for up to 232 days	LD25 to LD50 for hexavalent Mo compounds (12)
10	LD50 for calcium molybdate (12)
100	LD50 for MoO ₃ (12)
125	LD50 for ammonium molybdate (12)
333	
Atmospheric concentrations, in mg Mo/m ³ 64; 2 h	Outwardly normal, some microscopic damage due to MoO ₃ exposure (12)
Up to 5000 ammonium paramolybdate, 12,000 Mo dioxide, 15,000 Mo trioxide, or 30,000 metallic molybdenum; exposure for 1 h	At 4 weeks postexposure, there were no adverse effects except for irritation of upper respiratory passage (12)
Feeding levels, in mg Mo/kg diet	

Table 30.4 (continued) Molybdenum Effects on Selected Species of Mammals

Species, Dose, and Other Variables	Effects (Reference)^a
50	Diet avoidance (19). In low sulfate diets and 5 weeks exposure, rats had reduced growth and mandibular exostoses (10)
80; copper deficient	Inhibited growth and reduced survival (5, 26)
80; 35 mg CuSO ₄ /kg	No measurable effects (5, 26)
100; lifetime exposure	Appetite loss, weight loss, reduced growth, anemia, mandibular exostoses, bone deformities, liver and kidney histopathology, increased liver copper residues, male sterility (11)
400	After 5 weeks, growth depression, anemia, mandibular exostoses; some deaths at lifetime exposures (12)
500 or 800	No deaths in 6 weeks; growth retardation and anemia (12)
500 or 1000; 77 mg Cu/kg	Poor growth (5, 26)
5000	Lethal in 2 weeks (11, 12)
Dose, in mg Mo/kg BW	
0.00002–0.001	50% excretion (Tb 1/2) in 60–113 h for kidney, liver, spleen, small intestine, and skin (10)
0.003	Tb 1/2 in 47 h (10)
>0.003	Tb 1/2 in 3 h when administered subcutaneously, 6 h for intragastric application (10)
4.5, intravenous injection	Biliary excretion of Mo ⁺⁶ compounds was more rapid than Mo ⁺⁵ compounds (27)
100	When inhaled as MoO ₃ , irritating to eyes and mucous membranes and eventually lethal. Repeated oral administration leads to histopathology of liver and kidney (13)

30.5 RECOMMENDATIONS

Although molybdenum is generally recognized as an essential trace metal for plants and animals, and may reduce the incidence and severity of carcinomas in rats (Luo et al. 1983; Wei et al. 1985) and dental caries in humans (Shamberger 1979), there is no direct evidence of molybdenum deficiency being detrimental to animal health. The minimum daily molybdenum requirements in diets are not yet established due to problems in preparing molybdenum-free rations (Chappell et al. 1979). As a consequence, no regulatory agency recognizes molybdenum as safe and necessary, and molybdenum cannot be legally incorporated into animal feeds (Penumarthi and Oehme 1978).

The richest natural sources of molybdenum (i.e., 1.1 to 4.7 mg Mo/kg fresh weight) are plants unusually high in purines such as legumes and whole grains (Schroeder et al. 1970), followed by leafy vegetables, liver, and kidney (Shamberger 1979). The poorest sources are fruits, sugars, oils, and fat (Schroeder et al. 1970).

The greatest economic importance of molybdenosis is associated with subclinical manifestations of copper deficiency resulting from forages containing a low copper:molybdenum ratio. Unfortunately, these conditions are often difficult to diagnose accurately, and animal response to copper may be difficult to demonstrate (Ward 1978). One recommended treatment for afflicted cattle is 2 g daily of copper sulfate to cows and 1 g daily to young stock, or intravenous injection of 200 to 300 mg copper sulfate daily for several days (Underwood 1971).

The animals most sensitive to molybdenum insult are domestic ruminants, especially cattle. Diets containing more than 15 mg Mo/kg dry weight and with a low copper:molybdenum ratio, or drinking water levels more than 10 mg Mo/L were frequently associated with molybdenosis in cattle (Table 30.5). By contrast, adverse effects were documented in birds at dietary levels more than 200 mg Mo/kg ration, in ruminant wildlife at dietary levels greater than 2500 mg Mo/kg, and in aquatic organisms — with one exception — at more than 50 mg Mo/L (Table 30.5). The exception was newly fertilized eggs of rainbow trout, which were about 21 times more sensitive to molybdenum than were zygotes approximately one third through embryonic development, and about 90 times more sensitive than adult fish (Table 30.5).

Proposed criteria for human health protection include drinking water concentrations less than 50 µg Mo/L, and daily dietary intakes less than 7 µg Mo/kg food — based on a 70-kg adult (Table 30.5). Molybdenum concentrations in blood of “healthy” people averaged 14.7 µg Mo/L, distributed between the plasma and erythrocytes. Anemic people had significantly lower blood molybdenum levels. In leukemia patients, molybdenum levels increased significantly in whole blood and erythrocytes but not in plasma (Shamberger 1979). Additional work is recommended on the use of blood in fish and wildlife as an indicator of molybdenum stress and metabolism (Eisler 1989).

Increasing problems associated with marginal mineral deficiencies and unfavorable mineral interaction — as has been the case in the older agricultural areas of northern Europe — can be anticipated as pasture and forage production becomes more intensive (Ward 1978). Research has been recommended in areas having a high molybdenum content in soils and vegetation, and also in noncontaminated areas where consumption habits favor a high molybdenum intake and an imbalance in relation to other dietary constituents of importance, such as copper (Friberg et al. 1975). In some parts of the world where molybdenum has been substituted for lime, the soils have become more acidic, thus making them difficult to farm. Liming under these conditions may elevate soil molybdenum from levels previously considered safe, to levels potentially hazardous to grazing animals through high-molybdenum herbage (Gupta and Lipsett 1981). The addition of molybdenum fertilizers to sheep pastures resulted in small increments in molybdenum content with negligible risk of induced copper deficiency. But it would be unwise to apply molybdenum fertilizers to temperate grasslands grazed by animals of low initial copper status, as judged by growth retardation of lambs from pastures supplemented with molybdenum (Suttle 1983a).

Table 30.5 Proposed Molybdenum Criteria for the Protection of Living Resources and Human Health

30.6 SUMMARY

The element molybdenum (Mo) is found in all living organisms and is considered to be an essential or beneficial micronutrient. However, molybdenum poisoning of ruminants has been reported in at least 15 states and 8 foreign countries. Molybdenum is used primarily in the manufacture of steel alloys. Its residues tend to be elevated in plants and soils near molybdenum mining and reclamation sites, fossil-fuel power plants, and molybdenum disposal areas. Concentrations of molybdenum are usually lower in fish and wildlife than in terrestrial macrophytes.

Aquatic organisms are comparatively resistant to molybdenum salts: adverse effects on growth and survival usually appeared only at water concentrations >50 mg Mo/L. But in one study, 50% of newly fertilized eggs of rainbow trout (*Oncorhynchus mykiss*) died in 28 days at only 0.79 mg Mo/L. High bioconcentration of molybdenum by certain species of aquatic algae and invertebrates — up to 20 g Mo/kg dry weight — has been recorded without apparent harm to the accumulator. However, hazard potential to upper trophic organisms (such as waterfowl) that may feed on bioconcentrators is not clear. Data on molybdenum effects are missing for avian wildlife and are inadequate for mammalian wildlife. In domestic birds, adverse effects on growth have been reported at dietary molybdenum concentrations of 200 mg Mo/kg, on reproduction at 500 mg/kg, and on survival at 6000 mg/kg.

Molybdenum chemistry is complex and inadequately known. Its toxicological properties in mammals are governed to a remarkable extent through interaction with copper and sulfur; residues of molybdenum alone are not sufficient to diagnose molybdenum poisoning. Domestic ruminants, especially cattle, are especially sensitive to molybdenum poisoning when copper and inorganic sulfate are deficient. Cattle are adversely affected — and die if not removed — when grazing on pastures where the ratio of copper to molybdenum is <3 , or if they are fed low copper diets containing molybdenum at 2 to 20 mg/kg diet; death usually occurs when tissue residues exceed 10 mg/kg body weight. The resistance of other species of mammals tested, including domestic livestock, small laboratory animals, and wildlife, was at least tenfold higher than that of cattle. Mule deer (*Odocoileus hemionus*), for example, showed no adverse effects at dietary levels of 1000 mg/kg.

Additional research is needed in several fields, including:

- The role of molybdenum on inhibition of carcinomas and dental caries
- The establishment of minimum, optimal, and upper daily requirements of molybdenum in aquatic and wildlife species of concern
- The improvement in diagnostic abilities to distinguish molybdenum poisoning from copper deficiency
- The determination of sensitivity of early developmental stages of fishes to molybdenum insult.

CHAPTER 31

Selenium

31.1 INTRODUCTION

Selenium poisoning is an ancient and well-documented disease (Rosenfeld and Beath 1964). Signs of it were reported among domestic livestock by Marco Polo in western China near the borders of Turkestan and Tibet in about the year 1295; among livestock, chickens, and children in Colombia, South America, by Father Pedro Simon in 1560; among human adults in Irapuato, Mexico, in about 1764; and among horses of the U.S. Cavalry in South Dakota in 1857 and again in 1893 (Rosenfeld and Beath 1964). In 1907/08, more than 15,000 sheep died in a region north of Medicine Bow, Wyoming, after grazing on seleniferous plants. The incidents have continued, and recent technical literature abounds with isolated examples of selenosis among domestic animals and wildlife.

Selenium (Se) was first identified as an element in 1817 by the Swedish chemist Berzelius. It is now firmly established that selenium is beneficial or essential in amounts from trace to $\mu\text{g/kg}$ (ppb) concentrations for humans and some plants and animals, but toxic at some concentrations present in the environment (Rosenfeld and Beath 1964). Selenium deficiency was reported among cattle grazing in the Florida Everglades, which showed evidence of anemia, slow growth, and reduced fertility (Morris et al. 1984). Selenium deficiency has been demonstrated in Atlantic salmon, *Salmo salar* (Lorentzen et al. 1994), in various species of deer in Florida and Washington (Hein et al. 1994; McDowell et al. 1995), and in free-ranging ungulates in Washington state, including moose (*Alces alces*) and bighorn sheep (*Ovis canadensis*) (Hein et al. 1994). Conversely, calves of Indian buffaloes died of selenium poisoning after eating rice husks grown in naturally seleniferous soils (Prasad et al. 1982). Adverse effects of excess selenium are reported on reproduction of cattle, monkeys, sheep, swine, rats, and hamsters, including fetal and maternal death, and a dramatic increase in developmental abnormalities (Domingo 1994). Severe reproductive and developmental abnormalities were observed in aquatic birds nesting at selenium-contaminated irrigation drainwater ponds in the San Joaquin Valley, California (Ohlendorf et al. 1986, 1986a, 1987, 1989, 1990; Hoffman et al. 1988; Schuler et al. 1990; Besser et al. 1993; Lemly 1996b). Accumulation of more than 8 mg Se/kg dry weight in fish gonads is the probable cause of reduced reproduction and subsequent species disappearances in Belews Lake, North Carolina, and the endangered razorback sucker (*Xyrauchen texanus*) from the Green River, Utah, in 1991 (Cumbie and Van Horn 1978; Hamilton and Waddell 1994; Waddell and May 1995).

Selenium has been the subject of many reviews (Rosenfeld and Beath 1964; Frost 1972; Sandholm 1973; Zingaro and Cooper 1974; Frost and Ingvoldstad 1975; Anonymous 1975; National Academy of Sciences [NAS] 1976; Harr 1978; U.S. Environmental Protection Agency [USEPA] 1980, 1987; Lo and Sandi 1980; Shamberger 1981; Wilber 1980, 1983; Fishbein 1977, 1983; National Research Council [NRC] 1983; Reddy and Massaro 1983; Eisler 1985; Lemly and Smith

1987; Ohlendorf 1989; Hodson 1990; Goede 1993; Lemly 1993, 1996a, 1996b; Heinz 1996; U.S. Public Health Service [USPHS] 1996). These authorities agree that selenium is widely distributed in nature, being especially abundant with sulfide minerals of various metals, such as iron, lead, and copper. The major source of environmental selenium is the weathering of natural rock. The amount of selenium entering the atmosphere as a result of anthropogenic activities is estimated to be 3500 metric tons annually, of which most is attributed to combustion of coal and the irrigation of high-selenium soils for crop production. However, aside from highly localized contamination, the contribution of selenium by human activities is small in comparison with that attributable to natural sources. Collectively, all authorities agree that selenium may favorably or adversely affect growth, survival, and reproduction of algae and higher plants, bacteria and yeasts, crustaceans, molluscs, insects, fish, birds, and mammals (including humans). Most acknowledge that sensitivity to selenium and its compounds is extremely variable in all classes of organisms and, except for some instances of selenium deficiency or of selenosis, metabolic pathways and modes of action are imperfectly understood. For example, selenium indicator plants can accumulate selenium to concentrations of thousands of parts per million (mg/kg) without ill effects. In these plants, selenium promotes growth; whereas in crop plants, accumulations as low as 25 to 50 mg/kg may be toxic. Thus, plants and waters high in selenium are considered potentially hazardous to livestock and to aquatic life and other natural resources in seleniferous zones.

31.2 ENVIRONMENTAL CHEMISTRY

Selenium is characterized by an atomic weight of 78.96, an atomic number of 34, a melting point of 271°C, a boiling point of 685°C, and a density of 4.26 to 4.79. Chemical properties, uses, and environmental persistence of selenium were documented by a number of researchers whose works constitute the major source material for this section: Rosenfeld and Beath (1964); Bowen (1966); Lakin (1973); Stadtman (1974, 1977); Frost and Ingvoldstad (1975); Chau et al. (1976); Harr (1978); Wilber (1980, 1983); Zieve and Peterson (1981); Robberecht and Von Grieken (1982); Cappon and Smith (1982); Nriagu and Wong (1983); Eisler (1985); USPHS (1996).

There was general agreement on four points.

1. Selenium chemistry is complex, and additional research is warranted on chemical and biochemical transformations among valence states, allotropic forms, and isomers of selenium.
2. Selenium metabolism and degradation are significantly modified by interaction with heavy metals, agricultural chemicals, microorganisms, and a variety of physicochemical factors.
3. Anthropogenic activities (including fossil fuel combustion and metal smelting) and naturally seleniferous areas pose the greatest hazards to fish and wildlife.
4. Selenium deficiency is not as well documented as selenium poisoning, but may be equally significant.

Selenium chemistry is complex (Rosenfeld and Beath 1964; Harr 1978; Wilber 1983; Porcella et al. 1991; Wiedmeyer and May 1993; Besser et al. 1994; USPHS 1996). In nature, selenium exists: as six stable isotopes (Se-74, -76, -77, -78, -80, and -82), of which Se-80 and -78 are the most common, accounting for 50% and 23.5%, respectively; in three allotropic forms; and in five valence states. Changes in the valence state of selenium from -2 (hydrogen selenide) through 0 (elemental selenium), +2 (selenium dioxide), +4 (selenite), and +6 (selenate) are associated with its geologic distribution, redistribution, and use. Soluble selenates occur in alkaline soils, are slowly reduced to selenites, and are then readily taken up by plants and converted into organoselenium compounds, including selenomethionine, selenocysteine, dimethyl selenide, and dimethyl diselenide. In drinking water, selenates represent the dominant chemical species. Selenites are less soluble than the corresponding selenates and are easily reduced to elemental selenium. In seawater, selenites are the dominant chemical species under some conditions (Cappon and Smith 1981). Selenium dioxide is formed by combustion of elemental selenium present in fossil fuels or rubbish.

Selenium is the most strongly enriched element in coal, being present as an organoselenium compound, a chelated species, or as an adsorbed element. On combustion of fossil fuels, the sulfur dioxide formed reduces the selenium to elemental selenium. Elemental selenium is insoluble and largely unavailable to the biosphere, although it is still capable of satisfying metabolic nutritional requirements. Hydrogen selenide is highly toxic (at 1 to 4 µg/L in air), unstable, acidic, and irritative. Selenides of mercury, silver, copper, and cadmium are very insoluble, although their insolubility may be the basis for the reported detoxification of methylmercury by dietary selenite, and for the decreased heavy metal toxicity associated with selenite. Metallic selenides are thus biologically important in sequestering both Se and heavy metals in a largely unavailable form.

In areas of acid or neutral soils, the amount of biologically available selenium should steadily decline. The decline may be accelerated by active agricultural or industrial practices. In dry areas, with alkaline soils and oxidizing conditions, elemental selenium and selenides in rocks and volcanic soils may oxidize sufficiently to maintain the availability of biologically active selenium. Concentrations of selenium in water are a function of selenium levels in the drainage system and of water pH. In Colorado, for example, streams with pH 6.1 to 6.9 usually contain <1 µg Se/L, but those with pH 7.8 to 8.2 may contain 270 to 400 µg/L (Lakin 1973). Selenium volatilizes from soils at rates that are modified by temperature, moisture, time, season of year, concentration of water-soluble selenium, and microbiological activity. Conversion of inorganic and organic selenium compounds to volatile selenium compounds (such as dimethyl selenide, dimethyl diselenide, and an unidentified compound) by microorganisms has been observed in lake sediments of the Sudbury area of Ontario. This conversion may have been effected by pure cultures of *Aeromonas*, *Flavobacterium*, *Pseudomonas*, or an unidentified fungus, all of which are found in methylated lake sediments. Production of volatile selenium is temperature dependent. Compared with the amount of $(CH_3)_2Se$ produced at an incubation temperature of 20°C, 25% less was produced at 10°C and 90% less at 4°C. Details of selenium reduction and oxidation by microorganisms are not clear. One suggested mechanism for selenite reduction in certain microorganisms involves attachment to a carrier protein and transformation from selenite to elemental selenium, which in turn may be oxidized to selenite by the action of *Bacillus* spp., as one example. It is apparent that much additional research on this problem is warranted. It now appears that selenates and selenites are absorbed by plants, reduced, and then incorporated in amino acid synthesis. The biological availability of selenium is higher in plant foods than in foods of animal origin (Lo and Sandi 1980). The net effect of soil, plant, and animal metabolism is to convert selenium to inert and insoluble forms such as elemental selenium, metallic selenides, and complexes of selenite with ferric oxides.

Selenium was used in the early 1900s as a pesticide to control plant pests, and is still used sparingly to control pests of greenhouse chrysanthemums and carnations (Rosenfeld and Beath 1964). It has been used to control cotton pests (in Trinidad), mites and spiders that attack citrus, and mites that damage apples. Although no insect-resistant strains have developed, the use of selenium pesticides has been discontinued, owing to their stability in soils and resultant contamination of food crops, their high price, and their proven toxicity to mammals and birds (Rosenfeld and Beath 1964; Eisler 1985). In Canada and France, sodium selenite applied to the soil to discourage deer from browsing conifer seedlings when deer numbers were high was unsuccessful and should be avoided (Jobidon and Prevost 1994). Selenium shampoos, which contain about 1% selenium sulfide, are still used to control dandruff in humans and dermatitis and mange in dogs. Selenium is used extensively in the manufacture and production of glass, pigments, rubber, metal alloys, textiles, petroleum products, medical therapeutic agents, and photographic emulsions (Eisler 1985).

Domestic consumption of selenium in 1981 exceeded 453,000 kg. About 50% was used in electronic and copier components, 22% in glass manufacturing, 20% in chemicals and pigments, and 8% miscellaneous (Cleveland et al. 1993). In 1987, world production of selenium was about 1.4 million kg (USPHS 1996). In 1986, 46% of the global selenium produced was used in the semiconductor and photoelectric industries; 27% in the glass industry to counter coloration impurities from iron; 14% in pigments; and 13% in medicine, in antidandruff shampoos, as catalysts in

pharmaceutical preparations, in nutritional feed additives for poultry and livestock, and in pesticide formulations (USPHS 1996).

Air and surface waters generally contain nonhazardous concentrations of selenium. Significant increases of selenium in specific areas are attributed exclusively to industrial sources, and to leaching of groundwater from seleniferous soils. In the United States, about 4.6 million kg selenium are released annually into the environment: 33% from combustion of fossil fuels, 59% from industrial losses, and 8% from municipal wastes. Of the total, about 25% is in the form of atmospheric emissions, and the rest in ash. Mining and smelting of copper–nickel ores at Sudbury, Ontario, Canada, alone releases about 2 metric tons selenium to the environment daily, and probably represents the greatest point source of selenium release in the world. In 1977, 680,000 kg selenium was produced at Sudbury, but only about 10% was recovered, suggesting that about 90% was lost to the environment. Of the amount lost, perhaps 50 metric tons were dispensed into the atmosphere, probably as selenium dioxide (airborne Se levels 1 to 3 km from Sudbury were as high as $6.0 \mu\text{g}/\text{m}^3$). The rest was probably associated with mine tailings, wastewater, and scoria, and is a local source of selenium contamination, most notably in lakes. The present annual rates of selenium accumulation in lake sediments in the Sudbury area range from 0.3 to $12.0 \text{ mg}/\text{m}^2$. These deposition rates exceed those of pre-colonial times by factors of 3 to 18, and are among the highest recorded in North America (Nriagu and Wong 1983).

Selenium is a serious hazard to livestock and probably to people in a wide semiarid belt that extends from inside Canada southward across the United States into Mexico (NRC 1983). Selenium tends to be present in large amounts in areas where the soils have been derived from Cretaceous rocks. Total selenium in such soils averages about 5 mg/kg, but is sometimes as high as 80 mg/kg. Lack of rainfall has prevented the solution of the selenium minerals and the removal of their salts in drainage waters. In some areas, modern fertilization practices and the buildup of sulfates in the soil due to acid precipitation partly lessen the availability of selenium to plants and forage crops. In the United States, highly seleniferous natural areas (200 to 300 $\mu\text{g}/\text{kg}$ in forage) are most abundant in the Rocky Mountain and High Central Plains areas. Areas with lower concentrations (20 to 30 $\mu\text{g}/\text{kg}$) in forage are typical in the Pacific Northwest and the Southeast. However, huge variations are not uncommon from one specific location to another. Among plants, primary and secondary selenium accumulators are almost always implicated in cases of acute or chronic selenium poisoning of livestock. Primary selenium accumulator plants, such as various species of *Astragalus*, *Oenopsis*, *Stanelya*, *Zylorrhiza*, and *Machaeranthera*, may require 1 to 50 mg Se/kg in either soil or water for growth, and may contain 100 to 10,000 mg Se/kg as a glutamyl dipeptide or selenocystanthionine. Secondary accumulator plants (representative genera: *Aster*, *Gutierrezia*, *Atriplex*, *Grindelia*, *Castillaja*, and *Comandra*) grow in either seleniferous or nonseleniferous soils and may contain 25 to 100 mg Se/kg. Nonaccumulator plants growing on seleniferous soils contain 1 to 25 mg Se/kg fresh weight. Meat and eggs of domestic animals may contain 8 to 9 mg Se/kg in seleniferous areas, compared with 0.01 to 1.0 mg/kg in nonseleniferous areas. Tissues from animals maintained on high-Se feeds generally contain 3 to 5 mg Se/kg fresh weight vs. up to 20 mg/kg in animals dying of selenium poisoning (Harr 1978).

Selenium is nutritionally important as an essential trace element, but is harmful at slightly higher concentrations. Although normal selenium dietary levels required to ensure human health range from 0.04 to 0.1 mg/kg, toxicity may occur if food contains as little as 4.0 mg/kg. Minimum selenium concentrations required are usually higher in livestock than in humans. In areas with highly seleniferous soils, excess selenium is adsorbed onto a variety of plants and grains and can be fatal to grazing livestock. There is general agreement, however, that selenium inadequacy can be of greater concern to health than selenium toxicity. Selenium has a comparatively short effectual biological life in various species of organisms for which data are available. Studies with radio-selenium-75 indicated that its biological half-life is 10 to 64 days: 10 in pheasants, 13 in guppies and voles, 15 in ants, 27 in eels, 28 in leeches, and 64 in earthworms (Wilber 1983). Many investigators concluded that the greatest current and direct use of selenium is in the transportation of grains grown in seleniferous areas to selenium-deficient areas as animal and human food.

31.3 CONCENTRATIONS IN FIELD COLLECTIONS

Selenium concentrations in nonbiological materials extend over several orders of magnitude (Table 31.1; Lemly 1996b). In terrestrial materials, concentrations in excess of 5 mg Se/kg are routinely recorded in meteorites, copper–nickel ores, coal and other fossil fuels, lake sediments in the vicinity of a nickel–copper smeltery, and in sediments of flyash settling ponds. Water concentrations exceeding 50 µg Se/L have been documented in groundwater, especially in areas with seleniferous soils, in sewage wastes, in irrigation drain water, and in water of flyash settling ponds. Selenium concentrations in air samples were >0.5 µg/m³ in the vicinity of selenium production plants, and these were at least 500 times higher than in a control area (Table 31.1).

^a 1, Frost and Ingvaldstad 1975; 2, Ebens and Shacklette 1982; 3, de Goeij et al. 1974; 4, NAS 1976; 5, Kuhn et al. 1980; 6, Harr 1978; 7, Heit et al. 1980; 8, Adams and Johnson 1977; 9, Speyer 1980; 10, Robberecht and Von Grieken 1982; 11, Nriagu and Wong 1983; 12, Whittle et al. 1977; 13, Ohlendorf et al. 1986; 14, Furr et al. 1979; 15, USPHS 1996.

As a result of natural and anthropogenic processes, comparatively high concentrations of selenium in nonbiological materials may offer protection or pose significant risks to fish and wildlife. In Finland, for example, agricultural fertilizers were supplemented with 6 to 16 mg Se/kg beginning in 1985. In Finnish lakes, selenium concentrations have increased in sediments and fish muscle from this activity and from atmospheric fallout, but no adverse biological effects were observed (Wang et al. 1995). In Sweden, selenium treatment raised the lake water concentrations from 3 μg Se/L at the start to 5 μg /L. This treatment lowered mercury concentrations in mercury-contaminated northern pike (*Esox lucius*) and yellow perch (*Perca flavescens*) in treated Swedish lakes by 60 to 85% (Paulsson and Lundbergh 1991). Selenium is normally present in surface waters at about 0.1 to 0.3 $\mu\text{g}/\text{L}$. However, at 1 to 5 $\mu\text{g}/\text{L}$, it can biomagnify in aquatic food chains and pose a concentrated dietary source of selenium that is toxic to fish and wildlife (Lemly 1993c, 1996a).

Selenium concentrations in representative species of freshwater, marine, and terrestrial flora and fauna are listed in [Table 31.2](#). Additional information on body and tissue burdens of selenium was given by Birkner (1978), Jenkins (1980), Lo and Sandi (1980), Eisler (1981, 1985), and Wilber (1983). It is emphasized that selenium concentrations in all organisms tended to be significantly higher when collected from locales having certain characteristics: highly seleniferous soils or sediments (de Goeij et al. 1974; Birkner 1978; Speyer 1980; Wilber 1983); high human population densities (Beal 1974); heavy accumulations of selenium-laden wastes, such as effluents from systems used to collect flyash scrubber sludge or bottom ash (Cumbie and Van Horn 1978; Sorensen et al. 1982, 1984); and selenium-contaminated subsurface irrigation drainwater (Ohlendorf et al. 1986, 1987; Presser and Ohlendorf 1987; Schuler et al. 1990; Lemly 1993c; Hothem and Welsh 1994). Accumulation, transfer, and release of selenium by aquatic biota may affect the speciation and toxicity of dissolved selenium in aquatic environments (Besser et al. 1994). Depletion of dissolved selenite and increased concentrations of organoselenium compounds occur during seasonal peaks in phytoplankton abundance in freshwater and marine systems. For example, green algae (*Chlamydomonas reinhardtii*) previously exposed to inorganic radioselenium-75 produced increased concentrations of organoselenium species during population blooms and crashes (Besser et al. 1994).

Among terrestrial plants, selenium accumulations in species of *Aster*, *Astragalus*, and several other genera are sometimes spectacularly high ([Table 31.2](#)). *Astragalus* is the most widely distributed. About 24 of its more than 200 species are selenium accumulators that require selenium to grow well. The highest reported concentration in plants was 15,000 mg Se/kg DW, in loco weed (*Astragalus racemosus*) (Wilber 1983). Consumption of these and other selenium-accumulating forage plants by livestock has induced illness and death from selenium poisoning. Even at much lower concentrations, selenium may harm animals that eat considerable amounts of the forage. Plants that accumulate selenium tend to be deeper rooted than the grasses and survive more severe aridity, thus remaining as the principal forage for grazing in time of drought (Wilber 1983). There is little danger to human health of selenium toxicity from consuming game that foraged in high-selenium environments (Medeiros et al. 1993).

Selenium levels in freshwater biota are relatively low compared with those in their marine counterparts. In freshwater organisms, about 36% of the total selenium was present as selenate, and the rest as selenite and selenide. In marine samples, only 24% of the total selenium was present as selenate (Cappon and Smith 1982). The implications of this difference are not now understood, but have relevance in the ability of selenium to complex and detoxify various potentially toxic heavy metals, such as mercury and cadmium. In a nationwide monitoring of selenium and other contaminants in freshwater fishes, selenium ranged from 0.05 to 2.9 mg/kg FW whole fish and averaged about 0.6 mg/kg. Stations where concentrations in fish exceeded 0.82 mg/kg (>85th percentile) were in three areas: Atlantic coastal streams, Mississippi River system, and California ([Table 31.2](#)) (May and McKinney 1981). Among fish from Atlantic coastal streams, those from the Delaware River near Camden, New Jersey, had elevated whole-body concentrations (i.e., >1.0 and <3.0 mg Se/kg FW), which were attributed to the industrialized character of the river. In the Big Horn and Yellowstone Rivers, high selenium concentrations in fish may result from geologic sources of the element, including coal, phosphate, and sedimentary rock. Fish from the South Platte River near Denver, Colorado, may receive selenium from industrial effluents, or from natural and anthropogenic activities associated with the removal of deposits of coal, barite, and sulfur (May and McKinney 1981). These same trends persisted in more recent nationwide monitoring of freshwater fishes, with selenium concentrations usually highest in whole fish from stations in Utah, Nevada, Texas, California, Hawaii, and in arid locations of the western United States ([Table 31.2](#); Schmitt and Brumbaugh 1990). In California, where selenium was elevated in fish from the San Joaquin River, it was speculated that Selocide, a selenium-containing pesticide registered for use on citrus fruits in the 1960s, may have been a source, although contaminated irrigation drainwater was considered a more likely possibility (Ohlendorf et al. 1986). Of seven species of fishes analyzed

from the San Joaquin Valley, California, in 1986/1987, mosquitofish (*Gambusia affinis*) had the highest concentrations (11.1 mg Se/kg DW whole body); these fish were collected from canals and sloughs in the Grasslands Water District that received large inflows of subsurface agricultural drainage water (Saiki et al. 1991, 1992). Selenium persisted in the biota of the Grasslands drainage regions for at least 1 year after the switch to uncontaminated drainage water (Hothem and Welsh 1994).

Selenium bioconcentrates and biomagnifies in aquatic food chains from invertebrates to birds (Rusk 1991; Saiki et al. 1993). Maximum selenium concentrations reported in Cibola Lake in the lower Colorado River Valley in 1989/90 were 5.0 µg/L in water, and — in mg Se/kg DW — 3.3 in sediments, 1.2 in aquatic plants (*Myriophyllum*, *Ceratophyllum*), 4.6 in crayfish (*Procambarus clarkii*), and 9.2 in bluegills (*Lepomis macrochirus*) (Welsh 1992). Diet is the primary source of selenium to fish, as judged by radioiselenium-75 uptake studies in Canadian oligotrophic lakes (Harrison et al. 1990). Hatchery-reared smolts and adults of silver salmon (*Oncorhynchus kisutch*) had less selenium in livers than did wild fish, and this could account for the higher survival and better health of wild fish (Felton et al. 1990).

Belews Lake in North Carolina was contaminated with selenium during the 1970s from coal-fired power plant wastewater, causing mortality and reproductive failure in the fish population (Lemly 1993a, 1993c). Selenium concentrations in fish tissues were as high as 125 mg Se/kg DW and were as much as 100 times higher than those from nearby reference sites. There was a positive relation between tissue selenium concentrations and frequency of developmental malformations for largemouth bass and bluegill over the range 1 to 80 mg Se/kg DW tissue and 0% to 70% deformities. In 1992, selenium residues had declined to less than 20 mg/kg DW, but were still 5 to 18 times higher than those in reference lakes, and deformity frequency was 7 times higher (Lemly 1993a). Alterations in zooplankton species densities and dominance — but not diversity — were observed in Belews Lake between 1970 (uncontaminated), 1976/77 (selenium contamination), and 1984 to 1986. Observed changes are attributed to the dominance of planktivorous fishes (Marcogliese et al. 1992).

All reported selenium levels in tissues of marine invertebrates and plants were less than 2 mg Se/kg on a fresh weight (FW) basis, or 12 mg/kg dry weight (DW). In marine algae, most of the selenium accumulated was associated with proteins and may represent a form of storage prior to detoxification (Boisson et al. 1995). Higher levels are routinely recorded in liver and kidney tissues of marine and coastal vertebrates, including teleosts, birds, and mammals. Livers from adult seals were comparatively rich in selenium (Table 31.2); however, high concentrations in liver of maternal California sea lions were not reflected in the livers of newborn pups (Martin et al. 1976). In marine mammals, selenium concentrations are positively correlated with increasing age (Teigen et al. 1993; Mackey et al. 1996) and with increasing mercury residues in piscivorous mammals (Reijnders 1980; Wren 1984; Leonzio et al. 1992; Teigen et al. 1993). The mercury:selenium ratio was close to 1.0 in tissues of marine mammals at mercury concentrations >15 mg Hg/kg FW (Skaare et al. 1994). Increasing mercury concentrations in tissues of marine teleosts are also positively correlated with selenium (Ganther et al. 1972; Leonzio et al. 1982), although the evidence is conflicting (Tamura et al. 1975; Speyer 1980; Maher 1983). Selenium varies seasonally in crustaceans (Zafiroopoulos and Grimanis 1977). In general, concentrations of selenium in various tissues are usually higher in older than in younger organisms. Among marine vertebrates, selenium increases were especially pronounced among the older specimens of predatory, long-lived species (Eisler 1984).

Selenium concentrations in avian tissues are modified by the age, condition, and diet of the organism, the presence of other metals, and other variables. Fish-eating birds had the highest selenium concentrations in livers, and herbivorous species the lowest; omnivores were intermediate (Mora and Anderson 1995). Selenium concentrations were elevated in livers of molting birds compared to nonmolting conspecifics (Jenny et al. 1990), elevated in feathers of older terns and egrets when compared to younger stages (Burger et al. 1994), and elevated in tissues of marine birds that consume invertebrate prey animals with elevated selenium burdens (Goede et al. 1993).

Selenium concentrations in tissues of shorebirds were positively correlated with concentrations of copper, zinc (Wenzel and Gabrielsen 1995), and iron (Goede and Wolterbeek 1994). Feathers have been proposed as indicators of selenium exposure. However, variability in selenium concentrations in whole feathers is considerable (Goede 1991) (Table 31.2). In shorebirds, for example, the highest selenium concentrations are found in wing feathers, specifically in the outer primaries, notably primary 8. Moreover, within the vane of a single feather, the highest selenium concentrations are in the tip and the lowest at the basis. All of these differences need to be considered before feathers are routinely used as indicators of selenium exposure (Goede 1991).

Subsurface agricultural drainage waters from the western San Joaquin Valley, California, had elevated selenium concentrations, as selenate. In 1978, these drainage waters were diverted to Kesterson Reservoir, a pond system within the Kesterson National Wildlife Refuge (KNWR), with diversion complete by 1982. In 1983, aquatic birds at KNWR had unusual rates of death and developmental abnormalities attributed to selenium (Presser and Ohlendorf 1987). In 1984/85, selenium-induced recruitment failure was observed at KNWR in American avocets (*Recurvirostra americana*) and black-necked stilts (*Himantopus mexicanus*); unlike a nearby reference area, chicks at KNWR of either species did not survive to fledging (Williams et al. 1989). Selenium concentrations in livers of diving ducks from San Francisco Bay in 1982 were similar to those of dabbling ducks in the nearby San Joaquin Valley where reproduction was severely impaired (Ohlendorf et al. 1986b). Mean concentrations of selenium in kidneys of seven species of coastal birds collected from the highly industrialized Corpus Christi, Texas, area usually varied between 1.7 and 5.6 mg Se/kg FW, but were 10.2 mg/kg FW in one bird. According to White et al. (1980), selenium concentrations of this magnitude may be sufficient to impair reproduction in shorebirds. Barn swallows (*Hirundo rustica*) nesting at a selenium-contaminated lake in Texas had elevated concentrations of selenium in eggs and tissues when compared to conspecifics at a reference site. However, nest success of barn swallows was significantly higher at the contaminated site; development was normal at both sites (King et al. 1994).

31.4 DEFICIENCY AND PROTECTIVE EFFECTS

Selenium is an essential nutrient for most plants and animals. It constitutes an integral part of the enzyme glutathione peroxidase and may have a role in other biologically active compounds, especially Vitamin E and the enzyme formic dehydrogenase. Some animals require selenium-containing amino acids (*viz.* selenocysteine, selenocystine, selenomethionine, selenocystathione, selenium-methylselenocysteine, and selenium-methylselenomethionine), but reportedly are incapable of producing them. Selenium also forms part of certain proteins, including cytochrome c, hemoglobin, myoglobin, myosin, and various ribonucleoproteins (Rosenfeld and Beath 1964; Eisler 1985; USPHS 1996).

The availability of selenium to plants may be lessened by modern agricultural practices, eventually contributing to selenium deficiency in animal consumers. For example, fertilizers containing nitrogen, sulfur, and phosphorus all influence selenium uptake by plants through different

modes of action, the net effect being a reduction in selenium uptake (Frost and Ingvoldstad 1975). The buildup of sulfur (as sulfates) in the soil — due to acid rain, fertilizers, and other sources — interferes with selenium accumulation by crops (Frost and Ingvoldstad 1975). In addition, high dietary levels of various heavy metals (including copper, zinc, silver, and mercury) contribute to selenium deficiency in animals (Frost and Ingvoldstad 1975; Harr 1978), presumably as a result of selenium binding with the metal into biologically unavailable forms (Harr 1978; Kaiser et al. 1979).

Clinical selenium deficiency in ruminants is expressed as white muscle disease, lethargy, impaired reproduction, weight loss and reduced growth, shedding, decreased immune response, decreased erythrocyte glutathione peroxidase, and sudden death (Knox et al. 1987; Flueck and Flueck-Smith 1990). Selenium deficiency — as judged by blood concentrations <0.1 mg Se/L — has been documented in California among domestic cattle, mule deer (*Odocoileus hemionus*), pronghorn antelope (*Antilocapra americana*), elk (*Cervus elaphus*), and bighorn sheep (*Ovis canadensis*) (Oliver et al. 1990a). More than 95% of black-tailed deer (*Odocoileus hemionus columbianus*) in northern California had inadequate blood selenium levels (37 µg/kg whole blood FW), as judged by recommended levels for cattle (>40 µg/kg) and sheep (>50 µg/kg) (Flueck 1994). Selenium deficiency in red deer was reversed with subcutaneous injection of 50 mg Se/mL as barium selenate at 2 mL per 50 kg body weight (Knox et al. 1987). Selenium boluses calibrated to release 1.0 mg selenium daily, given orally to selenium-deficient adult female black-tailed deer, effectively raised whole blood levels to 121 µg Se/kg FW. These selenium-supplemented females produced fawns with increased survival (0.83 fawns/female) when compared to untreated does (0.32 fawns/female) (Flueck 1994). Supplementation of selenium-deficient mule deer does with intraruminal selenium pellets can triple fawn survivability (Oliver et al. 1990a). Some feral animals selectively prefer plants with comparatively elevated selenium content. The black rhinoceros (*Diceros bicornis*) in Kenya, for example, prefers 10 of 103 plants ingested; preferred vegetation contained 3.0 to 6.3 µg Se/kg FW vs. 1.8 to 2.7 µg/kg FW in nonpreferred plants (Ghebremeshel et al. 1991).

There is a general consensus that selenium deficiency in livestock is increasing in many countries, resulting in a need for added selenium in the food. Selenium deficiency is considered by some researchers to constitute a greater threat to health than selenium poisoning. Studies with animals and humans have suggested that selenium deficiency, in part, underlies susceptibility to cancer, arthritis, hypertension, heart disease, and possibly periodontal disease and cataracts (Frost and Ingvoldstad 1975; Shamberger 1981; Robberecht and Von Grieken 1982). These linkages have not yet been demonstrated conclusively. For example, eye lens cataract was induced in 10-day-old male rats by selenate, selenite, selenomethionine, and selenocystine, presumably through interference with glutathione metabolism (Ostadalova and Babicky 1980). On the other hand, adverse effects of selenium inadequacy have been clearly documented for a wide variety of organisms, including bacteria, protozoans, Atlantic salmon, rainbow trout, Japanese quail, ducks, poultry, rats, dogs, horses, domestic sheep, bighorn sheep, swine, cattle, antelopes, gazelles, deer, monkeys, and humans (Jensen 1968; Frost and Ingvoldstad 1975; Jones and Stadtman 1975; Fishbein 1977; Harr 1978; Kaiser et al. 1979; Hilton et al. 1980; Shamberger 1981; Bovee and O'Brien 1982; Robberecht and Von Grieken 1982; NRC 1983; Levander 1983, 1984; Knox et al. 1987; Morris et al. 1984; Flueck and Smith-Flueck 1990; Oliver et al. 1990a; USPHS 1996). Selenium deficiency, whether induced experimentally by use of low-selenium feeds supplemented with alpha-tocopherol or by chronic ingestion of low-selenium diets, has caused a number of maladies:

- High embryonic mortality in cattle and sheep
- Anemia in cattle
- Poor growth and reproduction in sheep and rats
- Reduced viability of newly hatched quail

- Nutritional myopathy (white muscle disease) in sheep, swine, and cattle
- Hepatic necrosis and lameness in dogs, horses, and breeding bulls
- Hair loss and sterility in rat offspring
- Spermatozoan abnormalities in rats

Deficiencies were usually prevented or reversed by supplements with sodium selenate or selenite at 100 µg Se/kg ration, or 20 µg Se/kg body weight administered parenterally.

The protective action of selenium against the adverse or lethal effects induced by mercury, cadmium, arsenic, thallium, copper, zinc, silver, and various pesticides is well documented for a wide variety of plant and animal species (Hill 1976; Wilber 1985; Eisler 1985; USPHS 1996). Among marine organisms, for example, selenium protects against toxic levels of mercury in algae (Gotsis 1982), shrimp (Lucu and Skreblin 1982), crabs and oysters (Glickstein 1978), fish (Sheline and Schmidt-Nielsen 1977), and mammals (Koeman et al. 1975). Similar observations have been recorded for copper and marine algae (Gotsis 1982); cadmium and freshwater snails (Wilber 1983), marine crabs (Bjerragaard 1982), earthworms (Helmke et al. 1979; Beyer et al. 1982), and rats (Harr 1978); mercury or methylmercury and rats (Cappon and Smith 1982), eggs of lake trout (Klaverkamp et al. 1983b), freshwater teleosts (Kim et al. 1975, 1977) and (temporarily) Japanese quail (El-Bergearmi et al. 1977, 1982; Beijer and Jernelov 1978); and arsenic and freshwater and marine teleosts (Luten et al. 1980; Orvini et al. 1980). Not all tests were conclusive. Studies with some species of freshwater teleosts demonstrated negligible antagonism of selenium against mercury (Klaverkamp et al. 1983a) or cadmium (Duncan and Klaverkamp 1983). Selenium reportedly protects mammals and poikilotherms against poisoning by thallium, the herbicide paraquat, cadmium, mercury, lead, arsenic, and copper (Wilber 1983; USPHS 1996). Selenium also protects against fatal biological agents. Juvenile chinook salmon (*Oncorhynchus tshawytscha*) naturally infected with *Renibacterium salmoninarum*, the causative agent of bacterial kidney disease, were protected when diets were supplemented with 2.5 mg Se/kg DW ration and Vitamin E (Thorarinsson et al. 1994).

Reasons to account for the antagonism of selenium and heavy metals (here, mercury is used as an example) include the dietary source and chemical form of selenium, influence of sulfur, biological translocation of selenium or mercury to less-critical body parts, and chemical linkage of selenium to mercury on a linear basis. The exact mode of interaction is probably complex and has not yet been resolved. In regard to diet, selenium of animal origin and in the form of selenate is less effective than selenium from plant and inorganic sources in preventing methylmercury neurotoxicity in experimental animals (Cappon and Smith 1982). Disruption of sulfur metabolism by selenium, the sulfur being replaced by seleno-amino acids and other cell constituents containing selenium in living organisms, is one probable cause of selenosis. It is conceivable that Se–Hg compounds formed within the organism would be sufficiently nonreactive biologically to interfere with sulfur kinetics, presumably –SH groups (Koeman et al. 1975; Beijer and Jernelov 1978; Cappon and Smith 1982; Gotsis 1982). Differential redistribution of selenium or mercury to less-critical body parts may partly account for observed antagonisms. Pretreatment of marine minnows with selenium protects against mercury poisoning and causes a marked redistribution of mercury among organs, presumably to noncritical body parts, and this transfer may partly account for the observed Se–Hg antagonisms in that species (Sheline and Schmidt-Nielsen 1977). Some investigators have reported that selenium results in increased mercury accumulations. Increased retention of mercury and other metals may lead to a higher level of biomagnification in the food chain and higher body burden in the individual, which might counteract the positive effect of decreased intoxication (Beijer and Jernelov 1978). Extensive research is under way on the chemical linkage of selenium and mercury. In marine mammals and humans, selenium and mercury concentrations are closely related, almost linearly in a 1:1 molar ratio, but this relation blurs in teleosts in which selenium is in abundance, and fails in birds (Koeman et al. 1975; Beijer and Jernelov 1978; Orvini et al. 1980; Cappon and Smith 1982).

31.5 LETHAL EFFECTS

31.5.1 Aquatic Organisms

Among representative species of aquatic organisms, death was observed at water concentrations between 60 and 600 µg Se/L; early life history stages that were subjected to comparatively lengthy exposures accounted for most of these data (Hamilton and Wiedmeyer 1990; Cleveland et al. 1993; Table 31.3). Sensitive species of fishes had reduced survival after extended exposure to 10 to 47 µg Se/L. Adult bluegills (*Lepomis macrochirus*), for example, had reduced survival after exposure to 10 µg Se/L for 1 year; those exposed to 30 µg Se/L all died (Hermanutz et al. 1992). Adult bluegills exposed for 60 days to 10 µg Se/L as selenite, plus 33.3 mg Se/kg ration as seleno-L-methionine, were normal but produced fry with reduced survival (Coyle et al. 1993). Exposure for 1 year to 25 µg/L caused reduced survival and reproduction of perch and grass carp (Crane et al. 1992). Mortality of 35% occurred at 47 µg Se/L, as selenite, in chinook salmon exposed for 90 days at the yolk-sac stage; 70% died at 100 µg/L (Lemly et al. 1993). Survival was reduced in chinook salmon fingerlings when their diets contained >9.6 mg Se/kg ration (Hamilton et al. 1990; Lemly et al. 1993).

Latent mortality after exposure to comparatively high selenium concentrations has been documented, but not extensively. For example, all embryos of the zebrafish (*Brachydanio rerio*) survived exposure to 3000 µg Se/L during development, but more than 90% of the resultant larvae died soon after hatching. At 1000 µg/L, survival was similar to that in controls (Niimi and LaHam 1975). It has been suggested (USEPA 1980) that selenite is more toxic than selenate and is preferentially concentrated over selenate by mussels, *Mytilus galloprovincialis* (Measures and Burton 1980). Selenite is generally more toxic to early life history stages, and effects are most pronounced at elevated temperatures (Klaverkamp et al. 1983a). Also, selenium salts may be converted to methylated forms by microorganisms, and these are readily accumulated by aquatic vertebrates (Klaverkamp et al. 1983a). Among freshwater algae species, it has been demonstrated that selenite, selenate, selenomethionine, and selenopurine are all toxic, but that sulfur, as sulfate, has a significant protective role against selenium toxicity (Kumar and Prakash 1971). Numerous additional chemical compounds and mixtures probably protect against selenium toxicity, much as selenium protects against toxic effects of mercury salts and other chemicals, but data are sparse on selenium protective agents.

More than 60 years ago, Ellis et al. (1937) recorded a long list of signs of selenium poisoning in teleosts: loss of equilibrium, lethargy, contraction of dermal chromatophores, loss of coordination, muscle spasms, protruding eyes, swollen abdomen, liver degeneration, reduction in blood hemoglobin and erythrocyte number, and increase in white blood cells. Sorensen et al. (1984) observed most of these signs in selenium-poisoned green sunfish (*Lepomis cyanellus*), together with elevated liver selenium concentrations, reduced blood hematocrit, enlarged liver, histopathology of kidney and heart, swollen gill lamellae with extensive cellular vacuolization, and necrotic and degenerating ovarian follicles. Other signs of selenosis in freshwater fishes include loss of osmotic control and liver histopathology (Hodson 1990).

^b MATC = maximum acceptable toxicant concentration. Lower value in each MATC pair indicates highest concentration tested producing no measurable effect on growth, survival, reproduction, and metabolism during chronic exposure. Higher value indicates lowest concentration tested producing a measurable effect.

31.5.2 Mammals and Birds

“The element selenium can be traced in an orderly sequence from its origin in the Earth’s crust to specific geological formation, to distribution of specific genera and groups of plants which require the element for their growth, to the accumulation in vegetation, and to its subsequent toxicity to birds or mammals that consume the seleniferous foods” (Rosenfeld and Beath 1964). Selenosis in warm-blooded organisms is modified by numerous factors, including method of administration, chemical form of selenium, dietary composition, and age and needs of the organism. Concurrent ingestion of minerals and rough or high protein feeds reduces selenium toxicity, and exposure by diet is less toxic than exposure parenterally or by inhalation. Many compounds are known to prevent or reduce toxic effects of subacute and chronic selenosis in pigs, beef cattle, and other warm-blooded organisms. A partial list includes arsenic, strychnine sulfate, tungsten, germanium, antimony, beet pectin, high-fat diets, ACTH injections, sulfate, increased dietary proteins, lactalbumin, ovalbumin, wheat protein, dried brewer’s yeast, desiccated liver, linseed oil meal, glucosamine, hemocysteine, creatine, methionine, and choline. Not all of these compounds afforded equal protection against various selenium formulations. The reasons for the difference are not clear, but it appears that the subject of selenoprotective agents warrants additional research effort. Selenium poisoning in livestock, discussed here, was largely extracted from reviews by Rosenfeld and Beath (1964), Frost (1972), Fishbein (1977), Harr (1978), Shamberger (1981), NRC (1983), Wilber (1983), and USPHS (1996).

In livestock, there are three basic types of selenium poisoning:

- Acute, resulting from consumption (usually in a single feeding) of a sufficient quantity of highly seleniferous weeds
- “Blind staggers,” from consumption of moderately toxic amounts of seleniferous weeds over an extended period of time
- “Alkali disease,” caused by the consumption of moderately seleniferous grains and forage grasses over a period of several weeks to months

Acute poisoning is associated with plant materials containing 400 to 800 mg Se/kg: sheep died when fed amounts of plant material ranging from 8 to 16 g/kg BW, or about 3.2 to 12.8 mg Se/kg BW. The minimum lethal dose of Se administered orally as selenite (mg Se per kg body weight) ranged from 3.3 for horses and mules, to 11 for cattle, and 15 for swine. Other modes of administration were more toxic; for example, 2 and 1.2 mg Se/kg BW given subcutaneously killed swine in 4 h and 5 days, respectively; and 1.5 to 6.0 mg Se/kg BW given intravenously or intraperitoneally to rats and rabbits were fatal. Accidental toxicosis of sheep and cattle from overtreatment with commercial mixtures of Se salts and Vitamin E are also documented for Australia and New Zealand. Acute Se poisoning in domestic livestock is characterized by abnormal movements, lowered head, drooped ears, diarrhea, elevated temperature, rapid pulse, labored breathing, bloating with abdominal pain, increased urination, and dilated pupils. Before death, which is due to respiratory failure, there is complete prostration and lethargy. Duration of illness extends from a few hours to several days, depending on the toxicity of plant material ingested. In these cases, selenium is distributed by the circulatory system to all body organs, the concentrations being highest in liver, blood, kidney, spleen, and brain, and lowest in muscle, skin, hair, and bone. Elimination is primarily in the urine; smaller quantities are excreted with the feces, breath, perspiration, and bile. Postmortem examinations indicate many pathological changes in the heart, lungs, rumen, liver, kidney, and other organs. No effective treatment is known for counteracting toxic effects of large amounts of ingested selenium.

Chronic selenosis in mammals may be induced by dietary exposure to natural selenite, selenate, or seleniferous feedstuffs at dietary concentrations between 1 mg/kg (rat) and 44 mg/kg (horse), or from water containing 0.5 to 2.0 mg Se/L. Cattle fed 0.5 mg Se/kg BW three times weekly lost their appetite; sheep fed up to 75 mg selenite daily developed myocardial degeneration and fibrosis, pulmonary congestion, and edema. The minimum toxic concentration of selenium in lifetime exposure of rats (a comparatively sensitive species) fed Se-deficient diets fortified with selenium was 0.35 mg Se/kg diet, as judged by changes in liver chemistry; and 0.75 mg Se/kg diet, as judged by longevity, and histological changes in heart, kidney, and spleen. These concentrations are 10 times the nutritional threshold for selenium, and about 25% of the minimum lifetime exposure to selenium in natural feedstuffs that produces similar effects under the same experimental conditions. Signs of chronic selenosis include skin lesions, lymph channel inflammation, loss of hair and nails, anemia, enlarged organs (spleen, pancreas, liver), fatigue, lassitude, and dizziness. “Blind staggers” is characterized by anorexia, emaciation, and sudden collapse, followed by death. Typically, the upper intestinal tract is ulcerated. In “alkali disease” in cattle, hogs, and horses that had eaten seleniferous grains, the signs were deformation and sloughing of the hooves, hair loss, lassitude, erosion of the articular cartilages, reduced conception, increased reabsorption of fetuses, and degeneration of heart, kidney, and liver. It is likely that selenium displaces sulfur in keratin, resulting in structural changes in hair, nails, and hooves (Fishbein 1977).

Elevated selenium concentrations were measured in tissues and diet of two captive California sea lions (*Zalophus californianus*) that died shortly after performing at a show in 1988. Selenium concentrations, in mg/kg FW, were 49 and 88 in liver, 42 and 47 in kidney, and 5.1 and 5.2 in blood. Selenium concentrations in their fish diet was 2.5 mg/kg FW, and in thawed fish fluids 45 mg/kg FW (Alexander et al. 1990).

Fatal chronic selenosis in aquatic birds is characterized by low body weight or emaciation, liver necrosis, enlarged kidneys (up to 40% heavier than normal), and more than 66 mg Se/kg DW liver

(Albers et al. 1996). Selenomethionine was the most toxic form of selenium tested against mallards (Lemly et al. 1994). Mallard ducklings fed 8 mg Se/kg ration as selenomethionine for 120 days had hepatotoxicity as adults; 10 mg/kg ration for 120 days inhibited reproduction; 15 mg/kg ration for 28 days inhibited growth; and 60 mg/kg ration for 60 days was fatal to all ducklings (Lemly et al. 1994) (Table 31.4). All fatal cases of selenomethionine-induced poisoning in mallards were characterized by histologic lesions of the liver, pancreas, spleen, and lymph nodes, and severe atrophy and degeneration of fat (Green and Albers 1997).

Table 31.4 Selenium Effects on Birds

Species, Dose, and Other Variables	Effect	Reference ^a
MALLARD, <i>Anas platyrhynchos</i>		
Adults given drinking water containing 0, 0.5, or 3.5 mg Se/L as sodium selenite, or 2.2 mg Se/L as selenomethionine for 12 weeks	Selenomethionine group had altered immune function, altered serum enzyme activities, and elevated concentrations of selenium in liver (4 times control values) and breast muscle (14 times). Sodium selenite-treated birds had normal immune function and selenium tissue burdens; however, serum enzyme activity was disrupted in the 3.5 mg/L group	1
Breeding adults fed diets for 100 days containing 0, 1, 2, 4, 8, or 16 mg Se/kg fresh weight (FW) ration as seleno-DL-methionine, or 16 mg Se/kg ration as seleno-DL-cysteine	Adults normal. Impaired reproduction (reduced survival of ducklings, increased developmental abnormalities) for selenomethionine occurs between 4 and 8 mg/kg ration; selenocysteine did not impair reproduction at 16 mg Se/kg ration	2
Breeding adults fed diets containing 0, 1, 5, 10, 25, or 100 mg Se/kg ration as sodium selenite for as long as 12 weeks, or 10 mg Se/kg ration as seleno-DL-methionine for as long as 12 weeks	Sodium selenite groups had normal growth, survival, and reproduction at 10 mg/kg ration and lower; growth and reproduction inhibited in the 25- and 100-mg/kg groups. Selenomethionine birds produced fewer ducklings with a high incidence of developmental abnormalities; surviving ducklings had impaired growth	3
Breeding adults fed diets containing 0, 3.5, or 7 mg Se/kg ration as seleno-DL-methionine for as long as 21.8 weeks. Ducklings produced received the same treatment as their parents for 14 days, then killed	No deaths or histopathology in any group. Dose-dependent decrease in adult growth, duckling weight, and hatching success; dose-dependent increase in selenium concentrations in adult liver, eggs, and duckling liver	4
Adults and resultant ducklings fed diets supplemented with up to 400 mg As (as sodium arsenate)/kg ration and zero or 10 mg Se (as seleno-DL-methionine)/kg ration	Arsenic or selenium at dose levels and forms given adversely affect mallard reproduction and duckling growth and survival. In mixtures, arsenic reduced selenium accumulation in liver and eggs and alleviated adverse affects of selenium on hatching success and embryo deformities	5
Day-old mallard ducklings fed diets for 2 weeks containing 0, 15, or 30 mg Se/kg ration in a 75% wheat diet (22% protein). Selenium given as seleno-DL-methionine, seleno-L-methionine, or selenized yeast	All forms of selenium caused significant increases in plasma and hepatic glutathione peroxidase activities. Seleno-L-methionine at 30 mg/kg ration was the most toxic form, resulting in high mortality (64%), impairing growth more than 50% in survivors, and the greatest increase in the ratio of oxidized to reduced hepatic glutathione. When the basal diet was a commercial duck feed (22% protein), survival was not adversely affected and oxidative effects were less pronounced	6
Adult males fed diets containing 0.2 (control), 1, 2, 4, 8, 16, or 32 mg Se/kg ration as selenomethionine for 14 weeks	Plasma glutathione peroxidase activity increased at 2 mg/kg ration and greater; altered liver enzyme activity in 8 mg/kg ration and higher; dose-dependent increase in liver selenium, reaching 29 mg Se/kg FW in the 32-mg/kg group; the high-dose group had decreased survival, altered blood chemistry, and hepatotoxicity	7
Adults fed diets 6 weeks before egg laying through day 7 of incubation containing either sodium selenite — at 1, 5, 10, or 25 mg Se/kg ration — or selenomethionine at 10 or 16 mg Se/kg ration	The 25 mg/kg group of sodium selenite had 42% fewer eggs than controls that hatched, more birth defects (4.2%), and decreased embryo weights. Developmental abnormalities in the selenomethionine groups were 13.1% in the 10-mg/kg group and 68.0% in the 16-mg/kg group	8

Table 31.4 (continued) Selenium Effects on Birds

Species, Dose, and Other Variables	Effect	Reference^a
Ducklings fed diets containing 0, 10, 20, 40, or 80 mg Se/kg ration as selenomethionine or sodium selenite from hatching to age 6 weeks	At 80 mg/kg ration, all ducklings were dead in the selenomethionine group and 98% were dead in the selenite group. At 40 mg/kg ration, 25% were dead in the selenomethionine group and 13% in the selenite group. Survival was normal in other groups. Growth was decreased at 20 mg/kg ration and higher — regardless of chemical form — due to decreases in food consumption. The 10-mg/kg selenite group had significantly heavier livers than controls	9
Adult males fed diets containing 0, 10, 20, 40, or 80 mg Se/kg ration as seleno-DL-methionine for 16 weeks	All dead at 80 mg/kg ration. Survival reduced, growth impaired, and molt delayed at 40 mg/kg ration. Dose-dependent increase in tissue selenium concentrations. Dead birds had consistent histologic lesions in the liver, kidneys, and organs of the immune system	10, 13
Adults males given a choice between a control diet or diets with 5, 10, or 20 mg Se/kg ration as selenomethionine	Mallards avoided diets containing 10 or 20 mg Se/kg; avoidance may not be due to aversion to the taste of selenium	11
Adult males were fed diets supplemented with 0, 10, 20, 40, or 80 mg Se/kg ration as selenomethionine for 16-week exposure that began in November. Survivors were fed untreated diets for 4 more weeks	No deaths in controls or 10-mg/kg group, 25% dead in the 20-mg/kg group, 95% in the 40-mg/kg group, and 100% in the high-dose group. Body weights depressed in the 20-, 40-, and 80-mg/kg groups; but after 4 weeks on untreated diet, the 20-mg/kg group was the same as controls	12
Mallards fed diet containing 0 or 15 mg Se/kg ration as seleno-DL-methionine for 21 weeks, untreated food for 12 weeks, followed by 100 mg Se/kg ration for 5 weeks for both groups	No difference between groups in survival (85%), weight loss in survivors (40%), or liver burdens (35–40 mg Se/kg FW)	14
Adults fed diet containing 10 mg Se/kg ration as selenomethionine for 6 weeks followed by 6 weeks on untreated diet	Equilibrium reached in liver in 7.8 days and in muscle in 81 days with half-time persistence of 19 days in liver and 30 days in muscle	15
Fed diet with 15 mg Se/kg ration as selenomethionine for 21 weeks during winter, ending with onset of reproductive season	Selenium group had elevated concentrations in eggs, decreased survival, and higher incidence of deformed embryos. Reproduction and survival normal after 2 weeks on an uncontaminated diet	16
Ducklings fed diets for 4 weeks containing 15 or 60 mg Se/kg ration as selenomethionine, with and without 1000 mg boron/kg ration	Severe adverse effects of 60 mg Se/kg ration on survival, growth, and liver histology; effects exacerbated by the addition of boron	17
Females that had just initiated egg laying were fed diet containing 20 mg Se/kg ration as selenomethionine for 20 days, then an untreated diet for 20 days	Selenium concentrations in eggs reached a maximum of 20 mg Se/kg FW in about 2 weeks on the treated diet. Concentrations fell to less than 5 mg/kg FW after 10 days on the untreated diet	18
Ducklings fed diet containing 22% protein and 60 mg Se/kg ration as selenomethionine for 4 weeks	Selenium-induced reduction in growth and survival, and increase in liver histopathology. Effects exacerbated at 7% and 44% protein. Effects alleviated by addition of 200 mg As/kg ration as sodium arsenite, and partially alleviated by methionine dietary supplement	19, 20
AMERICAN KESTREL, <i>Falco sparverius</i>		
Adults fed diets for 11 weeks containing 5 or 9 mg Se/kg DW ration as seleno-L-methionine or naturally incorporated selenium (mammals from Kesterson National Wildlife Refuge, California)	All birds seemed normal during the study. Maximal Se concentrations in blood were measured at week 5 in the seleno-L-methionine groups: 4.3 mg Se/kg DW (low Se group) and 8.4 mg Se/kg DW (high Se group) vs. 1.6 mg/kg in controls. Excreta Se levels were 5.8 and 1.8 mg/kg DW in the low and high seleno-L-methionine groups, respectively, vs. 1.4 in controls. All treatment groups had reduction of Se concentration in excreta, but not in blood, to baseline values 4 weeks after treatment ended	22

Table 31.4 (continued) Selenium Effects on Birds

Species, Dose, and Other Variables	Effect	Reference ^a
EASTERN SCREECH-OWL, <i>Otus asio</i>		
Breeding adults fed diets containing 0, 4.4, or 13.2 mg Se/kg ration as seleno-DL-methionine for 3 months (equivalent to 0, 10, and 30 mg seleno-DL-methionine/kg ration)	Growth and reproduction inhibited at high dose. No malformed nestlings at low dose, but femur lengths were shorter than controls. Altered liver biochemistry of nestlings from parents fed low dose	21

31.6 SUBLETHAL AND LATENT EFFECTS

Results of laboratory studies and field investigations with fish, mammals, and birds have led to general agreement that elevated concentrations of selenium in diet or water were associated with reproductive abnormalities, including congenital malformations, selective bioaccumulation by the organism, and growth retardation. Not as extensively documented, but nevertheless important, are reports of selenium-induced chromosomal aberrations, intestinal lesions, shifts in species composition of freshwater algal communities, swimming impairment of protozoans, and behavioral modifications.

31.6.1 Aquatic Organisms

Adverse effects on reproduction are among the most insidious effects of selenium in freshwater ecosystems. Adult bluegills exposed to 2.5 µg Se/L as sodium selenite for 319 days in an experimental stream ecosystem produced fry with a high incidence of edema, lordosis, and hemorrhaging (Coyle et al. 1993). Fathead minnows (*Pimephales promelas*) held in ecosystems containing 10 or 30 µg Se/L for 1 year produced a high incidence of malformed progeny with humped backs, missing scales, and malformations of the jaw, head, operculum, snout, and mandible. The frequency of malformations in the controls was 0.3%; in the 10- and 30-µg/L groups, these frequencies were 8% and 29.8%, respectively (Hermanutz 1992). Selenium concentrations in whole fathead minnows from the 10-µg Se/L group were 3.9 mg/kg FW vs. 0.3 in the controls (Schultz and Hermanutz 1990). Mosquitofish reproduction was inhibited when whole-body selenium concentrations were >100 mg Se/kg DW vs. normal reproduction in a reference area at 1.5 mg Se/kg DW whole body (Saiki and Ogle 1995).

In green sunfish from a lake in North Carolina receiving selenium (as flyash wastes from a coal-fired power station), reproduction failed and the population declined markedly. In these fish, selenium levels were elevated in liver (up to 21.4 mg/kg FW) and other tissues; kidney, heart, liver, and gill showed histopathology; and blood chemistry was altered. Ovaries of fish had numerous necrotic and ruptured egg follicles that may have contributed to the population extinction (Sorensen et al. 1984). It is probable that selenium uptake by plankton (containing 41 to 97 mg/kg DW) from lake water (9 to 12 µg/L) introduced selenium to the food chain, where it ultimately reached elevated levels in fish through biomagnification (Cumbie and Van Horn 1978). In laboratory tests, however, eggs of common carp hatched normally when incubated in media containing 5000 µg Se/L (Huckabee and Griffith 1974), as did eggs of lake trout (*Salvelinus namaycush*) at 10,000 µg Se/L (Klavertkamp et al. 1983b). In frogs (*Xenopus laevis*), cranial and vertebral deformities and lowered survival were documented during development in water with concentrations of 2000 µg Se/L or higher (Browne and Dumont 1979).

Reduced growth of freshwater fishes was associated with tissue concentrations of 3.6 to 6.7 mg Se/kg DW (Hamilton and Wiedmeyer 1990), and dietary concentrations between 5.3 and 25 mg Se/kg DW ration (Hamilton et al. 1990; Cleveland et al. 1993; Lemly et al. 1993). Toxic sublethal effects of selenium in aquatic systems were more pronounced for organoselenium compounds than inorganic compounds and more pronounced for inorganic selenite than inorganic selenate compounds (USEPA 1987; Hamilton and Buhl 1990; Chapman 1992; Boisson et al. 1995) (Table 31.3). In salmon, younger stages were more sensitive than older stages (Hamilton and Buhl 1990; Chapman 1992). Adverse effects of selenium stress to freshwater fishes were reduced with increasing water hardness (Hamilton and Buhl 1990; Hamilton et al. 1990), and fishes were more sensitive to selenium stress under conditions of reduced temperature and photoperiod (Lemly 1993c).

At water concentrations of 47 to 53 µg/L, selenium was associated with anemia and reduced hatch of rainbow trout (Hodson et al. 1980), growth retardation of freshwater green algae (Hutchinson and Stokes 1975; Klaverkamp et al. 1983a), and shifts in species composition of freshwater algal communities (Patrick 1978). At 250 µg Se/L, growth was reduced in rainbow trout fry after exposure for 21 days (Adams 1976), and goldfish demonstrated an avoidance response after 48 h (Weir and Hine 1970). At water concentrations of 7930 to 11,000 µg Se/L, growth was inhibited in freshwater and marine algae (Patrick 1978; USEPA 1980), and swimming rate was reduced in the protozoan *Tetrahymena pyriformis* (Bovee and O'Brien 1982). Eggs of channel catfish exposed to certain metals (including cadmium, mercury, and copper) produced an increased percentage of albino fry; however, eggs exposed to 250 µg Se/L produced fry with normal pigmentation (Westernman and Birge 1978).

A significant number of chromosomal aberrations were induced in the edible goby (*Boleophthalmus dussumieri*) by selenium after intramuscular and water exposures (Krishnaja and Rege 1982). Intramuscular injections as low as 0.1 mg Se/kg BW, or 3200 µg/L in the water column, were associated with a marked enhancement of polyploid cells 76 to 96 h postadministration. Some deaths were recorded at higher test concentrations. Selenite was more effective than selenate in inducing chromosomal aberrations. The authors concluded that a relatively narrow range of selenium concentrations leads to a mutagenic rather than lethal effect.

Accumulation of selenium by aquatic organisms is highly variable. In short-term (48-h) laboratory tests at water concentrations of 0.015 to 3.3 µg Se/L, Nassos et al. (1980) reported biological concentration factors (BCFs) of 460 for mosquitofish to 32,000 for a freshwater gastropod. Values were intermediate for daphnids (2100), plankton (2600), and *Fundulus kansae* (3300), the freshwater killifish. High BCFs (>680) were recorded for freshwater diatoms subjected to maximum concentrations of 40 µg Se/L (Patrick 1978). Livers from rainbow trout and brown trout may contain from 50 to 70 mg Se/kg FW during lifetime exposure in seleniferous (12.3 to 13.3 µg/L) water, and have BCF values of 3759 to 5691 (Kaiser et al. 1979). BCF values were 361 to 390 for skin, and about 180 for muscle (Kaiser et al. 1979). In short-term exposures, most of the selenium was probably adsorbed to the body surface (Fowler and Benayoun 1976c), and then rapidly lost on transfer to selenium-free media (Browne and Dumont 1979). In longer exposures, the BCF values in aquatic organisms were lower after immersion in high ambient selenium concentrations over extended periods. Thus, marine crabs exposed to a water concentration of 250 µg Se/L for 29 days accumulated selenium over water concentration level by a factor of 25 for carapace, and 3.8 for gill; accumulations in muscle and hepatopancreas were negligible. Cadmium in solution enhanced selenium uptake (Bjerragaard 1982). Exposure of common carp to 1000 µg Se/L for 85 days resulted in a whole-body BCF of 6; additional studies of 7 weeks exposure plus 7 weeks postexposure at concentrations between 500 and 5000 µg Se/L (Sato et al. 1980) yielded a BCF range of 0.6 (5000 µg/L) to 1.8 (500 µg/L). Highest BCF values in carp were 50 for kidney and 80 for liver after exposure of the fish to 100 µg Se/L for 7 weeks plus 7 weeks in selenium-free media. For carp, selenium tended to accumulate in kidney, liver, gill, gall bladder, heart, bone, and muscle, in that general order (Sato et al. 1980). Studies with freshwater organisms collected from a farm pond

contaminated by flyash with high selenium levels (Furr et al. 1979), and with marine bivalves and nereid worms held for 4 months in seawater flowing through coal flyash containing 6200 µg Se/L (Ryther et al. 1979), showed that accumulation was slight. Contrasted to this are the observations of Cherry et al. (1976) and Ohlendorf et al. (1986). Cherry and co-workers collected mosquitofish from a drainage system that received high coal flyash concentrations at one end and thermal discharges at the other. Mosquitofish contained up to 9.0 mg Se/kg whole-body fresh weight. Of 40 elements examined, only selenium, zinc, and calcium were accumulated in excess of the levels measured in the water. Ohlendorf et al. found mean residues of 172 mg/kg DW (range 110 to 280 mg/kg) in whole mosquitofish from irrigation drainwater ponds contaminated by about 300 µg Se/L; based on a wet/dry factor of 4, the BCF for whole mosquitofish was >91.

Selenium accumulation is modified by water temperature, age of the organism, organ or tissue specificity, mode of administration, chemical species, and other factors. In freshwater fishes, selenium concentrations in tissues increased with increasing exposure (Hamilton and Wiedmeyer 1990) and increasing dose (Hamilton and Wiedmeyer 1990; Cleveland et al. 1993), and decreased with increasing water hardness (Hamilton and Wiedmeyer 1990). Food chain accumulation of selenium can severely affect reproductive success of bluegills (Coyle et al. 1993). Bluegills tend to accumulate inorganic selenium compounds through the diet, and organoselenium compounds through the medium as well as the diet (Besser et al. 1993). Dietary selenite accumulates in liver and gonads, and selenomethionine in muscle and whole fish (Gillespie et al. 1988; Lorentzen et al. 1994).

Diet is the major route of selenium intake by mussels (*Mytilus edulis*). Studies with radio selenium-75 demonstrated that selenium efficiency was 28 to 34% from the diet and 0.03% from the medium (Wang et al. 1996). Authors concluded that 96% of the selenium in mussels is obtained from ingested food under conditions typical of coastal waters (Wang et al. 1996). In the marine mussel *Mytilus galloprovincialis*, an increase in water temperature from 13 to 29°C doubled the bioconcentration factor (BCF) in 13 days (Fowler and Benayoun 1976b). Mussels preferentially accumulated selenite over selenate (Fowler and Benayoun 1976b); however, mussels did not reach a steady state in 63 days (Fowler and Benayoun 1976c), indicating that selenium kinetics in some species are difficult to elucidate in short-term studies. Accumulation rates were higher in small than in large mussels (Fowler and Benayoun 1976b), as they were in freshwater teleosts (Furr et al. 1979). However, the reverse was documented for marine mammals and teleosts (Eisler 1984). When selenium was available from both the diet and the medium, concentrations were highest in liver, kidney, and gills of teleosts (Sorensen et al. 1982; Furr et al. 1979; Kaiser et al. 1979), exoskeleton of crustaceans (Fowler and Benayoun 1976c; Bjerragaard 1982), and visceral mass and gills of molluscs (Fowler and Benayoun 1976c). When selenium was administered in food to marine shrimps, concentrations were highest in viscera and exoskeleton, suggesting that ingested selenium is readily translocated from internal to external tissues (Fowler and Benayoun 1976c). Concentrations of selenium in crustaceans usually were higher in fecal pellets than in the diet; fecal pellets may represent a possible biological mechanism for downward vertical transport of selenium in the sea (Fowler and Benayoun 1976a), as well as in freshwater environments.

The time for 50% excretion of accumulated selenium was found to range from 13 to 181 days in various species of marine and freshwater fauna. Biological half-life of selenium accumulated from the medium was estimated at 28 days for carp (Sato et al. 1980), 37 days for the marine euphausiid crustacean *Meganctiphanes norvegica* (Fowler and Benayoun 1976a), 63 to 81 days for the marine mussel *Mytilus galloprovincialis* (Fowler and Benayoun 1976b), 58 to 60 days for the marine shrimp *Lysmata caudata* (Fowler and Benayoun 1976b), and, as reviewed by Stadtman (1974, 1977), 13 days for guppies, 27 days for eels, and 28 days for leeches. Studies by Lemly (1982a) with bluegills and largemouth bass showed elevated tissue levels after exposure to 10 µg Se/L for 120 days. Time for 50% excretion in 30-day elimination trials was about 15 days from

gill and erythrocytes; however, there was essentially no elimination from spleen, liver, kidney, or muscle. It appears that research is needed on preferential tissue retention of selenium and its implications for biochemical and metabolic transport mechanisms. Urine is a major excretory route for selenium in marine mammals. Urine of minke whales (*Balaenoptera acutorostrata*) contains 1.5 mg Se/L, or about 30 times more selenium than human urine (Hasunuma et al. 1993). There are at least five selenium components in urine of minke whales, including trimethylselenium ion; the significance of this observation is imperfectly understood (Hasunuma et al. 1993).

31.6.2 Terrestrial Invertebrates

Concentrations of selenium decreased in whole earthworms from 22.4 to 15.0 mg/kg (dry weight) as the rate of sludge application increased from 15 to 60 metric tons/ha. Concentrations of selenium in soil and sludge were 0.3 and 0.5 mg/kg dry weight, respectively (Helmke et al. 1979). Other studies indicated that some metals, notably cadmium, decreased in worms living in soils amended with sewage sludge but that selenium concentrations were not affected (Beyer et al. 1982). The biological half-life of selenium in earthworms is estimated to be 64 days, a period consistent with values of 10 to 81 days documented for ants, birds, mammals, and aquatic biota (Stadtman 1974, 1977).

31.6.3 Birds

Embryos of the domestic chicken (*Gallus domesticus*) are extremely sensitive to selenium. The hatchability of eggs is reduced by concentrations of selenium in feeds (6 to 9 mg/kg) that were too low to produce poisoning in other avian species. Dietary selenium excess was associated with decreased egg weight, decreased egg production and hatchability, anemia, elevated kidney selenium residues in chicks, and a high incidence of grossly deformed embryos with missing or distorted eyes, beaks, wings and feet (Ort and Latshaw 1978; Harr 1979). Similar results were observed by El-Bergarmi et al. (1977) in Japanese quail at 6 and 12 mg/kg dietary selenite. Ohlendorf et al. (1986) reported severe reproductive effects in ducks (*Anas* spp.), American coot (*Fulica americana*), and other species of aquatic birds nesting at irrigation drainwater ponds in the San Joaquin Valley, California. Water in these ponds contained abnormally high concentrations of about 300 µg Se/L, but low or nondetectable levels of silver, chromium, arsenic, cadmium, mercury, lead, and zinc. Of 347 nests examined from this site, about 40% had at least one dead embryo, and about 20% had at least one embryo or chick with obvious external anomalies, including missing or abnormal beaks, eyes, wings, legs, or feet. In addition, brain, heart, liver, and skeletal anomalies were recorded. Concentrations of selenium (mg/kg, dry weight) were 2 to 110 in eggs and 19 to 130 in livers of birds, 12 to 79 in plants, 23 to 200 in invertebrates, and 110 to 280 in fish from the ponds, or 7 to 130 times those found at a nearby control area. It was concluded that selenium was the probable cause of poor reproduction and developmental abnormalities in the aquatic nesting birds, due to interference with their reproductive processes. The concentrations of selenium in breast muscle of coots were sufficiently high (up to 11.0 mg Se/kg FW) to induce state agencies to post the area, advising against the consumption of more than one meal per week of this species, or of any coots by children or pregnant women (Ohlendorf et al. 1986).

Selenomethionine is the predominant form of selenium in commercial grains (Heinz et al. 1989), usually as seleno-L-methionine (Heinz et al. 1996). Selenomethionine is more teratogenic and embryotoxic to avian waterfowl than inorganic forms of selenium tested (Heinz and Fitzgerald 1993b; Heinz et al. 1996; Hoffman et al. 1996) (Table 31.4), possibly due to higher uptake of organoselenium (Hoffman and Heinz 1988). Blood selenium concentrations in American kestrels (*Falco sparverius*) seemed to reflect dietary concentrations of seleno-L-methionine (Yamamoto

et al. 1998). Embryotoxic and teratogenic effects of selenomethionine were observed in mallards at dietary concentrations exceeding 4 mg Se/kg FW ration in the laboratory, causing effects similar to those found in field studies (Heinz et al. 1987, 1989; Hoffman and Heinz 1988). Excess dietary selenium, as seleno-DL-methionine has a more pronounced effect on hepatic glutathione metabolism and lipid peroxidation than selenite (Hoffman et al. 1989), and may enhance selenium accumulation (Moksnes 1983; Hoffman et al. 1989). In aquatic birds, developmental malformations were associated with lipid peroxidation in livers. Selenomethionine causes lipid peroxidation in livers of aquatic birds, and this is consistent with the observation that selenomethionine is the primary causative agent of selenium-induced embryonic mortality and overt teratogenesis in waterfowl at Kesterson Reservoir (Hoffman et al. 1988). Dietary selenomethionine effects were modified by salts of boron (Hoffman et al. 1991b; Stanley et al. 1996), arsenic (Hoffman et al. 1992a; Stanley et al. 1994), and protein composition (Hoffman et al. 1992b, 1996), with significant interactions between mixtures.

31.6.4 Mammals

Pregnant long-tailed macaques (*Macaca fascicularis*) given L-selenomethionine for 30 days at doses of 25, 150, or 300 µg Se/kg body weight daily showed dose-dependent increases in erythrocyte and plasma selenium, glutathione peroxidase activities, hair and fecal selenium, and urinary selenium excretion. Adverse effects, including body weight loss, were associated with daily doses of 150 and 300 µg Se/kg BW and concentrations of erythrocyte selenium >2.3 mg/L, plasma selenium >2.8 mg/L, and hair selenium >27 mg/kg FW (Hawkes et al. 1992). Young adult female mice (*Mus* sp.) given intraperitoneal injections of sodium selenate or selenomethionine (in each case, three injections of 2 mg Se/kg BW at 2-day intervals) had altered blood composition 24 days after the last injection. Both forms of selenium induced a transient, marked decrease in the number of circulating leukocytes (a condition known as leukopenia) following serial injections. Leukopenia was more extensive and of greater duration for selenomethionine-treated mice (Hogan 1998).

Harr (1978) and NRC (1983) summarized nonlethal effects of selenium on mammals, including reproductive anomalies. Selenosis caused congenital malformations in rats, mice, swine, and cattle. In general, young born to females with selenosis were emaciated and unable to nurse. Mice given selenium in drinking water reproduced normally for three generations, but litters were fewer and smaller when compared to controls, pups were runts with high mortality before weaning, and most survivors were infertile.

In rats, selenium did not induce cirrhosis or neoplasia; however, intestinal lesions were observed among those fed diets containing 0.8 to 1.0 mg Se/kg ration during lifetime exposure. The threshold requirement for optimal rat nutrition under similar conditions is about 0.08 mg Se/kg ration, again demonstrating the relatively narrow range separating selenium deficiency from selenium poisoning. Absorption of oral radioselenite by rats was as high as 95 to 100%. A single dose of radioselenite concentrated, in descending order of accumulation, in pancreas, intestine, erythrocytes, liver, kidney, and testes; tissue distributions from chronic exposure were similar. As expected, levels of selenium in poisoned rats were highest in liver and kidney. Rats, and probably other mammals, can regulate dietary selenium accumulations. Dietary concentrations in excess of 54 to 84 µg/kg ration were usually excreted in urine (Harr 1978; NRC 1983). Urine is the major excretory route for selenium. In urine of selenium-challenged rats, the trimethylselenium ion — a metabolic product of selenite or selenoamino acid, such as selenomethionine — is dominant (Hasunuma et al. 1993). However, when selenium intake exceeded 1000 µg/kg ration, pulmonary excretion was active (Harr 1978; NRC 1983). Excretion of selenium in feces, bile, saliva, and hair appears to be relatively constant, regardless of the amount of exposure. Yonemoto et al. (1983) demonstrated that some selenotoxic effects in mice, including abortion and maternal death, were prevented by prior treatment with Vitamin E, but exacerbated by reduced glutathione. The mechanisms for these interactions are unknown, and merit additional research.

31.7 RECOMMENDATIONS

All investigators appear to agree on four points:

1. Insufficient selenium in the diet may have harmful and sometimes fatal consequences.
2. Exposure to grossly elevated levels of selenium in the diet or water is inevitably fatal over time to terrestrial and aquatic organisms.
3. There is a comparatively narrow concentration range separating effects of selenium deficiency from those of selenosis.
4. Additional fundamental and basic research is required on selenium metabolism, physiology, recycling, interactions with other compounds or formulations, and chemical speciation in order to elucidate its nutritive role as well as its toxic effects.

Accordingly, the proposed selenium criteria shown in [Table 31.5](#) for prevention of selenium deficiency and for protection of aquatic life, livestock, crops, and human health, should be viewed as guidelines, pending acquisition of additional, more definitive, data.

Table 31.5 Proposed Criteria for Prevention of Selenium Deficiency and for Protection Against Selenosis (Values are in mg of selenium/kg fresh weight [FW] or dry weight [DW].)

Criterion	Selenium Concentration	Reference ^a
PREVENTION OF SELENIUM DEFICIENCY		
Rainbow trout (water levels of 0.4 µg Se/L)		
Diet	>70 µg/kg FW	1
Diet	150–380 µg/kg DW	26
Poultry		
Diet	>30–50 µg/kg FW	2
Dietary supplement allowed		
Chickens, ducks	100 µg/kg DW ration as sodium selenate or selenite	37
Turkeys	200 µg/kg DW ration as sodium selenate or selenite	37
Rats		
Diet	>54–84 µg/kg FW	3
Livestock		
Diet	>20 µg/kg FW	2
Dietary supplement allowed		
Cattle, sheep, adult swine	100 µg/kg DW ration as sodium selenate or selenite	37
Weanling swine	300 µg/kg DW ration as sodium selenate or selenite	37
Forage, grazing sheep and cattle	>100 µg/kg DW	4
Blood	>40–80 µg/L FW	17
White-tailed deer		
Heart	>150 µg/kg DW	17
Kidney	>3000 µg/kg DW	17
Liver	>250 µg/kg DW	17
Serum	>30 µg/L FW	17
Humans		
Diet	40–200 µg/kg FW	3, 5
Daily intake		
Recommended		
Females	55 µg (= 1.0 µg/kg BW daily)	18, 40
Males	70 µg (= 1.0 µg/kg BW daily)	18, 40
Children	0.004 µg/kg BW	18
Maximum	500 µg	40

Table 31.5 (continued) Proposed Criteria for Prevention of Selenium Deficiency and for Protection Against Selenosis (Values are in mg of selenium/kg fresh weight [FW] or dry weight [DW].)

Criterion	Selenium Concentration	Reference ^a
Drinking water		
Bottled water	<10 µg/L FW	18
Assuming water is sole selenium source, 2 L daily	20 µg/L FW	6
PROTECTION AGAINST SELENOSIS		
Crop protection		
Irrigation water	<50 µg/L	5, 12
Aquatic life protection		
Freshwater		
Total dissolved	Average 4-day concentration not to exceed 5 µg acid-soluble Se/L more than once every 3 years; average 1-h concentration not to exceed 20 µg/L more than once every 3 years	7, 18–20
Total recoverable ^b	After filtration through 0.45-µ filter, <2 µg total Se/L, sometimes <1 µg/L for organoselenium compounds	27
Waterborne selenium	<2 µg/L	42
Adverse effects on fish reproduction possible	>2 µg inorganic Se/L; >1 µg organic Se/L; sometimes, <1 µg organic Se/L	42
Fish		
Diet		
Freshwater fishes		
Acceptable	<3000 µg/kg DW ration	42
Lethal	>6500–54,000 µg/kg DW feed	42
Growth reduction	>5000–20,000 µg/kg DW feed	42
Kidney damage	>11,000 µg/kg DW feed	42
Juvenile chinook salmon		
Adverse effects	>3000–5000 µg total Se/kg DW	21
Safe	<3000 µg total Se/kg DW	21
Rainbow trout, safe	<3000 µg/kg DW	26
Tissue residues, acceptable		
Whole body	<12,000 µg/kg DW	22
Gonads	<8000–<10,000 µg/kg DW	23, 25, 27
Carcass or ovaries, bluegills	<6000 µg/kg FW	24
Freshwater and anadromous fishes		
Whole body	<4000 µg/kg DW	27, 42
Liver	<12,000 µg/kg DW	27, 42
Muscle	<8000 µg/kg DW	27, 42
Ovaries and eggs	<10,000 µg/kg DW	42
Great Lakes		
Water	<10 µg/L	8, 18
Saltwater		
Total dissolved	Average 4-day concentration not to exceed 71 µg acid-soluble Se/L more than once every 3 years and 1-h concentration does not exceed 300 µg/L more than once every 3 years	7, 18
Birds		
Diet		
Mallard		
Maximum tolerated	<10,000 µg/kg DW	31
Reproduction inhibited	7000–11,000 µg/kg DW, as selenomethionine	33, 34, 41, 42
Malformed embryos	16,000 µg/kg DW, as selenomethionine	34

Table 31.5 (continued) Proposed Criteria for Prevention of Selenium Deficiency and for Protection Against Selenosis (Values are in mg of selenium/kg fresh weight [FW] or dry weight [DW].)

Criterion	Selenium Concentration	Reference ^a
Fatal	10,000–20,000 µg/kg, as selenomethionine	33
Water		
Sensitive fish-eating species	<0.8–<1.9 µg dissolved Se/L	28
Mallard	<2.1 µg dissolved Se/L	28
Aquatic birds, most species		
Minimal hazard	<2.3 µg dissolved Se/L	29
Hazardous	3–20 µg dissolved Se/L	29
Maximum allowable	<10.0 µg dissolved Se/L	29
Tissues		
Eggs		
Reproductive impairment		
Unlikely	<2000 µg/kg DW; <3000–<3300 µg/kg FW	27, 31, 35, 41

Adverse effects	>10,000 µg/kg FW	41
Poisoned	>66,000 µg/kg DW	32
Lethal	>20,000 µg/kg FW	41
Mammals (non-humans)		
Livestock protection		
Drinking water	<50 µg/L FW	5, 9
Diet (total)	<2000 µg/kg DW	10
Diet (natural)	<4000 µg/kg DW	5, 39
Feeds (natural)	<2000 µg/kg DW	11
Forage (natural)	<5000 µg/kg DW	11
Tissues		
Blood		
Adequate	80 µg/L FW	17
Toxic	>3000 µg/L FW	17, 36
Kidney		
Toxic	>3000–6000 µg/kg FW	36
Liver		
Toxic	>12,000–15,000 µg/kg FW	36
Monkeys		
Adverse effects		
Erythrocytes	>2300 µg/kg FW	38
Hair	>27,000 µg/kg FW	38
Plasma	>2800 µg/L FW	38
Drinking water		
River otter	<0.7 µg dissolved Se/L	28
Bats and shrews	<0.9 µg dissolved Se/L	28
Mink	<1.1 µg dissolved Se/L	28
Human health protection		
Seafood	Not to exceed 2000 µg/kg FW	13
Drinking water		
Most states	<10 µg/L FW	18
Minnesota	<20 µg/L FW	18
International	<10 µg/L FW	18
Maximum permissible ^c	<50 µg/L FW	18
Health advisory, chronic		
Child	<31 µg/L FW	18
Adult	<107 µg/L FW	18

Table 31.5 (continued) Proposed Criteria for Prevention of Selenium Deficiency and for Protection Against Selenosis (Values are in mg of selenium/kg fresh weight [FW] or dry weight [DW].)

Criterion	Selenium Concentration	Reference ^a
Food (natural)	<5000 µg/kg FW; <850 µg daily	5, 18
Milk or water	<500 µg/L FW	5
Daily intake (all sources)		
Adults		
Safe	<200 µg	4
Safe, chronic ^d	<5 µg/kg BW (= <350 µg for a 70-kg adult)	18
Normal	60–250 µg	14
Maximum tolerable level	<500 µg	15
Infants	4–<35 µg	14
Children		
Age 1–3	20–<80 µg	15
Age 4–6	30–<120 µg	15
Age 7–11+	50–<200 µg	15
Air		
Japan	<100 µg/m ³	16
Russia	<100 µg/m ³	16
United States	Usually <200 µg/m ³ ; some states 2–<5 µg/m ³	16, 18

^b High potential for biomagnification in aquatic food chains, dietary toxicity, and reproductive toxicity.

^c Based on a NOAEL (no observable adverse effect level) of 400 µg Se daily, equivalent to 5.7 µg/kg BW daily for a 70-kg person.

^d Based on a NOAEL of 15 µg/kg BW daily for dermal effects and an uncertainty factor of 3 to account for sensitive individuals (USPHS 1996).

Regarding selenium deficiency, it appears that diets containing 50 to 100 µg Se/kg ration provide adequate protection to humans and to various species of fish, small laboratory mammals, and livestock (Table 31.5). Factors contributing to selenium deficiency in crops include increasing use of agricultural fertilizers and increasing atmospheric fallout of sulfur. Furthermore, foliar applications of selenate, although efficient in raising selenium levels in plants, have only short-term value (Frost and Ingvoldstad 1975). There is a general consensus that selenium deficiency in livestock in many countries is increasing, resulting in a need for added selenium in the food chain.

Recommendations for protection of freshwater aquatic life include acid-soluble total selenium concentrations in the water of less than 5 µg/L on a daily average, or 20 µg/L at any time (Table 31.5). These values are higher for saltwater life: 71 µg/L daily average, 300 µg/L at any time. The concentration range of 5 to 20 µg/L recommended for protection of freshwater aquatic life is below the range of 60 to 600 µg/L that is fatal to various sensitive species of marine and freshwater fauna, and in this respect affords an adequate measure of protection. It is also below the range (47 to 53 µg/L) that has been associated with growth inhibition of freshwater algae, anemia and reduced hatch in rainbow trout, and shifts in species composition of freshwater algal communities. But studies by Cumbie and Van Horn (1978) and Sorensen et al. (1984) showed that water concentrations of 9 to 12 µg Se/L were associated with reduced reproduction of freshwater fishes, and their results strongly indicated that some downward modification of the selenium freshwater aquatic life protection criterion may be appropriate. Furthermore, high bioconcentration

and accumulation of selenium from the water column by numerous species of algae, fish, and invertebrates is well documented at levels between 0.015 and 3.3 µg Se/L, which is substantially below the recommended range of 5 to 20 µg/L in freshwater. The significance of selenium residues in aquatic biota in terms of bioavailability and selenium receptor sites is imperfectly understood, and it appears that much additional research is warranted on formulating suitable models of selenium biogeochemistry and pharmacokinetics in aquatic environments (Hodson 1990; Bowie and Grieb 1991; Hermanutz et al. 1992).

Resource managers and aquatic biologists need data on selenium concentrations in water, food-chain organisms, and fish and wildlife tissues in order to adequately assess the overall selenium status and health of aquatic ecosystems (Lemly 1993b). Because selenium is depurated rapidly in aquatic birds, resource managers should be concerned primarily about current exposure in nature and not previous exposures (Heinz 1993b). The potential for food-chain biomagnification and reproductive impairment in fish and birds is the most sensitive biological response for estimating ecosystem-level impacts of selenium contamination (Baumann and Gillespie 1986; Lemly 1996a), and these are best reflected in selenium concentrations in gravid ovaries and eggs of adult fish and aquatic bird populations (Ohlendorf et al. 1986a; Lemly 1993b). More research is recommended on biomarkers of selenium exposure and effect (USPHS 1996).

Field studies demonstrated that migratory waterfowl were heavily and adversely affected while nesting at selenium-contaminated irrigation drainwater ponds in California, where food chain organisms contained between 12,000 and 280,000 µg Se/kg. The source and fate of selenium in irrigation drainwater ponds are largely unknown; they must be determined so that alternate technologies for selenium control can be implemented to protect waterfowl in that geographical region.

Livestock appear to be protected against selenosis provided that their diets contain less than 4000 µg Se/kg of natural (i.e., nonsupplemented) selenium (Table 31.5). This concentration is somewhat higher than levels reported for rats (Wilber 1983). Minimum toxic concentrations of selenium in lifetime exposure of rats given diets containing natural selenium were 1400 µg/kg ration as judged by evidence of liver changes, and 3000 µg/kg ration as estimated from longevity and histological changes in heart, kidney, and spleen. These values were only 350 and 750 µg/kg ration, respectively, when rat diets contained purified, rather than natural, selenium. This relationship emphasizes that accidental poisoning of livestock, and presumably fish and wildlife, may occur when soils are deliberately supplemented with purified selenium, or when soils or aquifers are contaminated as a result of faulty waste disposal practices. Although the concentration of <50 µg Se/L for livestock drinking water and irrigation water for crop protection is inconsistent with that of <35 µg Se/L for aquatic life protection, neither livestock nor crops appear threatened at the higher level. Since many waterways that abut agricultural lands or areas of high anthropogenic loadings of selenium contain valuable and desirable aquatic species, it would appear that some downward modification of the current livestock drinking water concentration of selenium is necessary. Selenium is a proven teratogen in fishes and birds, but this has not been established in mammals (USPHS 1996). More research is needed on possible teratogenic effects of organoseelenium compounds in mammals.

Acute lethal doses for livestock species ranged from 3300 µg Se/kg body weight for horses and mules to 15,000 µg/kg for swine; appetite loss in cattle was noted at 500 µg/kg. For humans, the maximum tolerance level is usually set at 500 µg Se daily (Lo and Sandi 1980), and the "safe" level at 200 µg/day (Shamberger 1981). Selenium dietary levels for humans should not exceed 5000 µg/kg ration; however, recommended maximum dietary levels in other mammals ranged from 1000 µg/kg for rats to 4000 µg/kg for horses. For all species, including humans, there is a tendency to list selenium dosage levels in terms of "natural" and "supplemented" levels, with the tacit understanding that "natural" levels are about one fourth as toxic as "supplemented" values. Given the complexities of selenium metabolism and speciation, it appears that greater precision and clarity are necessary in formulating selenium criteria if these criteria are to become administratively enforced standards through passage of appropriate legislation.

Aerosol concentrations in excess of 4.0 µg Se/m³ are potentially harmful to human health (Harr 1978). Concentrations in excess of this value (6.0 µg Se/m³) were regularly encountered in the vicinity of the smeltery at Sudbury, Ontario, Canada (Nriagu and Wong 1983). It is not now known whether respiration rates of wildlife, particularly birds, are comparable to those of humans, whether selenium absorption energetics are similar, or whether wildlife species that frequent point sources of air contaminated by high selenium levels for protracted periods are at greater risk than humans. Until additional and more conclusive data become available, aerosol concentrations of less than 4.0 µg Se/m³ are recommended for the protection of sensitive wildlife species.

31.8 SUMMARY

Most authorities agree on five points.

1. Selenium deficiency is not as well documented as selenosis, but may be equally significant.
2. Selenium released as a result of anthropogenic activities (including fossil fuel combustion and metal smelting), as well as that in naturally seleniferous areas, poses the greatest threat of poisoning to fish and wildlife.
3. Additional research is required on chemical and biological transformations among valence states, allotropic forms, and isomers of selenium.
4. Metabolism and degradation of selenium are both significantly modified by interaction with various heavy metals, agricultural chemicals, microorganisms, and numerous physicochemical factors; and until these interactions are resolved, it will be difficult to meaningfully interpret selenium residues in various tissues.
5. Documented biological responses to selenium deficiency or to selenosis vary widely, even among closely related taxonomic groups.

It is generally agreed that selenium deficiency can be prevented in fish, small laboratory mammals, and livestock by feeding diets containing 50 to 100 µg Se/kg. The concentration range of total acid-soluble selenium currently recommended for aquatic life protection — 5 µg/L in freshwater to 71 µg/L in marine waters — is below the range of 60 to 600 µg/L that is fatal to sensitive aquatic species. In freshwater, it is also below the range of 47 to 53 µg/L associated with growth inhibition of freshwater algae, anemia and reduced hatching in trout, and shifts in species composition of freshwater algae communities. Accordingly, current recommendations for selenium with respect to aquatic life appear to afford an adequate measure of protection. However, some studies have shown that water concentrations of 9 to 12 µg Se/L are associated with inhibited reproduction of certain freshwater teleosts, suggesting that selenium criteria for protection of freshwater life should be revised downward. Also, high bioconcentration and accumulation of selenium from water by numerous species of algae, fish, and invertebrates is well documented at levels of 0.015 to 3.3 µg Se/L, which are substantially below the recommended range of 5 to 71 µg Se/L. The significance of selenium residues in aquatic biota is still unclear, and more research appears to be needed on selenium pharmacokinetics in aquatic environments.

Aerosol concentrations exceeding 4.0 µg Se/m³ are considered potentially harmful to human health. However, no comparable database for birds and other wildlife species is available at this time. Selenium poisoning in livestock is prevented if diets do not exceed 5.0 mg Se/kg natural forage, or 2.0 mg Se/kg in feeds supplemented with purified selenium. Minimum toxic concentrations of selenium in the rat (a sensitive species) fed diets containing natural selenium were 1400 µg Se/kg as judged by evidence of liver changes, and 3000 µg Se/kg as estimated from longevity and histopathology. These values were only 350 and 750 µg/kg, respectively, when diets low in natural selenium were fortified with purified selenium. The evidence is incomplete for migratory waterfowl and other birds, but diets containing more than 3.0 mg Se/kg are demonstrably harmful, as are total selenium concentrations in excess of 5 mg/kg FW in eggs and 10 mg/kg DW in livers.

CHAPTER 32

Radiation

32.1 INTRODUCTION

Life on Earth has evolved under the ubiquitous presence of environmental solar, X-ray, gamma, and charged-particle radiation. On a global basis, radiation from natural sources is a far more important contributor to radiation dose to living organisms than radiation from anthropogenic sources (Aarkrog 1990). However, ionizing radiation can harm biological systems (Aarkrog 1990; Nozaki 1991; Severa and Bar 1991), and this harm can be expressed (1) in a range of syndromes from prompt lethality to reduced vigor, shortened life span, and diminished reproductive rate by the irradiated organism and (2) by the genetic transmission of radiation-altered genes that are most commonly recessive and almost always disadvantageous to their carriers (Bowen et al. 1971). Direct effects of radiation were documented in lampreys in 1896 — soon after H. Becquerel discovered radioactivity — and in brine shrimp (*Artemia* sp.) in 1923 (Whicker and Schultz 1982a). Genetic effects of ionizing radiation, and thus X-rays, as a mutagenic agent were first documented in 1927 in fruit flies, *Drosophila melanogaster* (Evans 1990). The discovery of radioactivity of nuclear particles and the discovery of uranium fission resulted in a great upsurge of nuclear research. During and shortly after World War II, nuclear reactors, testing of nuclear weapons, and use of radionuclides as tracers in almost all scientific and technical fields were developed rapidly (Severa and Bar 1991). Environmental radiation from anthropogenic sources caused serious concerns beginning in the early 1940s when fission of uranium and transuranic nuclei became possible in reactors and in explosions of nuclear weapons (Aarkrog 1990). The first nuclear explosion resulted from a 19-kiloton (TNT-equivalent) source in New Mexico in July 1945 (Whicker and Schultz 1982a). On August 6, 1945, about 75,000 people were killed when the United States Army Air Corps dropped a uranium nuclear bomb on Hiroshima, Japan; on August 9, 1945, about 78,000 Japanese were killed and more than 100,000 injured when a plutonium nuclear bomb was detonated at Nagasaki (Kudo et al. 1991). The former Soviet Union detonated its first nuclear device in August 1949; and in 1952, the United Kingdom exploded a device in Australia (Whicker and Schultz 1982a). Since 1960, nuclear devices have also been detonated by France, India, Pakistan, The People's Republic of China, and possibly others. Nuclear devices have been developed that can release energy in the megaton range. The first such device was detonated by the United States in 1954 at Bikini Atoll and accidentally contaminated Japanese fishermen and Marshall Island natives. Between 1945 and 1973, an estimated 963 nuclear tests were conducted by The People's Republic of China, France, the former Soviet Union, the United Kingdom, and the United States; 47% of them were atmospheric and 53% subsurface (Whicker and Schultz 1982a).

Today, the most important environmentally damaging anthropogenic radiation comes from atmospheric testing of nuclear weapons conducted 20 to 30 years ago, authorized discharges to the sea from nuclear reprocessing plants, and from the Chernobyl accident in 1986 (Aarkrog 1990).

By the year 2000, the United States will have an estimated 40,000 tons of spent nuclear fuel stored at some 70 sites and awaiting disposal. By 2035, after all existing nuclear plants have completed 40 years of operation, about 85,000 metric tons will be awaiting disposal (Slovic et al. 1991).

Ecological and toxicological information on radiation is especially voluminous, and the reader is strongly advised to consult several of the reviews listed below.*

32.2 PHYSICAL PROPERTIES OF RADIATION

32.2.1 General

Radiation is usually defined as the emission and propagation of energy through space in the form of waves and subatomic particles (Weast 1985; Kiefer 1990). For regulatory purposes in the United States, radiation is narrowly defined as α , β , γ , or X-rays; neutrons; and high-energy electrons, protons, or other atomic particles; but not radio-waves nor visible, infrared, or ultraviolet light (U.S. Code of Federal Regulations [USCFR] 1990). Readers may wish to consult the glossary at the end of this chapter.

In current atomic theory, all elementary forms of matter consist of small units called atoms. All atoms of the same element have the same size and weight. Atoms of different elements differ in size and weight. Atoms of the same or different elements may unite to form compound substances called molecules. Each atom consists of a central nucleus and several negatively charged electrons in a cloud around the nucleus. The nucleus is composed of positively charged particles called protons, and particles without charge called neutrons. Electrons are arranged in successive energy levels around the nucleus, and the extranuclear electronic structure of the atom is characteristic of the element. Electrons in the inner shells are tightly bound to the nucleus but can be altered by high-energy waves and particles (Weast 1985). Atoms are classified chemically into 92 naturally occurring elements and another dozen or so artificial elements based on the number of protons in their nucleus (= the atomic number) (Rose et al. 1990; Severa and Bar 1991). Atoms of the same element may occur as isotopes that differ in the number of neutrons accompanying the protons in the nucleus. The sum of the number of protons and neutrons in the nucleus is called the mass number (see Glossary), and is indicated by a superscript that precedes the chemical symbol of the element. For example, three isotopes of hydrogen (one proton) are denoted as ^1H (no neutrons), ^2H (1 neutron, also known as deuterium), and ^3H (2 neutrons, also known as tritium). A nuclide is an elemental form distinguished from others by its atomic and mass numbers. Some nuclides, such as ^{238}U and ^{137}Cs , are radioactive and spontaneously decay to a different nuclide with the emission of characteristic energy particles or electromagnetic waves; isomers of a given nuclide that differ in energy content are metastable (i.e., ^{115m}Cd) and characterized, in part, by the half-life of the isomer (Rose et al. 1990; Severa and Bar 1991).

Chemical forms with at least one radioactive atomic nucleus are radioactive substances. The capability of atomic nuclei to undergo spontaneous nuclear transformation is called radioactivity. Nuclear transformations are accompanied by emission of nuclear radiation (Severa and Bar 1991). The average number of nuclei that disintegrate per unit time (= activity) is directly proportional to the total number of radioactive nuclei. The time for 50% of the original nuclei to disintegrate (= half-life or Tb 1/2) is equal to $\ln 2/\text{decay constant}$ for that element (Kiefer 1990). Radiations

that have sufficient energy to interact with matter to produce charged particles are called ionizing radiations (Hobbs and McClellan 1986; UNSCEAR 1988). Radiation injury is related to the production of ions inside the cell. Ionizing radiations include electromagnetic radiation such as gamma (γ) and X-rays and particulate or corpuscular radiation such as alpha (α) particles, beta (β) particles, electrons, positrons, and neutrons. Ionizing radiation may be produced from manufactured devices such as X-ray tubes or from the disintegration of radioactive nuclides. Some nuclides occur naturally, but others may be produced artificially, for example, in nuclear reactors. The basic reaction of ionizing radiation with molecules is either ionization or excitation. In ionization, an orbital electron is ejected from the molecule and forms an ion pair. Directly ionizing particles are charged and possess the energy to produce ionizations along their path from impulses imparted to orbital electrons via electrical forces between the charged particles and electrons. In excitation, an electron is raised to a higher energy level. Indirectly ionizing radiations are not charged and penetrate a medium until they collide with elements of the atom and liberate energetically charged ionizing particles.

32.2.2 Electromagnetic Spectrum

The electromagnetic spectrum is defined as the ordered array of known electromagnetic radiations, including cosmic rays; gamma rays; X-rays; ultraviolet, visible, and infrared radiations; and radio-waves (Weast 1985). The energy transfer by electromagnetic waves can be described by discrete processes with elementary units called photons (Kiefer 1990). Their energy, E, is given by $E = hv$, where h is Planck's constant and v the frequency. Because velocity C, wavelength λ , and frequency v are related ($C = \lambda v$), $E = hc/\lambda$ (Kiefer 1990). The relationships between E, v, and λ for parts of the total spectrum of the electromagnetic waves are shown in Figure 32.1. The high-energy radiation that enters the Earth's atmosphere from outer space is known as primary cosmic rays. On interaction with the nuclei of atoms in the air, secondary cosmic rays and a variety of reaction products (cosmogenic nuclides) such as ^3H , ^7Be , ^{10}Be , ^{14}C , ^{22}Na , and ^{24}Na are produced (UNSCEAR 1988).

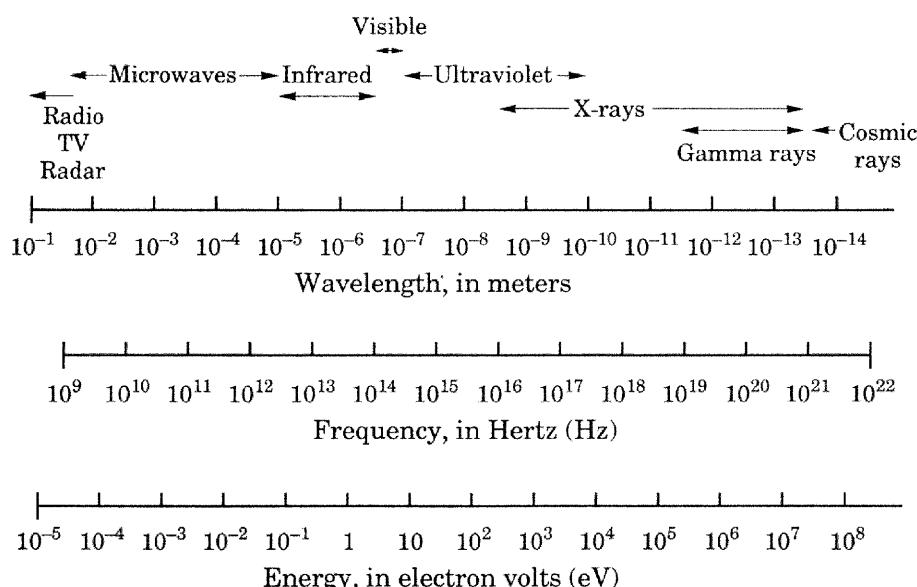

Figure 32.1 The spectrum of electromagnetic waves, showing the relationship between wavelength, frequency, and energy. (Modified from Kiefer, J. 1990. *Biological Radiation Effects*. Springer-Verlag, Berlin. 444 pp.)

32.2.3 Radionuclides

Radioactive nuclides contain atoms that disintegrate by emission of subatomic particles and gamma or X-ray photons (Weast 1985; Hobbs and McClellan 1986; Kiefer 1990; Rose et al. 1990). In alpha decay, a helium nucleus of two protons and two neutrons is emitted and reduces the mass number by 4 and the atomic number by 2. In beta decay, an electron — produced by the disintegration of a neutron into a proton, an electron, and an antineutrino — is emitted from the nucleus and increases the atomic number by 1 without changing the mass number. Sometimes, a positron together with a neutrino is emitted. And sometimes an electron may be captured from the K (outermost) shell of the atom; the resultant electron hole in the K shell is filled by electrons from outer orbits and causes the emission of X-rays. Alpha and beta decay generally leave the resultant daughter nuclei in an excited state that is deactivated by emission of γ photons. Although γ emission accompanies most decays, it is not always detected, especially not with light β emitters such as ^3H , ^{14}C , ^{32}P , and ^{35}S . The half-life of individual radionuclides can be measured (i.e., the time during which half the atoms of the radionuclide spontaneously decay to a daughter nuclide). Another form of nuclear breakdown is fission, in which the nucleus breaks into two nuclides of approximately half the parent's size (Rose et al. 1990). The symbol, mass number, atomic number, half-life, and decay mode of all radionuclides mentioned herein are listed in [Table 32.1](#).

Table 32.1 Selected Radionuclides: Symbol, Mass Number, Atomic Number, Half-Life, and Decay Mode

Nuclide	Symbol	Mass Number	Atomic Number	Half-life ^a	Major Decay Mode ^b
Hydrogen-3	^3H	3	1	12.26 y	β^-
Beryllium-7	^7Be	7	4	53.3 d	EC
Beryllium-10	^{10}Be	10	4	1,600,000 y	β^-

^b Observed modes of decay for all radioactive species: α = particle emission; β^- = beta emission, β^+ = positron emission; EC = electron capture resulting in X-ray emission; IT = isomeric transition from higher to lower energy state; SF = spontaneous fission.

Modified from Whicker and Schultz 1982a, 1982b; Weast 1985; Kiefer 1990; Severa and Bar 1991.

Four general groups of radionuclides are distinguished:

1. A long half-life group (i.e., Tb 1/2 > 10⁹ years) of elements, including ^{238}U , ^{235}U , ^{232}Th , ^{40}K , ^{87}Rb , and ^{143}Sm , formed about 4.5 billion years ago
2. Shorter-lived daughters of U and Th such as Ra and Rn that form as a result of the decay of their long-lived parents
3. Nuclides (i.e., ^{14}C and ^3H) formed by continuing natural nuclear transformations driven by cosmic rays, natural sources of neutrons, or energetic particles that are formed in the upper atmosphere by cosmic rays
4. Nuclides formed as a result of nuclear weapons tests, nuclear reactor operations, and other human activities. Important members of this group include ^{90}Sr , ^{137}Cs , ^{14}C , and ^3H ; note that many members of the third group — such as ^{14}C and ^3H — are also formed in this fourth fashion (Rose et al. 1990).

Radioactive decay usually does not immediately lead to a stable end product, but to other unstable nuclei that form a decay series (Kiefer 1990). The most important examples of unstable nuclei are started by very heavy, naturally occurring nuclei. Because the mass number changes only with α decay, all members of a series can be classified according to their mass numbers (see the uranium-238 decay series in Figure 32.2). A total of three natural decay series — formed at the birth of our planet — are named after their parent isotope: ^{232}Th , ^{235}U , and ^{238}U (Figure 32.3). Several shorter decay series also exist. For example, ^{90}Sr decays with a Tb 1/2 of 28 years by β emission to ^{90}Y , which in turn disintegrates (β emission) with a Tb 1/2 of 64 h to the stable ^{90}Zr (Kiefer 1990). Other examples of known radionuclides since the Earth's origin include ^{40}K and ^{87}Rb . In hazard assessments, all members of a decay series must be considered.

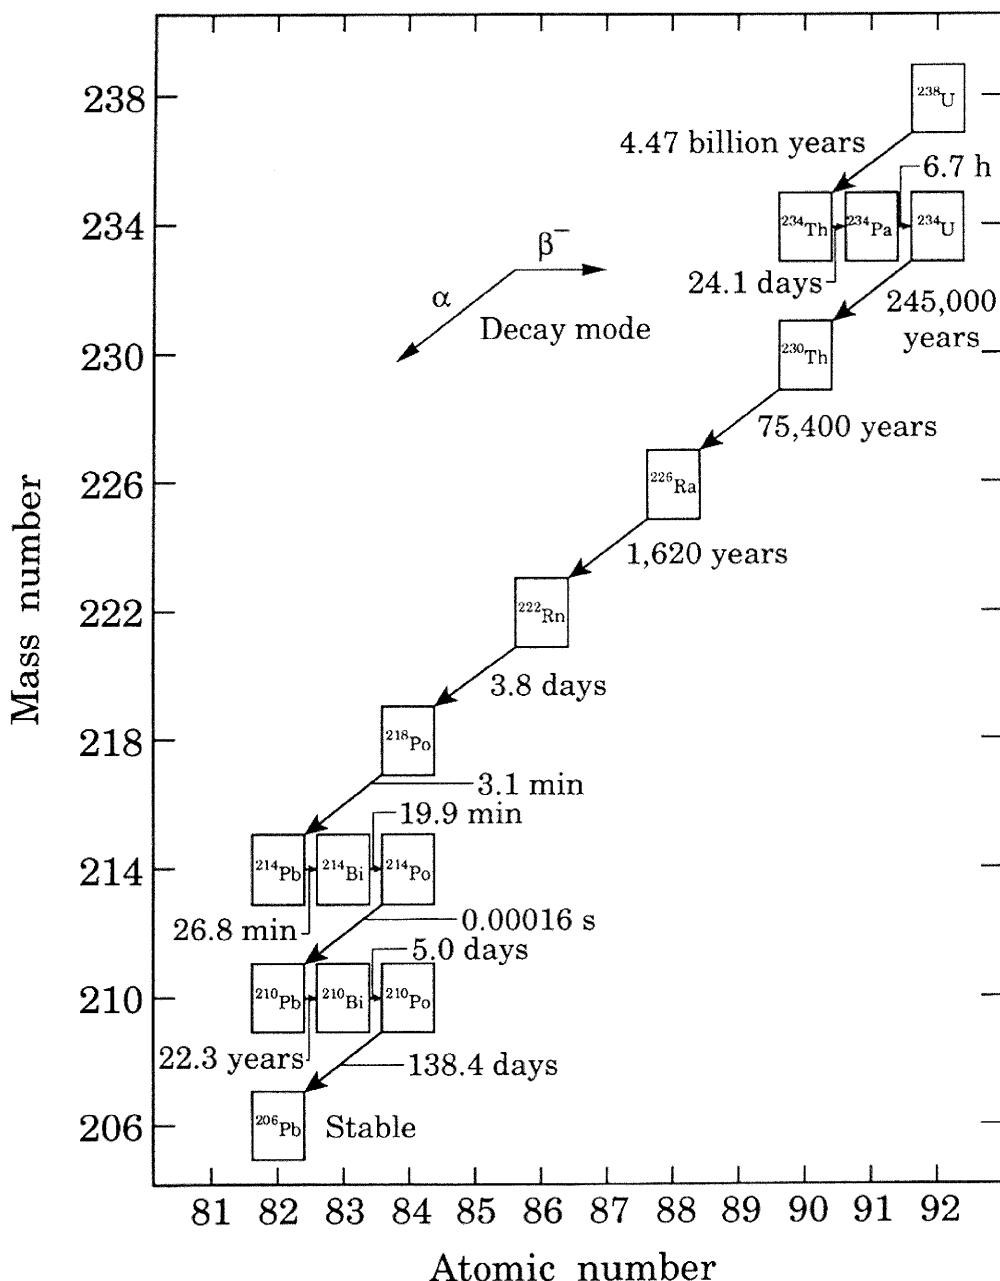

Figure 32.2 The principal uranium-238 decay series, indicating major decay mode and physical half-time of persistence. (Modified from Cecil, L.D. and T.F. Gesell. 1992. Sampling and analysis for radon-222 dissolved in ground water and surface water. *Environ. Monitor. Assess.* 20:55-66.)

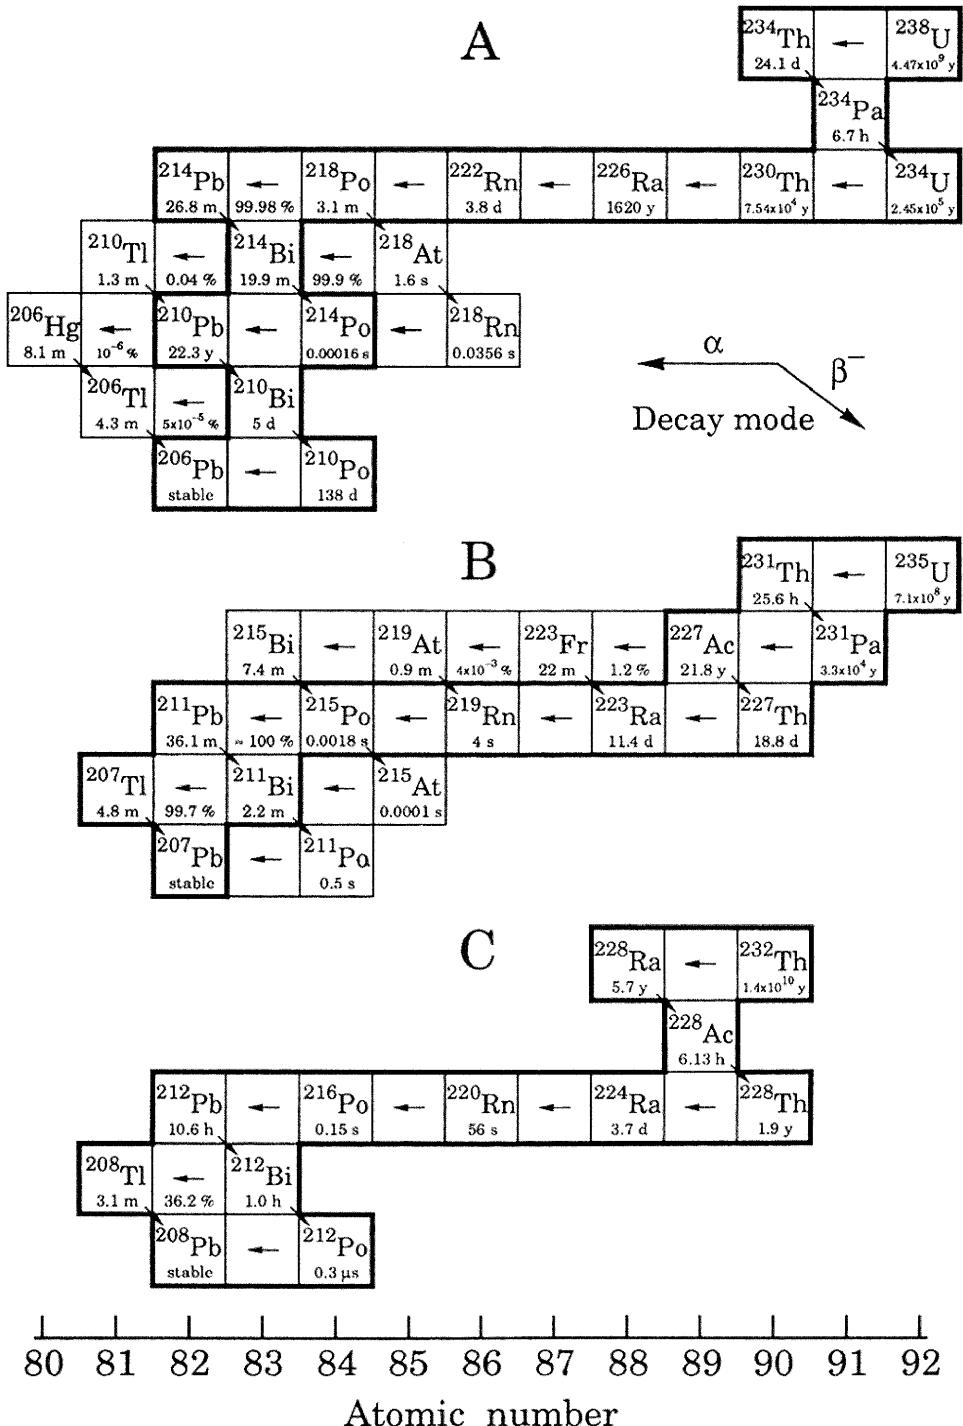

Figure 32.3 The three still-existing natural decay series. **A.** Uranium-238; **B.** Uranium-235; and **C.** Thorium-232. (Modified from Holtzman 1969; LWV 1985; UNSCEAR 1988; Kiefer 1990; Rose et al. 1990). Principal decay products occur within the heavy borders outlined.

32.2.4 Linear Energy Transfer

The deposition of energy in an exposed body is mediated almost exclusively by charged particles. These particles cause ionizations but lose energy with each ionization until they reach the end of their range. Depending on the type of particle, the ionizations are more or less closely spaced and described by the energy loss of a traversing particle. The linear energy transfer (LET) is defined as the amount of locally absorbed energy per unit length; that is, only the energy fraction that leads to ionizations or excitations in the considered site is counted (Kiefer 1990; ICRP 1991a). Because radiation effects are dependent on the nature of the radiation, a weighting factor is used to modify the absorbed dose and to define the dose equivalent. This factor — now called the Radiation Weighting Factor — is a function of LET. Approximate weighting values range from 1 (X-rays, electrons, gamma rays) to 10 (neutrons, protons, singly charged particles of rest mass greater than one atomic mass of unknown energy), and to 20 (alpha particles and multiply charged particles of unknown energy) (ICRP 1977; Whicker and Schultz 1982a; Hobbs and McClellan 1986; Severa and Bar 1991). The relation between radiation type and energy to weighting factors is shown in [Table 32.2](#).

Table 32.2 Radiation Weighting Factors for Various Types of Ionizing Radiations

Radiation Type and Energy Range	Radiation Weighting Factor
X-rays, gamma rays, beta particles, electrons, muons; all energies	1
Neutrons	
10 keV	5
10 keV–100 keV	10
>100 keV–2 MeV	20
>2 MeV–20 MeV	10
>20 MeV	5
Protons	5
Alpha particles, fission fragments, heavy nuclei	20

Data from International Commission on Radiological Protection 1991a.

32.2.5 New Units of Measurement

A variety of units have been used for the assessment of exposures to ionizing radiation. The current international standard terminology is shown in [Table 32.3](#). This chapter uses the new terminology exclusively; this frequently necessitated data transformation of units from early published accounts into the currently accepted international terminology.

Table 32.3 New Units for Use with Radiation and Radioactivity

Variable	Old Unit	New Unit	Old Unit in Terms of New Unit
Activity	Curie (Ci) = 3.7×10^{10} disintegrations per s (dps)	Becquerel (Bq) = 1 dps	1 Ci = 3.7×10^{10} Bq
Exposure	Roentgen (R) = 2.58×10^{-4} Coulombs/kg	Coulomb/kg (C/kg)	1 R = 2.58×10^{-4} C/kg
Absorbed dose	Rad = 100 erg/g	Gray (Gy) = 1 J/kg	1 Rad = 0.01 Gy
Dose equivalent	Rem = damage effects of 1 R	Sievert (Sv) = 1 J/kg	1 Rem = 0.01 Sv

Note: See Glossary (Section 32.11).

Data from International Commission on Radiological Protection [ICRP] 1977, 1991a; Hobbs and McClellan 1986; United Nations Scientific Committee on the Effects of Atomic Radiation [UNSCEAR] 1988.

32.3 SOURCES AND USES

32.3.1 General

Most external exposure of living organisms to radiation is from naturally occurring electromagnetic waves, and most internal exposure from naturally occurring radionuclides, such as potassium-40. Natural radiation doses vary significantly with altitude, radionuclide concentrations in the biogeophysical environment, and uptake kinetics. The major source of global anthropogenic radioactivity is fallout from military atmospheric weapons testing; locally, radiation levels tend to be elevated near nuclear power production facilities, nuclear fuel reprocessing plants, and nuclear waste disposal sites. Dispersion of radioactive materials is governed by a variety of physical, chemical, and biological vectors, including winds, water currents, plankton, and avian and terrestrial wildlife.

32.3.2 Natural Radioactivity

Exposure to natural sources of radiation is unavoidable. Externally, individuals receive cosmic rays, terrestrial X-rays, and gamma radiation. Internally, naturally occurring radionuclides of Pb, Po, Bi, Ra, Rn, K, C, H, U, and Th contribute to the natural radiation dose from inhalation and ingestion. Potassium-40 is the most abundant radionuclide in foods and in all tissues. The mean effective human dose equivalent from natural radiations is 2.4 milliSieverts (mSv). This value includes the lung dose from radon daughter products and is about 20% higher than a 1982 estimate that did not take lung dose into account ([Table 32.4](#)).

Table 32.4 Annual Effective Dose Equivalent to Humans from Natural Sources of Ionizing Radiation

Source of Radiation	Dose Equivalents (mSv)
Cosmic rays	
Ionizing component	0.30
Neutron component	0.06
Cosmogenic radionuclides (mainly ^{3}H and ^{14}C)	0.02
Primordial radionuclides	
Potassium-40	0.33
Rubidium-87	0.01
Uranium-238 series	1.34
Thorium-232 series	0.34
Total	2.4

Data from Whicker and Schultz 1982a; Hobbs and McClellan 1986; United Nations Scientific Committee on the Effects of Atomic Radiation [UNSCEAR] 1988; Aarkrog 1990.

The dose of natural radiation that an organism receives depends on height above sea level, amount and type of radionuclides in the soil of its neighborhood, and the amount taken up from air, water, and food (ICRP 1977; Whicker and Schultz 1982a; Hobbs and McClellan 1986; UNSCEAR 1988; Aarkrog 1990; Kiefer 1990; Nozaki 1991). Natural radiations in various ecosystems result in radiation dose equivalents that usually range between <0.005 and 2.07 mSv annually ([Figure 32.4](#)). Radiation doses are substantially higher at typically elevated local sites ([Table 32.5](#)), such as Denver, and sometimes exceed 17 mSv annually in mountainous regions of Brazil and the former Soviet Union (Whicker and Schultz 1982a).

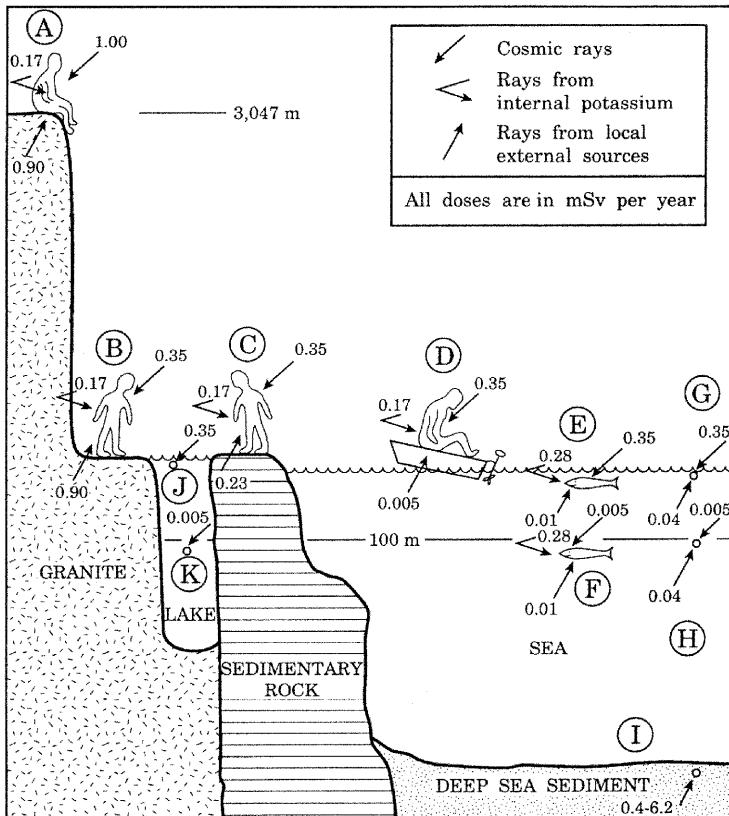

Figure 32.4 Natural radiations in selected radiological domains. (Modified from Folsom, T.R. and J.H. Harley. 1957. Comparisons of some natural radiations received by selected organisms. Pages 28-33 in National Academy of Sciences. The Effects of Atomic Radiation on Oceanography and Fisheries. Publ. No. 551, Natl. Acad. Sci.-Natl. Res. Coun., Washington, D.C.) **A.** Human over granite at 3047 m (10,000 feet) elevation above sea level; total annual dose equivalent of 2.07 mSv (cosmic rays 1.00, granite 0.90, internal emitters 0.17). **B.** Human over granite at sea surface; total annual dose of 1.42 mSv. **C.** Human over sedimentary rock at sea level; total annual dose of 0.75 mSv. **D.** Human over sea; total annual dose of 0.525 mSv. **E.** Large fish in sea near surface; total annual dose of 0.64 mSv. **F.** Large fish in sea at depth of 100 m; total annual dose of 0.295 mSv. **G.** Microorganism in water >100 m deep in sea; total annual dose of 0.045 mSv. **H.** Microorganism in water near sea surface; total annual dose of 0.045 mSv. **I.** Microorganism buried in deep sea sediments; total annual dose between 0.4 and 6.2 mSv. **J.** Microorganism near freshwater surface; total annual dose of 0.35 mSv. **K.** Microorganism 100 m deep in a freshwater lake; total annual dose of 0.005 mSv.

32.3.3 Anthropogenic Radioactivity

Nuclear explosions and nuclear power production are the major sources of anthropogenic activity in the environment. But radionuclide use in medicine, industry, agriculture, education, and production and transport, use, and disposal from these activities present opportunities for wastes to enter the environment (Whicker and Schultz 1982a; [Table 32.6](#)). Radiation was used as early as 1902 in the treatment of diseases, including enlarged thymus, tinea capitis, acne, and cancers of childhood and adolescence (Bowden et al. 1990). The use of X-rays by physicians and dentists represents the largest source of annual dose equivalent of the U.S. population to artificial radiation: 0.78 to 1.01 mSv to bone marrow and 0.016 mSv to the upper GI tract; radiopharmaceuticals contribute an additional 0.14 mSv or a yearly total mean dose of 0.94 to 1.17 mSv to bone marrow (Hobbs and McClellan 1986).

Table 32.5 Annual Whole-Body Radiation Doses to Humans from Various Sources

Source of Radiation	Dose (mSv)
Natural external background	
Denver, Colorado	1.65
Washington state, mean	0.88
United States, average	0.84
Hanford, Washington	0.59
Average medical dose per capita, United States	0.36
Average internal dose from natural radioactivity, United States	0.25
Global weapons fallout	0.05
Consumer product radiation (TV, smoke detector, and other sources)	0.02
Total	1.27–2.33

Data from Gray, R.H., R.E. Jaquish, P.J. Mitchell, and W.H. Rickard. 1989. Environmental monitoring at Hanford, Washington, USA: a brief site history and summary of recent results. *Environ. Manage.* 13:563–572.

Table 32.6 Sources and Applications of Atomic Energy

Source and Output	Application
Nuclear reactor	
Steam, electricity	Electric power (stationary or portable plants), desalination, propulsion of submarines and surface ships
Heat, electricity, neutrons	Spacecraft and satellite power, spacecraft propulsion, research and special materials production
Nuclear explosives, kinetic energy	Military and civilian applications: large-scale earth moving, subsurface excavation, mineral extraction from underground
Encapsulated radioisotopes	
Electricity	Marine navigation aids, unmanned weather stations, spacecraft project power, artificial human organs
Beta and gamma radiation	Food preservation, polymerization, sterilization of medical supplies, thickness gauges
Radionuclides, beta and gamma radiation	Medical uses, tracers in scientific research, measures of manufacturing processes

Data from Joseph, A.B., P.F. Gustafson, I.R. Russell, E.A. Schuert, H.L. Volchok, and A. Tamplin. 1971. Sources of radioactivity and their characteristics. Pages 6–41 in *National Academy of Sciences. Radioactivity in the Marine Environment*. Natl. Acad. Sci., Panel on Radioactivity in the Marine Environment, Washington, D.C.

Atmospheric testing of nuclear weapons is an important human source of environmental radiation (Hobbs and McClellan 1986; UNSCEAR 1988; Aarkrog 1990) (Table 32.7). The first test explosion of a nuclear weapon took place in 1945. Atmospheric tests by the United States, the former Soviet Union, and the United Kingdom continued until they were banned in 1963. France and The People's Republic of China continued to conduct limited atmospheric tests, although no atmospheric nuclear explosions have taken place since 1980. Large nuclear explosions in the atmosphere carry most of the radioactive material into the stratosphere where it remains for 1 to 5 years, depending on the altitude and latitude. Fallout can occur years after an explosion injected material into the atmosphere. Smaller explosions carry the radioactive material only into the troposphere, and fallout occurs within days or weeks. Fallout was highest in the temperate regions and in the northern hemisphere where most of the testing was done. The most abundant radionuclides from atmospheric tests to date are $^{14}\text{C} > ^{137}\text{Cs} > ^{95}\text{Zr} > ^{90}\text{Sr} > ^{106}\text{Ru} > ^{144}\text{Ce} > ^3\text{H}$. Of the many radionuclides produced in nuclear and thermonuclear explosions, the primary contributors to human radiation exposure include ^{14}C , $^{89+90}\text{Sr}$, ^{95}Zr , ^{106}Ru , ^{131}I , ^{137}Cs , ^{141}Ce , and ^{144}Ce . Isotopes of plutonium and americium — although present in quantity — are not significant contributors

Table 32.7 Annual Effective Dose Equivalent from Nuclear Weapons Testing to Humans in the North Temperate Zone

Nuclide	Dose (mSv ^a)
³ H	0.05

because of their low solubility. The primary dose from fallout radiation is through external gamma radiation, assimilation through the food chain, or beta radiation of the skin.

Radioisotope thermoelectric generators (RTGs) are sometimes used as power sources for space systems. In April 1964, a United States RTG navigational satellite, SNAP 9A, reentered the atmosphere and burned up at high altitude over the Mozambique Channel, releasing 629 trillion becquerels (TBq), equivalent to 17,000 Ci, of ²³⁸Pu and 0.48 TBq of ²³⁹Pu (Whicker and Schultz 1982a; Richmond 1989). In January 1978, a Soviet RTG satellite, Kosmos 954, reentered the atmosphere over Canada and spread radionuclides across parts of that country (Richmond 1989). The amount of radioactive materials in space applications is expected to increase (Richmond 1989).

Significant amounts of radioactivity are present in the Great Lakes basin, which has numerous nuclear reactors and uranium-mine waste areas (Joshi 1991). The prevailing low levels of artificially produced radionuclides, arising largely from previous fallout (Table 32.8), provide small doses of radiation to residents who consume lake water. Radionuclides enter the Great Lakes ecosystem from natural and anthropogenic processes. The main natural processes that introduce radioactivity are the weathering of rocks, which contain uranium- and thorium-series radionuclides, and fallout of cosmic ray-produced radionuclides such as ³H, ⁷Be, and ¹⁴C. Anthropogenic radioactivity is created, for example, by uranium mining, milling, and fuel fabrication; releases of artificially

produced radionuclides through nuclear power reactors and nuclear fuel processing plants; medical uses of radioisotopes; and coal-fired electrical generating plants (Joshi 1991).

Production of power from nuclear reactors involves uranium mining, fuel fabrication, the reactor operations, and storage of wastes. All of these processes may expose humans and the environment to radiation (Hobbs and McClellan 1986). Uranium production in the United States was 12,300 tons U₃O₈ in 1977, primarily from western states, Texas, and Florida (Whicker and Schultz 1982a). Mining from deep shafts or open pits is the preferred method of uranium extraction, although in Florida it is produced as a by-product of phosphate mining. Mines disperse radionuclides of uranium, thorium, and radium, which are associated with dust particles, and radon, which emanates from ore as a gas and decays to create a series of radioactive daughters. Groundwater also contains radionuclides of the uranium series. As many as 18 uranium mills were in operation, located close to major mining centers in the western states. Collectively, these mills process or processed about 30,000 tons of ore daily and use acid or alkali leach methods to extract 90 to 95% of the uranium from ore. Uranium is barreled at the mill for shipment as uranium oxide or as salt concentrates (yellowcake) that contain 70 to 90% U₃O₈ by weight. Residues of the uranium extraction process are usually pumped as a slurry to liquid-retention impoundments; about 0.55 TBq of ²³⁰Th and ²²⁶Ra enter tailings each day from milling operations. Radium-226 produces gaseous ²²²Rn; daughters of ²²²Rn, such as ²¹⁰Pb, expose the surrounding biota to measurable radiation. Purification of yellowcake to UF₆ (uranium hexafluoride) and its enrichment to ²³⁵U causes a loss of about 0.55 TBq annually. Nuclear reactor fuel contains about 3% ²³⁵U. A nuclear explosion in a nuclear reactor is highly unlikely because the nuclear fuel suitable for weapons must contain >90% ²³⁵U. Following enrichment, UF₆ is hydrolyzed to uranyl fluoride, converted to ammonium diuranate, and calcined to the dioxide UO₂. Uranium dioxide pellets at one time were prepared by as many as ten commercial fuel fabrication plants and subsequently transported to nuclear reactors (Whicker and Schultz 1982a). In the current light-water-cooled reactors, the most abundant radionuclides in the reactor effluents under normal conditions are ³H, ⁵⁸Co, ⁶⁰Co, ⁸⁵Kr, ⁸⁵Sr, ⁹⁰Sr, ¹³⁰I, ¹³¹I, ¹³¹Xe, ¹³³Xe, ¹³⁴Cs, ¹³⁷Cs, and ¹⁴⁰Ba (Hobbs and McClellan 1986). Gaseous and volatile radionuclides, such as ⁸⁵Kr, ¹³¹Xe, and ¹³³Xe, contribute to the external gamma dose, whereas the others contribute to the dose externally by surface deposition and internally by way of the food chain. The mean dose from environmental releases of all radionuclides from nuclear reactors in the United States is <0.01 mSv/year (Hobbs and McClellan 1986). Nuclear fission follows the capture of a neutron by an atom of fissionable material, such as ²³⁵U or ²³⁹Pu. The fission releases 1 to 3 neutrons and, if additional fissionable material is present in sufficient quantity and in the right configuration, a chain reaction occurs (Hobbs and McClellan 1986). Radionuclides formed per megaton of fission include fission products (⁸⁹Sr, ⁹⁰Sr, ⁹⁵Zr, ¹⁰³Ru, ¹⁰⁶Ru, ¹³¹I, ¹³⁷Cs, ¹⁴⁴Ce) and activation products in air (³H, ¹⁴C, ³⁹Ar) and soil (²⁴Na, ³²P, ⁴²K, ⁴⁵Ca, ⁵⁵Fe, ⁵⁹Fe) (Whicker and Schultz 1982a). Fission-product radionuclides of potential biological importance include ⁹⁰Sr, ¹³⁷Cs, ¹³¹I, ¹²⁹I, ¹⁴⁴Ce, ¹⁰³Ru, ¹⁰⁶Ru, ⁹⁵Zr, ¹⁴⁰Ba, ⁹¹Y, ¹⁴³Ce, ¹⁴⁷Nd (Kahn 1971; Whicker and Schultz 1982a), and others (Table 32.9).

Most of the world's supply of uranium consists of about 0.7% ²³⁵U and 99% ²³⁸U. In theory, about 2.27 kg of ²³⁵U can release energy equivalent to 20,000 tons of TNT (Hobbs and McClellan 1986). ²³⁸U and ²³²Th can be converted into fissionable material following neutron capture. Radionuclides of biological significance produced by neutron activation in nuclear reactors include ³H, ¹⁴C, ²⁴Na, ³²P, ³⁵S, ⁴⁵Ca, ⁵⁴Mn, ⁵⁵Fe, ⁵⁷⁺⁵⁸⁺⁶⁰Co, ⁶⁵Zn, ²³⁹Pu, ²³⁹Np, ²⁴¹Am, and ²⁴²Cm (Whicker and Schultz 1982a). Nuclear energy can also be released by fusion of smaller nuclei into larger nuclei that is accompanied by a decrease in mass (Hobbs and McClellan 1986). Fusion reactors — which do not yet exist — require very high temperatures of several million degrees; no fission products are produced in the fusion process (Whicker and Schultz 1982a).

Radioactive wastes are usually stored in underground tanks or in temporary storage at reactor sites for recycling or disposal (Whicker and Schultz 1982a). For low-level wastes, containment and isolation are the preferred disposal options, including burial, hydraulic injection into deep geological strata, and ocean disposal (Table 32.10). Options for the disposal of high-level wastes include

retrievable surface storage and entombment in deep geological strata; many risks are associated with these options, and more suitable alternative disposals are needed. Spent nuclear fuel elements are usually stored for about 3 months to allow the decay of shorter-lived radionuclides before reprocessing or disposal. Reprocessing involves extractions to separate uranium and plutonium from the fission products into UF_6 and plutonium dioxide. Longer-lived fission products, such as ^{90}Sr and ^{137}Cs , are sometimes chemically separated and encapsulated for storage or disposal. Fuel reprocessing tends to release measurable quantities of various radionuclides that are detected in fish, wildlife, and food for humans (Whicker and Schultz 1982a). Liquid discharges from the Sellafield reprocessing plant (Table 32.10) have been reduced by a factor of more than 100 since

the mid-1970s (Aarkrog 1990). Human populations that consume higher than average quantities of marine fish and shellfish from the Sellafield area theoretically receive about 3.5 mSv annually from radioactivity associated with nuclear power production. Human populations in the vicinity of nuclear power production discharging directly into the marine environment — except for Sellafield — generally receive <0.05 mSv annually from this source (Aarkrog 1990).

Radioactive transuranic elements with atomic numbers that are greater than 92 have been introduced into the environment since the 1940s from atmospheric testing of nuclear weapons, discharges of nuclear wastes, and nuclear fuel reprocessing (Noshkin et al. 1971; Hetherington et al. 1976; Sibley and Stohr 1990; Morse and Choppin 1991). Transuranic isotopes with half-lives of more than 10,000 years (i.e., ^{247}Cm , ^{248}Cm , ^{239}Pu , ^{242}Pu , ^{244}Pu , ^{237}Np) will persist over geologically significant time periods. Transuranics at detectable but considered nonhazardous levels to biota are now widely dispersed throughout the environment in most waters, soils, sediments, and living organisms including humans. Of current primary concern are ^{244}Cm , ^{241}Am , $^{238+239+240+241}\text{Pu}$, and ^{237}Np — especially ^{241}Am , which is increasing globally as a result of ^{241}Pu decay (Sibley and Stohr 1990; Morse and Choppin 1991). However, the estimated peak dose received from Pu and Am radioisotopes seems to be decreasing in the vicinity of the Sellafield nuclear fuel reprocessor (Table 32.11). Miscellaneous exposures include radiations from television sets, luminous dial watches, smoke detectors, electron microscopes, building materials, and air travel (Hobbs and McClellan 1986). Most of the exposure in building materials is due to naturally occurring radionuclides. Similarly, air travel increases radiation exposure of travelers from increased exposure to cosmic radiations. Cigarette smokers may receive dose-equivalent rates up to 3 times higher than nonsmokers because of inhalation of ^{210}Po and ^{210}Pb from the cigarette. Some of the lung dose is also received from radionuclides released during combustion of fossil fuels, which contain small quantities of naturally occurring radionuclides (Hobbs and McClellan 1986).

Table 32.11 Theoretical Peak Dose, in microsieverts per year, Received from Plutonium and Americium by Three Human Populations

Population	Year		
	1973	1987	2000
Average person near Sellafield nuclear fuel reprocessor	24	4	2
Critical group, mainly agricultural workers	35	20	16
Heavy consumers of Irish Sea fish and shellfish in local fishing communities	—	250	55–90

Data from McKay, W.A. and N.J. Pattenden. 1990. The transfer of radionuclides from sea to land via the air: a review. *Jour. Environ. Radioactiv.* 12:49-77.

32.3.4 Dispersion

Radioactive materials are cycled throughout the environment by a variety of physical, chemical, and biological vectors. Dispersion through the atmosphere is governed by the magnitude, frequency, and direction of the wind. In the hydrosphere, transport is modified by water depth, motion, temperature, winds, tides, and groundwater (Whicker and Schultz 1982b). Deposition from the atmosphere is a function of particle size, precipitation, and dry deposition. Small radioactive particles may be elevated into the airstream from the ground surface; resuspension is a function of disturbances by wind at the soil surface, atmospheric variables (i.e., velocity, turbulence, density, viscosity), and soil-ground variables such as texture, cohesiveness, moisture content, density, vegetation cover, ground surface roughness, and topography (Whicker and Schultz 1982b). Only 1 kg of the original 15 kg Pu was fissioned from the dropping of the plutonium nuclear bomb on Nagasaki, Japan, on August 9, 1945 (Kudo et al. 1991). The remaining 14 kg Pu escaped into the environment. Local fallout accounted for about 37 g or 0.26% of the total global fallout; the highest $^{239+240}\text{Pu}$ concentration measured was 64 Bq/kg soil about 2.8 km from ground zero (Kudo et al. 1991).

Biological agents can also transport radioactive wastes. Birds, especially waterfowl, disperse accumulated radiocesium and other radionuclides along their migratory flyways (Brisbin 1991). Native mammalian herbivores and their predators that have come in contact with radioactivity in food or soils disperse the material in their feces, urine, or regurgitated pellets (O'Farrell and Gilbert 1975). For example, the black-tailed jackrabbit (*Lepus californicus*) in the vicinity of radioactive waste-disposal trenches dispersed radioactive fecal pellets over an area of 15 km². Elevated radioactivity readings were recorded in jackrabbits and in their predators, including feces of coyotes (*Canis latrans*) and bones of hawks (O'Farrell and Gilbert 1975).

Biological transport of trace elements and radionuclides in the sea is provided mainly through phytoplankton and zooplankton because of their (1) ability to accumulate these elements to high levels, (2) diurnal vertical migration, and (3) production of detritus in the form of fecal pellets, molts, and carcasses (Lowman et al. 1971). Considerations related to biomass, feeding rates, conversion efficiencies, migratory habits of zooplankton, and the chemical properties of trace elements suggest that the major downward transport of these elements and radionuclides is through gravitational action on fecal pellets, molts, and carcasses; direct biological transport accounts for <10% of the total downward movement. In estuarine and near-shore regions, the bottom sediments and their associated epiphyton often significantly influence the distribution of added radionuclides. Large populations of sessile filter feeders may drastically increase the rate of sedimentation of added trace elements and radionuclides (Table 32.12).

Table 32.12 Time Required to Transport Selected Radionuclides Added into Marine Waters at Surface out of the Upper Mixed Layer by Biological Transport (Processes include diurnal vertical migration, fecal pellets, and sinking of dead matter.)

Radionuclide	Time required to transport radionuclides (years)		
	Eastern North Pacific	Coastal Areas	Upwelling Areas
⁵⁴ Mn	74	7	3
⁵⁵⁺⁵⁹ Fe	7.2	0.7	0.3
⁵⁷⁺⁵⁸⁺⁶⁰ Co	220	20	8.8
⁶⁵ Zn	12	1.1	0.5
⁹⁵ Zr	5.4	0.5	0.2
²¹⁰ Pb	7.3	0.7	0.3

Data from Lowman, F.G., T.R. Rice, and F.A. Richards. 1971. Accumulation and redistribution of radionuclides by marine organisms. Pages 161-199 in *National Academy of Sciences. Radioactivity in the Marine Environment*. Natl. Acad. Sci., panel on radioactivity in the marine environment. Washington, D.C.

In some coastal areas, some of the radionuclides discharged into coastal waters from industrial establishments are recycled via the air/sea interface back onto land (McKay and Pattenden 1990). At the sea surface, aerosol is generated by bubble bursting and wave shearing. The aerosol is advected to land by onshore winds and deposited in coastal regions. Sea-to-land transfer has been documented from the vicinity of nuclear fuel reprocessing facilities in England, Scotland, and France; however, the sea-to-land transfer pathway was only about 8% of that from the seafood pathway (McKay and Pattenden 1990). The solubility of different radionuclides at the sediment/seawater interface is variable. Plutonium solubility, for example, depends on pH, Eh, ionic strength, complexing ions, organic chelators, living accumulator organisms, and oxidation state (Mo and Lowman 1976). The oceanic distributions of many nuclides are strongly controlled by interactions with particulate matter (Nozaki 1991). Thorium is an extreme case; the high reactivity of this element accounts for its residence of only a few decades in the ocean from which it is removed largely by vertical transport in association with settling particulate matter. ²¹⁰Pb and ²³¹Pa are also particle-reactive but to a lesser extent than Th. Their oceanic mean residence time is about 100 years.

The mean oceanic residence time of ^{227}Ac and Ra isotopes is about 1000 years because of particulate scavenging; these nuclides are supplied by insoluble parents in underlying sediments and are released to overlying waters by porewater diffusion. ^{228}Ra can serve as a novel tracer in ocean circulation for about 30 years; ^{227}Ac can be used for about 100 years. The distribution of ^{226}Ra is largely governed by biogeochemical cycling, much like dissolved silica (Nozaki 1991).

32.4 RADIONUCLIDE CONCENTRATIONS IN FIELD COLLECTIONS

32.4.1 General

The wide dispersion of anthropogenic radiocontaminants has significantly altered natural background levels of radioactivity in many parts of the globe. Radionuclide concentrations in selected abiotic materials and living organisms were usually elevated in samples from the vicinity of human nuclear activities, especially atmospheric military tests. Radionuclide concentrations in organisms were significantly modified by the organism's age, sex, diet, metabolism, trophic level, proximity to point source, and many other biological, chemical, and physical variables, as discussed later. Additional and more detailed data on environmental radionuclide concentrations and isotopic composition and levels of radioactive wastes discharged into the biosphere from nuclear plants and other anthropogenic activities are given in Schultz and Klement (1963), Nelson and Evans (1969), Nelson (1971), IAEA (1976), Whicker and Schultz (1982a, 1982b), and UNSCEAR (1988).

32.4.2 Abiotic Materials

Radionuclide concentrations in selected nonliving materials (Table 32.13) show that concentrations are elevated in samples from the site of repeated nuclear detonations, near nuclear fuel reprocessing and waste facilities, and from locations receiving radioactive fallout from atmospheric military tests. Rocks, especially granite, had high levels of naturally occurring radionuclides such as ^{40}K . Concentrations were usually low or negligible in drinking water and cow's milk for human consumption. Nuclear-weapons testing has resulted in large environmental releases of radionuclides. Between 1961 and 1966, for example, the Republic of Korea received fallout from nuclear tests by the former Soviet Union in 1961 and by the United States in 1962 and from three explosions by The People's Republic of China (Bai 1969). The highest levels of total combined β and γ activity in various Korean samples during 1962 to 1964, in Bq/L or Bq/kg, were: 0.0002 in air, 133 in water, 1572 in milk, 2023 in rain, 16,428 in plants, and 99,345 in soils (Bai 1969).

Water in the Great Lakes in 1981 contained measurable concentrations of ^{137}Cs , ^3H , and ^{90}Sr , and detectable — but extremely low — concentrations of ^{241}Am , ^{113m}Cd , ^{144}Ce , ^{210}Pb , $^{239+240}\text{Pu}$, ^{226}Ra , ^{125}Sb , and ^{228}Th (Joshi 1991). Radiocesium-137 in water from the Hudson River estuary, New York, decreased tenfold between 1964 and 1970, but the ^{137}Cs content in fish and in sediments remained relatively constant (Wrenn et al. 1971). The effluent from the United Kingdom's Atomic Energy Agency Sellafield facility on the Cumberland Coast of the Irish Sea contained ^{90}Sr and ^{137}Cs , which are soluble in seawater and tend to remain in solution, and ^{106}Ru , ^{144}Ce , and $^{95}\text{Zr}/^{95}\text{Nb}$, which are relatively insoluble in seawater and coprecipitate or adsorb on free inorganic and organic surfaces (Pentreath et al. 1971).

Soils in the vicinity of an English nuclear fuel reprocessing facility in the period 1979 to 1985 contained as much as 42 times more ^{241}Am , 12 times more ^{137}Cs , 13 times more ^{90}Sr , and 87 times more $^{239+240}\text{Pu}$ than soils from a reference site (Curtis et al. 1991). In the United States, radiological trends in abiotic materials were difficult to interpret. For example, one nationwide monitoring program for radionuclide concentrations in air, drinking water, milk, groundwater, and precipitation (Table 32.13) was not consistent in the selection of measured radionuclides, frequency of sampling, and types of samples analyzed.

Table 32.13 Radionuclide Concentrations in Field Collections of Selected Abiotic Materials
 (Concentrations are in becquerels per kilogram fresh weight [FW], or dry weight [DW].)

Material, Radionuclide, and Other Variables	Concentration (Bq/kg or Bq/L)	Reference ^a
COMMON ROCK TYPES		
Shale, limestone, sandstone, basalt		
⁴⁰ K	63–518 DW	2
²³² Th	4–48 DW	2
²³⁸ U	6–44 DW	2
Granite vs. beach sands		
⁴⁰ K	1184 DW vs. 100 DW	2
²³² Th	74 DW vs. 25 DW	2

32.4.3 Aquatic Ecosystems

Field studies indicate that effects of radiation on marine ecosystems cannot be demonstrated at prevailing dose rates (Templeton et al. 1971). Two major periods of worldwide fallout occurred in Arctic ecosystems. The first and most sustained occurred from 1953 to 1959, and the second from 1961 to 1964, reflecting the atmospheric nuclear-weapons test regimes of Great Britain, the former Soviet Union, and the United States (Hanson 1976). Military accidents created localized radiocontamination of the Arctic environment. In one case, a B-52 aircraft from the U.S. Air Force crashed on the ice in northwestern Greenland in January 1968. Plutonium from the nuclear weapons onboard contaminated the benthos (Figure 32.5). The $^{239+240}\text{Pu}$ concentrations in various environmental samples declined at a much faster rate than the physical half-life of ^{239}Pu (24,000 years), suggesting that Pu becomes increasingly unavailable to the benthos over time as a result of dispersion from the epicenter and a dilution effect (Aarkrog 1990).

In marine environments, the major portion of the background dose rate in plankton and fish arises from the incorporated activity of natural alpha emitters, such as ^{210}Po , and from ^{40}K ; in molluscs, crustaceans, and benthos, the gamma radiation from the seabed provides the major background dose (IAEA 1976). The situation is similar in freshwater environments, although water containing appreciable levels of ^{222}Rn and its daughter radionuclides may exert an additional burden, especially to phytoplankton. Artificial radionuclides that contribute significantly to background concentrations of marine organisms include ^{239}Pu and ^{90}Sr ; of freshwater organisms, ^{137}Cs and ^{90}Sr (IAEA 1976). The total natural radiation received by a marine flounder (*Pleuronectes platessa*) in the Irish Sea consisted of 63% from radiations from seabed sediments, 16% from ^{40}K in seawater, 15% from internal ^{40}K , and 6% from cosmic radiation (Templeton et al. 1971). The estimated dose rates in aquatic environments from natural background are as high as 3.5 mGy annually and of the same order as those in most terrestrial environments. By 1976, the estimated dose rates from global fallout had declined to the same range as natural dose rates, although environments receiving radioactive wastes had variable responses (IAEA 1976).

Muscle of largemouth bass (*Micropterus salmoides*) collected from lakes in South Carolina in May and June of 1993 contained 109 to 4607 Bq $^{137}\text{Cs}/\text{kg DW}$. Increasing concentrations of ^{137}Cs were correlated with increasing DNA damage (Sugg et al. 1995). Increasing levels of ^{137}Cs in the muscle of fish in Minnesota between 1954 and 1966 reflect fallout from atmospheric nuclear testing. The effective half-time for ^{137}Cs in these lakes, as judged from small fish, is about 30 months (Gustafson 1969). In game fish from Colorado, ^{137}Cs in muscle was up to 7 times higher in 1968 than in 1965; higher in fish in mountain lakes than in fish from reservoirs in the plains, foothills, lakes, and rivers; and highest in trout from alpine lakes and reservoirs (Nelson and Whicker 1969).

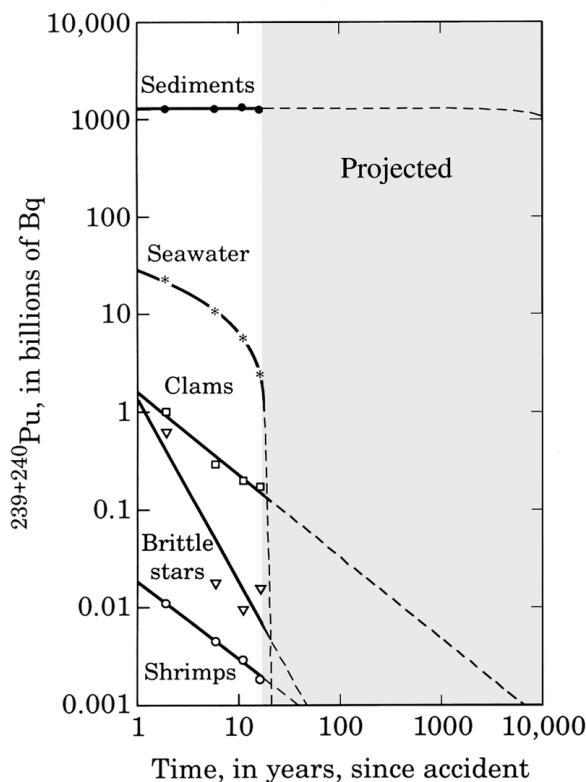

Figure 32.5 Plutonium-239+240 in environmental samples at Thule, Greenland, between 1970 and 1984, after a military accident in 1968. (Modified from Aarkrog, A. 1990. Environmental radiation and radiation releases. *Inter. Jour. Radiation Biol.* 57:619-631.) Within the contaminated area of $3.2 \times 10^9 \text{ m}^2$, the fresh weight biomass of shrimps was $0.11 \times 10^9 \text{ kg}$; of brittle star echinoderms $0.06 \times 10^9 \text{ kg}$; and of clam (*Macoma balthica*) soft parts $0.32 \times 10^9 \text{ kg}$. The seawater mass was $3 \times 10^{14} \text{ kg}$, and the dry weight of the upper 15-cm sediment layer was $3 \times 10^{11} \text{ kg}$.

In 1966, ^{137}Cs levels in trout from Colorado alpine lakes were 8 to 18 times higher than mean levels in muscle of deer from Colorado during the same period, and 20 to 300 times higher than domestic meat products (Nelson and Whicker 1969). Radionuclides in livers of tunas from southern California during the period 1964 to 1970 originated mainly from weapons tests in 1961/62, although ^{65}Zn may have reached southern California waters from nuclear reactors in Hanford (Washington) and from French or Chinese nuclear tests (Folsom et al. 1971).

Many variables are known to modify radionuclide concentrations in biota. In general, lower trophic levels of aquatic organisms are likely to have greater concentrations of radionuclides than higher trophic levels (Bowen et al. 1971). However, radionuclide concentrations in biota are modified significantly by the organism's age, size, sex, tissue, season of collection, and other variables — and these have to be acknowledged when integrating radiological analyses. For example, older *Fucus vesiculosus* had higher radioactivity concentrations than younger algae; concentrations of ^{60}Co and ^{54}Mn were highest in older parts of plants during spring and summer; and ^{137}Cs and ^{40}K were highest in receptacles and new vegetative fronds (Carlson and Erlandsson 1991). Changes in concentrations of ^{60}Co and ^{137}Cs in freshwater plankton from the discharge canal of an Italian

nuclear power station seem to reflect changes in water concentrations of these isotopes; changes were lowest in winter and highest in summer (Smedile and Queirazza 1976). Marine bivalve molluscs and algae from Connecticut in 1960 and 1961 had the highest levels of gross beta radioactivity in spring and summer and the lowest in winter ([Table 32.14](#)) (Hatfield et al. 1963); natural ^{40}K probably accounted for most of the beta radioactivity. Similar seasonal variations in gross beta radioactivity in other species of marine algae and molluscs were documented, suggesting a correspondence with periods of dormancy and activity (Hatfield et al. 1963). Although fat in the liver of crabs accounted for 47% of the fresh weight (74% on a dry weight basis), the gross beta activity of the fat fraction amounted to <0.5% of the total radioactivity, suggesting that radiological liver analyses be compared on the basis of nonfat solids (Chakravarti and Eisler 1961). In mosquitofish (*Gambusia holbrooki*) from some locations in a ^{137}Cs -contaminated reservoir, males contained higher ^{137}Cs concentrations than females, and smaller females contained more ^{137}Cs than larger females (Newman and Brisbin 1990). Strontium-90 concentrations in the carapace bone of turtles from five southwestern states in 1970 were used as indicators of ^{90}Sr fallout. However, older turtles tended to have lower concentrations of ^{90}Sr and concentrations differed geographically. Concentrations were highest in Georgia and increasingly lower in Tennessee, Mississippi, Arkansas, and Florida ([Table 32.14](#)) (Holcomb et al. 1971).

Consumption of shellfish represents a negligible radiological risk to humans (Crowley et al. 1990), although bivalve molluscs seem to be effective accumulators of radioisotopes. After the Chinese nuclear tests in May and December 1966, concentrations of ^{144}Ce , ^{103}Ru , ^{95}Zr , ^{95}Nb , ^{140}Ba , and ^{140}La in three species of bivalves in the Neuse River, North Carolina, increased suddenly (Wolfe and Schelske 1969). In 1973, Pacific oysters (*Crassostrea gigas*) from the discharge canal of a nuclear power plant in Humboldt Bay, California, rapidly accumulated ^{54}Mn , ^{60}Co , ^{65}Zn , and ^{137}Cs within 30 min of release. Isotope uptake correlated positively with particulates in the water, including living microorganisms, organic detritus, inorganic materials, and especially resuspended bottom sediments (Harrison et al. 1976). Although concentrations of cesium and plutonium in mussels (*Mytilus edulis*) from most Irish estuaries are essentially the same as global fallout levels, concentrations were elevated in mussels from the northeast coast (Crowley et al. 1990).

32.4.4 Birds

Television and newspaper reporters attributed radionuclides to a decline in bird numbers at the Ravenglass estuary, England, particularly of the black-headed gull (*Larus ridibundus*), although the concentrations of radionuclides in the avian diet, body tissues, and general environment were at least 1000 times too low to have had any effect ([Table 32.14](#)) (Lowe 1991). Although oystercatchers (*Haematopus ostralegus*) and shelducks (*Tadorna tadorna*) had the highest concentrations of ^{137}Cs in their tissues, the breeding success and population size of these birds were not affected. Black-headed gulls had less radiocontamination than other birds at Ravenglass, but their population continued to decline. The most likely cause was a combination of an uncontrolled fox population, a severe outbreak of myxomatosis in rabbits (normal fox prey), and a drought — all in the same year (Lowe 1991). Nesting success of birds was unaffected in the vicinity of nuclear power plants. For example, nesting barn swallows (*Hirundo rustica*) near radioactive leaching ponds had normal nesting success despite their consumption of arthropods from the pond and use of contaminated mud for nest construction (Millard and Whicker 1990; [Table 32.14](#)). Adult swallows received a total internal dose rate of 219 $\mu\text{Gy/day}$, mostly (72%) from ^{24}Na ; daily dose rates for eggs and nestlings during the nesting season were 840 μGy and 2200 μGy . The total dose to eggs and nestlings (54 mGy) and adults (450 mGy) had no measurable effect on survival and was below accumulated doses reported to cause death of passerines (Millard and Whicker 1990).

Strontium-90 behaves much like calcium in the biological environment. In birds, ⁹⁰Sr is expected to occur in bone and in the calcium-rich eggshell. In one case, a positive relation was demonstrated between reactor releases of ⁹⁰Sr to the Columbia River and ⁹⁰Sr concentrations in reed canary grass (*Phalaris arundinacea*) and eggshells of the Canada goose (*Branta canadensis moffitti*) (Rickard and Price 1990).

No human health problem is anticipated from consumption of ruffed grouse (*Bonasa umbellus*) contaminated with ²²⁶Ra in Canada or American coot (*Fulica americana*) contaminated with ¹³⁷Cs in Washington state. Tissues of ruffed grouse collected near discharged uranium tailings in Canada in 1987/88 did not contain grossly elevated levels of ²²⁶Ra over controls; consumption of grouse by humans did not present a radiological health problem (Clulow et al. 1992). Based on ¹³⁷Cs alone, humans who consume a single contaminated American coot captured at Hanford, Washington, would receive about 1.1% of the annual radiation protection dose of 1.70 mSv for individuals and populations in uncontrolled areas (Cadwell et al. 1979).

32.4.5 Mammals

Diets in Denmark contained elevated loadings of ¹³⁷Cs in 1964 because of the intensive atmospheric nuclear test series by the United States and the former Soviet Union in 1961 and 1962. Total ¹³⁷Cs intake declined in the Danish population from 72 Bq/kg BW in 1964 to <2 in 1985, but rose to about 13 in 1986 from the effects of debris from Chernobyl on dietary ¹³⁷Cs during the first year after the accident (Aarkrog 1990). The estimated dose equivalent from ¹³⁷Cs to human consumers of fish from the Great Lakes is about 0.01 µSv/kg fresh weight (FW) muscle from fish in Lakes Erie and Ontario, and 0.06 to 0.07 µSv/kg from fish in Lakes Superior and Huron (Joshi 1991). The guide for the protection of the general public from radiation is <5 mSv annually, and consumption of fish containing a dose equivalent greater than 0.02 µSv/kg fish flesh is not recommended (Joshi 1991). Some Scandinavians now receive a dose equivalent of about 5 mSv/year from intake of radio cesium in the diet (Johanson 1990). In Finland, uptake of radionuclides by humans in Finnish Lapland and in other areas with an arctic climate is attributed to ecological factors and to a high amount of local fallout. For example, reindeer-herding Finnish Lapps contained about 50 times more ¹³⁷Cs and 10 times more ⁵⁵Fe than other Finns during 1961 to 1967. For ¹³⁷Cs, this disparity is attributed mainly to the reliance by Finns on reindeer meat — which contains high levels of ¹³⁷Cs as a result of reindeer feeding on lichens — and secondarily, on freshwater fish and cow's milk (Miettinen 1969).

In the United States, the estimated annual whole-body human radiation dose equivalent is 1.61 mSv, mostly from natural sources (0.85 mSv) and medical sources (0.70 mSv), but also from fallout (0.03 mSv), miscellaneous sources (0.02 mSv), occupational hazards (0.008 mSv), and nuclear power (0.0001 mSv) (League of Women Voters [LWV] 1985). Radiation doses to people living near the Hanford nuclear industrial and research site in the state of Washington are well below existing regulatory standards. Only trace amounts of radionuclides from Hanford have been detected in the offsite environment (Gray et al. 1989). In December 1984, radon levels up to 130 times greater than considered safe under the current guideline for underground uranium miners were discovered in human residences in eastern Pennsylvania, New Jersey, and New York. About 25% of all residences in ten states exceeded the action level for radon of 0.185 Bq/L air (Cross 1990; Oge and Dickson 1990). The significance of this observation to avian and terrestrial wildlife merits investigation.

As a result of nuclear weapons testing, mandibles of Columbian black-tailed deer (*Odocoileus hemionus columbianus*) from California increased from <9 Bq ⁹⁰Sr/kg ash weight (AW) to >204 Bq/kg AW between 1952 and 1960 (Table 32.14) (Schultz and Longhurst 1963). Age and season affected strontium kinetics in male mule deer (*Odocoileus hemionus hemionus*) during the period of antler

growth; these variables did not affect strontium kinetics in females (Schreckhise and Whicker 1976). The concentrations of ^{90}Sr in forage of mule deer were higher in summer than in winter, and the differences were of sufficient magnitude to account for the ^{90}Sr variations in mule deer antlers (Farris et al. 1969); ^{137}Cs concentrations were similar in the forage and flesh of the white-tailed deer (*Odocoileus virginianus*) (Cummings et al. 1971). Levels of iodine-129 in thyroids of mule deer and pronghorns (*Antilocapra americana*) increased with proximity to nuclear fuel reprocessing plants in Colorado, Idaho, New Mexico, and Wyoming during 1972 to 1976, although levels were considered of no consequence to the health of the animals (Markham et al. 1983).

Radium-226, a bone-seeking α emitter with a half-life of 1600 years, may cause tissue damage and possibly subsequent osteosarcoma. Elevated ^{226}Ra concentrations have been reported in tissues of the common beaver (*Castor canadensis*) from the Serpent River watershed, Canada, the recipient of uranium tailings during 1984 to 1987 (Table 32.14). Measurable levels of ^{226}Ra were also found in feces of snowshoe hares (*Lepus americanus*) from this area and in black cutworms (*Agrotis ipsilon*) eaten by herring gulls (*Larus argentatus*) on the tailings (Clulow et al. 1991). Maximum levels in tissues of beavers from this watershed were <5 Bq $^{232}\text{Th}/\text{kg}$ dry weight (DW) in all tissues, 15 Bq $^{228}\text{Th}/\text{kg}$ DW bone, <5 Bq $^{228}\text{Th}/\text{kg}$ DW muscle and liver, 70 to 160 Bq $^{210}\text{Po}/\text{kg}$ DW bone, 11 to 75 Bq $^{210}\text{Po}/\text{kg}$ DW muscle, and 35 to 65 Bq $^{210}\text{Po}/\text{kg}$ DW liver. Consumption of these beavers would not be hazardous to human health. In the worst case, humans who consume substantial (71 kg) amounts of the flesh of beavers from the Serpent River drainage system would receive <10% of the annual limits set by Canadian regulatory authorities (Clulow et al. 1991).

Cesium-137 levels in grey seals (*Halichoerus grypus*) in 1987 seem to reflect ^{137}Cs levels in their fish diet, but there is no biomagnification of ^{137}Cs and other radionuclides. An estimated 29% of the ^{137}Cs in the diets of grey seals is from the Chernobyl accident and 71% from the nuclear facility at Sellafield, United Kingdom. The dose to grey seals from their diet is about 36 mSv annually and higher than the permissible dose limit of 5 mSv/year allowed the general public, but below the current limit for radiation workers of 50 mSv/year (S.S. Anderson et al. 1990).

The weekly dose rates from internal radionuclides were markedly different in muskrats (*Ondatra zibethicus*) and cotton rats (*Sigmodon hispidus*) collected at Oak Ridge, Tennessee, in August 1960 (20 to 1112 mSv for muskrats vs. 3 mSv for cotton rats). The difference is probably due to differences in diets and habitats (Kaye and Dunaway 1963). Foxes and wildcats contain 2 to 16 times more ^{137}Cs than their prey organisms, such as rats and rabbits (Jenkins et al. 1969), suggesting food-chain magnification. The biological half-time of ^{137}Cs is about 30 days in foxes, dogs, and pigs but about 60 days in humans (Jenkins et al. 1969). Jackrabbits (*Lepus californicus*) in 1958, one year after contamination at the Nevada test site, averaged 1908 Bq $^{90}\text{Sr}/\text{kg}$ AW bone within a 160-km radius from ground zero. In 1961, the average for the same population was only 984 Bq $^{90}\text{Sr}/\text{kg}$ AW bone, and the few higher values were restricted to older animals (Neel and Larson 1963). The authors concluded that ^{90}Sr from fallout in jackrabbits is at its maximum at an early time after contamination and that biological availability is later reduced by natural (unspecified) mechanisms. Jackrabbits at the Nevada test site also contained certain neutron activation products, including isotopes of Co, Mn, and W (Romney et al. 1971).

Radionuclide concentrations in sheep and cattle grazing near a nuclear fuel reprocessing facility amounted to a small fraction of the recommended limits. ^{241}Am , ^{137}Cs , and $^{239+240}\text{Pu}$ in the bone, liver, lung, and muscle of beef cattle were quite low from the vicinity of a nuclear fuel reprocessing facility in England between September and December 1986 and practically indistinguishable from control samples. Maximum concentrations, in Bq/kg FW, were 0.0015 $^{239+240}\text{Pu}$ in lung, 0.019 ^{241}Am in liver, and 3.1 ^{137}Cs in muscle (Curtis et al. 1991). Levels of ^{129}I were elevated in thyroids of cows near Mol, Belgium, in 1978 in the vicinity of a nuclear reprocessing plant closed in 1974 (Table 32.14) (Handl et al. 1990).

**Table 32.14 Radionuclide Concentrations in Field Collections of Selected Living Organisms
(Concentrations are in becquerels per kilogram fresh weight [FW], dry weight [DW], or ash weight [AW].)**

Ecosystem, Organism, Radionuclide, and Other Variables	Concentration (Bq/kg ^a)	Reference ^b
TERRESTRIAL PLANTS		
Sweet potato, <i>Ipomoea batatas</i> , Nagasaki, Japan, 1945, postatomic detonation		
¹³⁷ Cs	0.09 DW	1

32.5 CASE HISTORIES

Military weapons tests conducted at the Pacific Proving Grounds in the 1940s and 1950s resulted in greatly elevated local concentrations of radionuclides, and an accident at the Chernobyl nuclear power plant in the former Soviet Union in 1986 resulted in comparatively low concentrations of radionuclides dispersed over a wide geographical area. Both cases are briefly reviewed.

32.5.1 Pacific Proving Grounds

The first artificial, large-scale introduction of radionuclides into a marine environment was at Bikini Atoll in 1946. In succeeding years through 1958, Bikini and Eniwetok became the Pacific Proving Grounds where 59 nuclear and thermonuclear devices were detonated between 1946 and 1958 (Welander 1969; Templeton et al. 1971; Bair et al. 1979) (Table 32.15). Gross radiation injury to marine organisms has not been documented, possibly because seriously injured individuals do not survive and the more subtle injuries are difficult to detect. On land, the roof rat (*Rattus rattus*) survived heavy initial radiation by remaining in deep burrows. Terrestrial vegetation was heavily damaged by heat and blast, although regrowth occurred in 6 months. The land-dwelling hermit crab (*Coenobita* sp.) and coconut crab (*Birgus latro*) were subjected to higher levels of chronic radiation from internally deposited radionuclides than any other atoll organism studied. Levels remained constant in *Coenobita* at 166,000 Bq ⁹⁰Sr/kg skeleton and 16,835 Bq ¹³⁷Cs/kg muscle over 2 years; *Birgus* contained 25,900 Bq ⁹⁰Sr/kg skeleton and 3700 Bq ¹³⁷Cs/kg muscle over 10 years (Templeton et al. 1971). A survey in August 1964 at Eniwetok and Bikini Atolls (Welander 1969) (Table 32.15) showed that general levels of radioactivity were comparatively elevated and highest in soils and increasingly lower in aquatic invertebrates, groundwater, shorebirds, plants, rats, zooplankton, algae, fish, sediments, seawater, and seabirds. Cobalt-60 was found in all samples

of animals, plants, water, sediments, and soils and was the major radionuclide in the marine environment; on land, cesium-137 and ⁹⁰Sr predominated. All samples contained traces of ⁵⁴Mn; ¹⁰⁶Ru and ¹²⁵Sb were detected in groundwater and soil and trace concentrations in animals and plants. Trace amounts of ²⁰⁷Bi and ¹⁴⁴Ce were usually detected in algae, soils, and land plants. Iron-55 was comparatively high in vertebrates, and ²³⁹Pu was found in the soil and in the skin of rats and birds (Welander 1969).

32.5.2 Chernobyl

32.5.2.1 General

Several accidents in nuclear facilities have been extensively analyzed and reported. The three most widely publicized accidents were at Windscale (now known as Sellafield), United Kingdom, in 1957; Three Mile Island, Pennsylvania, in 1979; and Chernobyl, Ukraine, in 1986 (UNSCEAR 1988; Severa and Bar 1991; Eisler 1995). From the accident at Windscale about 750 trillion (T)Bq ^{131}I , 22 TBq ^{137}Cs , 3 TBq ^{89}Sr , and 0.33 TBq ^{90}Sr were released and twice the amount of noble gases that were released at Chernobyl, but 2000 times less ^{131}I and ^{137}Cs . From the Three Mile Island accident, about 2% as much noble gases and 50,000 times less ^{131}I than from the Chernobyl accident were released. The most abundant released radionuclides at Three Mile Island were ^{133}Xe , ^{135}Xe , and ^{131}I , but the collective dose equivalent to the population during the first post-accident days was <1% of the dose accumulated from natural background radiation in a year.

The most serious accident of a nuclear reactor occurred on April 26, 1986, at one of the four units at Chernobyl when at least 3,000,000 TBq were released from the fuel during the accident (Table 32.16). The accident happened while a test was conducted during a normal scheduled shutdown and is attributed mainly to human error: "...the operators deliberately and in violation of rules, withdrew most control rods from the core and switched off some important safety systems..." (UNSCEAR 1988). The first power peak reached 100 times the nominal power within 4 seconds. Energy released in the fuel by the power excursion suddenly ruptured part of the fuel into minute pieces. Small, hot fuel particles caused a steam explosion. After 2 or 3 seconds, another explosion occurred, and hot pieces of the reactor were ejected. The damage to the reactor allowed air to enter, causing combustion of the graphite (UNSCEAR 1988). About 25% of the released radioactive materials escaped during the first day of the accident; the rest, during the next 9 days (UNSCEAR 1988). The initial explosions and heat from the fire carried some of the radioactive materials to an altitude of 1500 m where they were transported by prevailing winds (Figure 32.6) and caused widespread radioactive contamination of Europe and the former Soviet Union, initially with ^{131}I , ^{134}Cs , and ^{137}Cs (Smith and Clark 1986; Anspaugh et al. 1988; Clark and Smith 1988; UNSCEAR 1988; Aarkrog 1990; Johanson 1990; Brittain et al. 1991; Palo et al. 1991). Long-range

Table 32.16 Selected Fission Products in the Chernobyl Reactor Core, and Their Estimated Escape into the Environment

Radionuclide	Trillions of becquerels (TBq)	
	In Core	Escaped ^a
⁸⁵ Kr	33,000	33,000

²⁴² Cm	26,000	780

^a Aarkrog (1990) estimates escapement of 100,000 TBq of ¹³⁷Cs; 50,000 TBq of ¹³⁴Cs; and 35,000 TBq of ¹⁰⁶Ru. Aarkrog (1990) also includes the following radionuclides in the Chernobyl escapement: 1500 TBq of ¹¹⁰Ag, 3000 TBq of ¹²⁵Sb, 6 TBq of ²⁴¹Am, and 6 TBq of ²⁴³⁺²⁴⁴Cm. Data from Severa, J. and J. Bar. 1991. *Handbook of Radioactive Contamination and Decontamination*. Studies in Environmental Science 47. Elsevier, New York. 363 pp.

atmospheric transport spread the radioactive materials through the northern hemisphere where it was first detected in Japan on May 2, in China on May 4, in India on May 5, and in Canada and the United States on May 5–6 1986 (UNSCEAR 1988). Airborne activity was also detected in Turkey, Kuwait, Monaco, and Israel in early May. No airborne activity from Chernobyl has been reported south of the equator (UNSCEAR 1988). Among the reactors now operating in the former Soviet Union are 13 identical to the one in Chernobyl, Ukraine, including units in Chernobyl, Leningrad, Kursk, and Smolensk (Mufson 1992).

Effective dose equivalents from the Chernobyl accident in various regions of the world were highest in southeastern Europe (1.2 mSv), northern Europe (0.97 mSv), and Central Europe (0.93 mSv) (Table 32.17). In the first year after the accident, whole-body effective dose equivalents were highest in Bulgaria, Austria, Greece, and Romania (0.5 to 0.8 mSv); Finland, Yugoslavia, Czechoslovakia, Italy (0.3 to 0.5 mSv); Switzerland, Poland, U.S.S.R., Hungary, Norway, Germany, and Turkey (0.2 to 0.3 mSv); and elsewhere (<0.2 mSv) (UNSCEAR 1988). Thyroid dose equivalents were significantly higher than whole-body effective dose equivalents because of significant amounts of ¹³¹I in the released materials. Thyroid dose equivalents were as high as 25 mSv to infants in Bulgaria, 20 mSv in Greece, and 20 mSv in Romania; the adult thyroid dose equivalents were usually 80% lower than the infant dose equivalents (UNSCEAR 1988).

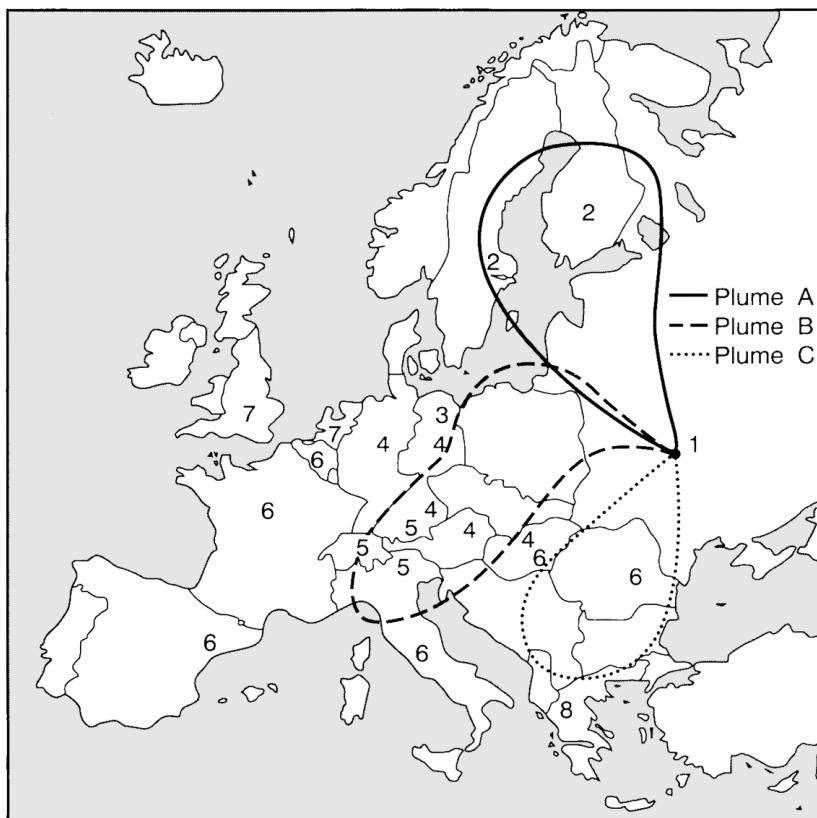

Figure 32.6 Chernobyl air plume behavior and reported initial arrival times of detectable radioactivity. Plume **A** originated from Chernobyl on April 26, 1986; Plume **B** on April 27–28; and Plume **C** on April 29–30. The numbers indicate initial arrival times: **1**, April 26; **2**, April 27; **3**, April 28; **4**, April 29; **5**, April 30; **6**, May 1; **7**, May 2; and **8**, May 3. (From United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR). 1988. Sources, *Effects and Risks of Ionizing Radiation*. United Nations, New York. 647 pp.)

Table 32.17 Regional Total Effective Human Dose Equivalent Commitment from the Chernobyl Accident

Region	Effective Dose Equivalent (mSv)
Southeastern Europe	1.2
Northern Europe	0.97
Central Europe	0.93
Former Soviet Union	0.81
Southwest Asia, West Europe	>0.1–<0.2
North Africa, Greenland, East Africa, Central Africa, South Asia, West Africa	>0.01–<0.1
East Asia, Southwest Europe, Southeast Asia, North America, Caribbean, South America, Central America	<0.01

Data from United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR). 1988. Sources, *Effects and Risks of Ionizing Radiation*. United Nations, New York. 647 pp.; Aarkrog, A. 1990. Environmental radiation and radiation releases. *Inter. Jour. Radiation Biol.* 57:619–631.

32.5.2.2 Local Effects

At Chernobyl, at least 115 humans received acute bone-marrow doses of greater than 1 Gy, as judged by lymphocyte aberrations (UNSCEAR 1988). The death toll within 3 months of the accident was at least 30 individuals, usually from groups receiving more than 4 Gy and including the reactor's operating staff and the fire-fighting crew. Local residents were evacuated from a 30-km exclusion zone around the reactor because of increasing radiation levels. More than 115,000 people, including 27,000 children, were evacuated from the Kiev region, Byelorussia, and the Ukraine. Tens of thousands of cattle were also removed from the contaminated area, and consumption of locally produced milk and other foods was banned. Agricultural activities were halted and a large-scale decontamination effort was undertaken (UNSCEAR 1988). The radiological effect of the accident to individual risk was insignificant outside a limited local region, either because contamination levels were generally low or because remedial actions to ban the consumption of highly contaminated foodstuffs prevented high exposures (UNSCEAR 1988).

Acute biological effects of the Chernobyl accident on local natural resources were documented by Sokolov et al. (1990). They concluded that the most sensitive ecosystems affected at Chernobyl were the soil fauna and pine forest communities and that the bulk of the terrestrial vertebrate community was not adversely affected by released ionizing radiation. Pine forests seemed to be the most sensitive ecosystem. One stand of 400 ha of *Pinus silvestris* died and probably received a dose of 80 to 100 Gy; other stands experienced heavy mortality of 10- to 12-year-old trees and up to 95% necrotization of young shoots. These pines received an estimated dose of 8 to 10 Gy. Abnormal top shoots developed in some *Pinus*, and these probably received 3 to 4 Gy. In contrast, leafed trees such as birch, oak, and aspen in the Chernobyl Atomic Power Station zone survived undamaged, probably because they are about 10 times more radioresistant than pines. There was no increase in the mutation rate of the spiderwort, (*Arabidopsis thaliana*) a radiosensitive plant, suggesting that the dose rate was less than 0.05 Gy/h in the Chernobyl locale.

Populations of soil mites were reduced in the Chernobyl area, but no population showed a catastrophic drop in numbers. By 1987, soil microfauna — even in the most heavily contaminated plots — were comparable to controls. Flies (*Drosophila* spp.) from various distances from the accident site and bred in the laboratory had higher incidences of dominant lethal mutations (14.7%, estimated dose of 0.8 mGy/h) at sites nearest the accident than controls (4.3%). Fish populations seemed unaffected in July/August 1987, and no grossly deformed individuals were found. However, ¹³⁴⁺¹³⁷Cs levels were elevated in young fishes. The most heavily contaminated teleost in May 1987 was the carp (*Carassius carassius*). But carp showed no evidence of mutagenesis, as judged by incidence of chromosomal aberrations in cells from the corneal epithelium of carp as far as 60 km from Chernobyl (Sokolov et al. 1990).

The most contaminated water body in the Chernobyl emergency zone was the Chernobyl cooling pond ecosystem (Kryshev 1995). On May 30, 1986, the total amount of radioactivity in the water of this system was estimated at 806 TBq, and in sediments 5657 TBq. In water, ¹³¹I contributed about 31% of the total radioactivity, ¹⁴⁰Ba-¹⁴⁰La 25%, ⁹⁵Zr-⁹⁵Nb 15%, ¹³⁴Cs and ¹³⁷Cs 11%, ¹⁴¹Ce and ¹⁴⁴Ce 10%, ¹⁰³Ru and ¹⁰⁶Ru 7%, and ⁹⁰Sr <1%. The distribution pattern in sediments was significantly different: about 41% of the total radioactivity was contributed by ⁹⁵Zr-⁹⁵Nb, 27% by ¹⁴¹Ce and ¹⁴⁴Ce, 16% by ¹⁰³Ru and ¹⁰⁶Ru, 12% by ¹⁴⁰Ba-¹⁴⁰La, 3% by ¹³⁴Cs and ¹³⁷Cs, 1% by ⁹⁰Sr, and 0.5% by ¹³¹I. Concentrations of radioactivity in water, sediments, and biota declined between 1986 and 1990, as judged by ¹³⁷Cs concentrations (Kryshev 1995). Cesium-137 concentrations in the Chernobyl cooling pond ecosystem declined in water from 210 Bq/L in 1986 to 14 Bq/L in 1990; for bottom sediments, these values were 170,000 Bq/kg FW in 1986 and 140,000 Bq/kg FW in 1990; for algae, 90,000 Bq/kg FW in 1986 to 19,000 Bq/kg FW in 1990; and for muscle of five species of fishes, ¹³⁷Cs concentrations ranged from 30,000 to 180,00 Bq/kg FW in 1986, and from

8000 to 80,000 Bq/kg FW in 1990 (Kryshev 1995). Silver carp (*Hypophthalmichthys molitrix*) born in 1989 from parents reared in Chernobyl cooling pond waters had a marked increase of 17 to 26% above controls in reproductive system anomalies in 1989 to 1992 (Makeyeva et al. 1995). Anomalies included degenerative changes in oocytes, spermatogonia, and spermatocytes, and the appearance of bisexual and sterile fish. The gonadal abnormalities are attributed to the high radiation dose of 7 to 10 Gy received by the parent fish during gonad formation and the continuing exposure of 0.2 Gy annually to this generation (Makeyeva et al. 1995). Silver carp from this ecosystem also had a dose-dependent decrease in hormonal control over Na^+ , K^+ -pump in erythrocytes, with increased passive permeability of the erythrocyte membrane to radioactive analogues of sodium and potassium (Kotelevtsev et al. 1996).

Several rodent species compose the most widely distributed and numerous mammals in the Chernobyl vicinity. It was estimated that about 90% of rodents died in an area that received 60 Gy and 50% in areas that received 6 to 60 Gy. Rodent populations seemed normal in spring 1987, and this was attributed to migration from adjacent nonpolluted areas. The most sensitive small mammal was the bank vole (*Clethrionomys glareolus*), which experienced embryonic mortality of 34%. The house mouse (*Mus musculus*) was one of the more radioresistant species. *Mus* from plots receiving 0.6 to 1 mG/h did not show signs of radiation sickness, were fertile with normal sperm, bred actively, and produced normal young. Some chromosomal aberrations were evident, namely, an increased frequency of reciprocal translocations (Sokolov et al. 1990). New data on the house mouse suggests that fertility was dramatically reduced in the 30-km zone around the Chernobyl nuclear power plant station in 1986/87 and that survivors had high frequencies of abnormal spermatozoa heads and dominant lethal mutations (Pomerantseva et al. 1996). Dose rates from soil to the house mouse between 1986 and 1993 ranged from 0.0002 to 2 mGy/h, and these were positively correlated with the frequency of reciprocal translocations in mouse spermatocytes. The frequency of mice heterozygous for recessive lethal mutations decreased over time after the accident (Pomerantseva et al. 1996).

During the early period after the accident, there was no evidence of increasing mortality, decline in fecundity, or migration of vertebrates as a result of the direct action of ionizing radiation. The numbers and distribution of wildlife species were somewhat affected by the death of the pine stand, the evacuation of people, the termination of cultivation of soils (the crop of 1986 remained standing), and the evacuation of domestic livestock. There were no recorded changes in survival or species composition of game animals and birds. In fact, because humans had evacuated and hunting pressure was negligible, many game species, including foxes, hares, deer, moose, wolves, and waterfowl, moved into the zone in fall 1986 to winter 1987 from the adjacent areas in a 50- to 60-km radius (Sokolov et al. 1990).

In 1991, 5 years after the accident, a female root vole (*Microtus oeconomus*) with an abnormal karyotype (reciprocal translocation) was found within the 30-km radius of the Chernobyl nuclear power plant. These chromosomal aberrations were probably inherited and did not affect the viability of vole populations (Nadzhafova et al. 1994). In 1994/95, the diversity and abundance of the small mammal population (12 species of rodents) at the most radioactive sites at Chernobyl were the same as reference sites (Baker et al. 1996). Rodents from the most radioactive areas did not show gross morphological features other than enlargement of the spleen. There were no gross chromosomal arrangements, as judged by examination of the karyotypes. Also observed within the most heavily contaminated site were red fox (*Vulpes vulpes*), gray wolf (*Canis lupus*), moose (*Alces alces*), river otter (*Lutra lutra*), roe deer (*Capreolus capreolus*), Russian wild boar (*Sus scrofa*), brown hare (*Lepus europaeus*), and feral dogs (Baker et al. 1996).

32.5.2.3 Nonlocal Effects

The partial meltdown of the 1000-megawatt reactor at Chernobyl on April 26, 1986, released large amounts of radionuclides into the environment — especially ^{131}I , ^{137}Cs , and ^{134}Cs — and

resulted in widely dispersed and deposited radioactive material in Europe and throughout the northern hemisphere (UNSCEAR 1988; Palo et al. 1991) (Table 32.18). Transuranics and to some extent ⁹⁰Sr were deposited closer to the accident site than more volatile radionuclides such as radiocesium; accordingly, radiological problems changed quantitatively and qualitatively with increasing distance from the accident site (Aarkrog 1990).

Soil and Vegetation. The radiocesium fallout in Sweden was among the highest in western Europe — exceeding 60,000 Bq/m² on Sweden's Baltic coast — and involved mainly upland pastures and forests (Johanson 1990; Brittain et al. 1991; Palo et al. 1991). In Norway, radiocesium deposition from the Chernobyl accident ranged from <5000 to >200,000 Bq/m² and greatly exceeded the deposition from prior nuclear weapons tests (Hove et al. 1990a). In Italy, heavy rainfall coincident with the passage of the Chernobyl radioactive cloud caused high local deposition of radionuclides in the soil, grass, and plants (Battiston et al. 1991). The Chernobyl plume reached Greece on May 1, 1986. A total of 14 gamma emitters were identified in the soil and vegetation in May 1986, and three (¹³⁴Cs, ¹³⁷Cs, ¹³¹I) were also detected in the milk of free-grazing animals in the area (Assimakopoulos et al. 1989). Radiocesium-134 and ¹³⁷Cs intake by humans in Germany during the period 1986/87 was mainly from rye, wheat, milk, and beef (Cloon and Aumann 1990). In the United Kingdom, elevated concentrations of radionuclides of iodine, cesium, ruthenium, and others were measured in the air and rainwater from May 2–5, 1986 (Smith and Clark 1986). The background activity concentrations were about 3 times normal levels in early May, and those of ¹³¹I approached the derived emergency reference level (DERL) of drinking water of 5 mSv ¹³¹I (equivalent to a thyroid dose of 50 mSv); however, ¹³¹I levels were not elevated in foodstuffs or cow's milk (Smith and Clark 1986). Syria — 1800 km from Chernobyl — had measurable atmospheric concentrations of ¹³⁷Cs and ¹³¹I and near-detection limit concentrations of ¹⁴⁴Ce, ¹³⁴Cs, ¹⁴⁰La, and ¹⁰⁶Ru (Othman 1990). The maximum ¹³¹I thyroid dose equivalent received by Syrians was 116 µSv in adults and 210 µSv in children. One year later, these values were 25 µSv in adults and 70 µSv in a 10-year-old.

The amount of fallout radioactivity deposited on plant surfaces depends on the exposed surface area, the developmental season of the plants, and the external morphology. Mosses, which have a relatively large surface area, showed the highest concentrations of radiocesium (Table 32.18). In northern Sweden, most of the radiocesium fallout was deposited on plant surfaces in the forest ecosystem and was readily incorporated into living systems because of browsing by herbivores and cesium's chemical similarity to potassium (Palo et al. 1991). Forest plants seemed to show less decrease than agricultural crops in ¹³⁷Cs activity over time (Bothmer et al. 1990). For example, the effective retention half-time of ¹³⁷Cs from Chernobyl was 10 to 20 days in herbaceous plants and 180 days in chestnut trees, *Castanea* spp. (Tonelli et al. 1990). The radioactive fallout from the Chernobyl accident also resulted in high ¹³⁷Cs levels in Swedish pasture grass and other forage, although levels in grain were relatively low (Andersson et al. 1990). Radiocesium isotopes were still easily measurable in grass silage harvested in June 1986 and used as fodder for dairy cows in 1988 (Voors and Van Weers 1991). The rejection of the first harvests of radiocesium-contaminated perennial pasture and in particular of rye grass (*Lolium perenne*) does not constitute a safe practice because later harvests — even 1 year after the contamination of the field — may contain very high values, as in Greece (Douka and Xenoulis 1991).

Aquatic Life. After Chernobyl, the consumption of freshwater fishes by Europeans declined, fish license sales dropped by 25%, and the sale of fish from radiocesium-contaminated lakes was prohibited (Brittain et al. 1991). Many remedial measures have been attempted to reduce radiocesium loadings in fishes, but none have been effective to date (Hakanson and Andersson 1992).

Radiocesium concentrations in muscle of fishes from the southern Baltic Sea increased 3 to 4 times after Chernobyl (Grzybowska 1989), and ¹³⁴⁺¹³⁷Cs and ¹⁰⁶Ru in fishes from the Danube River increased by a factor of 5. However, these levels posed negligible risk to human consumers

(Conkic et al. 1990). Chernobyl radioactivity, in particular ^{141}Ce and ^{144}Ce , entering the Mediterranean as a single pulse, was rapidly removed from surface waters and transported to 200 m in a few days, primarily in fecal pellets of grazing zooplankton (Fowler et al. 1987). Bioconcentration factors (BCF) of ^{137}Cs in fishes from Lake Paijanne, Finland — a comparatively contaminated area — ranged between 1250 and 3800; the highest BCF values were measured in the predatory northern pike (*Esox lucius*) a full 3 years after the Chernobyl accident; consumption of these fishes was prohibited (Korhonen 1990).

After the Chernobyl accident, radiocesium isotopes were also elevated in trees and lichens bordering an alpine lake in Scandinavia and in lake sediments, invertebrates, and fishes (Table 32.18). Radiocesium levels in muscle of resident brown trout (*Salmo trutta*) remained elevated for at least 2 years (Brittain et al. 1991). People consuming food near this alpine lake derived about 90% of their effective dose equivalent from the consumption of freshwater fish, reindeer meat, and milk. The average effective dose equivalent of this group during the next 50 years is estimated at 6 to 9 mSv with a changed diet and 8 to 12 mSv without any dietary changes (Brittain et al. 1991).

Wildlife. Reindeer (*Rangifer tarandus*) — also known as caribou in North America — are recognized as a key species in the transfer of radioactivity from the environment to humans because (1) the transfer factor of radioactivity from reindeer feed to reindeer muscle is high, (2) lichens — which constitute a substantial portion of the reindeer diet — are efficient accumulators of strontium, cesium, and actinide radioisotopes, and (3) reindeer feed is not significantly supplemented with grain or other feeds low in contamination (Jones et al. 1989; Rissanen and Rahola 1989; 1990; Eikelmann et al. 1990; Skogland and Espelien 1990). During 1986/87, about 75% of all reindeer meat produced in Sweden was unfit for human consumption because ^{137}Cs exceeded 300 Bq/kg FW. In May 1987, the maximum permissible level of ^{137}Cs in Swedish reindeer, game, and freshwater fish was raised to 1500 Bq/kg FW; however, about 25% of slaughtered reindeer in 1987 to 1989 still exceeded this limit (Ahman et al. 1990b). Concentrations in excess of 100,000 Bq $^{134+137}\text{Cs}/\text{kg}$ FW lichens have been recorded in the most contaminated areas and in the 1986/87 season was reflected in reindeer muscle concentrations >50,000 Bq/kg FW from the most contaminated areas of central Norway (Roed et al. 1991). Norwegian reindeer containing 60,000 to 70,000 Bq $^{137}\text{Cs}/\text{kg}$ FW in muscle receive an estimated yearly dose of 500 mSv (Jones 1990). The maximum radiation dose to reindeer in Sweden after the Chernobyl accident was about 200 mSv/year, with a daily dose rate of about 1 mSv during the winter period of maximum tissue concentrations (Jones et al. 1989). In general, reindeer calves had higher ^{137}Cs levels in muscle than adult females (4700 vs. 2700 Bq/kg FW) during September 1988, suggesting translocation to the fetus (Eikelmann et al. 1990). Two reindeer herds in Norway that were heavily contaminated with radiocesium had a 25% decline in survival of calves; survival was normal in a herd with low exposure (Skogland and Espelien 1990). Several compounds inhibit uptake and reduce retention of ^{137}Cs in reindeer muscle from contaminated diets, but the mechanisms of the action are largely unknown. These compounds include:

- Zeolite — a group of tectosilicate minerals — when fed at 25 to 50 g daily (Ahman et al. 1990a)
- Ammonium hexacyanoferrate — also known as Prussian Blue or Giese salt — at 0.3 to 1.5 g daily (Hove et al. 1990b; Mathiesen et al. 1990; Staalund et al. 1990)
- Bentonite — a montmorillonite clay — when fed at 2% of diet (Ahman et al. 1990a)
- High intakes of potassium (Ahman et al. 1990a)

Much additional work seems needed on chemical and other processes that hasten excretion and prevent uptake and accumulation of radionuclides in livestock and wildlife. Reindeer herding is the most important occupation in Finnish Lapland and portions of Sweden (Rissanen and Rahola

1989). Swedish Lapland reindeer herders have experienced a variety of sociocultural problems as a result of the Chernobyl accident. The variability of contamination has been compounded by the variability of expert statements about risk, the change in national limits of Bq concentrations set for meat marketability, and the variability of the compensation policy for slaughtered reindeer. These concerns may result in fewer Lapps becoming herders and a general decline in reindeer husbandry (Beach 1990).

Caribou in northern Quebec contained up to 1129 Bq $^{137}\text{Cs}/\text{kg}$ muscle FW in 1986/87, but only 10 to 15% of this amount originated from Chernobyl; the remainder is attributed to fallout from earlier atmospheric nuclear tests (Crete et al. 1990). The maximum concentration of ^{137}Cs in meat of caribou (*Rangifer tarandus granti*) from the Alaskan Porcupine herd after the Chernobyl accident did not exceed 232 Bq/kg FW, and this is substantially below the recommended level of 2260 Bq $^{137}\text{Cs}/\text{kg}$ FW (Allaye-Chan et al. 1990). Radiocesium transfer in an Alaskan lichen-reindeer-wolf (*Canis lupus*) food chain has been estimated. If reindeer forage contained 100 Bq/kg DW in lichens and 5 Bq/kg DW in vascular plants, the maximum winter concentrations — at an effective half-life of 8.2 years in lichens and 2.0 years in vascular plants — were estimated at 20 Bq/kg FW in reindeer-caribou skeletal muscle and 24 Bq/kg FW in wolf muscle (Holleman et al. 1990).

The radioactive body burden of exposed reindeer and the character of chromosomal aberrations — which was different in exposed and nonexposed reindeer — indicated a genetic effect of radiation from the Chernobyl accident (Roed et al. 1991). Chromosomal aberrations in Norwegian female reindeer positively correlated with increasing radiocesium concentrations in flesh (Skogland and Espelien 1990). The frequency of chromosomal aberrations in reindeer calves from central Norway were greatest in those born in 1987 when tissue loadings were equivalent to fetal doses of 70 to 80 mSv and lower in 1988 (50 to 60 mSv) and 1989 (40 to 50 mSv), strongly suggesting a dose-dependent induction (Roed et al. 1991). Mutagenicity tests have also been used successfully with feral rodents to evaluate the biological effects of the radiation exposure from the Chernobyl accident. Increased mutagenicity in mice (*Mus musculus domesticus*) was evident, as judged by tests of the bone-marrow micronucleus at 6 months and 1 year after the accident. Rodents with increased chromosomal aberrations also had ^{137}Cs burdens that were 70% higher 6 months after the accident and 55% higher after 1 year, but elevated radiocesium body burdens alone were not sufficient to account for the increase in mutagenicity (Cristaldi et al. 1990). In bank voles, however, mutagenicity (micronucleated polychromatic erythrocytes) correlated well with the ^{137}Cs content in muscle and in the soil of the collection locale (Cristaldi et al. 1991). The estimated daily absorbed doses (4.2 to 39.4 μGy) were far lower than those required to produce the same effect in the laboratory (Cristaldi et al. 1991).

For many households in Sweden, moose (*Alces alces*) are an important source of meat (Palo et al. 1991). Radiocesium concentrations in the foreleg muscle of moose in Sweden during 1987/88 were highest in autumn when the daily dietary intake of the animals was about 25,000 Bq ^{137}Cs and lowest during the rest of the year when the mean daily intake was about 800 Bq (Bothmer et al. 1990). Cesium-137 levels in moose flesh did not decrease significantly for about 2 years after the Chernobyl accident (Johanson 1990). The selection of food by moose is paramount to the uptake of environmental contaminants and the changes in tissue levels over time. Increased foraging on highly contaminated plant species, such as bilberry (*Vaccinium myrtillus*), aquatic plants, and mushrooms, might account for the increased ^{137}Cs radioactivity in moose (Palo et al. 1991). Habitat is a useful indicator of ^{137}Cs radioactivity in moose muscle; radioactivity was highest in moose captured in swamp and marsh habitats and lowest in farmlands (Nelin 1995). For reasons that are not yet clear, transfer coefficients of ^{137}Cs from diet to muscle were about the same in moose (0.03) and beef cattle (0.02), but were significantly higher in sheep (0.24) (Bothmer et al. 1990).

The songthrush (*Turdus philomelas*) collected in Spain in November 1986 had elevated concentrations of ^{134}Cs , ^{137}Cs , and ^{90}Sr . The contamination probably occurred in central and northern Europe before the birds' migration to Spain (Baeza et al. 1991). Spaniards who ate songthrushes

contaminated with radiocesium isotopes usually received about 58 $\mu\text{Sv}/\text{year}$, which is well below current international guidelines (Baeza et al. 1991). Consumption of game or wildlife in Great Britain after the Chernobyl accident probably also does not exceed the annual limits of intake (ALI) based on $^{134+137}\text{Cs}$ concentrations in game and the numbers of animals that can be eaten in 1 year before ALI is exceeded (Lowe and Horrill 1991). For example, a person who eats hares containing 3114 Bq $^{134+137}\text{Cs}/\text{kg FW}$ in muscle would have to consume 99 hares before exceeding the ALI. For the consumption of red grouse (3022 Bq/kg), this number is 441 grouse; and for the consumption of woodcock (55 Bq/kg), it is 45,455 woodcocks (Lowe and Horrill 1991). Rabbits (*Oryctolagus* sp.) from northeastern Italy that were fed Chernobyl-contaminated alfalfa meal (1215 Bq $^{134+137}\text{Cs}/\text{kg diet}$) had a maximum of 156 Bq/kg muscle FW of $^{134+137}\text{Cs}$, a value much lower than the current Italian guideline of 370 Bq/kg FW for milk and children's food and 600 Bq/kg FW for other food (Battiston et al. 1991). More than 85% of the ingested radiocesium was excreted by rabbits in their feces and urine; about 3% was retained (Battiston et al. 1991).

Cesium radioactivity in tissues and organs of the wolverine (*Gulo gulo*), lynx (*Felis lynx*), and Arctic fox (*Alopex lagopus*) in central Norway after the Chernobyl accident was highly variable. In general, cesium-137 levels were substantially lower in these carnivores than in lower trophic levels (Ekker et al. 1990), suggesting little or no food-chain biomagnification, and at variance with results of studies of the omnivore and herbivore food chain.

Domestic Animals. Radiocesium isotopes from the Chernobyl accident transferred easily to grazing farm animals (Hove et al. 1990a). Both ^{134}Cs and ^{137}Cs were rapidly distributed throughout the soft tissues after dietary ingestion and were most highly concentrated in muscle (Book 1969; Van Den Hoek 1989). Radiocesium activity in milk and flesh of Norwegian sheep and goats increased three- to fivefold 2 years after the accident and coincided with an abundant growth and availability of fungal fruit bodies with $^{134+137}\text{Cs}$ levels as much as 100 times greater than green vegetation (Hove et al. 1990a). In cattle, coefficients of radiocesium transfer from diet to muscle were about 2.5% in adults and 16% in calves. The higher value in calves was probably due to a high availability of cesium from the gastrointestinal tract and to daily uptake of potassium in growing animal muscle (Daburon et al. 1989). There was no correlation between the retention of ^{137}Cs and the pregnancy stage in cattle (Calamosca et al. 1990). Radiocesium concentrations in pork in Czechoslovakia did not decline between 1986 and 1987 because the feed of pigs during this period contained milk by-products contaminated with $^{134+137}\text{Cs}$ (Kliment 1991).

Sheep farming is the main form of husbandry in the uplands of west Cumbria and north Wales, a region that received high levels of radiocesium fallout during the Chernobyl accident. Afterwards, typical vegetation activity concentrations were ~6000 Bq/kg (down to ~1000 Bq/kg in January 1989). But sheep muscle concentrations exceeded 1000 Bq $^{137}\text{Cs}/\text{kg FW}$, which is the United Kingdom's dietary limit for human health protection (Crout et al. 1991). Contaminated lambs — which usually had higher concentrations of ^{137}Cs than ewes — that were removed to lowland pastures (<50 Bq/kg vegetation) rapidly excreted radiocesium in feces and urine, and cesium body burdens had an effective half-life of 11 days. This practice should not significantly increase radiocesium levels in the soil and vegetation of lowland pastures (Crout et al. 1991). The absorption and retention of radiocesium by suckling lambs is highly efficient, about 66%. Fecal excretion was an important pathway after the termination of ^{137}Cs ingestion. In weaned animals, the absorption of added ionic cesium was about twice that of cesium fallout after the accident at Chernobyl (Moss et al. 1989). Silver-110m was also detected in the brains and livers of ewes and lambs in the United Kingdom. The transfer of $^{110\text{m}}\text{Ag}$ was associated with perennial rye grass harvested soon after deposition in 1986. Silver-110m was taken up to a greater extent than ^{137}Cs in liver; but unlike ^{137}Cs , the $^{110\text{m}}\text{Ag}$ was not readily translocated to other tissues. Other than cesium isotopes and ^{131}I , $^{110\text{m}}\text{Ag}$ was the only detected nuclide in sheep tissues (Beresford 1989).

Atmospheric deposition of ^{137}Cs from Chernobyl to vegetation and eventually to the milk of sheep, cows, and goats on contaminated silage was reported in Italy, the Netherlands, Japan, and the United Kingdom (Book 1969; Belli et al. 1989; Pearce et al. 1989; Voors and Van Weers 1989; Aii et al. 1990; Monte 1990). The effective half-life of ^{137}Cs was 6.7 days in pasture grass and 13.6 days in milk (Spezzano and Giacomelli 1991). The average transfer coefficient of $^{134+137}\text{Cs}$ from Chernobyl from a 70% grass silage diet to milk of Dutch dairy cows was about 0.25%/liter/day (Voors and Van Weers 1991). In goats (*Capra* sp.), about 12% of orally administered ^{137}Cs was collected in milk within 7 days after dosing (Book 1969).

Iodine-131 was one of the most hazardous radionuclides released in the Chernobyl accident because it is easily transferred through the pasture-animal-milk pathway and rapidly concentrated in the thyroid gland to an extent unparalleled by any other organ. Because of its high specific activity, ^{131}I can transmit a high dose of radiation to the thyroid (Ionannides and Pakou 1991). Iodine-131 levels of 618,000 Bq/kg FW sheep thyroids from northwestern Greece on July 3, 1986, are similar to maximal ^{131}I concentrations in sheep thyroids in Tennessee in 1957 after global atmospheric fallout from military weapons tests and in London after the Windscale accident (Ionannides and Pakou 1991). Iodine-131 has an effective whole-body half-life of about 24 h and is rapidly excreted from sheep and cows (Assimakopoulos et al. 1989). The effective half-life of ^{131}I in pasture grass was 3.9 days and 5 days in cow's milk (Spezzano and Giacomelli 1991). The transfer coefficients of ^{131}I from vegetation to cow's milk was 0.007% day/L milk. This value was 57 times higher (0.4) in sheep (Monte 1990), but the mechanism to account for this large interspecies difference is not clear.

Table 32.18 Radionuclide Concentrations in Biotic and Abiotic Materials from Various Geographic Locales Before or After the Chernobyl Nuclear Accident on April 26, 1986 (All concentrations are in Bq/kg fresh weight [FW], or dry weight [DW], unless noted otherwise.)

Locale, Radionuclide, Sample, and Other Variables	Concentration	Reference ^a
ALASKA AND YUKON TERRITORIES		
Barren-ground caribou (<i>Rangifer tarandus granti</i>); porcupine herd; March–November 1987; ^{137}Cs

Moose dietary plants; 1986 (post-Chernobyl)–1988; ^{137}Cs		
Birch, <i>Betula</i> spp.; leaves	1200 DW	34
Heather, <i>Calluna vulgaris</i> ; whole	13,000–32,000 DW	34, 35
Sedge, <i>Carex</i> spp.; whole	12,000 DW	35
Hair grass, <i>Deschampia flexuosa</i> ; whole	1900 DW	34
Fireweed, <i>Epilobium angustifolium</i> ; whole	400 DW	34
Grasses, various species; blades	2500 DW	34
Buckbean, <i>Menyanthes trifoliata</i> ; whole	3800 DW	34
Pine, <i>Pinus sylvestris</i> ; shoots	2500 DW	34
Aspen, <i>Populus tremula</i> ; leaves	700 DW	34
Willow, <i>Solix</i> spp.; leaves	300 DW	34
Mountain ash, <i>Sorbus aucuparia</i> ; leaves	1300 DW	34
Bilberry, <i>Vaccinium myrtillus</i> ; leaves		
July 1986	2000 FW; 4000 DW	32, 34
July 1987 vs. July 1988	1138 FW vs. 600 FW	32
Bog whortleberry, <i>Vaccinium uliginosum</i> ; foliage	5900 DW	34
Cowberry, <i>Vaccinium vitis-idaea</i> ; foliage	7500 DW	34
Cow's milk; ^{137}Cs ; July 1986 vs. 1987	Usually <250 FW, Max. 375 FW vs. usually <70 FW, Max. 120 FW	36
Lichen, <i>Bryoria fuscescens</i> ; ^{137}Cs ; June 4, 1986	34,000–120,000 DW	35
Roe deer, <i>Capreolus</i> sp.; muscle; ^{137}Cs ; 1986 (post-Chernobyl)	20–12,000 FW	33
Lichen, <i>Cladina</i> spp.; ^{137}Cs ; 1986 (post-Chernobyl)	Max. 40,000 DW	35
Bank vole, <i>Clethrionomys glareolus</i> ; collected from soil containing various concentrations of $^{134+137}\text{Cs}$; voles analyzed less skull and digestive organs		
1800 Bq/m ² soil (control)	Voles had 9 Bq $^{134}\text{Cs}/\text{kg}$ FW and 39 of ^{137}Cs ; mutation frequency of 1.3; total irradiation of 0.0042 mGy daily	37
22,000 Bq/m ² soil	In Bq/kg FW, voles had 279 ^{134}Cs and 1031 ^{137}Cs ; mutation frequency was 1.5; daily dose rate of 0.0088 mGy	37
90,000 Bq/m ² soil	Voles had 1356 Bq $^{134}\text{Cs}/\text{kg}$ FW and 5119 of ^{137}Cs ; mutation frequency 1.9; daily dose of 0.0268 mGy	37
145,000 Bq/m ² soil	Voles had 2151 Bq $^{134}\text{Cs}/\text{kg}$ FW and 7784 ^{137}Cs ; mutation frequency 2.6; daily dose of 0.0394 mGy	37
Buckbean, <i>Menyanthes trifoliata</i> ; foliage; ^{137}Cs ; 1985 vs. 1987	1800 DW vs. 3880 DW	35
Reindeer dietary lichens; ^{137}Cs ; April 1986	Usually 40,000–60,000 DW; Max. 120,000 DW	38
Reindeer		
Moved in November 1986 from a highly contaminated area (>20,000 Bq $^{137}\text{Cs}/\text{m}^2$) to a less-contaminated area (<3000 Bq/m ²) of natural pasture	^{137}Cs content in muscle declined from 12,000 FW in November to about 3000 FW in April	39
Reindeer; muscle; ^{137}Cs ; 1986 (post-Chernobyl)	100–40,000 FW	33
Rodents and insectivores; July–August 1986; ^{137}Cs		
Control site, soil	1800 Bq/m ²	40
Bank vole; whole less skull, stomach, viscera	39 FW	40
Common shrew, <i>Sorex araneus</i> ; whole less skull, stomach, viscera	48 FW	40
Site 2, soil	22,000 Bq/m ²	40
Bank vole vs. common shrew	676 FW vs. 751 FW	40
Site 3, soil	90,000 Bq/m ²	40
Bank vole vs. common shrew	5119 FW vs. 3233 FW	40
Site 4, soil	145,000 Bq/m ²	40
Bank vole vs. common shrew	7993 FW vs. 6289 FW	40

32.6 EFFECTS: NONIONIZING RADIATIONS

Living organisms are constantly exposed to nonionizing electromagnetic radiations, including ultraviolet (UV), visible, infrared, radio, and other low-energy radiations that form an integral part of the biosphere. Emissions from anthropogenic sources such as radios, microwave ovens, television

communications, and radar have significantly altered the character of our natural electromagnetic field (Garaj-Vrhovac et al. 1990). Although the primary focus of this review is on ionizing radiations, it would be misleading to assume that low-energy electromagnetic waves cannot elicit significant biological responses. For example, behavioral and biochemical changes are reported in rats, monkeys, rabbits, and other laboratory animals after exposure to nonionizing electromagnetic radiations. The severity of the effect is associated with the type and duration of the radiation and various physicochemical variables (Ghandi 1990). Selected examples follow.

Ultraviolet radiation should be considered a plausible factor contributing to amphibian malformations in field settings (Ankley et al. 1998). Ultraviolet radiation is linked to teratogenesis, growth inhibition, and DNA photodamage in larvae of the South African clawed frog, *Xenopus laevis* (Bruggeman et al. 1998). About 50% of newly fertilized eggs of the northern leopard frog (*Rana pipiens*) exposed to UV radiation for 24 h developed hindlimb malformations, such as missing limb segments, missing or reduced digits, and missing or malformed femurs (Ankley et al. 1998). The higher-energy portion of the ultraviolet spectrum (UV-B) was lethal to embryos of Canadian frogs, with death occurring in as little as 30 min; the lower-energy portion (UV-A) was not harmful to eggs or larvae at exposures twice that of ambient levels (Grant and Licht 1995). Exposure to solar radiation — even at low elevations — is lethal to amphibian eggs of species with relatively poor capacity to repair UV-damaged DNA (Blaustein et al. 1994, 1996). Increased UV-B radiation in the environment due to decreasing ozone levels has been suggested as a factor in the worldwide decline of sensitive species of amphibians (Blaustein et al. 1994; Ankley et al. 1998). However, UV-B radiation was not implicated in the decline of the endangered green and golden bell frog (*Litoria aurea*) in Australia (van de Mortel and Buttemer 1996).

UV radiation in mammals causes the aging of skin, making it wrinkled and leathery (Kligman and Kligman 1990). Dermatologists of the late 19th century described the devastating effects of sunlight on the skin of farmers and sailors when compared with indoor workers. Photoaged skin has a variety of neoplasms, deep furrows, extensive sagging, and profound structural alterations that are quite different from those in protected, intrinsically aged skin (Kligman and Kligman 1990). Similar results were documented for the skin of guinea pigs (Davidson et al. 1991) and rodents (Ananthaswamy and Pierceall 1990; Ronai et al. 1990) after exposure to UV radiation. UV radiation causes eye cancer in cattle (Anderson and Badzioch 1991), interferes with wound healing in guinea pig skin (Davidson et al. 1991), is a potent damaging agent of DNA and a known inducer of skin cancer in experimental animals (Ronai et al. 1990), and interferes with an immune defense mechanism that normally protects against skin cancer (Ananthaswamy and Pierceall 1990). Aquatic organisms exposed to UV radiation show disrupted orientation, decreased motility, and reduced pigmentation in *Peridinium gatunense*, a freshwater alga (Hader et al. 1990). Effects were similar in several species of marine algae (Lesser and Shick 1990; Hader and Hader 1991; Shick et al. 1991). Increased lipid peroxidation rates and a shortening of the life-span after UV exposure were reported in the rotifer *Asplanchna brightwelli* (Sawada et al. 1990). Cells of the goldfish (*Carassius auratus*) were damaged, presumably by DNA impairment, from UV exposure (Yasuhira et al. 1991).

Visible radiation adversely affected survival and growth of embryos of the chinook salmon (*Oncorhynchus tshawytscha*) (Eisler 1961), the chloroplast structure in the symbiotic marine dinoflagellate *Symbiodinium* sp. (Lesser and Shick 1990), and *in vitro* growth of cultured mammalian cells (Karu 1990). Infrared radiation contributes significantly to skin photoaging, producing severe elastosis; the epidermis and the dermis were capable of self-restoration when the exogenous injury ceased (Kligman and Kligman 1990).

Investigations of the cellular effects of radiofrequency radiation provide evidence of damage to various types of avian and mammalian cells. These effects involve radiofrequency interactions with cell membranes, especially the plasma membrane. Effects include alterations in membrane cation transport, Na^+/K^+ -ATPase activity, protein kinase activity, neutrophil precursor membrane receptors, firing rates and resting potentials of neurons, brain cell metabolism, DNA and RNA synthesis in glioma cells, and mitogenic effects on human lymphocytes (Cleary 1990).

Microwaves inhibit thymidine incorporation by DNA blockage in cultured cells of the Chinese hamster; irradiated cells had a higher frequency of chromosome lesions (Garaj-Vrhovac et al. 1990). Microwaves induce teratogenic effects in mice when the intensity of exposure places a thermal burden on the dams and fetuses, resulting in a reduction in fetal body mass and an increased number of resorptions (O'Connor 1990).

Extremely low frequency (ELF) electromagnetic fields — similar to fields that emanate from electrical appliances and the electrical power distribution network, usually <300 Hz — are used therapeutically in the healing of human nonunion bone fractures, in the promotion of nerve regeneration, and in the acceleration of wound healing (Anderson 1990). ELF electric and magnetic fields produce biological effects, usually subtle, and are of low hazard in short-term exposure. These effects include altered neuronal excitability, neurochemical changes, altered hormone levels, and changes in behavioral responses. For example, electric field perception has been reported in humans, mice, pigs, monkeys, pigeons, chickens, and insects; altered cardiovascular responses in dogs and chickens; and altered growth rate of chicks. No deleterious effects of ELF fields on mammalian reproduction and development or on carcinogenesis and mutagenesis have been documented (Anderson 1990). In the vicinity of a powerful radar station, some birds avoided nesting (flycatchers, *Myiarchus* spp.), and the percent of nesting boxes occupied by other species (tit, *Parus* spp.) increased significantly with increasing distance from the radar station (Liepa and Balodis 1994). ELF fields had no effect on the growth of bone in chicks (Coulton and Barker 1991). However, adult newts (*Notophthalmus viridescens*), regenerating amputated forelimbs, had grossly abnormal forelimbs 12% of the time when exposed for 30 days to ELF fields of the type reported to facilitate healing of human bone fractures (Landesman and Douglas 1990). Additional studies are recommended on the biological effects of nonionizing radiations on fishery and wildlife resources, especially on ELF radiations.

32.7 EFFECTS: IONIZING RADIATIONS

32.7.1 General

High acute doses of ionizing radiation produce adverse biological effects at every organizational level: molecular, cellular, tissue–organ, whole animal, population, community, and ecosystem (ICRP 1977; Whicker and Schultz 1982b; LWV 1985; Hobbs and McClellan 1986; UNSCEAR 1988; Kiefer 1990; Severa and Bar 1991). Typical adverse effects of ionizing radiation include:

- Cell death (McLean 1973; LWV 1985; Kiefer 1990)
- Decreased life expectancy (Lorenz et al. 1954; Brown 1966; Hobbs and McClellan 1986; Kiefer 1990; Rose 1992)
- Increased frequency of malignant tumors (Lorenz et al. 1954; ICRP 1977; Hobbs and McClellan 1986; UNSCEAR 1988; Hopewell 1990; Kim et al. 1990; Little 1990; Nagasawa et al. 1990; Raabe et al. 1990; Fry 1991)
- Inhibited reproduction (ICRP 1977; Barendson 1990; Kiefer 1990; Rose 1992)
- Increased frequency of gene mutations (ICRP 1977; Whicker and Schultz 1982b; Hobbs and McClellan 1986; Abrahamson 1990; Evans 1990; Kiefer 1990; Thacker 1990; Sankaranarayanan 1991a; 1991b; Rose 1992; Macdonald and Laverock 1998)
- Leukemia (ICRP 1977; Kiefer 1990)
- Altered blood–brain barrier function (Trnovec et al. 1990)
- Reduced growth and altered behavior (Rose 1992)

Species within kingdoms have a wide variation in sensitivity, and sometimes at low radiation exposures the response is considered beneficial (Luckey 1980; Rose 1992). Overall, the lowest

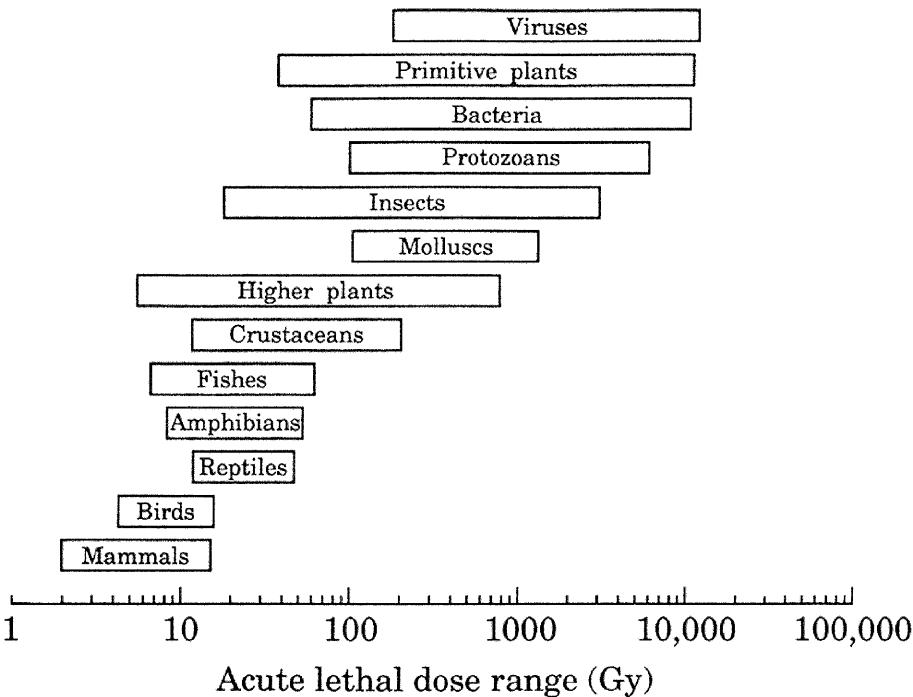

Figure 32.7 Acute radiation dose range fatal to 50% (30 days postexposure) of various taxonomic groups. (Modified from Whicker, F.W. and V. Schultz. 1982b. *Radioecology: Nuclear Energy and the Environment*. Vol. II. CRC Press LLC, Boca Raton, FL. 228 pp.; Hinton, T.G. and D.E. Scott. 1990. Radioecological techniques for herpetology, with an emphasis on freshwater turtles. Pages 267-287 in J.W. Gibbons (ed.). *Life History and Ecology of the Slider Turtle*. Smithsonian Instit. Press, Washington, D.C.)

dose rate at which harmful effects of chronic irradiation have been reliably observed in sensitive species is about 1 Gy/year; this value for acute radiation exposures is about 0.01 Gy (Rose 1992).

In general, the primitive organisms are the most radioresistant taxonomic groups, and the more advanced complex organisms — such as mammals — are the most radiosensitive (Figure 32.7). The early effects of exposure to ionizing radiation result primarily from cell death; cells that frequently undergo mitosis are the most radiosensitive, and cells that do not divide are the most radioresistant. Thus, embryos and fetuses are particularly susceptible to ionizing radiation, and very young animals are consistently more radiosensitive than adults (McLean 1973; Hobbs and McClellan 1986). In addition to the evolutionary position and cell mitotic index, many extrinsic and intrinsic factors modify the response of a living organism to a given dose of radiation. Abiotic variables include the type and energy of radiation, exposure rate, length of exposure, total exposure and absorbed dose, dose rate, spatial distribution of dose, season, temperature, day length, and environmental chemicals. Biotic variables include the species, type of cell or tissue, metabolism, sex, nutritional status, sensitizing or protective substances, competition, parasitism, and predation (Whicker and Schultz 1982b; Hobbs and McClellan 1986; UNSCEAR 1988; Kiefer 1990).

Radiosensitivity of cells is related directly to their reproductive capacity and indirectly to their degree of differentiation (Hobbs and McClellan 1986). Early adverse effects of exposure to ionizing radiation are due mainly to the killing of cells. Cell death may result from the loss of reproductive integrity, that is, when after irradiation a cell fails to pass through more than one or two mitoses. Reproductive death is important in rapidly dividing tissues such as bone marrow, skin, gut lining, and germinal epithelium. When the whole animal is exposed to a large dose of ionizing radiation,

some tissues are more prone to damage than others. Death rates of mammalian reproductive cells from ionizing radiations are modified by variations in the linear energy transfer of the radiation, the stage in the cell cycle, cell culture conditions, and sensitizing and protecting compounds (Barendsen 1990). The chemical form of the main stage of the acute radiation syndrome depends on the size and distribution of the absorbed dose. It is determined mainly by damage to blood platelets and other blood-forming organs at 4 to 5 Gy, to epithelial cells lining the small intestine at 5 to 30 Gy, and to brain damage at >30 Gy; death usually occurs within 48 h at >30 Gy (McLean 1973).

Cellular DNA is extremely sensitive to ionizing radiation, although other cell constituents may approach DNA in sensitivity (IAEA 1976; Billen 1990; Kiefer 1990; Lett 1990; Lucke-Huhle et al. 1990; Woloschak et al. 1990a; Shadley et al. 1991). Radiation-induced mutations are explainable on the basis of chromatin and DNA organization in cells and the biophysical properties of ionizing radiation (Sankaranarayanan 1991b). Based on studies of spontaneous and radiation-induced mutations in the mouse (Sankaranarayanan 1991a), more than 67% of the ionizing radiation-induced mutations are lethal, and almost all mutations, including enzyme activity variants, dominant visibles, and dominant skeletal mutations, are lethal. These findings are consistent with the view that most radiation-induced mutations in germ cells of mice are due to DNA deletions (Sankaranarayanan 1991a).

Experimental animal data clearly demonstrate that ionizing radiation at relatively high doses and delivered at high dose rates is mutagenic (Hobbs and McClellan 1986). However, radiation-induced genetic damage in the offspring of exposed parents has not been credibly established in any study with humans (Abrahamson 1990). In one human population — the ethnically isolated Swedish reindeer-breeding Lapps — elevated concentrations of fallout products have been ingested via the lichen–reindeer–human food chain since the 1950s. However, from 1961 to 1984, no increased incidence of genetic damage was evident in Lapps (Wiklund et al. 1990).

Radiation is carcinogenic. The frequency of death from cancer of the thyroid, breast, lung, esophagus, stomach, and bladder was higher in Japanese survivors of the atomic bomb than in nonexposed individuals, and carcinogenesis seems to be the primary latent effect of ionizing radiation. The minimal latent period of most cancers was <15 years and depended on an individual's age at exposure and site of cancer. The relation of radiation-induced cancers to low doses and the shape of the dose-response curve (linear or nonlinear), the existence of a threshold, and the influence of dose rate and exposure period have to be determined (Hobbs and McClellan 1986).

Radioactive materials that gain entry to the body, typically through ingestion or inhalation, exert effects that are governed by their physical and chemical characteristics which, in turn, influence their distribution and retention inside the body. The effective half-life includes both physical and biologic half-times. In addition, the type of radiation (i.e., α , β , γ) and its retention and distribution kinetics govern the radiation dose pattern. In general, the radiation dose from internal emitters is a function of the effective half-time, energy released in the tissue, initial amount of introduced radioactivity, and mass of the organ (Hobbs and McClellan 1986). Retention of radionuclides by living organisms is quite variable and modified by numerous biologic and abiotic variables. For example, ^{137}Cs retention in selected animals varies significantly with the body weight, diet, and metabolism of an organism ([Figure 32.8](#)). The time for 50% persistence of ^{137}Cs ranges between 30 and 430 days in ectotherms, and it was longer at lower temperatures and shortest in summer and under conditions of inadequate nutrition (Hinton and Scott 1990). In mammals, the ^{137}Cs biological half-life was between 6 and 43 days in rodents, dogs, mule deer, reindeer, and monkeys. In humans, this value ranged from 60 to 160 days. The biological half-life of ^{90}Sr ranges from 122 to 6000 days in ectotherms and is longer at colder temperatures and under laboratory conditions. In mammals and under conditions of chronic intake, the ^{90}Sr biological half-life was 533 days in rat, 750 days in humans, and at least 848 days in beagles (Hinton and Scott 1990).

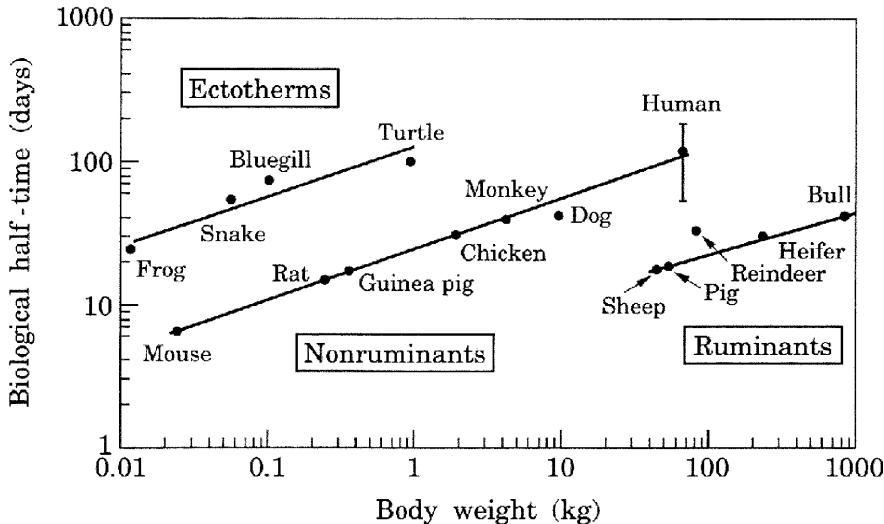

Figure 32.8 Relation between diet, metabolism, and body weight with half-time retention of longest-lived component of cesium-137. Data are shown for selected ruminant and nonruminant mammals (Richmond 1989) and ectotherms (Hinton and Scott 1990).

32.7.2 Terrestrial Plants and Invertebrates

Radiosensitive terrestrial plants exposed to single doses of ionizing radiation had reduced growth at 0.5 to 1.0 Gy and reduced survival at 3.0 to 4.1 Gy (Table 32.19). Chronic exposures of 0.2 to 0.65 Gy/day adversely affected sensitive forest ecosystems (Table 32.19). Chronic gamma irradiation of 131 Gy/year and higher of mixed forest ecosystems caused the disappearance of trees and shrubs and subsequent erosion of the soil (Poinsot-Balaguer et al. 1991). The radiation sensitivity of five plant communities suggested that pine forests were the most sensitive and that deciduous evergreen forests, tropical rainforests, herbaceous rock outcrop communities, and abandoned cropland were increasingly less sensitive (McCormick 1969). Neutrons were 3 to 4 times more effective than gamma rays in root growth inhibition (Witherspoon 1969). Altitude affects the response of vegetation to ionizing radiation. Peas (*Pisum sativum*) in gardens 2225 to 3750 m above mean sea level and exposed to 0, 5, 10, or 50 Gy had reduced growth from all treatments at increasing altitudes; however, a dose-response growth curve was evident only at <3049 m altitude (Osburn 1963). Seeds of tobacco (*Nicotiana tabacum*) exposed to cosmic rays aboard a spacecraft had a higher mutation rate than controls; effects occurred at total doses as low as 0.1 to 0.2 Gy (Gaubin et al. 1990), but this needs verification.

Sometimes, irradiation prevents the usual colonizing vegetation from becoming established (Poinsot-Balaguer et al. 1991). Germination and survival of shrub seedlings have been much slower at nuclear test sites than at non-disturbed sites (Romney et al. 1971). The return to its original state of the perennial shrub vegetation takes decades on a radiation-disturbed site, although native annual species and grasses have grown abundantly within 12 months. Transplanting of shrubs into radiation-disturbed areas has been largely unsuccessful because of intense browsing by rabbits and other small mammals (Romney et al. 1971). A nuclear detonation damages terrestrial vegetation by heat, blast, or radiation. Plant injury from thermal or ionizing radiation at an above-ground detonation site varied with stem rigidity and stability of the substratum, although radiation effects are ordinarily masked by damage from blasts. A typical nuclear detonation at the Nevada test site — an airburst of a 20- to 40-kiloton yield — denuded a zone of desert within a 0.8-km radius of shrub vegetation. Recovery at the Nevada site seemed complete within 4 years, suggesting little relation between

fatal injury, morphological aberration in vegetation, and ionizing radiation from nuclear detonations (Shields and Wells 1963). A northern Wisconsin forest experimentally subjected to a ^{137}Cs radiation source for 5 months showed several trends (Zavitkovski and Rudolph 1971):

1. Herbaceous and shrub species with a spreading form of growth are more radioresistant than upright forms.
2. Larger pine and oak trees are more radioresistant than smaller trees.
3. Perennial plants with shielded buds and vigorous asexual reproduction are relatively radioresistant.
4. Plants adapted to extreme habitats, such as old fields and granite rock outcrops, and plants typical of early successional stages are relatively radioresistant.
5. All plants are more radiosensitive during the growing season than during the dormant season.
6. Reproductive stages are always more radiosensitive than vegetative stages.

The recovery of vegetation in a tropical rainforest in Puerto Rico — after plants were deliberately subjected to lethal doses of gamma radiation — closely resembled secondary succession after other types of disturbances, such as mechanical stripping and treatment with the Picloram herbicide (Jordan 1969).

Table 32.19 Radiation Effects on Selected Terrestrial Plants

Species, Dose, and Other Variables	Effect	Reference ^a
Tropical rainforest tree, <i>Dacryodes excelsa</i> , 4–280 Gy per year	Growth stimulation	1
Deciduous evergreen forest		
40 Gy yearly	Minor effects	2
100 Gy yearly	Severe sublethal effects	2
350 Gy yearly	Lethal	2
Deciduous plants, 13 species		
4–15 Gy, single fast neutron doses	Shoot growth inhibited by >85%	3
60–85 Gy, single gamma radiation dose	Shoot growth inhibited by >85%	3
Forest ecosystem, northern Wisconsin, experimentally exposed to a ^{137}Cs point source for 5 months during a growing season. Distance from source (meters) and daily exposure (Gy)		
5 m, 15 Gy	No vegetation	4
5–10 m, 5–15 Gy	Lower plants present	4
10–15 m, 1.5 Gy	Resistant trees and shrubs present	4
10–15 m, 2.5–5.0 Gy	Some growth	4
20–30 m, 0.65–1.5 Gy	Resistant angiosperm trees	4
30–50 m, 0.2–0.65 Gy	Angiosperm trees present	4
50 m, 0.2 Gy	Original northern forest	4
Herbaceous rock outcrop community		
90 Gy yearly	Minor effects	2
400 Gy yearly	Severe sublethal effects	2
1000 Gy yearly	Lethal	2
Queensland mango, <i>Mangifera indica</i> , fruit irradiated postharvest, single dose, 250 or 750 Gy	At 250 Gy, skin and pulp color inhibited 50% due to irradiation-induced suppression of chlorophyll breakdown and reduction in carotenoid production. At 750 Gy, fruit respiration increased for 3–5 days, but no effect on fruit firmness	5
Mixed oak forest, southern France, experimentally irradiated for 18 years by a ^{137}Cs source at dose rates between 0.3 and 116 mGy/h, equivalent to a yearly rate between 2.6 and 1016 Gy	At 60–100 mGy/h (525–876 Gy yearly), all trees, shrubs, and litter were absent; low overall insect density; soil deficient in carbon, nitrogen, and water. At 15 mGy/h (131 Gy yearly), woody plants were present, but visibly abnormal	6

Table 32.19 (continued) Radiation Effects on Selected Terrestrial Plants

Species, Dose, and Other Variables	Effect	Reference^a
Tobacco, <i>Nicotiana tabacum</i> , 55 Gy per year	Growth stimulation	1
Pine forest		
1–10 Gy yearly	Minor effects	2
20 Gy yearly	Severe sublethal effects	2
30 Gy yearly	Lethal	2
Slash pine, <i>Pinus elliottii</i> , acute single exposure of 3 Gy	50% dead 1–4 months after exposure; no other deaths in 2 years	2
Sugar pine, <i>Pinus lambertiana</i> , acute single exposure of 4.1 Gy	LD50 (30 days postexposure)	1
Longleaf pine, <i>Pinus palustris</i>		
0.5 Gy, single dose	Growth inhibition	1
8 Gy, acute single exposure	50% of trees <5 years old died in 1–4 months; others survived for at least 2 years	2
>28 Gy, acute single exposure	Fatal to 50% of trees >5 years old in 1–4 months; no other deaths in 2 years	2
Winter wheat, <i>Triticum aestivum</i> , acute single exposure of 1.0 Gy	Growth inhibition	1
Tropical rainforest		
70 Gy yearly	Minor effects	2

^a **1**, Rose 1992; **2**, McCormick 1969; **3**, Witherspoon 1969; **4**, Zavitokovski and Rudolph 1971; **5**, Boag et al. 1990; **6**, Poinsat-Balaguer et al. 1991.

Hormesis — the beneficial physiological stimulation by low doses of a potentially harmful agent — is documented for ionizing radiation and many species of terrestrial plants and invertebrates (Luckey 1980). Radiation hormesis in plants includes increased germination, growth, survival, and yield. Some species of terrestrial invertebrates had increased fecundity, growth, survival, disease resistance, and longevity after exposure to low sublethal doses of ionizing radiation (Luckey 1980). The growth and development of some terrestrial invertebrates are stimulated at comparatively high sublethal acute doses (i.e., 2 Gy in silkworm, *Bombyx mori*), but survival is reduced at 10 Gy. In all cases, younger stages were the most sensitive (Table 32.20). Cockroaches (*Blaberus giganteus*) adapted to the dark reportedly can visually detect radiation sources as low as 0.001 mGy (Rose 1992). However, the mechanisms are not understood.

Following the successful application of radiation to sterilize male screw-worm flies (*Cochliomyia hominivorax*), various insect pests became the target of similar techniques throughout the world (Al-Izzi et al. 1990). The technique has suppressed populations of the Mediterranean fruitfly (*Ceratitis capitata*), a major pest of fruits, although results have not been as spectacular as with the screw-worm fly (McInnes and Wong 1990). The pestiferous Caribbean fruitfly (*Anastrepha suspensa*), heavily parasitized by a beetle, became sterile after acute exposures to ionizing radiation, although beetles remained fecund. Mass rearing and inundative release of the radioresistant beetle parasite is now considered an option for control of the Caribbean fruitfly (Table 32.20).

Table 32.20 Radiation Effects on Selected Terrestrial Invertebrates

Species, Dose, and Other Variables	Effect	Reference ^a
Caribbean fruitfly, <i>Anastrepha suspensa</i> ; larvae, heavily parasitized by the hymenopteron <i>Diachasmimorpha longicaudata</i> , exposed to single acute exposures of 10–70 Gy	50% of control flies developed into adults vs. 25% at 10 Gy, and <1% at 30 Gy. At 40 Gy and higher, no adults were recovered but parasite development was the same at all doses	1
Silkworm, <i>Bombyx mori</i> ; eggs, acute single exposure of 2, 5, or 10 Gy	At 2 Gy, an average increase of 23% in larval mass, cocoon shell weight, and silk production; no stimulatory effect at 5 Gy; at 10 Gy, larval development inhibited	2
Mediterranean fruitfly, <i>Ceratitis capitata</i> ; females, acute single exposure of 150–155 Gy	Inhibited oviposition	3
Moth, <i>Ectomyelois ceratoniae</i> ; male pupae, age 3 or 5 days, acute single exposure of 50–500 Gy	Younger pupae were more sensitive than older pupae. Only 3% of pupae developed into adults at 500 Gy. At >250 Gy, progeny development reduced 50%. Normal fecundity at 100–250 Gy when mated with control females	4
Leafmining fly, <i>Liriomyza trifolii</i> ; immature stages, on artificially infested bean seedlings; acute single exposure of 25–2000 Gy	All dead at >750 Gy; 80% dead at 250 Gy; eggs and prepupae were the most sensitive stages; no phytotoxic effects	5

32.7.3 Aquatic Organisms

Among aquatic organisms, it is generally acknowledged that primitive forms are more radioreistant than complex vertebrates and that older organisms are more resistant than the young (Donaldson and Foster 1957; Bonham and Welander 1963; Templeton et al. 1971) (Table 32.21). Developing eggs and young of some freshwater fish species are among the most sensitive tested aquatic organisms. Death was observed at acute doses of 0.3 to 0.6 Gy, and minor effects on physiology or metabolism were observed at chronic daily dose rates of 0.01 Gy (Bonham and Welander 1963; Templeton et al. 1971; IAEA 1976) (Table 32.21). Radiosensitivity correlated positively with the metabolic rate of the dividing cell, which accounts for the radioresistance of dormant eggs of aquatic invertebrates and the general sensitivity of early embryonic stages of all aquatic species (Donaldson and Foster 1957) (Table 32.21).

Adverse effects on the fecundity of sensitive aquatic vertebrates were detected at dose rates as low as 0.4 mGy/h; adverse effects on fecundity of resistant species were measured only at dose rates greater than 1.0 mGy/h. Thus, deleterious effects in populations of aquatic vertebrates are probably not detected until the 0.4 to 1.0-mGy/h dose rate is exceeded (NCRP 1991). Organisms, such as estuarine organisms, that are exposed to variable physicochemical conditions are more radioresistant than those in buffered environments, and this may be due to a higher degree of genetic polymorphism in species of fluctuating environment (IAEA 1976). Dose-effect estimates for the induction of chromosomal aberrations in polychaete annelid worms were dependent on cell stage at time of irradiation (S.L. Anderson et al. 1990). For reproduction, dose-effect estimates were dependent on potential for regeneration of gonadal tissue (S.L. Anderson et al. 1990).

Radiation causes dominant lethal mutations in the medaka (*Oryzias latipes*) (Shima and Shimada 1991). Mosquitofish (*Gambusia* spp.) from radionuclide-contaminated ponds in South Carolina differed from conspecifics in reference ponds, as judged by the frequency of DNA markers, and this is consistent with the hypothesis that these DNA markers may originate from genetic elements that provide a selective advantage in contaminated habitats (Theodorakis et al. 1998). Ionizing radiation at low-level chronic exposure reportedly has no deleterious genetic effects on aquatic populations because exposure is compensated by density-dependent responses in fecundity (IAEA 1976). However, this needs verification.

Table 32.21. Radiation Effects on Selected Aquatic Organisms

Taxonomic Group, Organism, Dose, and Other Variables	Effect	Reference ^a
ALGAE		
Diatom, <i>Nitzchia closterium</i> ; acute single exposure of 100 Gy	Lethal	1
Euglena, <i>Euglena gracilis</i> ; acute single exposure of 550 Gy	Tolerated	1
Freshwater algae, 7 species, held in water containing 1110 Bq $^{226}\text{Ra}/\text{L}$ for as long as 14 days	After 24 h, 4 species (<i>Ankistrodesmus falcatus</i> , <i>Chlorella vulgaris</i> , <i>Coelastrum cambricum</i> , <i>Scenedesmus obliquus</i>) had decreased oxygen production by 22–37%; after 14 days, no effect on growth or protein content	2
Various species, single acute exposure 80–1000 Gy 250–6000 Gy	LD50, 45 days, postexposure LD100, 45 days after single exposure	3 3
PROTOZOANS		
Various species, acute single exposure 100–300 Gy 180–12,500 Gy	LD50, up to 40 days postexposure LD100, up to 40 days postexposure	3 3
COELENTERATES		
Sea anemone, <i>Anthopleura xanthogrammica</i> ; 0.2 Gy, acute single exposure	Tentacles withdrawn	1
Jellyfish, <i>Aurelia aurita</i> ; acute single exposure 50–150 Gy 50–400 Gy	No deaths in 60 days Dose-dependent increase in developmental abnormalities and abnormal budding rates and patterns	4 4
100 Gy	Metamorphosis and budding inhibited; reduction in pulsation rate	4
150 Gy	Inhibited reproduction	4
200 Gy	60% died in 60 days	4
400 Gy	90% died in 30 days	4
MOLLUSCS		
Water snail, <i>Physa heterostropha</i> ; exposure of 2.4–5.5 Gy daily for 1 year	Increased growth rate	1
Various species, acute single exposure 50–200 Gy 100–500 Gy	LD50, up to 2 years postexposure LD100, up to 2 years postexposure	3 3
CRUSTACEANS		
Brine shrimp, <i>Artemia salina</i> ; acute single exposure 0.004 Gy 0.1–9 Gy	No adverse effects on development of cysts Decreased development when exposed as cysts	5 5
4.5–9 Gy	LD50, nauplii, 20–25 days postexposure	6
130 Gy	LD50, adults, 25 days after exposure	6
486–2084 Gy	Dose-dependent delay in development of eggs	7
3000 Gy	LD50, cysts	5
Blue crab, <i>Callinectes sapidus</i> ; continuous exposure to 0.76 Gy daily for 1 year	Increased growth rate	1

Table 32.21. (continued) Radiation Effects on Selected Aquatic Organisms

Taxonomic Group, Organism, Dose, and Other Variables	Effect	Reference ^a
Shore crab, <i>Carcinus maenas</i>		
Americium-241, dose unknown	After 8 days, bioconcentration factors (BCF) were 145 in whole crab, 960 in gills, and 240 in exoskeleton; 50% elimination in 45 days	8
Plutonium-237, dose unknown	After 8 days, BCF values were 75 in whole crab, 340 in gills, and 70 in exoskeleton; 50% elimination in 55 days	8
Daphnid, <i>Daphnia pulex</i> ; daily exposure to 8.2–17.8 Gy for 1 year	Increased growth rate	1
Various species, single acute exposure		
5–900 Gy	LD50, up to 80 days postexposure	3
50–800 Gy	LD100, up to 80 days postexposure	3
ANNELIDS		
Polychaete, <i>Neanthes arenaceodentata</i> ; acute single exposure		
1–4 Gy	Adverse effects on reproduction	9
2–100 Gy	Significant increase in frequency of chromosomal aberrations	9
>100 Gy	Decreased life span	9
>500 Gy	Death	9
FISH		
Common carp, <i>Cyprinus carpio</i>		
Adults, 3 Gy, acute single exposure	No effect on growth	1
Fertilized eggs, exposed through hatch		
144 million Bq ²³⁸ Pu/L	Increased abnormalities	10
277 million Bq ²³⁸ Pu/L	Decreased hatch	10
44 million Bq ²³² U/L	Increased abnormalities	10
815 million Bq ²³² U/L	Decreased hatch	10
Anchovy, <i>Engraulis</i> sp.; fertilized eggs, ⁹⁰ Sr– ⁹⁰ Y, continuous exposure		
7.4 Bq/L	Increased developmental abnormalities	10
740 Bq/L	Decreased hatch, retarded growth rate	10
Fish, various species, acute single exposure		
6–30 Gy	LD50, up to 460 days postexposure	3
3.7–200 Gy	LD100, up to 460 days postexposure	3
Pinfish, <i>Lagodon rhomboides</i> ; exposure to 0.197 Gy daily for 1 year	Increased growth rate	1
Bluegill, <i>Lepomis macrochirus</i> ; acute single exposure of 10, 20, or 30 Gy		
Marine teleosts, 6 species, 10–55 Gy, acute single exposure	At 20 and 30 Gy, serum proteins were reduced more than 50% within 24 h; damage to the GI capillary system and injury to the gastroepithelium accounted for the excessive protein loss	12
Silver salmon, <i>Oncorhynchus kisutch</i> ; acute single exposure	LD50	11
Early embryonic stages, 0.3–0.6 Gy	LD50 at hatch	13
Later embryonic stages, 9.2–18.7 Gy	LD50 at hatch	13
Rainbow trout, <i>Oncorhynchus mykiss</i>		
Embryos, acute single exposure		
0.6 Gy, 1-cell stage	LD50 by end of yolk resorption	10
0.8 Gy, 1-cell stage	LD50 at hatch	3
3.1 Gy, 32-cell stage	LD50 by end of yolk resorption	10
4.1 Gy, early eyed stage	LD50 by end of yolk resorption	3

Table 32.21. (continued) Radiation Effects on Selected Aquatic Organisms

Taxonomic Group, Organism, Dose, and Other Variables	Effect	Reference ^a
4.6 Gy, 32-cell stage	LD50 by hatch	3
9.0 Gy, late eyed stage	LD50 by end of yolk resorption	3
Embryos held in water containing 370 million Bq/L of ³ H from immediately after fertilization through hatching	No effect on hatching abnormalities	10
Embryos held in water containing 37 million Bq/L of ³ H from 6 h after fertilization through hatch	Suppressed immune response of fry	10
Immature, single acute exposure of 0.2 Gy	Growth stimulation	1
Juveniles exposed for 27 days to radioneptunium isotopes and analyzed 2–15 days postexposure	Maximum BCF values were 8.7 for whole fish, 1.1 for skin, and 0.34 for muscle	14
Yearlings, force-fed 185,000, 1.85 million, or 18.5 million Bq ⁹⁰ Sr– ⁹⁰ Y/kg BW daily for 21 weeks	At highest dose, adverse effects on growth (week 12) and survival (week 15); survivors had leucopenia and gut histopathology, and concentrations of 9.2 billion Bq/kg FW in bone and 9.99 million Bq/kg FW in muscle. Residues in the 1.85-million group were 1.04 billion Bq/kg in bone and 2.96 million Bq/kg in muscle. For the 185,000 group, these values were 77.7 million Bq/kg in bone and 74,000 Bq/kg in muscle	11, 15
Yearlings force-fed 370,000, 3.7 million, or 37 million Bq ⁶⁵ Zn/kg BW daily for 17 weeks, or 370 million Bq ⁶⁵ Zn/kg BW daily for 10 weeks	Adverse effects on growth, survival, or gut histology at any dose; leucopenia evident at week 10 at the highest dose. Residues, in Bq/kg FW, in the 37 million group at 17 weeks were 148 million in bone and 12.9 million in muscle	11, 15
Yearlings force-fed 222,000, 2.2 million, or 22.2 million Bq ³² P/kg BW daily for as long as 25 weeks	At highest dose tested, adverse effects on growth, survival, and gut histology between day 17 and 77. In the intermediate 2.2-million group, adverse effects on growth at 17 weeks; residues (Bq/kg FW) were 66.6 million in bone and 8.5 million in muscle. The 220,000 group had no adverse effects in 25 weeks on growth, survival, or tissue alterations	11
Gametes of adults, single acute exposure of 0.5–1.0 Gy	50% reduction in fecundity	3
Adults, single acute exposure of 15 Gy	LD50	3
Chinook salmon, <i>Oncorhynchus tshawytscha</i>		
0.0004 Gy/h, eggs, 81-day exposure, total dose of 0.78 Gy	Significant adverse effects on survival and development	21
0.005 Gy daily, continuous exposure from egg fertilization through yolk sac absorption; total dose of 0.35 Gy	No adverse effects on growth and survival or on numbers of returning adults after seaward migration	22
0.028 Gy daily, continuous exposure from egg fertilization through yolk sac absorption; total dose of 1.99 Gy	No adverse effects observed prior to seaward migration	22
0.2 Gy, single acute exposure	Growth increase	1
10 Gy, eyed eggs, single acute exposure	LD50	3
12.5–25 Gy, fingerlings, single acute exposure	LD50	3
Medaka, <i>Oryzias latipes</i> ; adult males receiving single acute exposure of 0.64, 4.75, or 9.5 Gy	Dose-dependent increase in total mutations in sperm, spermatids, and spermatogonia	16
Sea lamprey, <i>Petromyzon marinus</i> ; males captured during spawning run, single acute exposure		
20 Gy	LD50, 45 days postexposure; survivors sterile	17
30 Gy	All died before spawning	17

Table 32.21. (continued) Radiation Effects on Selected Aquatic Organisms

Taxonomic Group, Organism, Dose, and Other Variables	Effect	Reference ^a
Fathead minnow, <i>Pimephales promelas</i> ; developing eggs, continuous exposure 4440 Bq ^{144}Ce – ^{144}Pr /L 9.6 million Bq ^{238}Pu /L 48.1 million Bq ^{238}Pu /L 7.4 million Bq ^{232}U /L 18.5 million Bq ^{232}U /L	No effect on embryonic development or hatch Increased abnormalities Decreased hatch Increased abnormalities Decreased hatch Increased mortality of embryos and fry	10 10 10 10 10 10
Atlantic salmon, <i>Salmo salar</i> ; fertilized eggs, continuous immersion in 92.5 Bq ^{137}Cs /L or 185 Bq ^{90}Sr /L	Increased mortality of embryos and fry	10
Brown trout, <i>Salmo trutta</i> Fertilized eggs continuously immersed in water containing 3.7 million Bq/L of ^{90}Sr – ^{90}Y through hatch Juveniles held in water containing 30,000 Bq ^{110m}Ag /L for 57 days, then transferred to uncontaminated media for 28 days	No effect on hatch or developmental abnormalities At day 57, whole trout contained 105,000 Bq ^{110m}Ag /kg FW; about 70% was in liver. No detectable radioactivity after depuration for 28 days	10 18
Juveniles fed diet containing 3,343,000 Bq ^{110m}Ag /kg for 1 week (5 times weekly), then 269,000–296,000 Bq ^{110m}Ag /kg diet between weeks 2 and 5. Depuration for 28 days	At end of exposure, whole trout contained 27,400 Bq ^{110m}Ag /kg, equivalent to 11.7% of ingested radioactivity; liver accounted for 63%. No detectable radioactivity after depuration for 28 days	19

Accumulation of radionuclides from water by aquatic organisms varies substantially with ecosystem, radionuclide, and trophic level (Tables 32.22, 32.23, 32.24, respectively); with numerous biological, chemical, and physical variables; and with proximity to sources of radiation (Bowen et al. 1971; Lowman et al. 1971; Templeton et al. 1971; Mo and Lowman 1976; Shure and Gottschalk 1976; Whicker and Schultz 1982b; Becker 1990; Poston et al. 1990; Joshi 1991). Accumulated radionuclides within embryos of the scorpionfish (*Scorpaena porcus*) and turbot (*Scophthalmus maeoticus*) increased the frequency of nuclear disruptions in these species; ^{90}Sr – ^{90}Y and ^{91}Y had greater cytogenetic effects than other radionuclides tested (Polikarpov 1973). In the absence of site-specific data, the U.S. Nuclear Regulatory Commission recommends the use of

Table 32.22 Concentration Factors for Cesium-137 and Strontium-90 in Aquatic Organisms

Radionuclide and Ecosystem	Molluscs, Whole	Crustaceans, Whole	Fish, Muscle
CESIUM-137

Table 32.23 Approximate Maximum Concentration Factors for Selected Transuranics in Marine Sediments, Macroalgae, and Fish

Transuranic Nuclide	Concentration Factor		
	Sediments	Macroalgae	Fish
Neptunium	1000	5000	10
Plutonium	100,000	2000	40
Americium, curium, berkelium, californium	2,000,000	8000	50

Note: Concentration factors given in Bq per gram fresh weight sample/Bq per mL water.

Data from Morse, J.W. and G.R. Choppin. 1991. The chemistry of transuranic elements in natural waters. *Rev. Aquat. Sci.* 4:1-22.

listed concentration ratios — the concentration of the element in the organism (in mg/kg FW) divided by the concentration in the medium (in mg/L) — for various elements in marine and freshwater fishes and invertebrates (Whicker and Schultz 1982b). However, the Commission clearly indicates that these values are only approximations.

After more than 400 atmospheric nuclear test explosions and the fallout from Chernobyl, ¹³⁷Cs became the most frequently released nuclear fission product throughout central Europe (Jandl et al. 1991). Cesium behaves like potassium: it has a ubiquitous distribution inside the body, especially in soft tissues. In the gastropod *Helix pomatia*, the biological half-time after a single 24-h dietary dose was 2.5 days for the short-lived component and 28.5 days for the long-lived component (Jandl et al. 1991). Concentration factors (CF) of ¹³⁷Cs in muscle (ratio of Bq/kg FW muscle:Bq/L filtered seawater) of marine fishes from the North Sea between 1978 and 1985 ranged from a low of 39 in the plaice (*Pleuronectes platessa*) to a high of 150 in the whiting (*Merlangius merlangius*); CF values were intermediate in the haddock (*Melanogrammus aeglefinus*; CF of 58) and Atlantic cod (*Gadus morhua*; CF of 92). These data seem to support the use of a CF of 100 for ¹³⁷Cs in muscle of marine fishes in generalized assessments, although some adjustment is necessary when particular species, such as whiting, form the bulk of a consumer's diet (Steele 1990). In the Great Lakes, the maximum CF values of ¹³⁷Cs range from 1000 to 10,000 in algae, amphipods, and fishes, and from 100 to 1000 in zooplankton (Joshi 1991). Maximum concentration factors of ¹³⁷Cs in a contaminated creek in South Carolina were 4243 in suspended particulates, 938 in detritus, 4496 in algae and macrophytes, 997 in omnivores, 1292 in primary carnivores, and 1334 to 2595 in top carnivores, such as redbreast sunfish (*Lepomis auritus*), largemouth bass (*Micropterus salmoides*), and water

Table 32.24 Maximum Concentration Factors Reported for Selected Elements in Marine Organisms at Various Trophic Levels

Element	Algae	Grazers	Predators
Ag	1000	20,000	3000
Cd	6000	2,000,000	10,000
Ce	4500	300	12
Co	1000	10,000	50,000
Cr	600	300,000	3900
Cs	50	15	10

Mo	200	175	200
Mn	20,000	60,000	100,000
Ni	1000	10,000	80
Pb	3,000,000	2,000,000	200,000
Ru	1000	16	10
Sr	90	85	5
Ti	30,000	20,000	3000
Zn	3000	100,000	20,000
Zr	20,000	30,000	40,000

Note: Concentration factors given in Bq per gram fresh weight tissue/Bq per mL seawater.

Data from Bowen, V.T., J.S. Olsen, C.L. Osterberg, and J. Ravera. 1971. Ecological interactions of marine radioactivity. Pages 200-222 in National Academy of Sciences. *Radioactivity in the Marine Environment*. Natl. Acad. Sci., Panel on Radioactivity in the Marine Environment. Washington, D.C.

snakes (*Natrix spp.*) (Shure and Gottschalk 1976). Cesium uptake by oligochaete worms (*Limnodrilus hoffmeisteri*) is inhibited by low temperatures, potassium concentrations >1 mg/L, and the presence of bacteria (*Escherichia coli*) that compete with the worms for ¹³⁷Cs (Steger and Goodnight 1976).

Atmospheric fallout from nuclear testing is the main pathway by which transuranic nuclides, such as Np, Pu, Cm, and Am, enter the aquatic environment (Guary and Fowler 1990). In general, transuranics are strongly partitioned onto particulates. Living organisms are less enriched than particulate matter by as much as 1000 times, and concentration factors by marine biota are similar for transuranics beyond neptunium (Morse and Choppin 1991). The uptake of ²⁴¹Am and ²⁴⁴Cm from contaminated sediments by a freshwater amphipod (*Hyalella sp.*) and oligochaete (*Tubifex sp.*) is reported, presumably by way of adsorption, and this is considered the principal uptake pathway by benthic organisms in freshwater and marine ecosystems (Sibley and Stohr 1990). Transuranics ingested with food by various crabs were initially excreted with feces; the remaining transuranics entered a soluble radionuclide pool within the animal that was slowly excreted. Decapod crustaceans assimilate and retain 10 to 40% of the transuranic nuclides in their diets. Initially, absorbed radionuclides accumulate in the hepatopancreas but are then translocated to other tissues, particularly to tissues of the exoskeleton. Accordingly, molting strongly influences elimination in crustaceans (Guary and Fowler 1990). Neptunium isotopes have a higher potential for environmental transport in aquatic systems and groundwater than other actinides tested. Laboratory studies with ²³⁵Np and ²³⁷Np, for example, show concentration factors between 275 and 973 in a green alga (*Selenastrum capricornutum*); between 32 and 72 in a daphnid (*Daphnia magna*); 2 in an amphipod (*Gammarus sp.*); and in juvenile rainbow trout, 8.7 in carcass, 1.1 in skin, and 0.3 in muscle over a 96-h period (Poston et al. 1990). When the much higher biological effectiveness of alpha vs. beta or gamma radiation is considered, plutonium isotopes may contribute more artificial radiation dose equivalent to marine invertebrates than either ⁹⁰Sr or ¹³⁷Cs. Concentration factors of

^{239}Pu and marine organisms ranged from 300 to 100,000 in seaweeds, 250 to 690 in molluscs, 760 to 1020 in echinoderms, 2100 in sponges, and as much as 4100 in worms (Noshkin et al. 1971). Concentration factors of $^{239+240}\text{Pu}$ in Lake Michigan ranged between 1 and 10 in predatory salmonids, between 10 and 300 in nonpredatory fish, between 900 and 1200 in amphipods and shrimp, about 200 in zooplankton, and about 6000 in algae (Joshi 1991).

Iodine-131 (half-life of 8 days) may cause deleterious effects in marine teleosts — although ^{131}I concentrations in tissues were not detectable. In one case, coral reef fishes from Eniwetok Atoll collected as long as 8 months after a nuclear explosion had thyroid necroalteration, suggesting a thyrotoxic level of ^{131}I in the environment. Laboratory studies with teleosts injected with ^{131}I showed similar signs of histopathology. Herbivorous fishes and species that habitually consumed bivalve molluscs were the most severely affected (Gorbman and James 1963).

Strontrium-90 is an anthropogenic radionuclide in liquid effluents from some European nuclear power plants. Algae and sediments are the most important accumulators of ^{90}Sr , although levels in gastropods and fish bone and scales are also elevated, suggesting piscine uptake through gills and skin (Stanek et al. 1990). Fish tend to accumulate calcium more than strontium, even when Ca levels in food and water were low. Gill tissue was the most and gut the least discriminatory against Sr. Strontium assimilation was linked to the Sr:Ca ratio in food and water, amounts of Ca derived from each source, and biological discrimination against Sr relative to Ca (Ophel and Judd 1976). The ability of organisms to discriminate between strontium radioisotopes is also documented. In one case, ^{85}Sr was taken up rapidly in bluegill (*Lepomis macrochirus*) muscle and blood and quickly exchanged with stable strontium. However, ^{90}Sr was retained longer than 35 days in these tissues (Reed and Nelson 1969).

Ruthenium-106 appeared in clams from North Carolina within 2 weeks after the third and fifth Chinese nuclear tests in 1965 to 1967. Its retention was resolved into two rate functions with apparent effective half-lives of 40 days and 7 days (Wolfe and Jennings 1971). Iron-55 is a neutron-activation product produced in large quantities from ferrous materials in the immediate vicinity of a nuclear detonation. Concentration factors of ^{55}Fe and plankton in Bikini Atoll ranged from 15,000 to 25,000 (Schell 1976). Silver-110m has been detected in marine organisms after atmospheric weapon tests in the Pacific, in fishes from the Rhone River after the Chernobyl accident, and in fishes near reactor-waste outfalls (Garnier et al. 1990). Silver-110m is depurated rapidly by brown trout (*Salmo trutta*) after high intake exposures via the water or diet (Garnier et al. 1990; Garnier and Baudin 1990). Radiotungsten is produced in quantity by certain types of nuclear devices. In one case, tungsten was the most abundant radionuclide in the environment, accounting for about 90% of the total fallout activity 167 days after the detonation (Reed and Martinedes 1971). Tungsten-181 tended to concentrate in the hepatopancreas and gut of the crayfish (*Cambarus longulus longirostris*). Whole-body elimination consisted of two components: a rapid 1-day component and a second slower component with a biological half-time of 12.2 days (Reed and Martinedes 1971). Benthic organisms take up limited amounts of heavy metals and radionuclides associated with bottom sediments and recycle them to benthic and pelagic food webs. For example, polychaete worms (*Nereis diversicolor*) in contact with ^{65}Zn -contaminated sediments for 5 days lost 50% of accumulated ^{65}Zn in about 19 days on transfer to uncontaminated sediments (Renfro and Benayoun 1976).

32.7.4 Amphibians and Reptiles

Radiation adversely affects limb regeneration of amphibians, alters DNA metabolism, and increases the frequency of chromosomal aberrations and liver lesions (Table 32.25). In some species of amphibians and reptiles, as in many mammals, mortality rates after acute exposure to radiation do not stabilize within 30 days — effectively invalidating the conventional LD50 (30-day postexposure) value. In the rough-skinned newt (*Taricha granulosa*), for example, the minimal LD50 dose at 200 days after irradiation was 2.5 Gy, compared with 350 Gy at 30 days (Willis and

Table 32.25 Radiation Effects on Selected Amphibians and Reptiles

Species, Dose, and Other Variables	Effect	Reference ^a
Leopard lizard, <i>Crotaphytus wislizenii</i> ; chronic field exposure of 0.04–0.06 Gy daily (4–5 Sv yearly) for 3–6 years	No female reproduction in years 3 and 4. In year 5, males were sterile and females had complete regression of ovaries, undeveloped oviductal walls, and hypertrophied fat bodies. In year 6, 75% of females lacked ovaries and 25% had normal ovaries with signs of recent egg deposition; males appeared normal	1
Mud puppy, <i>Necturus maculosus</i> ; 1.1 Gy, single acute exposure	LD50, 30 days postexposure	2
Salamander, <i>Necturus</i> sp.; 0.8 Gy, single acute exposure	LD50, 200 days postexposure	3
Newt, <i>Notophthalmus viridescens</i> ; adults, single acute exposure of 20 Gy, one limb shielded; or 22 Gy, whole body, no limbs shielded	Forelimb regeneration completely suppressed when limbs to be amputated were irradiated directly. Irradiated limbs had severe and protracted inflammation, with total resorption of the affected limbs in 85% of the cases. Shielded limbs subsequently amputated had delays — but not suppression — in rate of forelimb regeneration and skin graft rejection	4
Frog, <i>Rana</i> sp., single acute exposure 7.0–7.2 Gy	LD50, 730 days after exposure	3
7.8 Gy	LD50, 150 days after exposure	3
Snakes, 2 species, 3–4 Gy, single acute exposure	LD50, 90 days after exposure	3
Rough-skinned newt, <i>Taricha granulosa</i> ; single acute exposure 2.5 Gy	LD50, 200 days after exposure; skin lesions and depigmentation	5
>6.5 Gy	Progressive anemia over 6-week postirradiation period; reduction in erythrocyte numbers and weight of spleen	5
80 Gy	LD50, 100 days after exposure	5
350 Gy	LD50, 30 days after exposure	5
Turtles, 4 species, <8–15 Sv, single acute exposure	LD50, 120 days postexposure	3
Slider turtle, <i>Trachemys scripta</i> ; inhabiting a radioactive reservoir, in Aiken, South Carolina. Radionuclide concentrations, in Bq/kg, whole-body fresh weight, (FW) were 1002 for 137Cs and 550 for 90Sr. For controls, these values were 2 for 137Cs and 260 for 90Sr	Contaminated turtles, when compared with controls, had greater variation in DNA content of red blood cell nuclei, suggesting genetic damage. The biological half-life of 137Cs in soft tissues was 64 days; for 90Sr in shell and bone, it was 364 days	6
Spiny tailed lizard, <i>Uromastix hardwickii</i> ; single acute exposure, held for up to 14 days after irradiation 2.25 Gy	No lesions in liver	7
4.5 Gy	No liver lesions, but swollen hepatocytes, increases in bile pigmentation, and altered cytoplasmic degranulation; normal after 14 days	7
9.0 Gy	Some liver lesions, but all livers normal 14 days postexposure	7
Lizard, <i>Uta</i> sp.; 10–22 Gy, single acute exposure	LD50, 30 days postexposure	3

^a 1, Turner et al. 1971; 2, Rose 1992; 3, Hinton and Scott 1990; 4, Sicard and Lombard 1990; 5, Willis and Lappenbusch 1976; 6, Lamb et al. 1991; 7, Gupta and Umadevi 1990.

Lappenbusch 1976). Low temperatures seem to prolong the survival of amphibians exposed to ionizing radiation. The survival was greater of leopard frogs (*Rana pipiens*) held at low temperatures

(5 to 6°C) after total-body exposure to lethal doses of X-rays than of frogs held at higher temperatures. Prolonged survival at low temperatures was due to a prolongation of the latent period rather than to appreciable recovery (Patt and Swift 1948).

The South African clawed frog (*Xenopus laevis*) has been suggested as a bioindicator of radioactive contamination because of the greater radiosensitivity of amphibians than fishes, the ease of maintaining *Xenopus* in the laboratory, and the sensitivity of the *Xenopus* liver to radioactive contamination — including ⁴⁵Ca, which does not accumulate in the liver (Giannetti et al. 1990). *Xenopus* oocytes exposed to X-rays showed single- and double-strand breaks in DNA and oxidative-type base lesions at a frequency between 85 and 95%. *Xenopus* oocytes repaired X-ray induced damage in plasmid DNA; however, some X-ray lesions can stimulate homologous recombination in these cells (Sweigert and Carroll 1990). Slider turtles (*Trachemys scripta*) in a radioactive reservoir show evidence of genetic damage, and this was attributed to long-term exposure to low concentrations of long-lived radionuclides, including ¹³⁷Cs and ⁹⁰Sr (Lamb et al. 1991). Natural populations of toads (*Bufo valliceps*) reportedly can survive genetically damaging doses of ionizing radiation without impairment of population integrity (Whicker and Schultz 1982b). Toads and many other species share a high attrition on the large numbers of young produced each generation, and this provides an agency for intensive selection. Also under this regime, recessive mutants are eliminated as they are exposed through inbreeding in future generations (Whicker and Schultz 1982b). Sterility in field collections of the leopard lizard (*Crotaphytus wislizenii*) and the whip-tail lizard (*Cnemidophorus tigris*) was reported after long-term exposure of 3 to 5 years to various doses of gamma radiation (i.e., 4 to 5 Sv annually in *Crotaphytus* and 2.0 to 2.5 Sv annually in *Cnemidophorus*) (Turner et al. 1971). However, a third species of lizard in the study area (side-blotched uta, *Uta stansburiana*) reproduced normally (Turner et al. 1971).

The retention of selected isotopes by amphibians and reptiles is quite variable. For example, whole-body retention of ¹³¹I after intraperitoneal injection in the rough-skinned newt showed two distinct loss components with biological half-lives of 2 and 210 days. The slower component accounted for 26% of the administered activity; thyroid contained 78% of the total ¹³¹I and clearly accounted for the long-term component (Willis and Valett 1971). However, similar studies with ¹³¹I and the leopard frog showed three distinct loss components (0.1 day; 1.4 to 2.9 days; 44.3 to 69.4 days); loss of each component was greater at 25°C than at 10°C. Also, the fast component probably represented plasma clearance through urinary excretion (Willis and Valett 1971).

32.7.5 Birds

Among birds, as in most other tested species, there is a direct relation between dose and mortality at single high doses of ionizing radiations (Whicker and Schultz 1982b; [Table 32.26](#)). For any given total dose, the survival of a bird is higher if the dose is delivered at a lower rate or over a longer period of time and suggests that biological repair processes compensate for radiation-induced cellular and tissue damage over a prolonged period or at a comparatively low dose rate (Brisbin 1991). Nestling bluebirds (*Sialia sialis*) were more resistant to gamma radiation than young domestic chickens (*Gallus* sp.), and nestling great crested flycatchers (*Myiarchus crinitus*) were more sensitive than bluebirds (Willard 1963). Passerine nestlings are more resistant to radiation stress than adults of larger-bodied precocial species (Brisbin 1991). But the comparatively resistant passerine nestlings frequently show a disproportional disturbance in radiation-induced growth, resulting in a reduction of overall survival. For example, if feather growth is stunted, death results from the inability to escape predators because of impaired flight (Brisbin 1991).

Free-living, resident bird populations in the vicinity of sites contaminated with low levels of ionizing radiations generally have negligible genotoxic effects (George et al. 1991). However, 14% of mallards (*Anas platyrhynchos*) from an abandoned South Carolina reactor cooling reservoir heavily contaminated with ¹³⁷Cs (mallards contained an average of 2520 Bq ¹³⁷Cs/kg whole-body FW) had abnormal chromosome numbers and unusual variability in the concentration of erythrocyte

DNA (George et al. 1991). Contaminated waterfowl rapidly eliminate accumulated radionuclides, suggesting inconsequential long-term damage to the birds and little hazard to human consumers of waterfowl flesh (Halford et al. 1983). This conclusion was from a study wherein mallards were held for 68 to 145 days on liquid radioactive waste ponds in southeastern Idaho and then transferred to an uncontaminated environment for 51 days. The biological half-life in mallards under these conditions was 10 days for ^{131}I and ^{134}Cs , 11 days for ^{137}Cs , 22 days for ^{140}Ba , 26 days for ^{75}Se , 32 days for ^{58}Co , 67 days for ^{60}Co and ^{65}Zn , and 86 days for ^{51}Cr . At the time of removal from the waste ponds, radionuclide concentrations were highest in gut, then feather, liver, and muscle, in that order. After 51 days in a radionuclide-free environment, decreasing order of radionuclide concentrations was feather, liver, muscle, and gut (Halford et al. 1983).

Zinc-65 in trace amounts is accumulated by migratory waterfowl in the Pacific flyway of North America from ^{65}Zn discharged into the Columbia River from water-cooled reactors at Hanford, Washington (Curnow 1971). The retention of ^{65}Zn in mallards was affected by sex and season, but not by the age of the duck. Biological retention of ^{65}Zn was greater in males (Tb 1/2 of 34.7 days) than in females (29.8 days), and greater in October (38 days) than in the spring (32 days). Egg production accounted for the elimination of 25% of the ^{65}Zn and feather molt of 2% to 8% (Curnow 1971). Retention of ^{60}Co and ^{137}Cs — but not ^{109}Cd — in the common bobwhite (*Colinus virginianus*) after either acute or chronic exposure to contaminated food is similar. The biological half-life in bobwhites during exposure for 21 days was 8 days of ^{109}Cd , 11 days of ^{137}Cs , and 13 days of ^{60}Co . When radioisotopes were administered during a single 4-h feeding, Tb 1/2 values were 3 days of ^{109}Cd , 10 days of ^{137}Cs , and 15 days of ^{60}Co (Anderson et al. 1976). The biological half-life of ^{137}Cs in avian tissues is about 6.0 days in domestic chickens (Andersson et al. 1990); 6.7 days in the bluejay (*Cyanocitta cristata*) (Levy et al. 1976); 5.6 days in the American wood duck (*Aix sponsa*); and 11.7 days in mallards (Cadwell et al. 1979). Domestic poultry, when compared with mammals, seem to accumulate a higher fraction of the daily ingested $^{137}\text{Cs}/\text{kg}$ muscle, but levels were effectively reduced by feeding an uncontaminated ration for at least 10 days prior to slaughter (Andersson et al. 1990).

Table 32.26 Radiation Effects on Selected Birds

Species, Dose, and Other Variables	Effect	Reference ^a
Green-winged teal, <i>Anas carolinensis</i> ; 4.8 Gy, single acute exposure	LD50, 30 days postexposure	1
Northern shoveler, <i>Anas clypeata</i> ; 8.9 Gy, single acute exposure	LD50, 30 days postexposure	1
Blue-winged teal, <i>Anas discors</i> ; 7.2 Gy, single acute exposure	LD50, 30 days postexposure	1
Birds		
Eggs, passerine species, single acute exposure, 5–10 Gy	LD100	2
Nestlings, various species, 1 Gy daily	Growth retardation	3
Common quail, <i>Coturnix coturnix</i> ; fertilized eggs, exposed first 9 days of incubation, single acute exposure		
5 Gy	Negligible effect on survival	4
7 Gy	Mortality >50%	4
9 Gy	All dead before hatch	4
Domestic chicken, <i>Gallus</i> sp.		
Single acute exposure		
Eggs of broilers exposed to 0.05–2.1 Gy before incubation	No adverse effects on embryonic development at 1.6 Gy and lower; at 2.1 Gy, adverse effects on development, survival, and body weight of hatched chicks	5
Chicks, age 15 days		
2.1 Gy	Reversible changes in blood chemistry within 60 days; no deaths	6
6.6 Gy	Irreversible and permanent damage to red blood cells, hemoglobin, and hematocrit; all dead within 7 days	6

Table 32.26 (continued) Radiation Effects on Selected Birds

Species, Dose, and Other Variables	Effect	Reference ^a
Dietary exposure		
Laying hens fed diet containing 400 Bq $^{137}\text{Cs}/\text{kg}$ ration for 4 weeks	Of total ^{137}Cs ingested, 3% was distributed in egg contents (29–33 Bq/kg egg; 2 Bq egg); 9% in muscle (171 Bq/kg FW); and 81% in excreta	7
Broiler chickens fed diets containing 400 Bq $^{137}\text{Cs}/\text{kg}$ ration for 40 days; some diets contained up to 5% bentonite	Feeding with bentonite reduced ^{137}Cs concentration in muscle by 32% from 155 to 105 Bq/kg FW	7
Black-headed gull, <i>Larus ridibundus ridibundus</i> ; eggs, 9.6 Gy over 20 days	LD50	3
Great crested flycatcher, <i>Myiarchus crinitus</i> ; nestlings, single acute exposure >8 Gy	All dead by fledging	8
Eastern bluebird, <i>Sialia sialis</i> , single acute exposure		
Nestlings, age 2 days		
3 Gy	Reduced growth after 16 days	8
3–5 Gy	Reduced growth and shorter primary feathers at fledging	8
4–12 Gy	Developed normally and fledged successfully	2
5–6 Gy	LD50, nestling to fledgling	8
25 Gy	LD50, 16 days postexposure	8
30 Gy	All dead 4 days postexposure	2, 8
Fertilized eggs, 6 Gy	All dead before hatch	2
European starling, <i>Sturnus vulgaris</i> ; >2 Gy, single exposure	Fatal	9
Tree swallow, <i>Tachycineta bicolor</i>		
0.006 mGy/h during breeding season, equivalent to annual dose of about 50 mSv	No adverse effects on breeding performance of adults or growth performance of nestlings	10
0.9–4.5 Gy, single acute exposure, nestlings	Adverse effects on growth, survival, or both	2
1.0 Gy daily, chronic	Reduced hatch, depressed growth	2
House wren, <i>Troglodytes aedon</i> ; fledglings, 0.9 Gy, single acute exposure	Growth reduction	9

^a 1, Hinton and Scott 1990; 2, Millard and Whicker 1990; 3, Lowe 1991; 4, Wetherbee 1966; 5, Zakaria 1991; 6, Malhotra et al. 1990; 7, Andersson et al. 1990; 8, Willard 1963; 9, Rose 1992; 10, Zach et al. 1993.

32.7.6 Mammals

The mammalian sensitivity to acute and chronic exposures of ionizing radiation, ability to retain selected radionuclides, and effect of biological and abiotic variables on these parameters are briefly summarized in Table 32.27. These data clearly indicate a dose-dependent effect of radiation on growth, survival, organ development, mutagenicity, fatal neoplasms, kidney failure, skeletal development, behavior, and all other investigated parameters. In general, fetuses and embryos were most sensitive to ionizing radiation, and acute or chronic exposures between 0.011 and 0.022 Gy were demonstrably harmful to mice, rats, and guinea pigs.

Table 32.27 Radiation Effects on Selected Mammals

Species, Dose, and Other Variables	Effect	Reference ^a
Short-tailed shrew, <i>Blarina brevicauda</i> ; 7.8 Gy, single acute exposure	LD50, 30 days postexposure	1
Cow, <i>Bos</i> sp.		
Oral intake of 0.89 Bq ^{129}I , whole animal	Thyroid contained 0.97 Bq $^{129}\text{I}/\text{kg}$ fresh weight (FW) vs. <0.0012 Bq/kg FW for all other tissues	2
Fed 6.4 Bq ^{129}I daily for 8 days	After 8 days, 22% of total dose of 51.2 Bq was in thyroid; after 63 days, thyroid contained 1 Bq/kg FW and other tissues <0.01 Bq/kg FW	3

Table 32.27 (continued) Radiation Effects on Selected Mammals

Species, Dose, and Other Variables	Effect	Reference^a
Dog, <i>Canis familiaris</i>		
Beagle embryos age 55 days, or pups 2 days old, given single acute exposure of 0.16, 0.83, or 1.25 Gy	Dose-dependent increase in immature dysplastic glomeruli and other signs of progressive renal failure	4
Beagles, prenatal and early neonatal stages, given single acute dose of 0.2–1.0 Gy, then observed over 11-year life span	Irradiation at all ages was associated with increased risk of: decreased fertility; inhibited growth and development; lower brain weight; and increase in fatal neoplasms	5
Beagle embryos or pups. As above, 2.24–3.57 Gy	Reduction in total number of nephrons and progressive renal failure	4
Beagles, 17–20 months old, single intravenous injection of 200–440,000 Bq ^{226}Ra /kg body weight (BW)	Dose-dependent increase in skeletal malignancies in 36% of dogs during lifetime	6
Beagles, age 5 years, given single injection of ^{226}Ra , in Bq/kg BW, of 39,000, 116,000, or 329,000. Injected ^{226}Ra solutions also contained ^{210}Po , ^{210}Pb , and ^{210}Bi	At lowest dose of 39 kBq/kg BW, kidney was normal, death after 2032 days. At intermediate dose, death in 1210 days; at high dose, death in 581 days. Tubular degeneration and necrosis of kidney at 116 and 329 kBq	7
Beagles, age 7 years, single injection of ^{226}Ra (no contaminating ^{210}Po , ^{210}Pb , or ^{210}Bi) at 45,000 Bq/kg BW, or 122,000 Bq ^{210}Po /kg BW	No kidney damage with ^{226}Ra , but kidney damage with ^{210}Po	7
Beagles, age 7 years given single injection of 1,629,000 Bq ^{226}Ra /kg BW, equivalent to 1.89 Gy (from ^{210}Po contaminants), or 4,831,000 Bq ^{226}Ra /kg BW = 5.15 Gy from ^{210}Po	At low dose, all dead after 516 days; at high dose, all dead in 266 days. Death was from renal failure	7
Guinea pig, <i>Cavia</i> sp.; chronically irradiated daily during 8-h exposure. Daily dose, in Gy		
0.000	Mean survival time of 1372 days	8
0.001	50% dead in 1457 days	8
0.011	50% dead in 1224 days	8
0.022	50% dead in 978 days; anemia	8
0.044	50% dead in 653 days; anemia	8
0.088	50% dead in 187 days; anemia	8
Monkey, <i>Cebus apella</i> ; 1 Gy, whole body, single acute exposure	Leucocyte reduction in 6 days; blood chemistry normal after 90 days	9
Chinese hamster, <i>Cricetus</i> sp.; ovary cells, single acute dose ranging between 0.005 and 0.06 Gy	Increased frequency of sister chromatid exchange at 0.005 Gy; increased numbers of chromosomal aberrations at >0.02 Gy; no significant increase in cell death	10
Syrian hamster, <i>Cricetus</i> sp.; 0.12–2 Gy, single acute exposure	Genes modifying cytoskeletal development adversely affected at all doses within 3 h by both high LET (neutrons) and low LET (gamma rays, X-rays) radiations	11
Human, <i>Homo sapiens</i>		
Developing forebrain, 0.18–0.55 Gy (estimated dose to prenatally exposed Japanese atomic bomb survivors)	Seizures in childhood; reduced school performance at least through age 11 years; some cases of severe mental retardation by age 17 years	12
Fetus, 1 Sv, 8–15 weeks of gestation	40% probability of severe mental retardation; IQ score lowered 30 points	13
Sperm chromosomes, 0.23, 0.45, 0.91, or 1.82 Gy, single acute exposure	Chromosomal aberrations increased linearly from 6.1% at 0.23 Gy to 62% at 1.82 Gy	14
Thyroid, single acute exposure		
0.065 Gy	Minimum dose for induction of thyroid carcinoma	15
3–5 Gy	5% increase in thyroid malignancies 20 years after exposure, with tumors appearing 4–5 years after exposure	16

Table 32.27 (continued) Radiation Effects on Selected Mammals

Species, Dose, and Other Variables	Effect	Reference^a
7–10 Gy	Linear dose relation to thyroid cancer, and pathology in adjacent parathyroid and salivary glands	16
Whole body		
Single brief exposure		
0.05–0.11 Sv	Doubles rate of cancers	17
0.15 Sv	Temporary sterility, males	13
0.18–0.29 Sv	Doubles rate of pregnancy complications	17
0.5–2.0 Sv	Opacity of lens; depression of hematopoiesis	13
0.68–1.10 Sv	Doubles rate of F1 generation mortality	17
1 Sv, adults	1% probability of hereditary effects; 4% probability of fatal cancer in occupational workers	13
2.5–6.0 Sv	Sterility, females	13
3.5–6.0 Sv	Permanent sterility, males	13
5.0 Sv	Cataracts	13
<1 Gy	Survival almost certain	18
1–2 Gy	Survival probable	18
1–2 Gy	About 5% mortality in several months from infection and hemorrhage	19
2–5 Gy	Survival possible	18
2–7.5 Gy	Hematopoietic syndrome characterized by bone marrow damage, anemia, lowered immune response, hemorrhage, and sometimes death	20
3–5 Gy	Death in 30–60 days, bone marrow damage	13
5–10 Gy	100% adversely affected within weeks with bone marrow abnormalities; about 45% mortality	19
5–15 Gy	Death in 10–20 days; GI tract and lung damage	13
5–20 Gy	Survival improbable	18
7.5–30 Gy	Gastrointestinal damage: nausea, vomiting, anorexia, diarrhea, lethargy, weight loss, dehydration, exhaustion, and death	20
10–15 Gy	All adversely affected with intestinal problems within 30 min; 95% dead in 2 weeks from enterocolitis shock	19
>15 Gy	Death in 1–5 days; nervous system damage	13
>50 Gy	All dead in 48 h, usually from cerebral edema	19
Annual dose rate or protracted annual exposure for many years		
>0.1 Sv	Lens opacity	13
>0.15 Sv	Cataracts	13
>0.2 Sv	Sterility, females	13
0.4 Sv	Temporary sterility, males; hematopoiesis depression	13
2.0 Sv	Permanent sterility, males	13
Rhesus monkey, <i>Macaca mulatta</i>		
Females, single acute dose of 0.25–6.5 Gy, observed over a 17-year postexposure period	At doses >2 Gy, 53% developed endometriosis (abnormal uterine growth) vs. 26% in controls; irradiated monkeys weighed 43% less than controls, 35% were anorexic, 89% had abnormal uterine anatomy, and histopathology in most tissues exceed 50% frequency	21
Exposed to single brief whole-body proton irradiation (protons in the energy range encountered by astronauts) ranging between 0.25 and 12 Gy and observed for 24 years until death	Dose-dependent life shortening of at least 40 months at doses >4.5 Gy; mean life shortening was 200–500 monkey days per Gy (equivalent to 500–1250 human days). Brain cancer first observed in 8 Gy group after 13 months. Monkeys receiving 3–8 Gy had a	22

Table 32.27 (continued) Radiation Effects on Selected Mammals

Species, Dose, and Other Variables	Effect	Reference^a
Mammals	significantly higher proportion of cancer deaths than those receiving 0.25–2.8 Gy. Latent period for cancer in animals receiving 4–8 Gy ranged from 13 months to 20 years	
10 species, 2.8–8.05 Gy, single acute exposure	LD50, 30 days after exposure	23
Various species, bioconcentration factors (BCF) of selected radionuclides

Various species, biological half-life of selected radionuclides		
²⁴¹ Am		
Bone	27.4 years	25
Gonads	>27.4 years	25
Kidney, liver	11 years	25
Muscle	4 years	25
Serum	5 days	25
¹³⁷ Cs, kidney, liver, and muscle	30–50 days	25
²³⁸⁺²³⁹⁺²⁴⁰ Pu		
Bone	49 years	25
Gonads	>49 years	25
Kidney, liver	19 years	25
Muscle	5.5 years	25
Serum	5 days	25
Singing vole, <i>Microtus miurus</i> ; 8.46 Gy, single acute dose	LD50, 30 days after exposure	26
Creeping vole, <i>Microtus oregoni</i> ; 6.51 Gy, single acute dose	LD50, 30 days after exposure; sensitivity may be associated with low chromosome complement	26
Meadow vole, <i>Microtus pennsylvanicus</i> ; single brief exposure		
7.04 (6.35–7.98) Gy, irradiated in November	LD50, 30 days after exposure; irradiated voles released into environment	27
7.67 (7.01–8.39) Gy, irradiated in May	LD50, 30 days after exposure; irradiated voles released into environment	27
8.44 (8.17–8.77) Gy	LD50, 30 days after exposure; irradiated voles held in laboratory	7
Pine vole, <i>Microtus pinetorum</i> ; single brief exposure		
7 Gy	None dead 30 days after exposure; weight normal	28
8.8 Gy, males	LD50, 30 days after exposure; weight loss in survivors	28
10.0 Gy, females	LD50, 30 days postexposure; weight loss in survivors	28

Table 32.27 (continued) Radiation Effects on Selected Mammals

Species, Dose, and Other Variables	Effect	Reference^a
House mouse, <i>Mus musculus</i> ; single brief exposure		
7.5–8.8 Gy	LD50, 30 days postexposure	26, 29
7.8, 8.1, 8.3, or 9.8 Gy	LD50, 30 days after exposure; 4 different strains	1
Mouse, <i>Mus sp.</i>		
Intraperitoneal injection		
Single injection of 850 Bq $^{227}\text{Ac}/\text{kg}$ BW alone or in combination with ^{227}Th at 18,500, 74,000, or 185,000 Bq/kg BW	The highest bone cancer incidence was observed at the highest doses of ^{227}Th . The addition of ^{227}Ac resulted in an additional osteosarcoma incidence only at 18,500 Bq $^{227}\text{Th}/\text{kg}$ BW	30
Single injection of ^{241}Am at concentrations — in Bq/kg BW — of 0.02, 0.06, 0.19, 0.37, or 1.2	Survival time decreased from 594 days for controls and 0.02 group to 135 days in the 1.2 group; increased frequency of tumors in bone, liver and lymph	31
Adult males, 84 days old, given 2–64 Bq $^{224}\text{Ra}/\text{mouse}$, either as single injection, or 8 injections at 3.5-day intervals over 4 weeks; observed for 24 months	No difference in single or multiple injection effects. No effect at 16 Bq and lower. At 32 and 64 Bq, reduction in bone growth and osteonecrosis of mandible ("radium jaw")	32
Oocytes given single exposures of 0.1, 0.15, or 0.25 Gy; immature oocytes examined 8–12 weeks later	Controls had 100% survival and zero chromosome aberrations; the 0.1 Gy group had 30% survival and 2% chromosome aberrations; 0.15 Gy group had 17% survival and 6% chromosome aberrations; 0.25 Gy group had 5% survival and 23% chromosomal aberrations	33
Whole body, single brief exposure		
1 Gy	Acute exposure may extend life span	34
1.35 Gy	Doubles mutation rate of spermatogonia	17
7.6 Gy	LD50, 30 days postexposure	35
9.5 Gy	LD100, 30 days postexposure	35
10.0 Gy, adult males, 16–20 weeks old, observed for 7 days	At 90 min after irradiation, locomotor activity was suppressed and remained depressed; at 4 days, body weight decreased; at day 7, offensive aggressive behavior	20
12.5 Gy	LD100, days 3–7 postexposure	35
0.12–2.5 Sv	Doubles rate of heritable translocations in males	17
0.25–2.5 Sv	Doubles rate of congenital malformations in females	17
0.4–1.0 Sv	Doubles frequency of dominant lethal mutations	17
0.5–1.0 Sv	Doubles rate of heritable translocations in females	17
0.8–2.5 Sv	Doubles rate of congenital malformations in males	17
1.5–3.0 Sv	Doubles rate of recessive lethal mutations	17
Chronic exposure, daily dose over 8-h period, in Gy		
0.0	Mean survival time of 703 days	8
0.001	Mean survival of 761 days	8
0.011	Mean survival time of 684 days; 50% weight gain over controls	8
0.022	50% dead in 630 days	8
0.044	50% dead in 591 days	8
0.088	50% dead in 488 days	8
Total yearly dose, chronic exposure, 16 Gy (about 0.044 Gy daily)	Tolerated	34
Domestic ferret, <i>Mustela putorius</i> ; 2, 4, or 6 Gy; single brief exposure; adult males	All doses depressed locomotion; vomiting in 22 min at 2 Gy, 13 min at 4 Gy, and 11 min at 6 Gy. Various substituted benzamides reduced vomiting	36

Table 32.27 (continued) Radiation Effects on Selected Mammals

Species, Dose, and Other Variables	Effect	Reference^a
Marsh rice rat, <i>Oryzomys palustris</i> ; 5.25 Gy, single acute exposure	LD50, 30 days after exposure; this species was the most sensitive of the 10 rodent species tested	1
Domestic sheep, <i>Ovis aries</i>		
Ewes fed hay containing 9000 Bq ¹³⁷ Cs/kg DW for 50–60 days, then 40 days on uncontaminated hay; some diets contained 30 or 60 g of vermiculite daily, or 2 g of ammonium ferricyanoferrate (AFCF) daily	Maximum levels of ¹³⁷ Cs were reached in 10 days in milk and 35–40 days in muscle. Radionuclide transfer to milk and meat was reduced 2.5 times at daily intakes of 30 g vermiculite, and 8 times at 60 g vermiculite or 2 g AFCF	37
Ewes given oral dose of 74,000 Bq ¹³⁷ Cs, observed for 76 days	At 76 days, only 26% of ¹³⁷ Cs remained; tissue concentrations, in Bq ¹³⁷ Cs/kg FW, were: 77,000 in salivary gland; 42,000 in muscle; 24,000–36,000 in pancreas, liver, and kidney; 14,000–17,000 in spleen and lung; and <8000 in other tissues	38
Lambs fed 21 kg of vegetation containing 16,600 Bq of ²³⁸⁺²³⁹⁺²⁴⁰ Pu and 14,400 Bq of ²⁴¹ Am over a 14-day period, followed by 4 days on uncontaminated hay	Of the Pu ingested, 46% was in liver, 30% in bone, 12% in muscle, and 2% in lung; for ²⁴¹ Am, these values were 19% in liver, 15% in bone, 6% in meat, and 0.5% in lungs	39
Lamb given single intravenous injection of 23 Bq ²³⁸ Pu plus 27 Bq ²⁴¹ Am and held for 11 days	Liver retained up to 44% of the injected ²³⁸ Pu and 28% of the ²⁴¹ Am; bone had 21% of the ²³⁸ Pu and 20% of the ²⁴¹ Am	39
Great basin pocket mice, <i>Perognathus parvus</i> ; 8.56 Gy, single exposure	LD50, 30 days after exposure; hair loss within 7 days	26
White-footed mice, <i>Peromyscus leucopus</i> ; whole body, single brief exposure		
9.5 Gy, both sexes irradiated	No reproduction	40
9.5 Gy, males only irradiated	91% of pairs successful in producing young	40
9.5 Gy, females only irradiated	40% of pairs reproduced successfully	40
10.7 Gy	LD50, 30 days postexposure; this species was the most radioresistant of 10 species of rodents tested	1
Deer mice, <i>Peromyscus maniculatus</i> ; 9.19 Gy, single brief exposure	LD50, 30 days after irradiation	26
Old-field mouse, <i>Peromyscus polionotus</i> ; 11.25 Gy, single exposure	LD50, 30 days after exposure	29
Norway rat, <i>Rattus norvegicus</i> ; 8.67 Gy, single exposure	LD50, 30 days postexposure	1
Laboratory white rat, <i>Rattus</i> spp.		
0.001, 0.01, or 0.1 Gy; single acute whole-body exposure; adult males; killed up to 180 days after exposure	Fertility reduction was zero in the low-dose group, 25% at 0.01 Gy, and 66% at 0.1 Gy. Primary sites of damage were tubuli of the testes and spermatogonia. The high-dose group also had altered serum hormone chemistry after 30 days that persisted for 180 days	41
Pregnant rats given single, brief exposure to 0.25, 0.5, 0.75, or 1 Gy on gestational day 15; fetuses examined 24 h after irradiation	No effect at 0.5 Gy and lower on cerebral mantle of developing brain; however, dose-related increase in pyknotic cells and macrophages in cortical mantle of fetus for all doses	42
Pregnant females exposed on day 15 of gestation to 0.75 Gy; fetuses examined 1–3 months after birth	Rats irradiated <i>in utero</i> had impaired gait, slower motor behavior, difficulty in learning motor tasks, reduced growth rate, and reduced thickness of cerebral cortex	43
<1 Gy, whole body, single exposure	No brain pathology	44
2 Gy, whole body, single exposure	Brain pathology	44
Adult males conditioned to avoid electric shock by pressing a lever were subjected to various whole-body acute exposures		
1.5 Gy daily for 5 consecutive days (total 7.5 Gy)	No significant change in performance over 8 weeks	45

Table 32.27 (continued) Radiation Effects on Selected Mammals

Species, Dose, and Other Variables	Effect	Reference^a
4.5 Gy, single exposure	No effect on performance for at least 6 weeks	45
7.5 Gy, single exposure	Significantly decreased response rate over the first 4 weeks; performance normal during weeks 5–6; 9% reduction in body weight	45
9.5 Gy, single exposure	LD100, 30 days postexposure	45
Single local dose of 5–20 Gy to various salivary glands	Dose-dependent decrease in salivary flow rate and sodium composition of saliva; at 10 Gy and higher, changes were irreversible	46
25 Gy, single whole-body exposure	50% dead 30–60 days postirradiation from fatal stomach damage; significant liver damage in survivors	47
Eastern harvest mouse, <i>Reithrodontomys humulis</i> ; 9.5 Gy, single exposure	LD50, 30 days after exposure	1
Rodents, single brief exposure		
3.8–13.3 Gy, 13 species	LD50, 30 days postexposure; females more sensitive than males	48
4–8 Gy, 5 species	Dead rodents had histopathology of lymph nodes, thymus, bone marrow, liver, lung, and gonads; male survivors had atrophied testes	26
5.3–10.7 Gy, 10 species	Range of LD50 values (30 days after exposure); survivors showed conjunctivitis, ataxia, diarrhea, passiveness, cessation of feeding, aggressiveness, and graying of pelage	1
Squirrel monkey, <i>Saimiri</i> spp.; fetuses, 80–90 days postconception; given 0.1 or 1.0 Gy, single acute exposure; young observed from birth to age 2 years	No effect on behavior at 0.1 Gy. At 1 Gy, emotional stability and vision impaired at age 30 days, learning impaired at 1 year; normal at 2 years	44
Cotton rat, <i>Sigmodon hispidus</i>		
Females given 5, 7.5, 9, 10.5, or 12 Gy whole body once a month for 4 months, then released into a 0.4-ha impoundment with unirradiated males and females for 15 days	Survival was 91% at 5 Gy and 25% at 12 Gy; intermediate doses had intermediate survival	49
9.58 Gy, single brief exposure	LD50, 30 days after exposure	1
11.2 Gy, single acute exposure, adult females	LD50, 30 days after exposure	49
11.3 Gy, single exposure, adult females	LD50, 15 days postexposure	49
Eastern chipmunk, <i>Tamias striatus</i>		
2–4 Gy, single exposure	Irreversible injury throughout life, but life span was increased	50
Given single exposure of 2 or 4 Gy, then released into environment	Irradiated chipmunks had consistently smaller home ranges and moved shorter distances than did controls	51
Iodine-131, half-time release rate from thyroid; females vs. males		
Summer	2.3 h vs. 263 h	52
Spring	156 h vs. 217 h	52
Autumn	126 h vs. 129 h	52

32.7.6.1 Survival

Survival time is inversely related to dose in whole-body, acute exposures to ionizing radiation (Figure 32.9). In general, hematopoietic organs are most sensitive, and the gastrointestinal tract and central nervous system are next most sensitive (UNSCEAR 1988). Body weight is an important modifier, and heavier mammals are usually most sensitive to radiation (Figure 32.10). Feral rodent populations are at risk from ionizing radiation through the reduction in numbers from direct kill and indirectly from the radiation-caused diminution of reproduction (Di Gregorio et al. 1971).

Low doses of ionizing radiation are beneficial to many species of mammals. Effects of radiation hormesis include increased survival and longevity, lowered sterility, increased fecundity, and accelerated wound healing (Luckey 1980). Low doses of gamma irradiation cause irreversible injury to the eastern chipmunk (*Tamias striatus*), although the life-span was significantly longer (Thompson et al. 1990). Acquired radioresistance after exposure to a low dose of ionizing radiation has been described in rats, mice, and yeast (Yonezawa et al. 1990). In mice, for example, low doses of X-irradiation (not higher than 0.15 Gy) enhanced 30-day survival if given 2 months prior to a dose of 7.5 Gy. The low-dose exposure seems to stimulate the recovery of blood-forming stem cells after the second irradiation and favors a decrease in the incidence of bone-marrow death. The exact mechanisms of radiation hormesis are unknown because effects are not related to and not predictable from the high-dose exposure (Yonezawa et al. 1990).

Irradiated small mammals released into the environment had a lower survival rate than laboratory populations, suggesting that the extrapolation from laboratory results may overestimate the radioresistance of free-ranging voles and other small animals because of the general level of stress in the population (Iverson and Turner 1976). The opposite was observed in eastern chipmunks given high sublethal doses of X-rays. Chipmunks had an overall reduction in mobility when they were released

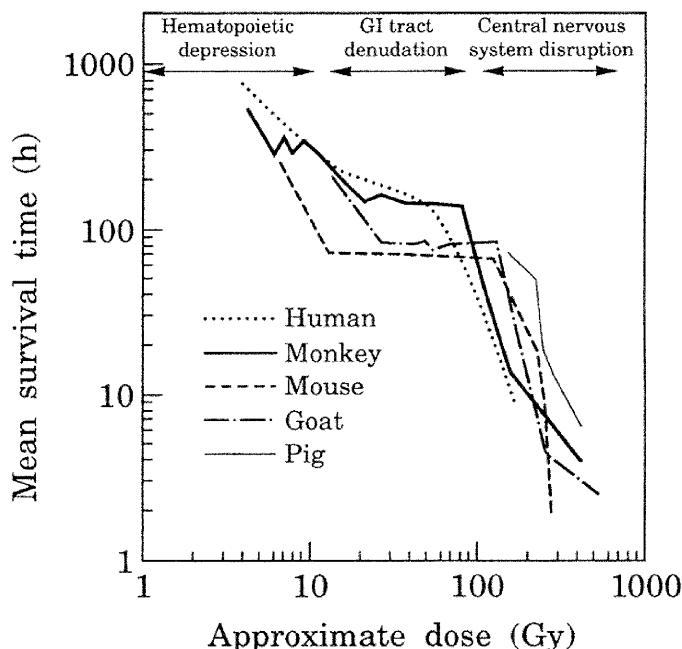

Figure 32.9 Survival time and associated mode of death of selected mammals after whole-body doses of gamma radiation. (Modified from Hobbs, C.H. and R.O. McClellan. 1986. Toxic effects of radiation and radioactive materials. Pages 669-705 in C.D. Klaassen, M.O. Amdur, and J. Doull [eds.]. *Casarett and Doull's Toxicology. Third Edition*. Macmillan, New York; United Nations Scientific Committee on the Effects of Atomic Radiation [UNSCEAR]. 1988. Sources, Effects and Risks of Ionizing Radiation. United Nations, New York. 647 pp.)

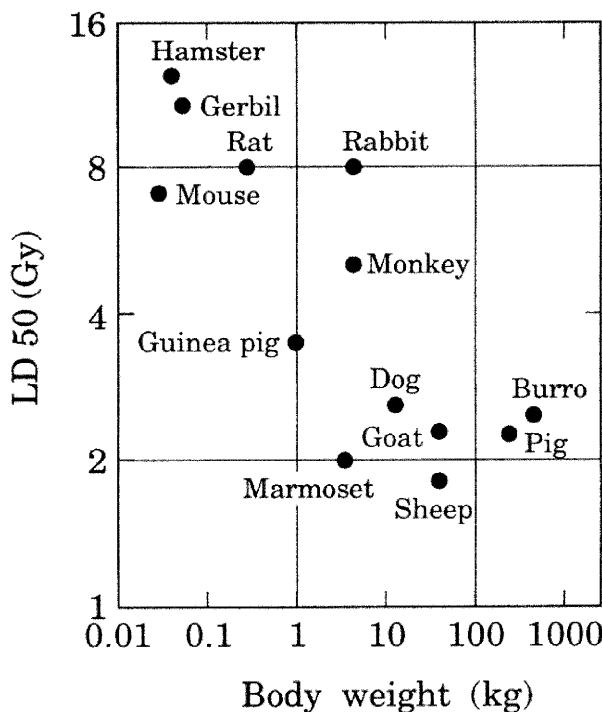

Figure 32.10 Relation between body weight and radiation-induced LD₅₀ (30 days postexposure) for selected mammals. (Modified from United Nations Scientific Committee on the Effects of Atomic Radiation [UNSCEAR]. 1988. Sources, *Effects and Risks of Ionizing Radiation*. United Nations, New York. 647 pp.)

into the environment and a higher survival rate than controls (Snyder et al. 1976), possibly because of increased predation on the more mobile controls.

32.7.6.2 Carcinogenicity

The risk of the induction of cancer is a recognized somatic effect of low doses of ionizing radiation, as judged by epidemiological studies of Japanese survivors of U.S. nuclear bombs (Coggle and Williams 1990) and of Marshall Islanders, underground miners, and radium watch dial workers (Bowden et al. 1990). However, Yoshimoto et al. (1990), in a study on the occurrence of malignant tumors in Japanese children <10 years old and born between 1946 and 1982 to survivors of the atomic bombings in 1945, found no statistically significant increase in malignant tumors in the children of parents exposed to >0.01 Sv whole-body radiation (mean gonadal exposure of 0.43 Sv) at the time of the atomic bombings when compared to a suitable control group. Nutritional status is important when treating malignant tumors. Unlike tumors of nonanemic individuals, tumors in anemic mice and humans frequently do not respond satisfactorily to radiotherapy (McCormack et al. 1990).

Ionizing radiation induces basal cell carcinomas in skin and is active in the initiation of malignant tumors and in the progression of benign to malignant tumors (Bowden et al. 1990). Skin has been widely used in studies of carcinogens because of its accessibility and the visibility of its tumors. All data on experimental radiogenic skin cancer in mice are on a relatively narrow and well-defined response curve. However, mouse skin is about 100 times more sensitive than human skin (Coggle and Williams 1990), strongly suggesting that appropriate animal models are necessary in the extrapolation of results to other species.

Thyroidal cancer in dogs and sheep has been induced with repeated administrations of ^{131}I , although single injections of ^{131}I failed to induce thyroid cancer in adult animals except in some strains of laboratory rodents (Walinder 1990). Humans with a prior history of ^{131}I and other radiation exposure in childhood are at a significantly higher risk of thyroid carcinogenesis, and females are at higher risk than males. The minimum latent period in humans is about 4 years, and neoplastic lesions may develop as late as 40 years after irradiation (Kim et al. 1990). Historically, the human thyroid received radiation from irradiation of the scalp for epilation (up to 0.5 Gy), thymus (up to 5 Gy), tonsils and adenoids (8 Gy), and facial acne (15 Gy). Higher doses of external irradiation (up to 50 Gy) were used from 1920 to 1940 for the treatment of hyperthyroidism in adults and are still used for the treatment of cervical malignancies in people of all ages (Refetoff 1990).

Radium-induced bone malignancies after exposure to ^{226}Ra are similar in beagles and humans, and the tibia in dogs is especially sensitive (Lloyd et al. 1991). “Radium jaw” has been described in humans as a late effect of accidental ingestion or therapeutic administration of long-lived radium isotopes, such as ^{226}Ra and ^{228}Ra , and is characterized by bone tumors, spontaneous fractures, and osteosclerosis (Robins 1990). However, the short-lived ^{224}Ra (T_b 1/2 of 3.6 days) produces similar effects in mice, suggesting that the events that trigger radium-induced bone disorders occur within days of incorporation, although the consequence is a late effect (Robins 1990).

Aerosol exposures of mice, rats, dogs, and hamsters to radon and its decay products resulted in lifetime shortening, pulmonary emphysema, pulmonary fibrosis, and respiratory tract carcinoma. Damage to the skin and kidney was also reported, but the lung seems to be the primary affected organ (Cross 1990). Small mammals and birds that live in burrows containing radon-rich soils (9900 Bq/m³ of ^{222}Rn) are expected to have an additional 17 lung cancers per 1000 animals than animals not similarly exposed. However, tumors have not been widely reported in these species (Macdonald and Laverock 1998). Radon and ^{222}Rn daughters have caused problems in miners who work underground in uranium mines. These miners had an excessive incidence of disease of the respiratory system, including lung cancer. The problem is related to the emanation of radon into the mines and the decay of the radon, the short-lived radioactive daughters (^{216}Po , ^{214}Pb , ^{214}Bi , ^{214}Po) that attach to dust particles, eventually resulting in alpha radiation exposure of the respiratory airways (Hobbs and McClellan 1986). A similar pattern was evident in rats exposed to ^{239}Pu . Rats exposed to $^{239}\text{PuO}_2$ aerosol of about 3700 Bq/lungs and examined 8 to 18 months after exposure had a very high frequency (as much as 80%) of malignant pulmonary neoplasms; genetic mutations were evident in 46% of the radiation-induced tumors (Stegelmeier et al. 1991).

The incidence of ovarian tumors in mice, guinea pigs, and rabbits increased after 3 years of chronic irradiation at doses as low as 1.1 mGy daily (Lorenz et al. 1954). Unlike other tumors, the induction of ovarian tumors depended on a minimum total dose and seemed to be independent of a daily dose (Lorenz et al. 1954). Radiation-induced neoplastic transformation of hamster cells may be associated initially with changes in expression of the genes modifying cytoskeletal elements (Woloschak et al. 1990b).

32.7.6.3 Mutagenicity

In general, ionizing radiation has produced mutations in every plant and animal species studied. Some genetic risks are associated with exposures, but the risk of inducing a dominant genetic disease is quite small because radiation-induced mutations are primarily recessive and usually lethal (Sankaranarayanan 1991c). Residents living near the site of extensive mining and milling of uranium operations in Texas have an increased frequency of chromosomal aberrations and a reduced DNA repair capacity; uranium-238 was much higher in these areas when compared to reference sites, possibly as a result of leaching into the groundwater (McConnell et al. 1998). The genetic doubling dose of radiation is the amount of acute or chronic radiation that doubles the naturally occurring spontaneous mutation rate each generation. For mice, the estimated genetic doubling dose equivalent

is 1.35 Sv from acute exposures and 4.0 Sv from chronic exposures to radiation (Neel and Lewis 1990). For protection from radiation, the estimated genetic risks to humans have largely been based on data from mice (Straume et al. 1991). Studies of children of Japanese survivors of nuclear bomb explosions showed that the genetic doubling dose equivalent of acute gonadal radiation is about 2.0 Sv (1.69 to 2.23); from chronic radiation, this value is about 4.0 Sv (Neel and Lewis 1990). Based on results of the study of Japanese survivors of the nuclear explosions, Yoshimoto et al. (1990) and Sankaranarayanan (1991c) concluded that there was no increase in the spontaneous mutation rate after parents were exposed. The high doubling dose of about 4 Sv estimated from these data is another way of stating that, relative to the assumed spontaneous rates, the rate of induction of mutations leading to the measured effects is too small (Sankaranarayanan 1991c). The transmission of radiation-induced genetic effects to offspring has not yet been demonstrated in any human population (Straume et al. 1991).

Specific point mutations were identified in ^{239}Pu -induced preneoplastic lesions and malignant neoplasms in the lungs of rats (Stegelmeier et al. 1991). Mice exposed to a single whole-body dose of 3 Gy produced a radiation-induced mutation that simultaneously generated distinct alleles of the limb deformity and agouti (grizzled fur color) loci, two developmentally important — but not adjoining — regions on a single chromosome. This phenomenon was probably associated with DNA breaks caused by inversion of a segment in another chromosome (Woychik et al. 1990). The plasma membrane in immature oocytes of mice is the hypersensitive lethal target in producing radiation-induced genetic damage (Straume et al. 1991).

32.7.6.4 Organ and Tissue Damage

In the abdomen, the kidneys are one of the most sensitive organs to serious or fatal radiation-induced damage (Jaenke and Angleton 1990). The relatively high incidence of kidney disease among mature beagles injected with ^{226}Ra and its accompanying ^{210}Bi and ^{210}Po resulted from alpha irradiation of the kidneys by the substantial amount of ^{210}Po that was in the injected solution (Bruenger et al. 1990). Hepatic injury induced by ionizing radiation can be a life-threatening complication. The main responses of the liver to acute radiation exposure include enlargement, dilation of blood vessels, fluid accumulation, and histopathology (Geraci et al. 1991). Damaging effects of ionizing radiation on the fetal cerebral cortex has been recognized for many years (Norton and Kimler 1990). The deleterious effects of ionizing radiation on the developing brain are prolonged and progressive. Doses <2 Gy of gamma radiation are harmful to the developing brain; and in humans, mental retardation may occur from doses as low as 0.2 Gy between week 8 and 15 of gestation (Norton et al. 1991).

Irradiated white-footed mice (*Peromyscus leucopus*) frequently had atrophied gonads, degenerating fetuses in the uterus, and greying hair (Di Gregorio et al. 1971). High sublethal doses (7 Gy) of radiation to the pine vole (*Microtus pinetorum*) caused pelage graying, wherein unpigmented hair from damaged follicles replaces molted pigmented hair. Pelage graying may decrease survival from increased predation (Dunaway et al. 1971), although this needs verification.

Human sperm chromosomes retain a high fertilizing ability after a high dose of X-irradiation, although mammalian spermatozoa have little capacity to repair DNA damage induced by radiation (Kamiguchi et al. 1990). Radiation-induced death of lymphoid cells in rats is associated with damage to the cell itself but may also be due to secretions from irradiation-activated natural killer cells that induce pycnosis and interphase death in lymphoid cells (Eidus et al. 1990).

32.7.6.5 Behavior

Numerous behavioral measures have been evaluated for their usefulness in providing a sensitive index of exposure to ionizing radiation. Radiation-related mental retardation is the most likely type of behavioral abnormality in humans; sensitivity peaked between 8 and 15 weeks of conception

and at doses >0.4 Gy (UNSCEAR 1988). No specific mechanism for the production of mental retardation has been established, although proposed mechanisms include the loss of cells, migration of neurons, and failure of synaptogenesis (Norton and Kimler 1990). In studies with rats, operant responses decreased (maintained by positive reinforcement such as food or water) at sublethal radiation doses (3.0 to 6.75 Gy) under various schedules of reinforcement (Mele et al. 1990). Disrupted operant responses under shock avoidance at >LD100 levels are reported in pigs and rhesus monkeys (Mele et al. 1990).

32.7.6.6 Absorption and Assimilation

The absorption, bioavailability, and retention of radionuclides in mammals are modified by:

- The age, sex, species, and diet of the organism
- Season of collection
- The chemical form of the radionuclide in tissue and blood
- Residence time in the digestive tract
- Preferential accumulation by selected organs and tissues
- Other variables (Kitchings et al. 1976; Whicker and Schultz 1982a, 1982b; Richmond 1989; Desmet et al. 1991; Harrison 1991).

Assimilation fractions of various elements recommended by the International Commission on Radiological Protection are presented in detail by Whicker and Schultz (1982b).

Many radionuclides preferentially accumulate in certain organs or tissues, but the critical organ is different for different radionuclides: liver for ^{54}Mn , erythrocytes and spleen for ^{55}Fe , liver and kidney for cobalt nuclides, liver and prostate for ^{65}Zn , skeletal muscle for ^{137}Cs , and GI tract for ^{95}Zr (Whicker and Schultz 1982a). The persistence of radionuclides in mammals varies with the chemical form, kinetics, species, and other variables. For example, the time for 50% persistence of selected radionuclides in whole-animal studies ranges from 19 h to 14 days of ^{134}Cs ; 4 to 35 days of ^{137}Cs ; 5 to 12 h of the short-lived component of ^{60}Co , and 5 to 21 days of the long-lived component; 25 to 593 days of ^{90}Sr ; and 4 to 26 days of ^{131}I (Kitchings et al. 1976; Whicker and Schultz 1982b).

Some radionuclides act antagonistically when administered together. The combined incorporation of ^{227}Ac and ^{227}Th at levels tested in mice shows a lower biological effect than the sums of the effects of the components administered singly. The less-than-additive effect is in good agreement with experiments with the incorporation of a mixture of β emitters, in which the effects are also less-than-additive (Muller et al. 1990). Uptake and retention characteristics of essential biological nutrients (i.e., H, C, P, I, K, Ca, Mn, Fe, Co, Zn) are largely controlled by biological processes (Whicker and Schultz 1982a). For example, ^{131}I , regardless of route of administration, is rapidly absorbed into the bloodstream and concentrated in the thyroid. Ionizing radiation associated with high levels of ^{131}I destroys the thyroid, affecting the thyroid hormone production (Hobbs and McClellan 1986).

Alkali metals (K, Rb, Cs) behave similarly and sometimes one is accumulated preferentially when another is deficient. A similar case is made for Sr and Ca (Whicker and Schultz 1982a). The most important alkali metal isotope is ^{137}Cs because of its long physical half-life (30 years) and its abundance as a fission product in fallout from nuclear weapons and in the inventory of a nuclear reactor or a fuel-reprocessing plant. Cesium behaves much like potassium. It is rapidly absorbed into the bloodstream and distributed throughout the active tissues of the body, especially muscle. The β and γ radiation from the decay of ^{137}Cs and its daughter, ^{137}Ba , result in essentially whole-body irradiation that harms bone marrow (Hobbs and McClellan 1986).

Because ^{226}Ra and ^{90}Sr are metabolic analogs of calcium, they are deposited in the skeleton. Both isotopes are associated with bone cancers (Hobbs and McClellan 1986). In pregnant rats, the total amount of ^{226}Ra transferred from the dam to the 8 to 10 fetuses in a litter was low after a single

injection and did not exceed 0.3% of the maternal content. The retained whole-body burden in dams was 53% at the first, 48% at the second, and 44% at the third pregnancy, mostly in the skeletal system (Kshirsagar 1990). The rare earths (i.e., ^{144}Ce , ^{152}Eu , ^{140}La , ^{147}Pr , ^{151}Sm) are usually not effectively absorbed from the GI tract, and elimination is rapid (Palumbo 1963). Cerium-144 is one of the more biologically hazardous radionuclides in this group because of its half-life (285 days) and the energetic β emissions from it and its daughter, ^{144}Pr (Hobbs and McClellan 1986).

The greatest uncertainty in dose estimates from the ingestion of long-lived alpha emitters is the values used for their fractional absorption from the GI tract (Harrison 1991). For transuranic elements, the fraction of the ingested material that was assimilated by the whole organism was always <0.01% and usually nearer 0.003% (Whicker and Schultz 1982b). The major hazard of plutonium nuclides to terrestrial organisms comes from inhalation; uptake by plants is low, and further uptake by humans through the gut is low (Noshkin et al. 1971). Americium-241 is an artificial, toxic bone-seeking radionuclide produced through beta decay of ^{241}Pu (Schoeters et al. 1991). Because of its long half-life, its high-energy alpha irradiation, and its accumulation in the liver and skeleton, consideration should be given to ^{241}Am in risk estimates of latent effects, such as induction of liver cancers, bone cancers, and leukemias. In comparison with ^{226}Ra , ^{241}Am is 20 times more effective in reducing life-span in mice and 13 times more effective in the rate of death from bone cancer (Schoeters et al. 1991).

Although radon has long been known as a health hazard to miners in the uranium industry, it was only in the 1980s that radon contamination of buildings was recognized as widely distributed over the Earth. However, years of exposure are required before a health problem develops (Majumdar et al. 1990). Exposure to radon-decay products can be expressed in two different ways: the amount of inhaled decay products (taking into account their potential to emit radiation energy) or the product of the time during which the decay products were inhaled and their concentration in the inhaled air. The potential alpha energy of the inhaled decay products may be expressed in joules (J). The potential alpha energy concentrations in air is expressed in joules per cubic meter; for radon in equilibrium with its decay product, this corresponds to 3700 Bq/m³ (UNSCEAR 1988).

Rodents dosed with tungsten-185 excreted 80% in 24 h; bone was the major retention site; the half-time persistence ranged from 5.7 days in femurs of mice to 86 days in femurs of rats; some components in the bone of rats persisted with a half-time >3 years (Reed and Martinedes 1971). Niobium-95 is produced directly by nuclear fission and indirectly by decay of ^{95}Zr . Routine discharges of ^{95}Nb from a nuclear fuel reprocessing plant in the United Kingdom in 1970 contributed about 5% of the bone-marrow dose to a 10-year-old child living in the vicinity (Harrison et al. 1990). Gastrointestinal absorption of ^{95}Nb by adult guinea pigs was about 1.1%, and supports the values of 1% absorption in adults and 2% in infants now used to calculate percentage absorption of niobium isotopes by humans (Harrison et al. 1990).

32.8 PROPOSED CRITERIA AND RECOMMENDATIONS

For the protection from radiation, effects of radiation have been characterized as stochastic or nonstochastic. The probability of a stochastic effect — and not its severity — varies as a function of dose in the absence of a threshold (i.e., hereditary effects or carcinogenesis). The probability and severity of nonstochastic effects vary with dose, and a threshold for the dose exists (i.e., cataract of lens, nonmalignant damage to the skin, cell depletion in the bone marrow causing hematological deficiencies, gonadal cell damage leading to impairment of fertility, or pneumotis and pulmonary fibrosis following lung irradiation) (ICRP 1977; Hobbs and McClellan 1986; UNSCEAR 1988). The prevention of nonstochastic effects is achieved by setting dose-equivalent limits at sufficiently low levels so that no threshold dose is reached, not even after exposure for the whole of a lifetime or for the total period of a working life (ICRP 1977, 1991a, 1991b). Guides for the protection from radiation are also predicated on the effective half-life of each isotope, the critical organ, the fraction

that reaches the critical organ by ingestion and inhalation, and the maximum tolerable whole-body burdens, as judged by radionuclide concentrations in air, water, and diet (Palumbo 1963).

At present, no radiological criteria or standards have been recommended or established for the protection of fish, wildlife, or other natural resources. All radiological criteria now promulgated or proposed are directed toward the protection of human health. It is generally assumed that humans are comparatively radiosensitive and that guides will probably also protect sensitive natural resources (UNSCEAR 1988; ICRP 1991a, 1991b; NCRP 1991; IAEA 1992; Zach et al. 1993), although this needs verification. Numerous radiological criteria now exist for the protection of human health ([Table 32.28](#)). Most authorities agree that some adverse effects to humans are likely under the following conditions:

- >5 mSv whole-body exposure of women during the first 2 months of pregnancy
- >50 mSv whole-body exposure in any single year or >2000 mSv in a lifetime
- An annual inhalation intake by a 60-kg individual — in Bq/kg BW — that exceeds 0.67 ^{232}Th , 3.3 ^{241}Am , 3.3 ^{239}Pu , 16 ^{252}Cf , 33 ^{235}U , 1666 ^{90}Sr , 16,666 ^{60}Co , or 166,666 ^{32}P
- An annual ingestion intake by a 60-kg individual — in Bq/kg BW — that exceeds 3333 ^{129}I , 16,666 ^{125}I , 16,666 ^{131}I , or 66,666 ^{137}Cs
- A total annual intake from all sources — in Bq/kg BW by a 60-kg person — that exceeds 66 ^{210}Pb , 166 ^{210}Po , 333 ^{226}Ra , 666 ^{230}Th , 833 ^{228}Th , or 1333 ^{238}U (see [Table 32.28](#)).

Astronauts between 25 and 55 years of age usually receive an average career dose of 2.0 Sv (1.0 to 3.0 Sv in females; 1.5 to 4.0 Sv in males); theoretically, this may cause a life shortening of 2000 to 3000 days (Wood 1991). Other environmental variables also result in life shortening and include cigarette smoking (2250 days), coal mining (1100 days), and being 30% overweight (1300 days); thus, models that assess the harm of a single variable — such as radiation — on life expectancy must incorporate all known data and their interacting effects (Wood 1991).

Environmental dose-response models and animal epidemiological data are most frequently used to assess the risk from ionizing radiation. In its ideal form, a risk assessment should clearly present the rationale for an estimate of risk and should include the recognition of the roles of assumptions, approximations, data, theories, models, and deductions in arriving at an inference and a discussion of the involved uncertainties (Cothorn et al. 1990). It now seems clear that current risk assessments of ionizing radiation hazards to all living organisms — not just humans — require additional data and reinterpretation of existing data. Specifically, more effort is needed in the following areas:

1. Measurement of concentrations of naturally occurring radionuclides and natural background doses in the environment as a baseline for studies on radiation effects (Templeton et al. 1971)
2. Refinement of models of radionuclide transfer in food chains to aid in the assessment of radioactive releases from nuclear reactors and other point sources, including possible biomagnification by trophic components and turnover rates by receptor organisms (Kitchings et al. 1976)
3. Continuance of protracted exposure studies to measure carcinogenesis in animal and human cell lines and the role of secondary factors — especially chemical agents — in radiation carcinogenesis (Little 1990)
4. Research on radiation-induced recessive lethal mutations — the predominant type of radiation-induced mutation — and dominant mutation systems (Sankaranarayanan 1991c)
5. Initiation of long-term studies to establish sensitive indicators of radiation stress on individuals and communities, including effects on growth and reproduction (Templeton et al. 1971)
6. Clarification of the role of enzymes and proteins in repair of radiation-damaged cellular DNA and of mechanisms of enzymatic reactions leading to altered nucleotide sequences (Hagen 1990)
7. Reinterpretation of low-level chronic irradiation effects on developing embryos under rigorously controlled conditions (Templeton et al. 1971)
8. Resolution of mathematical shape(s) of radiation dose-response curve(s) (Hobbs and McClellan 1986).

Table 32.28 Recommended Radiological Criteria for the Protection of Human Health

Criterion and Other Variables	Concentration or Dose	Reference^a
AIR		
United States; radon-222		
Average	<0.0555 Bq (<1.5 pCi)/L or <55 Bq/m ³	1
Acceptable	<0.148 Bq (<4.0 pCi)/L	1, 2
Allowable emission discharge	<0.74 Bq (<20 pCi)/m ² per sec; should not increase the radon-222 concentration in air at or above any location outside the disposal site by >0.0185 Bq (>0.5 pCi)/L or >18 Bq (>500 pCi)/m ³	3
Unacceptable	>0.185 Bq (>5 pCi)/L	2
ASTRONAUTS		
Age 25–55 years; expected whole-body career dose; females vs. males	1.0–3.0 Sv (100–300 rem) vs. 1.5–4.0 Sv (150–400 rem)	4
Adverse effects expected; lifetime exposure	>2.0 Sv (>200 rem)	4
CANCER RISK AND BIRTH DEFECTS		
Projected 0.04% increase in cancers; 0.01% increase in birth defects	0.11 mSv (0.011 rem) whole-body maximum per year; 0.69 mSv (0.069 rem) whole body over 30 years; or 1.00 mSv (0.1 rem) bone marrow over 30 years	5
Projected 0.18% increase in cancers; 0.07% increase in birth defects	0.51 mSv (0.05 rem) whole-body maximum per year; 3.30 mSv (0.33 rem) whole body over 30 years; or 4.60 mSv (0.46 rem) bone marrow over 30 years	5
Projected 0.92% increase in cancers; 0.38% increase in birth defects	3.03 mSv (0.3 rem) whole-body maximum per year; 19.0 mSv (1.9 rem) whole body over 30 years; or 23.0 mSv (2.3 rem) bone marrow over 30 years	5
Projected 4.4% increase in cancers; 1.8% increase in birth defects	20.1 mSv (2.0 rem) whole-body maximum per year; 91.0 mSv (9.1 rem) whole body over 30 years; or 110.0 mSv (11 rem) bone marrow over 30 years	5
DIET		
All foods; maximum recommended values		
Adults, Italy	600 Bq (16,200 pCi) cesium-134+137/kg fresh weight (FW)	6
Children, Italy	370 Bq (10,000 pCi) cesium-134+137/kg FW	6
Sweden, pre-Chernobyl	300 Bq (8100 pCi) cesium-134+137/kg FW	6
Caribou; muscle; North America	<2260 Bq (<61,000 pCi) cesium-137/kg FW	8
Fish; Great Lakes; muscle	Dose of <0.02 µSv (0.00002 rem)/kg FW fish flesh equivalent to consumers	9
Fish; Sweden	<1500 Bq (<40,500 pCi) cesium-137/kg FW	10
Fraction of ingested dose absorbed; recommended maximum; selected isotopes		
Americium, curium, neptunium, plutonium, thorium	<0.05%	11
Americium, plutonium	<0.1%	12
Californium, and higher mass radionuclides	<0.1%	11
Uranium	<5.0%	11
Milk; maximum values		
Italy	370 Bq (10,000 pCi) cesium-134+137/L	6
Japan	370 Bq (10,000 pCi) cesium-137/L	13
Sweden	300 Bq (8100 pCi) cesium-137/L	14
Meat and fish; Sweden; maximum values	1500 Bq (40,500 pCi) cesium-137/kg FW	14

Table 32.28 (continued) Recommended Radiological Criteria for the Protection of Human Health

Criterion and Other Variables	Concentration or Dose	Reference^a
Reindeer meat, game, animal meat, fish, berries, mushrooms; Sweden; post-Chernobyl; maximum values	1500 Bq (40,500 pCi) cesium-137/kg FW	15
Sheep, muscle	<1000 Bq (<27,000 pCi) cesium-134+137/kg FW	16
Sheep, muscle	<1000 Bq (<27,000 pCi) cesium-137/kg FW	17
DRINKING WATER		
Natural radioactivity; maximum allowed		
Radium-226+228	0.185 Bq (5 pCi)/L	18
Gross alpha	0.555 Bq (15 pCi)/L	18
Artificial radioactivity; maximum allowed		
Gross beta	1.85 Bq (50 pCi)/L	18
Tritium (Hydrogen-3)	740 Bq (20,000 pCi)/L	18
Strontium-90	0.296 Bq (8 pCi)/L	18
Great Lakes; maximum dose to consumers	10 µSv (0.001 rem)/year	9
GENERAL PUBLIC		
Annual effective dose ^b	<1 mSv (<0.1 rem)	19, 29
Cesium-137; total intake		
Sweden	<50,000 Bq (<1,350,000 pCi)/year, equivalent to <1 mSv (<0.1 rem)	15
North America	<300,666 Bq (<8,100,000 pCi)/year	8
United Kingdom	<400,000 Bq (<10,800,000 pCi)/year, equivalent to <5 mSv (0.5 rem)	20
Maximum permissible dose		
Eye lens	<15 mSv (<1.5 rem)/year	19
Skin	<50 mSv (<5 rem)/year	19
Whole body		
Individual, except students and pregnant women	<5 mSv (<0.5 rem)/year	9, 21–23
Students	<1 mSv (<0.1 rem)/year	21
Pregnant women	<5 mSv (<0.5 rem) during the first 2 months of pregnancy	22
Population dose limits, genetic or somatic	<1.7 mSv (<0.17 rem) yearly average	21
GROUNDWATER		
Maximum allowed		
Radium-226+228	0.185 Bq (5 pCi)/L	3
Alpha emitting radionuclides — including radium-226+228, but excluding radon isotopes	0.555 Bq (15 pCi)/L	3
Total beta and gamma radiation	Total annual whole-body dose equivalent, or dose to any internal organ, <0.04 mSv (<0.004 rem), based on individual consumption of 2 L daily of drinking water from a groundwater source	3
RADIOACTIVE WASTES		
Dose limits from spent nuclear fuel or transuranic radioactive wastes		
Whole body	<0.25 mSv (<0.025 rem)/year	3, 24
Thyroid	<0.75 mSv (<0.075 rem)/year	3, 24
Any other critical organ	<0.25 mSv (<0.025 rem)/year	3, 24
Stored for 10,000 years; maximum cumulative release allowed to the accessible environment per 1000 metric tons of heavy metal during storage		
Americium-241	3.7 trillion (T) Bq (100 TpCi)	3
Americium-243	3.7 TBq (100 TpCi)	3

Table 32.28 (continued) Recommended Radiological Criteria for the Protection of Human Health

Criterion and Other Variables	Concentration or Dose	Reference^a
Any alpha emitter with physical half-life >20 years	3.7 TBq (100 TpCi)	3
Any non-alpha emitter radionuclide with physical half-life >20 years	37.0 TBq (1000 TpCi)	3
Carbon-14	3.7 TBq (100 TpCi)	3
Cesium-135	37.0 TBq (1000 TpCi)	3
Cesium-137	37.0 TBq (1000 TpCi)	3
Iodine-129	3.7 TBq (100 TpCi)	3
Neptunium-237	3.7 TBq (100 TpCi)	3
Plutonium-238	3.7 TBq (100 TpCi)	3
Plutonium-239	3.7 TBq (100 TpCi)	3
Plutonium-240	3.7 TBq (100 TpCi)	3
Plutonium-242	3.7 TBq (100 TpCi)	3
Radium-226	3.7 TBq (100 TpCi)	3
Strontium-90	37.0 TBq (1000 TpCi)	3
Thorium-230	0.37 TBq (10 TpCi)	3
Thorium-232	0.37 TBq (10 TpCi)	3
Tin-126	37.0 TBq (1000 TpCi)	3
Uranium-233	3.7 TBq (100 TpCi)	3
Uranium-234	3.7 TBq (100 TpCi)	3
Uranium-235	3.7 TBq (100 TpCi)	3
Uranium-236	3.7 TBq (100 TpCi)	3
Uranium-238	3.7 TBq (100 TpCi)	3
Uranium by-product materials; maximum discharge rates allowed into water		
Radium-226+228	0.185 Bq (5 pCi)/L	24
Gross alpha particle activity, excluding radon and uranium isotopes	0.555 Bq (15 pCi)/L	24
Wastes from uranium fuel cycle entering the environment per billion watts/year of electrical energy produced by the fuel cycle; maximum allowed		
Krypton-85	1.85 TBq (50 TpCi)	24
Iodine-129	185 million Bq (5 billion pCi)	24
Plutonium-239 and other alpha emitting transuranics with Tb 1/2 >1 year	2.69 million Bq (72.6 million pCi)	24

OCCUPATIONAL WORKERS**Annual Limit of Intake^b**

Inhalation vs. oral		
Americium-241	200 Bq (5400 pCi) vs. 50,000 Bq	25
Californium-252	1000 Bq (27,000 pCi) vs. 200,000 Bq	25
Cesium-137	6 million Bq (162 million pCi) vs. 4 million Bq	25
Cobalt-60	1 million Bq (27 million pCi) vs. 7 million Bq	25
Hydrogen-3	3 billion Bq (81 billion pCi) vs. 3 billion Bq	25
Iodine-125	2 million Bq (54 million pCi) vs. 1 million Bq	25
Iodine-129	300,000 Bq (8,100,000 pCi) vs. 200,000 Bq	25
Iodine-131	2 million Bq (54 million pCi) vs. 1 million Bq	25
Phosphorus-32	10 million Bq (270 million pCi) vs. 20 million Bq	25
Plutonium-239	200 Bq (5400 pCi) vs. 200,000 Bq	25
Polonium-210	20,000 Bq (540,000 pCi) vs. 100,000 Bq	25
Radium-226	20,000 Bq (540,000 pCi) vs. 70,000 Bq	25
Strontium-90	0.1 million Bq (2.7 million pCi) vs. 1.0 million Bq	25
Thorium-232	40 Bq (1000 pCi) vs. 30,000 Bq	25
Uranium-235	2000 Bq (54,000 pCi) vs. 500,000 Bq	25
Total intake from all sources; Canada		
Lead-210	<4000 Bq (<108,000 pCi)	26, 27
Polonium-210	<10,000 Bq (<270,000 pCi)	26, 27

Table 32.28 (continued) Recommended Radiological Criteria for the Protection of Human Health

Criterion and Other Variables	Concentration or Dose	Reference ^a

^a 1, Gangopadhyay and Majumdar 1990; 2, Oge and Dickson 1990; 3, United States Code of Federal Regulations (USCFR) 1990; 4, Wood 1991; 5, Bair et al. 1979; 6, Battiston et al. 1991; 7, Andersson et al. 1990; 8, Allaye-Chan et al. 1990; 9, Joshi 1991; 10, Hakanson and Andersson 1992; 11, Harrison 1991; 12, Gilbert et al. 1989; 13, Aii et al. 1990; 14, Johanson et al. 1989; 15, Johanson 1990; 16, Moss et al. 1989; 17, Crout et al. 1991; 18, Rose et al. 1990; 19, International Commission on Radiological Protection (ICRP) 1991a; 20, Lowe and Horrill 1991; 21, Hobbs and McClellan 1986; 22, ICRP 1977; 23, Gray et al. 1989; 24, USCFR 1991; 25, Kiefer 1990; 26, Clulow et al. 1991; 27, Clulow et al. 1992; 28, ICRP 1991b; 29, National Council on Radiation Protection and Measurements (NCRP) 1991.

^b The Annual Limit of Intake (ALI) for any radionuclide is obtained by dividing the annual average effective dose limit (20 mSv) by the committed effective dose (E) resulting from the intake of 1 Bq of that radionuclide. ALI data for individual radionuclides are given in ICRP (1991b).

32.9 SUMMARY

This chapter is a selective review and synthesis of the voluminous technical literature on radiation and radionuclides in the environment, notably on fish, wildlife, invertebrates, and other natural resources. The subtopics include the physical and biological properties of the electromagnetic spectrum and of charged particles; radiation sources and uses; concentrations of radionuclides in field collections of abiotic materials and living organisms; lethal and sublethal effects, including effects on survival, growth, reproduction, behavior, metabolism, carcinogenicity, and mutagenicity; a synopsis of two case histories involving massive releases of radionuclides into the biosphere (military weapons tests at the Pacific Proving Grounds, and the Chernobyl nuclear reactor accident); current radiological criteria proposed for the protection of human health and natural resources; and recommendations for additional research. A glossary is included.

Nuclear explosions and nuclear power production are the major sources of human radioactivity in the environment. Other sources include radionuclide use in medicine, industry, agriculture,

education, and production; transport and disposal from these activities present opportunities for wastes to enter the environment. Dispersion of radioactive materials is governed by a variety of biogeochemical factors, including winds, water currents, and biological vectors. Living organisms normally receive most of their external exposure to radiation from naturally occurring electromagnetic waves and their internal exposure from naturally occurring radionuclides such as potassium-40. Radiation exposure doses from natural sources of radiation are significantly modified by altitude, amount and type of radionuclides in the immediate vicinity, and route of exposure.

Radionuclide concentrations in representative field collections of biota tend to be elevated in the vicinity of nuclear fuel reprocessing, nuclear power production, and nuclear waste facilities; in locations receiving radioactive fallout from nuclear accidents and atmospheric nuclear tests; and near sites of repeated nuclear detonations. Radionuclide concentrations in field collections of living organisms vary significantly with organism age, size, sex, tissue, diet, and metabolism; season of collection; proximity to point source; and other biological, chemical, and physical variables. To date, no extinction of any animal population has been linked to high background concentrations of radioactivity.

The accident at the Chernobyl, Ukraine, nuclear reactor on April 26, 1986, contaminated much of the northern hemisphere, especially Europe, by releasing large amounts of radiocesium-137 and other radionuclides into the environment. In the immediate vicinity of Chernobyl; at least 30 people died, more than 115,000 others were evacuated, and the consumption of locally produced milk and other foods was banned because of radiocontamination. The most sensitive local ecosystems were the soil fauna and pine forest communities. Elsewhere, fallout from Chernobyl measurably contaminated freshwater, marine, and terrestrial ecosystems, including flesh and milk of domestic livestock. Reindeer (*Rangifer tarandus*) calves in Norway showed an increasing frequency of chromosomal aberrations that seemed to correlate with cesium-137 tissue concentrations; tissue concentrations, in turn, were related to cesium-137 in lichens, an efficient absorber of airborne particles containing radiocesium and the main food source of reindeer during winter. A pattern similar to that of reindeer was documented in moose (*Alces*) in Scandinavia.

A dose- and dose-rate dependent radiation effect on growth, survival, organ development, mutagenicity, fatal neoplasms, and other parameters exists for almost all organisms tested under laboratory conditions. Some discoveries suggest that low acute exposures of ionizing radiation may extend the life-span of certain species, although adverse genetic effects may occur under these conditions. In living organisms, the sensitivity to radiation is governed by ontogeny and phylogeny. Thus, rapidly dividing cells, characteristic of embryos and fetuses, are most radiosensitive and evolutionarily advanced organisms such as mammals are more radiosensitive than primitive organisms. Between species within each taxonomic grouping are large variations in sensitivity to acute and chronic exposures of ionizing radiation and in ability to retain selected radionuclides; these processes are modified by numerous biological and abiotic variables.

Radiosensitive terrestrial plants are adversely affected at single exposures of 0.5 to 1.0 Gy and at chronic daily exposures of 0.2 to 0.65 Gy. Terrestrial insects are comparatively resistant to ionizing radiation; some species show growth stimulation and development at acute doses of 2 Gy — a demonstrably harmful dose for many species of vertebrates. Among aquatic organisms, the developing eggs and young of freshwater fish are among the most sensitive tested organisms; death was observed at acute doses of 0.3 to 0.6 Gy and adverse effects on physiology and metabolism at chronic daily exposure rates of 0.01 Gy. The ability of aquatic organisms to concentrate radionuclides from the medium varies substantially with ecosystem, trophic level, radionuclide, proximity to radiation point source, and many other biological, chemical, and physical modifiers. In amphibians, radiation adversely affects limb regeneration, alters DNA metabolism, causes sterility, and increases the frequency of chromosomal aberrations. Mortality patterns in some species of amphibians begin to stabilize about 200 days after exposure to a single acute dose of ionizing radiation and cannot be evaluated satisfactorily in the typical 30-day postexposure period. In birds,

adverse effects on growth were noted at chronic daily exposures as low as 0.9 to 1.0 Gy, and on survival and metabolism at single exposures to 2.1 Gy. Genotoxic effects were associated with whole-body loadings of 2520 becquerels (Bq) of cesium-137/kg in mallards (*Anas platyrhynchos*). The radionuclide retention in birds was modified by sex, season, and reproductive state. In mammals, embryos and fetuses of sensitive species were adversely affected at acute doses of 0.011 to 0.022 Gy. Humans exposed as fetuses to 0.18 to 0.55 Gy scored significantly lower on tests of intelligence.

No radiological criteria now exist for the protection of fish, wildlife, or other sensitive natural resources. All current guides for protection from radiation target human health and are predicated on the assumption that protection of comparatively radiosensitive humans confers a high degree of protection to other life forms. Most authorities agree that significant harmful effects to humans occur under the following conditions:

- Exposure of the whole body of women during the first 2 months of pregnancy to >5 millisieverts (mSv)
- Exposure of the whole body to >50 mSv in any single year or to >2000 mSv in a lifetime
- Annual inhalation intake by a 60-kg individual, in Bq/kg body weight (BW), of more than 0.7 of thorium-232, 3.3 of americium-241, 3.3 of plutonium-239, 16 of californium-252, 33 of uranium-235, 1670 of strontium-90, 16,670 of cobalt-60, or 166,670 of phosphorus-32
- Annual ingestion intake by a 60-kg individual, in Bq/kg BW, of more than 3330 of iodine-129, 16,670 of iodine-125, 16,670 of iodine-131, or 66,670 of cesium-137
- Total annual intake, in Bq/kg BW, from all sources by a 60-kg person exceeds 66 of lead-210, 166 of polonium-210, 333 of radium-226, 670 of thorium-230, 830 of thorium-228, or 1330 of uranium-238.

Current risk assessments of ionizing radiation hazards to living organisms require additional data and reinterpretation of existing data. Specifically, more effort seems needed in eight areas:

1. Establishing a baseline for studies on radiation through measurement of naturally occurring radionuclides and natural background radiation doses
2. Refining radionuclide food-chain transfer models
3. Measuring the role of chemical agents in radiation-induced carcinogenesis
4. Accelerating research on radiation-induced lethal mutations
5. Initiating long-term studies to establish sensitive indicators of radiation stress on individuals and ecosystems
6. Clarifying the role of enzymes and proteins in repair of radiation-damaged cellular DNA
7. Reinterpreting embryotoxic effects of low level chronic irradiation
8. Resolving the mathematical shapes of radiation dose-response curves.

32.11 GLOSSARY*

- Actinides:** Elements of atomic numbers 89 to 103 (Ac, Th, Pa, U, Np, Pu, Am, Cm, Bk, Cf, Es, Fm, Md, No, Lw).
- Activity:** The activity of a radioactive material is the number of nuclear disintegrations per unit time. Up to 1977, the accepted unit of activity was the curie (Ci), equivalent to 37 billion disintegrations/s, a number that approximated the activity of 1 g radium-226. The present unit of activity is the becquerel (Bq), equivalent to 1 disintegration/s.
- Alpha (α) particles:** An α particle is composed of two protons and two neutrons, with a charge of +2; essentially, it is a helium nucleus without orbital electrons. Alpha particles usually originate from the nuclear decay of radionuclides of atomic number >82, and are detected in samples containing U, Th, or Ra. Alpha particles react strongly with matter and consequently produce large numbers of ions per unit

length of their paths. As a result, they are not very penetrating and will traverse only a few centimeters of air. Alpha particles are unable to penetrate clothing or the outer layer of skin; however, when internally deposited, α particles are often more damaging than most other types of radiations because comparatively large amounts of energy are transferred within a very small volume of tissue. Alpha particle absorption involves ionization and orbital electron excitation. Ionization occurs whenever the α particle is sufficiently near an electron to pull it from its orbit. The α particle also loses kinetic energy by exciting orbital electrons with interactions that are insufficient to cause ionization.

Atom: The smallest part of an element that has all the properties of that element. An atom consists of one or more protons and neutrons (in the nucleus) and one or more electrons.

Atomic number: The number of electrons outside the nucleus of a neutral (nonionized) atom and the number of protons in the nucleus.

Becquerel (Bq): The presently accepted unit of activity is the becquerel, equivalent to 1 disintegration/s. About 0.037 Bq = 1 picocurie.

Beta (β) particles: Beta particles are electrons that are spontaneously ejected from the nuclei of radioactive atoms during the decay process. They may either be positively or negatively charged. A positively charged beta (β^+), called a *positron*, is less frequently encountered than its negative counterpart, the *negatron* (β^-). The *neutrino*, a small particle, accompanies beta emission. The neutrino has very little mass and is electrically neutral; however, neutrinos conduct a variable part of the energy of transformation and account for the variability in kinetic energies of beta particles emitted from a given radionuclide. Positrons (β^+) are emitted by many of the naturally and artificially produced radionuclides; they are considerably more penetrating than α particles, but less penetrating than X-rays and γ rays. Beta particles interact with other electrons as well as nuclei in the travel medium. The ultimate fate of a beta particle depends on its charge. Negatrons, after their kinetic energy is spent, combine with a positively charged ion or become free electrons. Positrons also dissipate kinetic energy through ionization and excitation; the collision of positrons and electrons causes annihilation and release of energy equal to the sums of their particle masses.

Breeder reactor: A nuclear chain reactor in which transmutation produces a greater number of fissionable atoms than the number of consumed parent atoms.

Cosmic rays: Highly penetrating radiations that originate in outer space.

Curie (Ci): The Ci is equal to that quantity of radioactive material producing 37 billion nuclear transformations/s. One millicurie (mCi) = 0.001 Ci; 1 microcurie (μ Ci) = 1 millionth of a Ci; 1 picocurie (pCi) = 1 millionth of a millionth Ci = 0.037 disintegrations/s. About 27 pCi = 1 becquerel (Bq).

Decay: Diminution of a radioactive substance because of nuclear emission of α or β particles or of γ rays.

Decay product: A nuclide resulting from the radioactive disintegration of a radionuclide and found as the result of successive transformations in a radioactive series. A decay product may be either radioactive or stable.

Effective dose equivalent: The weighted sum, in sieverts (Sv), of the radiation dose equivalents in the most radiosensitive organs and tissues, including gonads, active bone marrow, bone surface cells, and the lung.

Electron: An electron is a negatively charged particle with a diameter of 10^{-12} cm. Every atom consists of one nucleus and one or more electrons. Cathode rays and negatrons are electrons.

Electron-volt (eV): Energy acquired by any charged particle that carries unit electronic charge when it falls through a potential difference of 1 volt. One eV = 1.602×10^{-19} joule.

Fission: The splitting of an atomic nucleus into two fragments that usually releases neutrons and γ rays. Fission may occur spontaneously or may be induced by capture of bombarding particles. Primary fission products usually decay by β particle emission to radioactive daughter products. The chain reaction that may result in controlled burning of nuclear fuel or in an uncontrolled nuclear weapons explosion results from the release of 2 or 3 neutrons/fission. Neutrons cause additional fissile nuclei in the vicinity to fission, producing still more neutrons, in turn producing still more fissions. The speed of the chain reaction is governed by the density and geometry of fissile nuclei and of materials that slow or capture the neutrons. In nuclear reactors, neutron-absorbing rods are inserted to various depths into the reactor core. A nuclear explosion is not physically possible in a reactor because of fuel density, geometry, and other factors.

Fusion: A nuclear reaction in which smaller atomic nuclei or particles combine to form larger ones with the release of energy from mass transformation.

Gamma (γ) rays: Gamma rays have electromagnetic wave energy that is similar to but higher than the energy of X-rays. Gamma rays are highly penetrating, being able to traverse several cm of lead. See **Photons**.

Genetically significant dose (GSD): A radiation dose that, if received by every member of the population, would produce the same total genetic injury to the population as the actual doses received by the various individuals.

Gray (Gy): $1 \text{ Gy} = 1 \text{ joule/kg} = 100 \text{ rad}$.

Half-life: The average time in which half the atoms in a sample of a radioactive element decay.

Hertz (Hz): A measure of frequency equal to 1 cycle/s.

Indirectly ionizing particles: Uncharged particles such as neutrons or photons that directly liberate ionizing particles or initiate nuclear transformations.

Ion: An atomic particle, atom, or chemical radical with either a negative or positive electric charge.

Ionization: The process by which neutral atoms become either positively or negatively electrically charged by the loss or gain of electrons.

Isomer: One of two or more radionuclides having the same mass number and the same atomic number, but with different energies and radioactive properties for measurable durations.

Isotope: One of several radionuclides of the same element (i.e., with the same number of protons in their nuclei) with different numbers of neutrons and different energy contents. A single element may have many isotopes. Uranium, for example, may appear naturally as ^{234}U (142 neutrons), ^{235}U (143 neutrons), or ^{238}U (146 neutrons); however, each uranium isotope has 92 protons.

Joule (J): $1 \text{ J} = 10^7 \text{ ergs}$.

Latent period: Period of seeming inactivity between time of exposure of tissue to an acute radiation dose and the onset of the final stage of radiation sickness.

Linear energy transfer (LET): A function of the capacity of the radiation to produce ionization. LET is the rate at which charged particles transfer their energies to the atoms in a medium and a function of the energy and velocity of the charged particle. See **Radiation dose**.

Linear hypothesis: The assumption that any radiation causes biological damage in direct proportion of dose to effect.

Mass number: The total number of neutrons and protons in the nucleus of the element, and equal to the sum of the atomic number and the number of neutrons.

Meson: Particles of mass that are intermediate between the masses of the electron and proton.

Neutrinos: Neutrinos and antineutrinos are formed whenever a positron particle is created in a radioactive decay; they are highly penetrating.

Neutrons: Neutrons are electrically neutral particles that consist of an electron and a proton and are not affected by the electrostatic forces of the atom's nucleus or orbital electrons. Because they have no charge, neutrons readily penetrate the atom and may cause a nuclear transformation. Neutrons are produced in the atmosphere by cosmic ray interactions and combine with nitrogen and other gases to form carbon-14, tritium, and other radionuclides. A free neutron has a lifetime of about 19 minutes, after which it spontaneously decays to a proton, a β particle, and a neutrino. A high-energy neutron that encounters biological material is apt to collide with a proton with sufficient force to dislodge the proton from the molecule. The recoil proton may then have sufficient energy to cause secondary damage through ionization and excitation of atoms and molecules along its path.

Nucleus: The dense central core of the atom in which most of the mass and all of the positive charge is concentrated. The charge on the nucleus distinguishes one element from another.

Photons: X-rays and gamma (γ) rays, collectively termed photons, are electromagnetic waves with shorter wavelengths than other members of the electromagnetic spectrum such as visible radiation, infrared radiation, and radiowaves. X- and γ photons have identical properties, behavior, and effects. Gamma rays originate from atomic nuclei, but X-rays arise from the electron shells. All photons travel at the speed of light, but energy is inversely proportional to wavelength. The energy of a photon directly influences its ability to penetrate matter. Many types of nuclear transformations are accompanied by γ ray emission. For example, α and β decay of many radionuclides is frequently accompanied by γ photons. When a parent radionuclide decays to a daughter nuclide, the nucleus of the daughter frequently contains excess energy and is unstable; stability is usually achieved through release of one or more γ photons, a process called *isometric transition*. The daughter nucleus decays from one energy state to another without a change in atomic number or weight.

The most probable fate of a photon with an energy higher than the binding energy of an encountered electron is photoelectric absorption, in which the photon transfers its energy to the electron and photon existence ends. As with ionization from any process, secondary radiations initiated by the photoelectron produce additional excitation of orbital electrons.

Planck's constant (**h):** A universal constant of nature that relates the energy of a photon of radiation to the frequency of the emitting oscillator. Its numerical value is about 6.626×10^{-27} ergs/s.

Positron: A positively charged particle of mass equal to an electron. Positrons are created either by the radioactive decay of unstable nuclei or by collision with photons.

Proton: A positively charged subatomic particle with a mass of 1.67252×10^{-24} g that is slightly less than the mass of a neutron but about 1836 times greater than the mass of an electron. Protons are identical to hydrogen nuclei; their charge and mass make them potent ionizers.

Radiation: The emission and propagation of energy through space or through a material medium in the form of waves. The term also includes subatomic particles, such as α , β , and cosmic rays and electromagnetic radiation.

Radiation absorbed dose (rad): Radiation-induced damage to biological tissue results from the absorption of energy in or around the tissue. The amount of energy absorbed in a given volume of tissue is related to the types and numbers of radiations and the interactions between radiations and tissue atoms and molecules. The fundamental unit of the radiation absorbed dose is the rad; 1 rad = 100 erg (absorbed)/g material. In the latest nomenclature, 100 rad = 1 gray (Gy).

Radiation dose: The term "radiation dose" can mean several things, including absorbed dose, dose equivalent, or effective dose equivalent. The absorbed dose of radiation is the imparted energy per unit mass of the irradiated material. Until 1977, the rad was the unit of absorbed dose, wherein 1 rad = 0.01 Joule/kg. The present unit of absorbed dose is the gray (Gy), equivalent to 1 Joule/kg. Thus, 1 rad = 0.01 Joule/kg = 0.01 Gy. Different types of radiation have different Relative Biological Effectiveness (RBE). The RBE of one type of radiation in relation to a reference type of radiation (usually X or γ) is the inverse ratio of the absorbed doses of the two radiations needed to cause the same degree of the biological effect for which the RBE is given. Regulatory agencies have recommended certain values of RBE for radiation protection, and absorbed doses of various radiations are multiplied by these values to arrive at radioprotective doses. The unit of this weighted absorbed dose is the roentgen equivalent man (rem). The dose equivalent is the product of the absorbed dose and a quality factor (Q), and its unit is the rem. The quality factor is a function of the capacity to produce ionization, expressed as the linear energy transfer (LET). A Q value is assigned to each type of radiation: 1 to X-rays, γ rays, and β particles; 10 to fast neutrons; and 20 to α particles and heavy particles. The new unit of the effective dose equivalent is the sievert (Sv), replacing rem, where 1 Sv = 100 rem. In addition to absorbed dose and dose equivalent, there is also the exposure. Exposure is the total electrical charge of ions of one sign produced in air by electrons liberated by X- or gamma rays per unit mass of irradiated air. The unit of exposure is Coulomb/kg, but the old unit, the roentgen (R) is still in use. One roentgen = 2.58×10^{-4} Coulomb/kg.

Radioactivity: The process of spontaneous disintegration by a parent radionuclide, which releases one or more radiations and forms a daughter nuclide. When half the radioactivity remains, that time interval is designated the half-life (T_b 1/2). The T_b 1/2 value gives some insight into the behavior of a radionuclide and into its potential hazards.

Radionuclide: An atom that is distinguished by its nucleus composition (number of protons, number of neutrons, energy content), atomic number, mass number, and atomic mass.

Relative biological effectiveness (RBE): The biological effectiveness of any type of ionizing radiation in producing a specific damage (i.e., leukemia, anemia, carcinogenicity). See **Radiation dose**.

Roentgen (R): $1 R = 2.58 \times 10^{-4}$ Coulombs/kg air = production by X- or γ rays of one electrostatic unit of charge per cm³ of dry air at 0°C and 760 mmHg = 0.87 rad in air.

Roentgen equivalent man (rem): The amount of ionizing radiation of any type that produces the same damage to humans as 1 roentgen of radiation. One rem = 1 roentgen equivalent physical (rep)/relative biological effectiveness (RBE). In the latest nomenclature, 100 rem = 1 Sievert (Sv).

Roentgen equivalent physical (rep): One rep is equivalent to the amount of ionizing radiation of any type that results in the absorption of energy of 93 ergs/g, and is approximately equal to 1 roentgen of X-radiation in soft tissue.

Shell: Extranuclear electrons are arranged in orbits at various distances from the nucleus in a series of concentric spheres called shells. In order of increasing distance from the nucleus, the shells are designated the K, L, M, N, O, P, and Q shells; the number of electrons that each shell can contain is limited.

Sievert (Sv): New unit of dose equivalent. One Sv = 100 rem = 1 J/kg. See **Radiation dose**.

Specific activity: The ratio between activity (in number of disintegrations/min) and the mass (in grams) of material giving rise to the activity. Biological hazards of radionuclides are directly related to their specific activity and are expressed in Bq/kg mass.

Threshold hypothesis: A radiation-dose-consequence hypothesis that holds that biological radiation effects will occur only above some minimum dose.

Transmutation: A nuclear change that produces a new element from an old one.

Transuranic elements: Elements of atomic number >92. All are radioactive and produced artificially; all are members of the actinide group.

X-rays: See **Photons**.

CHAPTER 33

Cumulative Index to Chemicals and Species

33.1 INTRODUCTION

Indices are presented of biologically active compounds or substances, and common and scientific names of all living species listed in the three-volume *Handbook of Chemical Risk Assessment* series.

33.2 INDEX TO CHEMICALS

All chemicals, chemical trade names, and other substances with known biological properties listed in the *Handbook of Chemical Risk Assessment* series — a total of about 1600 — are presented in [Table 33.1](#).

33.3 INDEX TO SPECIES

Taxonomic nomenclatures for plants and animals are under constant revision. In the *Handbook of Chemical Risk Assessment* series, the author elected to conform as much as possible to the systems and spellings used by Scott and Wasser (1980) for plants, Swain and Swain (1948) for insects, Turgeon et al. (1988) for aquatic molluscs, Williams et al. (1989) for decapod crustaceans, Pratt (1935) and Hyman (1940, 1951a, 1951b, 1955) for miscellaneous invertebrates, Robins et al. (1991) for fishes, Ditmars (1966) for reptiles, Edwards (1974) and Howard and Moore (1991) for birds, and Nowak and Paradiso (1983) for mammals. Individual species are arranged alphabetically by scientific and common names ([Table 33.2](#)). In total, about 2300 species of animals and plants were cited, of which only 23 (1.0%) were listed in at least 20 chapters. The most widely cited species include:

- One species of plant (corn, *Zea mays*)
- Two species of invertebrates (freshwater crustacean, *Daphnia magna*; American oyster, *Crassostrea virginica*)
- Seven species of teleosts (channel catfish, *Ictalurus punctatus*; bluegill, *Lepomis macrochirus*; coho salmon, *Oncorhynchus kisutch*; rainbow trout, *Oncorhynchus mykiss*; fathead minnow, *Pimephales promelas*; brook trout, *Salvelinus fontinalis*; lake trout, *Salvelinus namaycush*)

- Three species of birds (mallard, *Anas platyrhynchos*; domestic chicken, *Gallus* sp.; Japanese quail, *Coturnix japonica*)
- Ten species of mammals (cow, *Bos* spp.; domestic dog, *Canis familiaris*; guinea pig, *Cavia* spp.; domestic cat, *Felis domesticus*; human, *Homo sapiens*; hamster, *Cricetus* spp.; domestic mouse, *Mus* spp.; domestic sheep, *Ovis aries*; laboratory white rat, *Rattus* spp.; domestic pig, *Sus* spp.).

It is probable that these species are not representative of unusually sensitive or endangered species, but they can be considered appropriate sentinel organisms for many species of free-living wildlife.

33.4 SUMMARY

An index is provided to the common and scientific names of approximately 2300 biological species listed in the *Handbook of Chemical Risk Assessment* series. A similar index is shown for the approximately 1600 chemicals, chemical trade names, and other substances with known biological properties.

- C. I. No. 77775, 416
 Cacodylic acid, 1503, 1504, 1530, 1531, 1532, 1533, 1534, 1543, 1544, 1546, 1547, 1548, 1549, 1550, 1551
 Cadmium, 1–34, 64, 102–103, 132, 134, 136, 172, 206, 374, 420, 461, 514, 559, 1508, 1655, 1674, 1685, 1783
 Cadmium-109, 27, 1711, 1787
 Cadmium-115, 27, 1711
 Cadmium chloride, 23, 25, 28, 268
 Cadmium cyanide, 906
 Cadmium fluoride, 19
 Cadmium fluoroborate, 19
 Cadmium-113m, 1711, 1725
 Cadmium-115m, 27, 1711
 Cadmium selenide, 1651
 Calciferol, 1451
 Calcineurin, 477
 Calcium, 23, 100, 139, 206, 420, 422, 507, 1099, 1425, 1530, 1531, 1571, 1575, 1582, 1614, 1684, 1749, 1784, 1799
 Calcium-45, 1710, 1721
 Calcium acetate, 425
 Calcium arsenate, 1504, 1506, 1531, 1547, 1548, 1551
 Calcium borate, 1573, 1597, 1598, 1603
 Calcium carbonate, 28, 31, 151, 155, 156, 157, 158, 159, 176, 207, 533, 540, 688, 926
 Calcium chromate, 75
 Calcium cyanide, 905, 906, 913, 938
 Calcium glutonate, 1424, 1425, 1445, 1450
 Calcium molybdate, 1634, 1636
 Calcium sodium EDTA, 105, 615
 Calcium trisodium diethylenetriamine penta acetic acid, 105
 Californium, 1782, 1802
 Californium-252, 1713, 1801, 1804
 Calmodulin, 422
 Camphechlor, 1460
 Camphofene Huilex, 1460
 Captafol, 812
 Captan, 977
 Carbaryl, 976
 Carbofuran, 799–817
 Carbofuran phenol, 803, 815
 Carbon, 1717, 1799
 Carbon-14, 1315, 1710, 1713, 1719, 1720, 1721, 1727, 1728, 1736, 1737, 1738, 1740, 1804
 Carbon dioxide, 917, 920, 921
 Carbon tetrachloride, 912, 1134, 1196, 1371
 Carbonyl nickel powder, 416, 424
 Carbopol, 1427
 4-Carboxy-*l*-methylpyridinium ion, 1166, 1167

 Silver (1+) nitrate, 504
 Silver oxide, 535
 Silver phosphate, 508
 Silver selenide, 1651
 Silver sulfate, 506
 Silver sulfide, 505, 508, 521, 523, 533
 Silver thiosulfate, 502, 504, 533
 Silvex, 1022, 1053, 1054
 Silvisar-510, 1543, 1549
 Sinituho, 1196
 S-Methyl-N-((methylcarbamoyl)oxy)-thioacetimidate, 976
 Sodium, 138, 1105
 Sodium-22, 1710
 Sodium-24, 1710, 1721, 1742
 Sodium acetate, 279, 1424, 1425, 1450
 Sodium alpha ketoglutarate, 1425
 Sodium arsanilate, 1547, 1552
 Sodium arsenate, 1502, 1504, 1529, 1531, 1543, 1547, 1548, 1549, 1550, 1551, 1553
 Sodium arsenite, 741, 1504, 1508, 1530, 1531, 1532, 1536, 1542, 1543, 1545, 1546, 1547, 1548, 1549, 1550, 1551
 Sodium bicarbonate, 1420
 Sodium bisulfite, 761
 Sodium borate, 1569, 1571, 1589, 1594, 1597, 1598, 1599 1600, 1603, 1604
 Sodium borohydride, 1595
 Sodium cacodylate, 1531, 1543, 1548, 1549, 1551
 Sodium chlorite, 103
 Sodium chromate, 66, 77
 Sodium chromate tetrahydrate, 69
 Sodium citrate, 211
 Sodium cyanide, 905, 906, 912, 913, 914, 917, 923, 924, 926, 928, 930, 933, 934, 935, 939, 941, 942, 943, 947, 1416
 Sodium dichromate, 45, 66
 Sodium diethyldithiocarbamate, 425
 Sodium ferrocyanide, 914
 Sodium fluoacetate, 1420
 Sodium fluoride, 907, 1427
 Sodium fluoroacetate, 1420
 Sodium hexacyanoferrate, 914
 Sodium hydroxide, 390
 Sodium molybdate, 1626, 1629, 1631
 Sodium monofluoroacetate, 1413–1452
 Sodium nitrite, 103, 911, 936, 951

- Sodium nitroprusside, 914, 933
 Sodium pentachlorophenate, 77, 1193, 1196, 1201
 Sodium phosphate, 1501
 Sodium pyruvate, 911, 1591
 Sodium selenite, 321, 1680
 Sodium succinate, 1424, 1445, 1450
 Sodium sulfate, 169, 174, 1250
 Sodium tetraborate, 1568, 1593, 1598, 1603
 Sodium thiocyanate, 912, 913
 Sodium thiosulfate, 911, 936, 951, 1508
 Spectracide, 962
 Spermidine, 740, 1182
 Spermine, 740
 Sphalerite, 203
 Stalinton, 551
 Stannite, 557
 Stannous fluoride, 557
 Stobane-T, 1460
 Strontium, 1783
 Strontium-85, 1710, 1719, 1721, 1738
 Strontium-89, 1710, 1719, 1721, 1726, 1727, 1753
 Strontium-90, 1710, 1713, 1719, 1720, 1721, 1722,
 1725, 1726, 1727, 1728, 1729, 1731, 1732,
 1733, 1734, 1735, 1737, 1738, 1741, 1742,
 1745, 1746, 1747, 1748, 1749, 1750, 1753,

 Trialkyllead, 208, 254, 266, 283
 Trialkyllead chlorides, 254
 Trialkyltins, 552, 584, 585
 Tributylmethyltins, 554
 Tributyltin chloride, 374, 573, 583, 589
 Tributyltin fluoride, 586
 Tributyltin oxide, 580, 583
 Tributyltins, 374, 551, 552, 555, 556, 564–565, 567, 568, 569, 570, 580, 581, 583, 585, 586, 589, 592, 594, 1247
 Trichlorobenzenes, 1022, 1054
 Trichlorobenzoquinones, 1199, 1215
 2,2'-5-Trichlorobiphenyl, 1241
 2,4,5'-Trichlorobiphenyl, 1241, 1299
 Trichlorobiphenyls, 1239, 1241, 1259, 1271, 1285, 1286
 Trichlorobornane, 1460
 2,3,7-Trichlorodibenzodioxin, 1049
 Trichlorodiols, 1199
 Trichlorohydroquinones, 1199, 1215
 2,4,5-Trichlorophenol, 1022
 2,4,6-Trichlorophenol, 1023, 1197
 Trichlorophenols, 1028, 1038, 1048, 1198
 2,4,5-Trichlorophenoxyacetic acid (2,4,5-T), 1022, 1053
 3,5,6-Trichloro-2-pyridinol, 884
 Trichloropyrophos, 884
 Tricyclohexyltin bromide, 580
 Tricyclohexyltin chloride, 583
 Tricyclohexyltin hydroxide, 584
 Tricyclohexyltins, 557, 590, 593
 Triethanolamine cacodylate, 1543, 1549
 Triethylenetetramine, 421
 Triethyllead, 254, 262, 263, 272, 279
 Triethyltin acetate, 551
 Triethyltin chloride, 583
 Triethyltin hydroxide, 580
 Triethyltins, 557, 573, 574, 584, 585, 588, 591, 592, 593
 Trihexyltins, 590
 Trimethylarsine, 1506, 1523, 1536
 Trimethylarsinoxide, 1549, 1551
 Trimethyllead, 262, 263, 273, 279
 Trimethylnaphthalenes, 1374
 Trimethylselenomium chloride, 1508
 Trimethyltin, 555, 556, 563, 564, 570, 573–574, 584, 585
 Trimethyltin chloride, 583
 Trimethyltin hydroxide, 580
 Trimethyltins, 556, 557, 568, 570, 571, 573, 583, 584, 588, 591
 Trimethyltin sulfate, 584
 Trioctyltins, 590
 Triorganotins, 551, 554, 555, 560, 580, 584, 592, 594
 Tripentyltins, 573, 579
 Triphenyltin acetate, 590
 Triphenyltin chloride, 583
 Triphenyltin hydroxide, 580
 Triphenyltins, 555, 556, 569, 573, 579, 582, 583, 586, 589, 593
 Tripropyltin chloride, 583
 Tripropyltin oxide, 580
 Tripropyltins, 556, 573, 574, 589
 Trithiomolybdates, 1616
 Trivalent chromium, 45, 46, 47, 60, 61, 63–64, 65, 66, 67, 79, 80
 Trivalent copper, 98
 Tungsten, 1614, 1616, 1678
 Tungsten-181, 1711, 1784
 Tungsten-185, 1712
 Tungsten-187, 1712
 Tyrosinase, 101
- ## U
- Uranium, 77, 1613, 1614, 1713, 1717, 1721, 1802
 Uranium-232, 1713, 1779, 1781
 Uranium-233, 1712, 1804
 Uranium-234, 1712, 1726, 1727, 1728, 1737, 1739, 1740, 1804
 Uranium-235, 1712, 1713, 1715, 1721, 1726, 1727, 1728, 1737, 1739, 1740, 1801, 1804
 Uranium-236, 1712, 1804
 Uranium-238, 1712, 1713, 1714, 1715, 1717, 1721, 1726, 1727, 1728, 1737, 1738, 1740, 1801, 1804, 1805
 Uranium dioxide, 1721
 Uranium hexafluoride, 1721, 1722
 Uridine diphospho N-acetyl glucosamine, 985, 1005
- ## V
- Vanadium, 61, 616, 1614, 1616
 Vapotone, 1460

Vectal, 769
Vectal SC, 769
Velsicol 1068, 824
Vigilante, 984
Vinyl acetate, 754

Yttrium-90, 1711, 1781
Yttrium-91, 1711, 1721, 1781

Z

Zinc, 17, 23, 26, 28, 64, 104, 134, 136, 138, 166, 169, 374, 456, 514, 559, 614, 1257, 1616, 1673, 1674, 1684, 1685, 1783, 1799
Zinc-65, 649, 669, 675, 1710, 1721, 1724, 1731, 1735, 1736, 1738, 1739, 1740, 1742, 1746, 1780, 1784, 1787, 1799
Zinc acetate, 615, 617
Zinc aquo ion, 608, 686, 695
Zinc bicarbonate, 609
Zinc borate, 1594
Zinc carbonate, 609
Zinc chloride, 608, 609, 616, 617, 677, 686, 691
Zinc chromate, 77
Zinc cyanide, 906, 920
Zinc humic acid, 609, 670
Zinc hydroxide, 609
Zinc oxide, 617, 680, 691
Zinc phosphide, 676, 679
Zinc sulfate, 174, 608, 609, 617, 679, 684
Zinc sulfide, 608, 610
Zirconium, 1713, 1783
Zirconium-95, 1711, 1719, 1720, 1721, 1724, 1725, 1731, 1735, 1736, 1737, 1738, 1739, 1740, 1742, 1753, 1755, 1765, 1799, 1800

X

Xanthines, 1287
Xanthones, 1287
Xenon-131, 1711, 1721
Xenon-133, 1711, 1721, 1753
Xenon-135, 1711
Xylene, 1134

Y

Yaltox, 800

Table 33.2 Common and Scientific Names of Plants and Animals Listed in the *Handbook of Chemical Risk Assessment series* (References are provided from common names to scientific names)

A

Abalone	<i>Agelaius phoeniceus</i> , 269, 370, 800, 806, 861, 862, 890, 964, 977, 1006, 1036, 1076, 1077, 1096, 1135, 1289, 1466
Black, <i>Haliotis cracherodii</i> , 147	<i>Agkistrodon piscivorus</i> , 1466
Red, <i>Haliotis rufescens</i> , 5, 52, 147, 256, 442, 515, 659	<i>Agosia chrysogaster</i> , 663
Various, <i>Haliotis tuberculata</i> , 442	<i>Agriolimax reticulatus</i> , 976
Abarenicola pacifica	<i>Agrobacter</i> sp., 67
Abelmoschus esculentus	<i>Agropyron cristatum</i> , 1427
Abies pindrow	<i>Agropyron smithii</i> , 1667
Abies spp.	<i>Agrostis capillaris</i> , 143
Acacia georginae	<i>Agrostis orthogonia</i> , 894
Acacia spp.	<i>Agrostis stolonifera</i> , 15
Acanthocephalan, <i>Paratenuisentis</i> sp.	<i>Agrostis tenuis</i> , 1168, 1516
Acanthogobius flavimanus	<i>Agrotis epsilon</i> , 1733
Acartia clausi	<i>Aix sponsa</i> , 12, 20, 332, 347, 1027, 1034, 1055, 1741, 1787
Acartia spp.	<i>Ajaia ajaja</i> , 350
Acartia tonsa	<i>Albacore</i> , <i>Thunnus alalunga</i> , 1740
Accipiter sp.	<i>Albatross</i> , 121
Accipiter cooperii	Black-footed, <i>Diomedea nigripes</i> , 1239
Accipiter fasciatus	Laysan, <i>Diomedea immutabilis</i> , 203, 220, 238, 1239
Accipiter gentilis	<i>Alburnus alburnus</i> , 579, 1110
Accipiter nisus	<i>Alcaligenes</i> sp., 453
Accipiter striatus	<i>Alca torda</i> , 1289, 1308
Acer macrophyllum	<i>Alces alces</i> , 13, 59, 61, 380, 437, 449, 1649, 1669, 1756, 1759, 1766, 1806
Acer rubrum	<i>Alces alces gigas</i> , 1623, 1633
Acheta domesticus	<i>Alcyonia alcyonium</i> , 628
Acheta pennsylvanicus	<i>Aldrichetta forsteri</i> , 63, 64
Acholla multispinosa	<i>Alectoris chukar</i> , 371, 890, 1543
Achylla sp.	<i>Alectoris graeca</i> , 1434
Acipenser nudiventris	<i>Alewife</i> , <i>Alosa pseudoharengus</i> , 55, 1148, 1202, 1288, 1320, 1517
Acipenser oxyrinchus	<i>Alfalfa</i> , <i>Medicago sativa</i> , 137, 337, 456, 483, 746, 1095, 1161, 1168, 1427, 1516, 1530, 1584, 1621, 1763
Acipenserstellatus	<i>Algae</i>
Acmaea digitalis	<i>Amphidinium</i> sp., 656
Acris crepitans	<i>Amphora coffeaeformis</i> , 582
Acris sp.	<i>Anabaena</i> sp., 748, 777, 1302
Acrobeloides sp.	<i>Anacystis</i> sp., 457, 458, 522, 655, 1586, 1675
Acrocheilus alutaceus	<i>Ankistrodesmus</i> sp., 893
Actinomycete, <i>Nocardiopsis</i> sp.	<i>Asterionella formosa</i> , 21
Actinomycetes sp.	<i>Asteromonas gracillis</i> , 573
Adamussium colbecki	<i>Bellerochea polymorpha</i> , 1587
Adelotus brevis	<i>Bladder wrack</i> , <i>Fucus vesiculosus</i> , 5, 52, 224, 440, 656, 1519, 1534, 1730, 1735
Adinia xenica	<i>Blidingia minima</i> , 224
Aechmophorus occidentalis	<i>Blue-green</i>
1524, 1659	<i>Anabaena flos-aquae</i> , 96
Aedes aegypti	<i>Aphanizomenon flos-aquae</i> , 96

Striped, *Morone saxatilis*, 7, 18, 22, 62, 155, 332, 342, 376, 462, 518, 575, 665, 767, 799, 841, 860, 886, 888, 1021, 1268, 1284, 1303, 1468, 1517, 1523, 1589, 1659, 1663, 1677, 1678, 1739
White, *Morone chrysops*, 839
Bat
 Big brown, *Eptesicus fuscus*, 243, 639, 823
 Common pipistrelle, *Pipistrellus pipistrellus*, 1217, 1219, 1299
 Dutch pond, *Myotis dasycneme*, 1202
 Eastern big-eared, *Plecotus phyllotis*, 990
 Fruit, *Pteropus* sp., 247
 Gray, *Myotis grisescens*, 641, 834, 853
 Greater horseshoe, *Rhinolophus ferrumequinum*, 1299
 Indiana, *Myotis sodalis*, 990
 Little brown, *Myotis lucifugus*, 222, 245, 834, 943
 Mexican free-tailed, *Tadarida brasiliensis*, 15, 249, 1526
 Schreiber's, *Miniopterus schreibersii*, 1299
 Southeastern, *Myotis austroriparius*, 641
Bean
 Buck, *Menyanthes trifoliata*, 1767
Castor, *Ricinus communis*, 746, 922
 Green, *Phaseolus vulgaris*, 252, 922, 1039, 1584
 Jack, *Canavalia* sp., 453, 918
 Lima, *Phaseolus lunatus*, 903, 989
Phaseolus sp., 521, 746, 812, 918, 1093
Vicia faba, 141, 426, 1776
Bears
 Brown, *Ursus arctos*, 59, 361, 383
 Polar, *Ursus maritimus*, 103, 123, 135, 336, 361, 363, 520, 834, 1264, 1298, 1301, 1464, 1671
Beaver
 Common, *Castor canadensis*, 336, 356, 438, 572, 1669, 1733, 1744
 European, *Castor fiber*, 13
 Mountain, *Aplodontia rufa*, 1029
Beaver(s), 4
Becium horblei, 132
Bee
 Alfalfa leaf cutter, *Megachile rotundata*, 1103, 1104
 Alkali, *Nomia melanderi*, 1104
 Bumble, *Bombus* spp., 112
 Cuckoo bumble, *Psithyrus bohemicus*, 112
 Honey, *Apis mellifera*, 111, 226, 621, 627, 961, 990, 991, 1012, 1013, 1102, 1103, 1169, 1428, 1532, 1533, 1585
Beet, *Beta vulgaris*, 434, 1531, 1577, 1583, 1626
Beetle
 aquatic
Hydrophilus triangularis, 996
Thermonectes basillaris, 996
Tropisternus lateralis, 996
 Burying, *Nicrophorus tomentosus*, 228
 Colorado potato, *Leptinotarsa decemlineata*, 1504
 Convergent lady, *Hippodamia convergens*, 991
Cotesia melanoscela, 991
Dendroides sp., 644
Diachasmimorpha longicaudata, 1777
 Ground, *Calosoma* sp., 1096
 Japanese, *Popillia japonica*, 837
 Leaf, *Paropsis atomaria*, 922
Perga dorsalis, 1428
 Sawtoothed grain, *Oryzaephilus surinamensis*, 883
 Tiger, *Megacephala virginica*, 922
 Yellow mealworm, *Tenebrio molitor*, 991
Bellerococha polymorpha, 1587
Bemisia tabaci, 1102
Berardius bairdii, 1271
Beroe cucumis, 1579
Berry
 Bil, *Vaccinium myrtillus*, 1759, 1767
 Bog whortle, *Vaccinium uliginosum*, 1767
 Cow, *Vaccinium vitis-idaea*, 1767
Beta vulgaris, 434, 1531, 1577, 1583, 1626
Beta vulgaris cicla, 224, 568
Bettong
 Brush-tailed, *Bettongia penicillata*, 1444
 Burrowing, *Bettongia leseur*, 1441
Bettongia leseur, 1441
Bettongia penicillata, 1444
Betula nana, 1765
Betula papyrifera, 438
Betula sp., 1762, 1767
 Bilberry, *Vaccinium* sp., 1762
 Bilby, greater, *Macrotis lagotis*, 1444
Biomphalaria alexandrina, 1170
Biomphalaria glabrata, 146, 574, 575, 579, 658
Biomphalaria spp., 560, 578, 750
Biomphalaria sudanica, 579

- Birch
 Dwarf, *Betula nana*, 1765
 Paper, *Betula papyrifera*, 438
 Various, *Betula* sp., 1762, 1767
- Birgus latro*, 1749
- Bison
 American, *Bison bison*, 124, 835, 1669
 European, *Bison bonasus*, 124
- Bison bison*, 124, 835, 1669
- Bison bonasus*, 124
- Blaberus giganteus*, 1776
- Blackbird
 Brewer's, *Euphagus cyanocephalus*, 1432, 1435
 Common, *Turdus merula*, 241, 638, 895, 1668
 Red-winged, *Agelaius phoeniceus*, 269, 370, 800, 806, 861, 862, 890, 964, 977, 1006, 1036, 1076, 1077, 1096, 1135, 1289, 1466
- Blackfish
 Common, *Gadopsis marmoratus*, 341
 Large-scale, *Girella punctata*, 324
 Sacramento, *Orthodon microlepidotus*, 55, 331, 1517
- Blackfly, *Simulium* sp., 228
- Blacktail, *Diplodus sargus*, 340
- Blarina brevicauda*, 13, 242, 248, 250, 336, 365, 645, 807, 1788
- Blattella germanica*, 883, 991, 1169, 1584, 1585
- Bleak, *Alburnus alburnus*, 579, 1110
- Blepharisma undulans*, 1102
- Blidingia minima*, 224
- Blissus leucopterus listus*, 895
- Bloater, *Coregonus hoyi*, 117, 1266, 1283, 1514
- Blueberry
 Common, *Vaccinium pallidum*, 225
 Lowbush, *Vaccinium angustifolium*, 128, 440, 1516
- Bluebird, eastern, *Sialia sialis*, 846, 1048, 1786, 1788
- Bluefish, *Pomatomus saltatrix*, 8, 332, 435

Gallus domestica, 138, 371, 931, 934, 1385, 1593, 1685
Gallus gallus, 1543
Gallus spp., 20, 61, 66, 142, 167, 210, 267, 270, 427, 446, 454, 464, 465, 482, 534, 584, 625, 635, 646, 676, 677, 679, 689, 752, 785, 786, 812, 861, 862, 890, 891, 892, 1005, 1006, 1048, 1055, 1076, 1115, 1137, 1142, 1167, 1176, 1214, 1292, 1302, 1307, 1310, 1322, 1436, 1503, 1544, 1623, 1786, 1787
Gambusia affinis, 26, 55, 340, 367, 377, 529, 664, 674, 750, 805, 856, 886, 888, 1000, 1002, 1042, 1096, 1110, 1139, 1173, 1206, 1374, 1380, 1382, 1465, 1517, 1578, 1589, 1656, 1664, 1676
Gambusia holbrooki, 1731, 1739
Gambusia sp., 250, 369, 893, 1777
Gammaurus duebeni, 369, 661, 671
Gammaurus fasciatus, 782, 858, 965, 1172, 1468
Gammaurus lacustris, 886, 887 1766
Gammaurus oceanicus, 577
Gammaurus pseudolimnaeus, 142, 151, 257, 367, 528, 782, 927, 998, 1108, 1209, 1304, 1373, 1469, 1533, 1537
Gammaurus pulex, 151, 613, 887, 923, 927
Gammaurus spp., 64, 459, 778, 1136, 1629, 1783
 Gannet, northern, *Morus bassanus*, *Sula bassanus*, 354, 834, 851, 1297
Gar

- Lepisosteus* sp., 313
 Longnose, *Lepisosteus osseus*, 924
 Spotted, *Lepisosteus oculatus*, 643, 1464, 1466
Garra rufa, 452
Gasterosteus aculeatus, 18, 260, 341, 529, 576, 614, 675, 859, 888, 1468
Gastrolobium grandiflorum, 1426
Gastrolobium spp., 1413, 1426, 1429
Gastrophryne carolinensis, 160, 367, 464, 480, 668, 675, 688, 1533, 1538
Gavia immer, 202, 238, 333, 334, 349, 379, 446, 1666
 Geese, white-fronted, *Anser albifrons*, 232
Geissosoma prainosum, 439
Geocoris punctipes, 991
Geomys breviceps, 1443
Geomys bursarius, 938
Geomys floridanus, 1443
Geomys personatus, 1437
Geranium, *Geranium* spp., 746
Geranium spp., 746
 Gerbil, *Gerbillus* sp., *Meriones*, 588
Gerbillus sp., 588
Geukensia demissa, 1170, 1172, 1283
 Gifblaar, *Dichapetalum cymosum*, 1413
Gila bicolor, 571
Gila elegans, 1588, 1676
Gilia altissima, 1208
 Ginger, *Zingiber officinale*, 1735
Girella punctata, 324
Glebula rotundata, 812, 813
Glenodinium halli, 656, 689
Globicephala macrorhynchus, 9, 1660
Globicephala melaena, 122, 640, 852, 1467
Globicephala melas, 9, 25
Glossiphonia complanata, 782
Glyceria dibranchiata, 909
Glyceria borealis, 1004
Glycine max, 12, 140, 253, 421, 453, 456, 521, 767, 774, 775, 909, 989, 1093, 1168, 1427, 1530, 1532, 1583
Glyptocephalus cynoglossus, 1548
Glyptotendipes paripes, 996
 Gnat, *Chaoborus* spp., 1136
 Gnatcatcher, blue-gray, *Polioptila caerulea*, 1005
Gnathonomes sp., 928
Gnathopodon caerulescens, 583, 889
 Goat, domestic, *Capra hircus*, *Capra* sp., 124, 276, 454, 469, 639, 649, 691, 865, 890, 905, 911, 1010, 1033, 1081, 1179, 1414, 1427, 1442, 1469, 1547, 1761
 Goatfish, *Mullus*, *Upeneus*, 633
 Goby
 Edible, *Boleophthalmus dussumieri*, 62, 69, 1683
 Lizard, *Rhinogobius flumineus*, 842
 Various, *Acanthogobius flavimanus*, 837
 Godwit, bar-tailed, *Limosa lapponica lapponica*, 1743
Goeldichironomus holoprasinus, 996
 Goldeneye
 Barrows, *Bucephala islandica*, 1623
 Common, *Bucephala clangula*, 220, 352, 446, 846, 1308
 Goldfish, *Carassius auratus*, 62, 69, 154, 165, 260, 377, 457, 461, 576, 579, 583, 750, 783, 805, 856, 859, 966, 1136, 1141, 1206, 1212, 1468, 1471, 1538, 1552, 1588, 1676, 1738, 1770
Gonatopsis borealis, 835
 Goose
 Aleutian Canada, *Branta canadensis leucoparlia*, 1416
 Cackling Canada, *Branta canadensis minima*, 846
 Canada, *Branta canadensis*, *Branta canadensis moffitti*, 219, 220, 235, 269, 895, 961, 1076, 1418, 1732, 1741
 Giant Canada, *Branta canadensis maxima*, 624, 679
 Greylag, *Anser anser*, 202, 219, 1308, 1743
 Lesser snow, *Chen caerulescens caerulescens*, 236, 284
 Various, *Anser* spp., *Branta*, 961, 968, 977
 Goosefish, *Lophius piscatorius*, 74
 Gopher
 Breviceps pocket, *Geomys breviceps*, 1443
 Texas pocket, *Geomys personatus*, 1437
 Tuza pocket, *Geomys floridanus*, 1443
 Various, *Geomys*, *Thomomys* sp., 961
Gopherus polyphemus, 1741
Gorgia flabellum, 835
Gorilla gorilla gorilla, 244
Gorilla gorilla gorilla, 244, 640
 Goshawk
 Brown, *Accipiter fasciatus*, 1432
 Various, *Accipiter gentilis*, 346, 1289
Gossypium hirsutum, 746, 810, 989, 1092, 1095
Gossypium sp., 812
 Gourami
 Blue, *Trichogaster* sp., 369
 Giant, *Colisa fasciata*, 461
 Grackle
 Common, *Quiscalus quiscula*, 370, 806, 807, 846, 861, 890, 1076
 Great-tailed, *Quiscalus mexicanus*, 1466
Grallina cyanoleuca, 1432, 1436
 Gram, *Cicer arietinum*, 774
 Grape, *Vitis* sp., 1093, 1668
 Grass
 Arrow, *Triglochin* spp., 905
 Bahia, *Paspalum notatum*, 1143
 Barley, *Hordeum glaucum*, 1168
 Blue, *Poa annua*, 1504
 Brome, *Bromus inermis*, *Bromus* spp., 224, 1626
 Buffalo, *Bouteloua dactyloides*, 1667
 Colonial bent-, *Agrostis tenuis*, 1168, 1516
 Common Bermuda, *Cynodon dactylon*, 1532, 1621
 Copper-tolerant, *Agrostis capillaris*, 143
 Crab, *Digitaria sanguinalis*, 1504
 Creeping bent, *Agrostis tenuis*, 15, 1168, 1516
 Crested wheat, *Agropyron cristatum*, 1427
 Eel, *Zostera* spp., 111
 Hair, *Deschampsia flexuosa*, 110, 128, 132, 434, 439, 1767
 Johnson, *Sorghum halepense*, 812, 905
 Kentucky blue, *Poa pratensis*, 1168, 1531
 Marsh, *Spartina* sp., 52, 435, 452
 Orchard, *Dactylis glomerata*, 1168
 Perennial rye, *Lolium perenne*, 521, 895, 1168, 1621, 1757, 1763
 Red fescue, *Festuca rubra*, 224, 1168
 Redhead, *Potamogeton perfoliatus*, 776, 779
 Reed canary, *Phalaris arundinacea*, 1732, 1734
 Rhodes, *Chloris gayana*, 1583

- Saltmarsh, *Spartina alterniflora*, 330, 441, 777, 780, 782, 1534
- Sea, *Heterozostera tasmanica*, 144
- Shoal, *Halodule wrightii*, 54, 780, 1527, 1671
- Star, *Cynodon plectostachyus*, 918, 936
- Sudan, *Sorghum sudanense*, *Sorghum alnum*, 905
- Turtle, *Thalassia testudinum*, 451
- Western wheat, *Agropyron smithii*, 1667
- Widgeon, *Ruppia maritima*, 1517, 1578, 1591
- Grasshopper**
- Oxya velox*, 106
 - Senegalese, *Oedaleus senegalensis*, 894
- Grayling, Arctic, *Thymallus arcticus*, 160, 463, 531, 619, 667
- Grebe**
- Eared, *Podiceps nigricollis*, 1666, 1667
 - Great crested, *Podiceps cristata*, 354
 - Pied-billed, *Podilymbus podiceps*, 1466
 - Western, *Aechmophorus occidentalis*, 119, 346, 348, 1524, 1659
- Greenfinch, *Carduelis chloris*, 636, 1433
- Grindelia* spp., 1652
- Grindelia squarrosa*, 1667
- Griselinia littoralis*, 1418
- Groundnut, *Arachis hypogaea*, 810, 1427
- Grouse**
- Black, *Tetrao tetrix*, 1768
 - Red, *Lagopus lagopus*, 1768
 - Ruffed, *Bonasa umbellus*, 120, 235, 436, 446, 518, 571, 1732, 1741
 - Sharp-tailed, *Tympanuchus phasianellus*, 1469
- Grunion, California, *Leuresthes tenuis*, 886, 888, 889, 1111, 1375
- Grus americana*, 202, 238, 1580
- Grus canadensis*, 202, 890, 1076, 1580
- Grus canadensis canadensis*, 1469
- Grus canadensis pulla*, 238
- Grylliidae, 613, 614, 855, 1102, 1103
- Gudgeon, topmouth, *Pseudorasbora parva*, 971
- Guillemet
- Brunnich's, *Uria lomvia*, 834, 851, 1661
 - Cephus sp., 1463, 1466
 - Common, *Uria aalge*, 136, 1027, 1297, 1660
- Gull**
- Audouin's, *Larus audouinii*, 1289, 1293
 - Bonaparte's, *Larus philadelphia*, 352
 - California, *Larus californicus*, 352, 799
 - Common black-headed, *Larus ridibundus*, L. r. *ridibundus*, 350, 1311, 1731, 1743, 1768, 1788

 Western jumping, *Zapus princeps*, 60
 White-footed, *Peromyscus leucopus*, 246, 248, 250, 365, 590, 645, 807, 814, 944, 962, 975, 978, 1095, 1440, 1445, 1793, 1798
 Wood, *Apodemus sylvaticus*, 124, 242, 248, 275, 355, 1515
 Yellow-necked field, *Apodemus flavicollis*, 644
 Mouth brooder, southern, *Pseudocrenilabrus philander*, 118
Moxostoma duquesnei, 230
Mudalia potosensis, 1374
 Mudpuppy, *Necturus maculosus*, 612, 909, 1785
Mugil cephalus, 860, 888, 1111, 1141, 1173, 1213, 1268, 1281, 1369, 1465, 1523
Mugil curema, 643
 Mule, *Equus asinus* X *Equus caballus*, 243, 1443
Mulinia lateralis, 1207
 Mullet
 Gray, *Chelon labrosus*, 73, 1541
 Striped, *Mugil cephalus*, 860, 888, 1111, 1141, 1173, 1213, 1268, 1281, 1369, 1465, 1523
 Various, *Rhinomugil corsula*, 1213
 White, *Mugil curema*, 643
 Yellow-eye, *Aldrichetta forsteri*, 63, 64
Mullus barbatus, 118, 567, 1269
Mummichog, *Fundulus heteroclitus*, 26, 27, 28, 63, 118, 154, 263, 369, 374, 375, 377, 462, 529, 578, 655, 664, 674, 893, 1000, 1040, 1074, 1110, 1205, 1213, 1283, 1304, 1739
Murex trunculus, 364
 Murre
 Common, *Uria aagle*, 136, 1027
 Thick-billed, *Uria lomvia*, 834, 851, 1660
 Murrel, *Channa punctatus*, 19, 69, 154, 376, 663, 811, 966
 Murrelet, marbled, *Synthliboramphus antiquus*, 1524
Musca autumnalis, 988, 1009, 1116
Musca domestica, 809, 969, 990, 1009, 1079, 1103, 1104, 1116, 1585
Musca sp., 812, 1072
Mus domesticus, 245
 Mushroom, *Agaricus*, *Amantia muscaria*, *Collybia*, *Lactarius*, 1516
 Muskellunge, *Esox masquinongy*, 444
 Muskox, *Ovibus moschatus*, 4, 32, 126
 Muskrat, *Ondatra zibethicus*, 126, 136, 246, 336, 358, 572, 1733, 1746
Mus musculus, 129, 247, 270, 449, 768, 806, 942, 964, 969, 975, 978, 1095, 1181, 1388, 1445, 1668, 1669, 1756, 1792
Mus musculus domesticus, 449, 1759, 1764
 Mussel
 Amblema sp., 112
 Anodonta, 102, 146, 441, 574, 578, 613, 994, 997, 1072, 1079
 Brown, *Perna indica*, 149
 California, *Mytilus californianus*, 336, 339, 514, 516, 669, 1384
 Common, *Mytilus edulis*, 6, 52, 71, 114, 134, 148, 161, 228, 262, 339, 368, 442, 459, 516, 523, 526, 569, 575, 582, 615, 622, 623, 629, 643, 655, 659, 669, 670, 742, 750, 805, 916, 928, 1038, 1201, 1202, 1265, 1281, 1362, 1366, 1378, 1520, 1541, 1622, 1627, 1629, 1658, 1684, 1731, 1736
 Duck, *Anodonta anatina*, *A. nuttalliana*, 441, 574, 578, 1207
 Green-lipped, *Perna viridis*, 115, 149, 570, 629, 660
 Hooked, *Ischadium recurvum* (formerly *Brachidontes exustus*), 642
 Ischadium exustus, 520
 Lagoon, *Mytila striata*, 114
 Lake, *Anodonta piscinalis*, 112, 129
 Mytilopsis sallei, 19, 22
 Mytilus sp., 114, 134, 161, 748, 1264, 1366
 Ribbed, *Geukensia demissa*, 1170, 1172, 1283
 Villosa iris, 149
 Zebra, *Dreissena polymorpha*, 55, 114, 134, 147, 227, 526, 569, 628, 1278, 1303, 1304, 1365
Mus spp., 23, 66, 126, 170, 277, 286, 471, 537, 587, 588, 589, 590, 613, 650, 683, 692, 757, 787, 863, 866, 939, 942, 1010, 1049, 1050, 1078, 1081, 1085, 1118, 1135, 1136, 1181, 1216, 1219, 1315, 1387, 1418, 1438, 1445, 1469, 1597, 1635, 1686, 1792
 Mustard, *Brassica juncea*, 774, 775
Mustela erminea, 1298, 1301
Mustela nigripes, 1415
Mustela nivalis, 24, 1298, 1301
Mustela putorius, 380, 939, 1298, 1300
Mustela putorius furo, 245, 683, 693
Mustela vison, 139, 171, 245, 336, 357, 373, 382, 449, 650, 693, 1050, 1144, 1150, 1298, 1300, 1302, 1312, 1316, 1322, 1421, 1446
Mustelus antarcticus, 1514
Mustelus canis, 53, 518
Mustelus manazo, 1515
Mustelus putorius, 101, 1445, 1792
Mya arenaria, 70, 71, 142, 148, 222, 262, 339, 368, 457, 459, 515, 526, 655, 659, 669, 1201, 1365
Mya sp., 25
Mycteria americana, 332, 352, 1668
Myiarchus cinerascens, 1432
Myiarchus crinitus, 1005, 1786, 1788
Myiarchus sp., 1771
Myocastor coypus, 1446
Myotis austroriparius, 641
Myotis dasycneme, 1202
Myotis grisescens, 641, 834, 853
Myotis lucifugus, 222, 245, 834, 943

- Myotis sodalis*, 990
Myotis spp., 14, 245
Myoxocephalus quadricornis, 842
Myoxocephalus scorpius, 8
Myoxocephalus sp., 1464

 Heermann's kangaroo, *Dipodomys heermanni*, 1439
 Kangaroo, *Dipodomys* spp., 1417, 1443, 1449
 Laboratory white, *Rattus* spp., 19, 23, 66, 127, 169, 172, 177, 208, 278, 373, 450, 454, 473, 483, 484, 535, 537, 587, 588, 589, 590, 613, 642, 651, 684, 693, 758, 774, 787, 806, 808, 812, 867, 870, 944, 984, 1011, 1014, 1055, 1068, 1078, 1083, 1085, 1114, 1120, 1135, 1136, 1142, 1182, 1215, 1220, 1302, 1308, 1313, 1317, 1322, 1387, 1388, 1426, 1441, 1469, 1474, 1476, 1546, 1550, 1624, 1636, 1640, 1793
 Marsh rice, *Oryzomys palustris*, 1793
 Morro Bay kangaroo, *Dipodomys heermanni morroensis*, 1450
 Norway, *Rattus norvegicus*, 247, 382, 768, 890, 1363, 1418, 1441, 1447, 1670, 1793
 Roof (black), *Rattus rattus*, 964, 968, 975, 978, 1441, 1447, 1749, 1751
 Swamp, *Rattus lutreolus*, 1447
 Thick-tailed, *Zyzomys argurus*, 1449
 Tunney's, *Rattus tunneyi*, 1447
 Water-, *Hydromys chrysogaster*, 1443
 White-throated wood, *Neotoma albigenula*, 1446
 Wood, *Neotoma intermedia*, 1446
Ratsbane, *Dichapetalum toxicarium*, 1413
Rattus alexandricus, 1447
Rattus fuscipes, 1447
Rattus lutreolus, 1447
Rattus norvegicus, 247, 382, 768, 890, 1363, 1418, 1441, 1447, 1670, 1793
Rattus rattus, 964, 968, 975, 978, 1441, 1447, 1749, 1751
Rattus sordidus, 1447
Rattus spp., 19, 23, 66, 127, 172, 177, 208, 278, 373, 382, 450, 454, 473, 483, 484, 535, 537, 587, 588, 589, 590, 613, 642, 651, 684, 693, 758, 774, 787, 806, 808, 812, 867, 870, 944, 984, 1011, 1014, 1055, 1068, 1078, 1083, 1085, 1114, 1120, 1135, 1136, 1142, 1182, 1215, 1220, 1302, 1308, 1313, 1317, 1322, 1387, 1388, 1426, 1441, 1469, 1474, 1476, 1546, 1550, 1624, 1636, 1640, 1793
Rattus tunneyi, 1447
Raven
 Australian, *Corvus coronoides*, 1432, 1435
 Common, *Corvus corax*, 234, 446, 625
 Little, *Corvus mellori*, 1435
Ray
 Electric, *Torpedo* sp., 1099
 Raja radiata, 341
 Thornback, *Raja clavata*, 533
 Various, *Raja* sp., 341, 1514, 1523
Razorbill, *Alca torda*, 1289, 1308
Recurvirostra americana, 1515, 1580, 1657, 1666
Redhead, *Aythya americana*, 120, 242, 446
Redhorse, black, *Moxostoma duquesnei*, 230
Redshank
 Common, *Tringa totanus*, 122
 Icelandic, *Tringa totanus robusta*, 1525
Regulus satrapa, 1006
Reindeer, *Rangifer tarandus*, 4, 32, 126, 380, 437, 450, 451, 1072, 1085, 1761, 1762, 1791
Reinhardtius hippoglossoides, 341
Reithrodontomys humulis, 1794
Reithrodontomys megalotis, 1439
Reithrodontomys raviventris, 1450
Renibacterium salmoninarum, 1674
Reticulitermes flavipes, 1626
Rhacomitrium sp., 451
Rheoxynius abronius, 1627
Rheumobates spp., 442
Rhinichthys osculus, 531
Rhinobatos lentiginosus, 118
Rhinoceros, black, *Diceros bicornis*, 1673
Rhinogobius flumineus, 842
Rhinolophus ferrumequinum, 1299
Rhinomugil corsula, 1213
Rhizobium sp., 885
Rhizoctonia solani, 774, 921
Rhizophora mangle, 451
Rhizopus sp., 1169
Rhizosolenia sp., 656, 689
Rhodotorula sp., 457
Rhyncostegium ripariooides, 145, 927
Rice
 Domestic, *Oryza sativa*, 225, 337, 382, 439, 453, 1204, 1530, 1532, 1667
 Wild, *Zizania aquatica*, 255
Richmondena cardinalis, 1096
Ricinus communis, 746, 922
Rissa tridactyla, 9, 333, 354, 624, 637, 1660
Rithropanopeus harrisi, 578, 614, 662, 689, 999, 1171, 1468
Rivulus, mangrove (fish), *Rivulus marmoratus*, 159
Rivulus marmoratus, 159
Roach (fish), *Rutilus rutilus*, 229, 1762
Robin

- American, *Turdus migratorius*, 13, 234, 241, 810, 846, 1542, 1623
 European, *Erithacus rubecula*, 1075
 Rosella, crimson, *Platycercus elegans*, 1433
Rostrhamus sociabilis, 166, 1214, 1215
 Rotifer, *Asplanchna*, *Brachionus*, 1004
Rubus frondosus, 644
Rubus sp., 130
 Rudd, *Scardinius erythrophthalmus*, 69
Ruppia maritima, 1517, 1578, 1591
Ruppia spp., 780, 927
Rutilus rutilus, 229, 1762
 Rye, perennial, *Lolium perenne*, 521, 895, 1168, 1621, 1757, 1763
 Rye, *Secale cereale*, 57, 1667
Rynchos niger, 355, 850, 1659, 1660
- S**
- Sabellidae*, 529
Saccharomyces cerevisiae, 746, 864, 1008, 1216
Saccharomyces spp., 1204
Saccharum officinarum, 746, 767, 1097, 1167
Saccharum sp., 1093
Saccobranchus fossilis, 69, 159, 164, 805, 860
Saccostrea commercialis, 115
Saccostrea cucullata, 115, 612, 629
Saccostrea sp., 516
 Saddleback, *Philesturnus carunculatus*, 1433
 Sagebrush, big, *Artemisia tridentata*, 56, 1577
Sagitta elegans, 1579
Saguinus fuscicollis, 961
Saimiri sciurea, 761
Saimiri spp., 1794
 Salamander
 Eastern red-backed, *Plethodon cinereus*, 130, 250
 Jefferson, *Ambystoma jeffersonianum*, 135, 261, 1586, 1588
 Marbled, *Ambystoma opacum*, 160, 264, 368, 463, 668, 1538
 Necturus, 1785
 Northwestern, *Ambystoma gracile*, 17, 22, 25
 Spotted, *Ambystoma maculatum*, 131, 1373, 1586, 1588
 Tiger, *Ambystoma tigrinum*, 1355
 Two-lined, *Eurycea bislineata*, 160
Salix spp., 4, 1765, 1767
Salmo clarki. see *Oncorhynchus clarkii*
Salmo gairdneri. see *Oncorhynchus mykiss*
 Salmon
 Atlantic, *Salmo salar*, 21, 135, 159, 567, 571, 607, 624, 633, 667, 674, 688, 842, 914, 930, 970, 1001, 1113, 1139, 1141, 1212, 1270, 1375, 1519, 1649, 1781
 Chinook, *Oncorhynchus tshawytscha*, 18, 68, 158, 531, 567, 666, 675, 751, 860, 929, 1030, 1148, 1212, 1269, 1282, 1284, 1302, 1322, 1539, 1590, 1630, 1664, 1674, 1677, 1770, 1780
 Chum, *Oncorhynchus keta*, 530, 567, 842, 1539
 Coho, *Oncorhynchus kisutch*, 18, 68, 155, 254, 462, 530, 665, 805, 860, 929, 1001, 1030, 1040, 1044, 1136, 1148, 1202, 1211, 1212, 1280, 1374, 1381, 1468, 1519, 1589, 1627, 1629, 1656, 1664, 1677, 1739, 1779
 Kokanee (see Sockeye)
 Pink, *Oncorhynchus gorbuscha*, 567, 1374, 1541
 Sockeye, *Oncorhynchus nerka*, 666, 1210, 1221, 1579, 1586, 1590, 1620, 1738
Salmonella pullorum-gallinarum, 534
Salmonella sp., 28, 617, 754, 759, 1473
Salmonella typhimurium, 67, 746, 815, 864, 1008, 1039, 1216, 1370, 1385, 1515, 1572
Salmo salar, 21, 135, 159, 567, 571, 607, 624, 633, 667, 674, 688, 914, 930, 970, 1001, 1113, 1139, 1141, 1212, 1270, 1375, 1519, 1649, 1781
Salmo spp., 343
Salmo trutta, 11, 21, 102, 159, 259, 531, 667, 673, 688, 751, 805, 860, 914, 931, 1026, 1173, 1202, 1270, 1363, 1372, 1519, 1738, 1758, 1766, 1781, 1784
Salmo trutta fario, 1031, 1270
Salpa fusiformes, 1579
 Saltbush, *Atriplex* spp., 1652, 1667
Salvelinus alpinus, 73, 218, 230, 1213, 1284, 1465
Salvelinus fontinalis, 18, 19, 20, 21, 65, 159, 259, 343, 367, 375, 384, 463, 634, 667, 783, 860, 931, 966, 970, 971, 972, 1001, 1040, 1046, 1139, 1141, 1213, 1471, 1472, 1540, 1628, 1677, 1738
Salvelinus namaycush, 56, 65, 159, 259, 343, 445, 463, 571, 578, 805, 842, 856, 888, 966, 1026, 1027, 1029, 1030, 1040, 1046, 1054, 1147, 1202, 1270, 1282, 1462, 1519, 1577, 1682, 1738
Sambucus spp., 905
 Sanddab, speckled, *Citharichthys stigmaeus*, 63, 74, 578
 Sand dollar, *Dendraster excentricus*, 663, 689
 Sanderling, *Calidris alba*, 57, 121
 Sandpiper
 Calidris pusilus, 57
 Erolia spp., 800
Saprolegnia parasitica, 929
Saprolegnia sp., 456
Sarcophilus harrisii, 1424, 1448
Sarcorhampus papa, 202
Sargassum fluvitans, 1519
Sargassum sp., 441, 452, 1519
 Sauger, *Stizostedion canadense*, 11, 839
 Scallop
 Antarctic, *Adamussium colbecki*, 112
 Bay, *Argopecten irradians*, 146, 161, 368, 525, 658
 Mizuhopecten yessoensis, 148
 Pacific, *Chlamys ferrei nipponensis*, 323
 Sea, *Placopecten magellanicus*, 6, 442, 516, 1520
Scaphirhynchus platyrhynchus, 832, 839
Scardinius erythrophthalmus, 69
Scarus gyttatus, 633
 Scaup
 Greater, *Aythya marila*, 348, 446, 518, 1291, 1666
 Lesser, *Aythya affinis*, 8, 235, 242
Sceloglaux albifascies; 1433
Scenedesmus acutiformis, 145, 458
Scenedesmus costatum, 1207
Scenedesmus obliquus, 1533, 1536, 1778

- Scenedesmus quadricauda*, 573, 656, 777, 856, 857, 927
Scenedesmus spp., 524, 1302
Scenedesmus subspicatus, 145
Schistoma gregaria, 894
Schistosoma mansoni, 750
Schroederella schroederi, 655, 657, 689
Sciaenops ocellatus, 96, 118, 159, 445, 838
Scinax nasica, 1174
Sciurus carolinensis, 15, 127, 360, 450, 854
Sciurus hudsonicus. see *Tamiasciurus hudsonicus*
Sclerotium rolfsii, 774
Scolopax minor, 1055, 1149
Scolopax rusticola, 1766, 1768
Scomberomorus cavalla, 634
Scomberomorus maculatus, 119
Scomber scombrus, 634

 Ivory, *Buccinum striatissimum*, 1514
 Pen, *Pinna nobilis*, 70, 442
 Spindle, *Hemifusus* spp., 1520, 1552
- Shiner
 Blacktail, *Notropis venustus*, 1464
 Common, *Notropis cornutus*, 1213
 Golden, *Notemigonus crysoleucas*, 62, 68, 632, 1096, 1303, 1740
 Spottail, *Notropis hudsonius*, 1030, 1147, 1538
 Willow, *Gnathopodion caerulescens*, 583, 889
- Shoveler, northern, *Anas clypeata*, 862, 1787
- Shrew
 Common, *Sorex araneus*, 15, 32, 173, 248, 436, 450, 643, 1515, 1671, 1747, 1767
 Least, *Cryptotis parva*, 448
 Long-tailed, *Sorex minutus*, 450
 Masked, *Sorex cinereus*, 450
 Short-tailed, *Blarina brevicauda*, 13, 242, 248, 250, 336, 365, 645, 807, 1788
- Shrike, loggerhead, *Lanius ludovicianus*, 848, 961, 1149, 1292
- Shrimp
 Aesop, *Pandalus montagui*, 7, 228, 443, 613, 631, 671, 672
 Brine, *Artemia salina*, *Artemia* sp., 660, 997, 1535, 1707, 1778
 Brown, *Penaeus aztecus*, 6, 54, 116, 443, 642, 750, 784, 858, 886, 966, 1374, 1377, 1521, 1527, 1627, 1677
 Clam, *Eulimnadia* spp., 998
 Freshwater, *Paratya australiensis*, 105, 152, 782
 Glass, *Palaemonetes kadiakensis*, 1468
 Grass
 Palaemonetes pugio, 7, 27, 72, 228, 528, 532, 578, 582, 631, 785, 887, 999, 1106, 1109, 1208, 1283, 1303, 1373, 1468, 1534
 Palaemonetes vulgaris, 17, 1074, 1141
 Korean, *Palaemon macrodactylus*, 858, 1468
Lysmata, 1534, 1535, 1658, 1684
 Mysid, *Mysidopsis* spp., 22, 65
Palaemonetes vulgaris, 17, 1074, 1141
- Pandalus jordani*, 115
Penaeopsis joyneri, 971
 Pink, *Penaeus duorarum*, 785, 858, 1106, 1109, 1376, 1377, 1468, 1629
- Sand
 Crangon allmanni, 442
 Crangon crangon, 17, 150, 262, 578, 1521
 Crangon septemspinosa, 857, 1107
Sergestes lucens, 1521
 Tadpole, *Triops longicaudatus*, 1000
 White, *Penaeus setiferus*, 377, 642, 894, 1521
- Sialia sialis*, 846, 1048, 1786, 1788
Sialia sp., 1171
 Sicklepod, *Cassia* spp., 224, 253
Siderastrea siderea, 835
Siganus oramin, 633
Sigara sp., 1172
Sigmodon hispidus, 59, 78, 280, 1095, 1448, 1551, 1733, 1745, 1794
 Silkworm, *Bombyx mori*, 1776, 1777
Sillago bassensis, 1536
 Silverside
 Atlantic, *Menidia menidia*, 63, 155, 462, 529, 888, 889, 1111, 1678
 Inland, *Menidia beryllina*, 888, 889, 1111, 1200, 1222
 Tidewater, *Menidia peninsula*, 155, 462, 665, 888, 889, 1111
Simocephalus serrulatus, 18, 859, 965, 1171, 1538
Simocephalus sp., 1468
Simocephalus vetulus, 887, 1208
Simulium sp., 228
Simulium vittatum, 995, 996
Siphonia cephalotes, 644
Siphlonurus lacustris, 1766
Siphlonurus sp., 893
Siphonaptera, 892
Sitophilus granarius, 923
Sitta carolinensis, 1432
 Skate, little, *Raja erinacea*, 321, 1040
Skeletonema costatum, 22, 165, 261, 522, 524, 573, 574, 577, 579, 657, 689, 995, 1107, 1207, 1540, 1587
Skeletonema sp., 993
 Skimmer, black, *Rynchops niger*, 355, 850, 1659, 1660
 Skink, *Lerista pectorittata*, *Morethia boulengeri*, *Tiliqua*, 860
 Skipper, mud, *Boleophthalmus dussumieri*, 62, 69, 1683
 Skua
 Great, *Catharacta skua*, 348, 354, 1659
 Various, *Catharacta maccormicki*, 361
 Skunk, striped, *Mephitis mephitis*, 823, 1440, 1444
Skwala sp., 997
 Slippersnail, common Atlantic, *Crepidula fornicata*, 368, 375, 442, 526
 Slug
 Grey field, *Deroberas reticulatum*, 621, 627
 Various, *Agriolimax reticulatus*, *Arion* spp., *Deroberas*, 976
 Smelt
 Rainbow, *Osmerus mordax*, 341, 571, 1030, 1148, 1202
 Top, *Atherinops affinis*, 153, 164, 1110

- Sminthopsis crassicaudata*, 1448
Sminthopsis macroura, 1448
Snail
Amnicola sp., 63
Ancylus fluviatilis, 657, 782
Aplexa hypnorium, 749
Apple, *Pomacea paludosa*, 129, 149, 166
Arcularia gibbosula, 339
Australorbis sp., 525
Biomphalaria spp., 560, 578, 750
Bulinus sp., 560, 750
Campeloma decisum, 147
Gillia altilis, 1208
Helisoma sp., 747, 1041
Helix spp., 253
Juga plicifera, 458, 997
Land, *Helix aspersa*, *Arianta arbustorum*, 112, 654, 812
Lanistes carinatus, 887
Lymnaea palustris, 257
Lymnaea peregra, 256
Melanoides sp., 452
Mud
Ilyanassa obsoleta, 114
Nassarius obsoletus, 165, 459, 515, 527, 578, 581, 660, 1541
Nassarius sp., 442
Mudalia potosensis, 1374
Neritina sp., 578
Physa sp., 142, 750, 997, 1003, 1041, 1206, 1376, 1382, 1676
Planorbis corneus, 1781
Pond, *Cipangopaludina malleata*, 971
Ram's horn, *Helisoma trivolvis*, 887, 1108
Red, *Indoplanorbis exustus*, 971, 1044
Thiara tuberculata, 149
Snake
 Cottonmouth, *Agkistrodon piscivorus*, 1466
Elaphe obsoleta, 1741
 Garter, *Thamnophis* sp., 1094, 1385
 Gopher, *Pituophis catenifer*, *Pituophis melanoleucus*, 1430, 1670
 Northern water, *Nerodia sipedon*, 231, 844
 Water, *Natrix* sp., *Nerodia* sp., 1466, 1665, 1783
 Western ribbon, *Thamnophis proximus*, 1096
Snakehead, green, *Ophiocephalus punctatus*, 158
Snapper
Lutjanus fulviflamma, 633
 Mangrove, *Lutjanus griseus*, 1376
Solanum melongena, 1093
Solanum sp., 1092
Solanum tuberosum, 225, 1204, 1667
Sole
 Dover, *Microstomus pacificus*, 444
 English, *Pleuronectes vetulus* (formerly *Parophrys vetulus*), 768, 1279, 1378, 1423
 Flathead, *Hippoglossoides elassodon*, 1282
Limanda sp., 7, 1515
 Sand, *Psettichthys melanostictus*, 1376, 1377
Solea solea, 578
Trinectes maculatus, 1141
Solea solea, 578
Solenopsis invicta, 855, 1102, 1104, 1133, 1152
Solenopsis richteri, 1133
Solenopsis sp., 1143, 1626
Somateria fischeri, 202, 233
Somateria mollissima, 9, 58, 121, 122, 233, 235, 514, 519, 1038, 1150, 1311, 1385
Sorbus aucuparia, 12, 1767
Sorex araneus, 15, 32, 173, 248, 436, 450, 643, 1515, 1671, 1747, 1767
Sorex cinereus, 450
Sorex minutus, 450
Sorex sp., 127, 1179
Sorghum, *Sorghum halepense*, *Sorghum* spp., *Sorghum vulgare*, 746, 767, 812, 905, 918
Sorghum alnum, 905
Sorghum halepense, 812, 905
Sorghum spp., 746, 918
Sorghum vulgare, 767
Sousa chinensis, 1620, 1625
Sowbug, *Asellus* sp., 338, 1171
Soybean, *Glycine max*, 12, 140, 253, 421, 453, 456, 521, 767, 774, 909, 989, 1093, 1168, 1427, 1530, 1532, 1583
Sparrow
 Chipping, *Spizella passerina*, 27, 1005
 House, *Passer domesticus*, 235, 239, 371, 508, 806, 807, 890, 967, 1436, 1668
 Song, *Melospiza melodia*, 1005
 Tree, *Passer montanus*, 235, 1005
Sparrowhawk, European, *Accipiter nisus*, 333, 346, 349, 379, 1289
Spartina alterniflora, 330, 441, 777, 780, 782, 1534
Spartina spp., 52, 435, 452
Sparus aurata, 1382
Sparus macrocephalus, 324
Spermophilus beecheyi, 1431, 1448
Spermophilus spp., 1442
Spermophilus variegatus, 127, 1670
Sphagnum, *Sphagnum* sp., 337, 1768
Sphagnum spp., 337, 1768
Sphaerooides maculatus, 1073
Sphyraena spp., 344
Spiders
Araneus umbripicatus, 217
Argiope aurantia, 112
Chiracanthium mildei, 1102
Dysdera crocata, 653
Lycosa sp., 1004
Pardosa sp., 1004
Spiderwort, *Aridopsis thaliana*, 1755
Spilogale sp., 1145
Spilosoma spp., 1428
 Spinach, *Spinacia oleracea*, 440, 521, 1095, 1097
Spinacia oleracea, 440, 521, 1095, 1097
Spirodela oligorrhiza, 1428
Spirodella oligorrhiza, 1171
Spirogyra sp., 96, 747, 1161
Spirorbis lamellora, 663
Spirostomum ambiguum, 525
Spisula solidissima, 527, 660
Spiza americana, 1094, 1096
Spizella passerina, 27, 1005
Spodoptera eridania, 922
Spodoptera littoralis, 990, 992
Spodoptera litura, 1093
Sponge
 Various, *Halichondria* sp., 441

- Various, *Halichondria* sp., *Spongilla* sp., 441, 607
Spongilla sp., 441, 607
Spoonbill
 Roseate, *Ajaia ajaja*, 350
 White, *Platalea leucorodia*, 1295
Spot, *Leiostomus xanthurus*, 155, 462, 643, 654, 664, 785, 1363, 1471
Springtail, *Folsomia candida*, *Tullbergia granulata*, 653, 1169
Squalus acanthias, 119, 421, 463, 571, 1466, 1523
Squash, *Cucurbita* spp., 746, 1093
Squatina squatina, 634
Squawfish
 Colorado, *Ptychocheilus lucius*, 1588, 1676, 1677
 Northern, *Ptychocheilus oregonensis*, 332
Squids, 25, 1515
Squilla sp., 325
Squirrel
 California ground, *Spermophilus beecheyi*, 1431, 1448
 Gray, *Sciurus carolinensis*, 15, 127, 360, 450, 854
 Ground, *Citellus* spp., *Spermophilus* spp., 1442
 Red, *Tamiasciurus hudsonicus*, 15, 450
 Rock, *Spermophilus variegatus*, 127, 1670
Srieba, *Astyanax bimaculatus*, 1205
Stanleya spp., 1652
Starfish. See *Asterias*; *Luidia clathrata*
Starling, European, *Sturnus vulgaris*, 13, 221, 241, 272, 370, 379, 800, 806, 833, 846, 850, 861, 862, 890, 932, 935, 968, 1074, 1077, 1135, 1386, 1431, 1525, 1788

Round, *Prosopium cylindraceum*, 343
Various, *Coregonus* spp., 217, 229
Whiting, *Merlangius merlangius*, *Sillago bassensis*, 344, 841, 1523, 1536, 1782
Wigeon, American, *Anas americana*, 799, 961, 1434
Wildcelery, *Vallisneria americana*, 4, 776, 779
Willet, *Catoptrophorus semipalmatus*, 120, 136, 634, 1524, 1579, 1666
Willow, *Salix* spp., 4, 1765, 1767
Wolf, *Canis lupus*, 1033, 1416, 1756, 1759
Wolfish, spotted, *Anarhichas minor*, 229
Wolverine, *Gulo gulo*, 1760
Wombat
Common, *Vombatus ursinus*, 1439, 1449
Southern hairy-nosed, *Lasiorhinus latifrons*, 1439, 1444
Woodchuck, *Marmota monax*, 126, 572, 1670
Woodcock
American, *Scolopax minor*, 1055, 1149
Eurasian, *Scolopax rusticola*, 1766, 1768
Woodlice, *Porcellio scaber*, *Oniscus asellus*, 177, 217, 253, 621, 628, 652, 654
Woodpeckers
Acorn, *Melanerpes formicivorus*, 1432
Worm
Black cut, *Agrotis ipsilon*, 1733
Cotton leaf, *Spodoptera littoralis*, 990, 992
Earth, *Allolobophora*, *Eisenia*, *Lumbricus*, *Octochaetus*, 441, 1039
Lesser meal, *Alphitobius diaperinus*, 1071, 1073
Limnodrilus sp., 134, 1378
Lug, *Arenicola cristata*, 578, 579, 582, 1136
Manure, *Eisenia foetida*, 57, 129, 382, 456, 653, 809, 1416
Marine, *Nereis*, *Nephtys*, 7
Nais sp., 63
Neanthes arenaceoedentata, 63, 64, 65, 73, 262, 662, 673, 1209, 1373, 1376, 1779
Oligochaete, *Lumbriculus variegatus*, 153, 163, 460, 533, 1372
Paranaïs sp., 1041
Rag, *Hediste diversicolor*, 153
Sand, *Nereis diversicolor*, 7, 53, 122, 153, 163, 443, 451, 460, 517, 623, 631, 655, 662, 673, 1737, 1784
Silk, *Bombyx mori*, 1776, 1777
Southern army, *Spodoptera eridanea*, 922
Spirorbis lamellora, 663
Stylodrilus sp., 1378
Tiger, *Eisenia foetida*, 57, 129, 382, 456, 653, 809, 1416
Tobacco horn, *Manduca sexta*, 975
Tubifex sp., 68, 1783

Wren
Bush, *Xenicus longipes*, 1418, 1433
House, *Troglodytes aedon*, 1788
Rock, *Xenicus gilviventris*, 1433

X

Xenicus gilviventris, 1433
Xenicus longipes, 1418, 1433
Xenopus laevis, 232, 427, 611, 668, 751, 1213, 1373, 1385, 1429, 1586, 1590, 1676, 1682, 1770, 1786
Xenopus sp., 1385
Xiphias gladius, 119, 345, 1659
Xyrauchen texanus, 1589, 1649, 1664, 1676

Y

Yeast, 1532, 1678
Cryptococcus terrens, 457
Rhodotorula sp., 457
Saccharomyces spp., 1204
Torulopsis glabrata, 457
Yellowhead, *Mohoua ochrocephala*, 1433
Yellowtail, *Seriola quinqueradiata* (also *Seriola lalandei*), 965

Z

Zalophus californianus, 10, 222, 335, 361, 514, 520, 1661, 1679
Zannichellia palustris, 781
Zannichellia sp., 747, 780
Zapus princeps, 60
Zea mays, 57, 132, 138, 252, 440, 521, 568, 653, 746, 767, 775, 801, 831, 903, 989, 1039, 1093, 1168, 1531, 1584, 1626, 1639, 1668
Zebrafish, *Brachydanio rerio*, *Danio rerio*, 154, 259, 367, 375, 461, 613, 674, 784, 965, 966, 1042, 1173, 1304, 1588, 1675
Zenaida (also *Zenaidura*) *macroura*, 202, 242, 273, 355, 1437, 1576
Zingiber officinale, 1735
Ziphius cavirostris, 1277
Ziphius sp., 1264
Zizania aquatica, 255
Zostera marina, 622, 627, 655, 781
Zostera spp., 111
Zygaena filipendulae, 918
Zygaena trifolii, 918, 922
Zygnuma sp., 451
Zylorrhiza, 1652
Zyzomys argurus, 1449
