### Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

# Foreword

For 60 years the Krause nutrition textbook has been used in colleges to teach nutrition and diet therapy. The first edition was published in 1952! The title has changed during the past 60 years, as have the editors and authors, but the 13th edition of *Krause's Food and the Nutrition Care Process* remains the comprehensive textbook for the beginner as well as a treasured resource for the competent dietetic practitioner. Kathleen Mahan remains the key editor, along with Sylvia Escott-Stump, 2011-2012 President of the American Dietetic Association, and this edition adds a new editor, Janice Raymond.

Historically, one or two or three authors could together write a fundamental book on nutrition, metabolism, nutrients needs and sources, lifespan issues, medical nutrition therapy, and the steps of the nutrition care process. Today, however, the depth and breadth of knowledge of the field requires experts writing the chapters to pass on their knowledge to the novices and beginners and to mentor the next generation. Although the students may not recognize the strengths of the chapter authors (I can remember being a new student!), I look at these authors and see a "Who's Who" of nutrition research and practice. All are prominent specialists or experts in their content area. I am fortunate to personally know approximately two thirds of them, and many could have written or in fact have written texts in their specialties. To distill this knowledge into a chapter for the emerging professional is a labor of love, and makes this a great book for students of all ages. I will add it to my own bookshelf and use it to improve my competence in those areas in which I have limited knowledge. I will use it with confidence, knowing that these authors have summarized the key points using the most up-to-date scientific evidence.

The content of the book combines the nutrition care process and its terminology in a useable way. It is essential for the standardized method of documenting what we do in nutritional care and for developing methodologies to describe the care we give individuals. It also allows multisite evaluation groups to demonstrate or improve our effectiveness in caring for clients and the public. The keys of

assessment, diagnosis, and intervention are incorporated into the first 15 chapters. The book covers the fundamentals of nutrition: digestion, absorption, metabolism, the role of genomics, nutrient metabolism, inflammation, and integrated care. This is followed by six chapters on life span issues and five chapters on nutrition for optimal health and performance.

Finally, the book is best known for its complete discussion of medical nutrition therapy (MNT). The book covers MNT for the key chronic diseases plus emerging areas such as rheumatic, thyroid, neurologic, and psychiatric disorders; pediatric needs for neonates; metabolic disorders; and developmental disorders.

This new edition includes more on inflammation; a chapter on thyroid and related disorders; and an emphasis on assessment, including laboratory analysis and physical assessment. The book is as current as a new book can be, even covering the new U.S. Department of Agriculture MyPlate system and new World Health Organization growth charts.

I congratulate the publishers and editors for including experts who can share their knowledge with dietetic students and practitioners. I thank the authors for being mentoring resources to the practitioner of the future—our entry-level dietetics students—and for providing a quick reference for areas that are not key focus areas for many of us. I encourage other allied health and nursing professionals, especially those in advanced practice programs, to use the book to help them understand what registered dietitians do as part of the team and to ground them in the science and practice of nutrition care.

Congratulations on the longevity of the book and on the new 13th edition!

**Julie O'Sullivan Maillet, PhD, RD, FADA**  
Professor, Department of Nutritional Sciences

Interim Dean  
University of Medicine and Dentistry of New Jersey,  
School of Health Related Professions  
American Dietetic Association President 2002-2003

# Preface

The 13th edition of this classic text supports the Nutrition Care Process as the standard for dietetics. Students and practitioners will embrace the standardized language for their own settings, whether for individuals, families, groups, or communities, and all readers are encouraged to use the most recent edition of the International Nutrition and Diagnostic Terminology in their practice.

## AUDIENCE

Scientific knowledge and clinical information is presented in a form that is useful to students in dietetics, nursing, and other allied health professions in an interdisciplinary setting. It is valuable as a reference for other disciplines such as medicine, dentistry, child development, health education, and lifestyle counseling. Nutrient and assessment appendices, tables, illustrations, and clinical insight boxes provide practical hands-on procedures and clinical tools for students and practitioners alike.

This textbook accompanies the graduating student into clinical practice as a treasured shelf reference. The popular features remain: having basic information on nutrients all the way through to protocols for clinical nutrition practice in one place, clinical management algorithms, focus boxes that give “nice to know” detailed insight, sample nutrition diagnoses for clinical scenarios, useful websites, and extensive appendices for patient education. All material reflects current evidence-based practice as contributed by authors, experts in their fields. This text is the first choice in the field of dietetics for students, educators, and clinicians.

## ORGANIZATION

This edition follows the Conceptual Framework for Steps of the Nutrition Care Process. All nutritional care process components are addressed to enhance or improve the nutritional well-being of individuals, their families, or populations. New to this edition is a flow of chapters according to the steps of assessment, nutrition diagnosis, intervention, monitoring, and evaluation. Also new is the separation of the pediatric medical nutrition therapy (MNT) chapters into their own section to assist with that specialty practice.

**Part 1, Nutrition Assessment**, organizes content for effective assessment. Chapters here provide an overview of the digestive system as well as calculation of energy requirements and expenditure, macronutrient and micronutrient needs, nutritional genomics, and food intake. A thorough review of biochemical tests, acid-base balance issues, and medications promote the necessary insight for provision of

excellent care. A new approach for this edition is a chapter titled “Clinical: Inflammation, Physical, and Functional Assessments,” which addresses the latest knowledge about inflammation as a cause of chronic disease and the necessity of assessing for it. The final chapter in this section addresses the behavioral aspects of an individual’s food choices within the community, a safe food supply, and available resources for sufficiency in food accessibility.

**Part 2, Nutrition Diagnosis and Intervention**, describes the critical thinking process from assessment to selection of relevant, timely, and measurable nutrition diagnoses. These nutrition diagnoses can be resolved by the registered dietitian or trained health professional. The process is generally used for individuals, but can be applied when helping families, teaching groups, or when evaluating the nutritional needs of a community or a population. A nutrition diagnosis requires an intervention and interventions relate to food and nutrient delivery (including nutrition support), use of bioactive substances and integrative medical nutrition, education, counseling, and referral when needed.

**Part 3, Nutrition in the Life Cycle**, presents in-depth information on the nutrition for life stages from nutrition in the womb during lactation and through infancy and childhood. There is a chapter on nutrition in adolescence and another that deals with the nutrition issues and chronic disease that usually start appearing in adulthood. Finally, nutrition and the aging adult is discussed in detail because much of the employment of nutrition professionals in the future is going to be in providing nutrition services to this growing population.

**Part 4, Nutrition for Health and Fitness**, provides nutrition concepts for the achievement and maintenance of health and fitness, as well as the prevention of many disease states. Weight management, problems with eating disorders, dental health, bone health, and sports nutrition focus on the role of nutrition in promoting long-term health.

**Part 5, Medical Nutrition Therapy**, reflects evidence-based knowledge and current trends in nutrition therapies. All of the chapters are written and reviewed by specialists in their fields who present nutritional aspects of conditions such as cardiovascular disorders; diabetes; liver disease; renal disease; pulmonary disease; infectious disease; endocrine disorders, especially thyroid disease; and rheumatologic, neurologic, and psychiatric disorders.

**Part 6, Pediatric Specialties**, describes the role of nutrition therapies in childhood disorders. Chapters provide details for low-birthweight, neonatal intensive care conditions, genetic metabolic disorders, and developmental disabilities.

## NEW TO THIS EDITION

- **New Title:** The new title reflects the profession's move to the "nutrition care process" while providing current, cutting-edge information upon which instructors and students alike have come to rely.
- **Newest Recommendations:** The dietary reference intakes are provided, with the new recommended dietary allowances for calcium and vitamin D that were published in 2010. The new MyPlate from the USDA in 2011, is also included.
- **Nutrition Care Process Tools:** The chapters are organized by the steps in the nutrition care process. In streamlined appendixes, the reader will find the essential clinical references and tools.
- **Medical Nutrition Therapy:** A new chapter is added to the Medical Nutrition Therapy section: "Medical Nutrition Therapy for Thyroid and Related Disorders." In addition, the three cardiovascular chapters on hypertension, atherosclerosis and congestive heart failure from past editions have been merged into one chapter for easier care understanding of the chronic disease and MNT planning.

## PEDAGOGY

- **UNIQUE Pathophysiology and Care Management Algorithms:** Pathophysiology related to nutrition care continues to be a basic highlight of the text. Newly edited algorithms illustrate pathophysiology and relevant medical and nutritional management. These algorithms equip the reader with an understanding of the illness as background for providing optimal nutritional care.
- **Focus On Boxes:** Focus On boxes provide thought-provoking information on key concepts for well-rounded study and to promote further discussion within the classroom.
- **New Directions Boxes:** New Directions boxes suggest areas for further research by spotlighting emerging areas of interest within the field.
- **Clinical Insight Boxes:** Clinical Insight boxes present information for better understanding that enriches the student's interaction with the patient around his or her nutritional care.
- **Key Terms:** Terms are colored and defined within the text.
- **Useful Websites:** A list of websites in each chapter direct the reader to online resources that relate to the chapter topics.

- **Chapter References:** References are current and extensive, with the purpose of giving the student and instructor lots of opportunity for further reading and understanding.

## ANCILLARIES

Accompanying this edition is the Evolve website which includes updated and invaluable resources for instructors and students. These materials can be accessed by going to <http://evolve.elsevier.com/Mahan/nutrition/>.

## INSTRUCTOR RESOURCES

- **Power Point presentations:** More than 900 slides to help guide classroom lectures.
- **Image Collection:** Approximately 200 images from the text are included in the PowerPoint presentations, as well as more illustrations that can be downloaded and used to develop other teaching resources.
- **Audience Response System Questions (for use with iClicker and other systems):** Three to five questions per chapter help aid incorporation of this new technology into the classroom.
- **Test Bank:** Each chapter includes NCLEX-formatted questions with page references specific to that chapter's content to provide more than 900 multiple-choice questions.
- **Animations:** Approximately 50 animations have been developed to visually complement the text and the processes described.
- **Nutrition Care Process Tools:** Consisting of assessment and monitoring tools and intervention tools, this information can be used by the new student and practitioner in teaching and guiding the client in his or her specific nutritional care.

## STUDENT RESOURCES

**Study Exercises with Answers:** With more than 20 questions per chapter, these exercises give instant feedback on questions related to the chapter's content.

We hope that instructors and students find this text as intriguing to study from as we find it in updating and keeping it current and relevant.

L. Kathleen Mahan, MS, RD, CDE  
 Sylvia Escott-Stump, MA, RD, LDN  
 Janice L. Raymond, MS, RD, CD

# Acknowledgments

We sincerely thank the contributors of this edition who have devoted hours and hours of time and commitment to researching the book's content for accuracy, reliability and practicality. We are greatly in debt to them and realize that we could not continue to produce this book without them. Thank you!

The contributors would like to thank Diana Noland, MPH, RD, CCN who reviewed Chapter 6 on Inflammation, Physical and Functional Assessments; Jillian Pollock, Simmons College Dietetic Intern, who assisted with updating the Nutrition in Adulthood chapter; Jean Cox, MS, RD who reviewed Chapter 16 on Pregnancy and Lactation; Russell Jaffe, MD, PhD, CCN, and Jean E. Lloyd, National Nutritionist, US Administration on Aging, for their review of the Nutrition in Aging chapter; Emily Mohar for research assistance in writing and Janice V. Joneja, PhD, CDR for review of Chapter 27 on Adverse Reactions to Foods; Carol Parrish, MS, RD, for her review of the MNT in Gastrointestinal Disorders chapters; Kwai Y. Lam, RD, and Erica Kasuli, RD for help and the deceased Victor Herbert, MD, JD, for inspiration in the writing of the MNT in

Anemia chapter; Kathie Swift, MS, RD and Jeff Bland, PhD for their review of the MNT in Thyroid and Related Disorders chapter; Debra Clancy, RD with her expertise on transplantation, Ann Lipkin, MS, RD, expert in continuous renal replacement therapy (CRRT) and Peggy Solan, RD with her expertise in renal pediatrics for help in the preparation of the MNT in Renal Disease chapter; Marta Mazzanti, MS, RD, CD, for her assistance in writing the chapter on MNT in Neurological Disease; Scot G. Hamilton for his review of the MNT in Cancer Prevention, Treatment and Recovery chapter; and Michael Hahn for his review and editing of many chapters.

We also wish to acknowledge the hard work of Yvonne Alexopoulos, Senior Editor, who keeps the vision; Danielle Frazier, Senior Developmental Editor, who along with Editorial Assistant, Kit Blanke, can get the "hot off the press" items we'd like included; and most of all Tracey Schriefer, Senior Project Manager, who accommodated our deadline misses, endless editing requests, and made this edition and us, all look good. Thank you!

# Nutrition Assessment

**F**ood provides energy and building materials for countless substances that are essential for the growth and survival of every human being. This section opens with a brief overview of the digestion, absorption, transportation, and excretion of nutrients. These remarkable processes convert myriads of complex foodstuffs into individual nutrients ready to be used in metabolism. Macronutrients (proteins, fats, and carbohydrates) each contribute to the total energy pool, but ultimately the energy they yield is available for the work of the muscles and organs of the body. Release of energy for synthesis, movement, and other functions requires the micronutrients (vitamins and minerals), which function as coenzymes, co-catalysts, and buffers in the miraculous, watery arena of metabolism. The way nutrients become integral parts of the body and contribute to proper functioning depends heavily on the physiologic and biochemical processes that govern their actions.

For the health provider, nutrition assessment is the first step in the nutrition care process. To implement a successful nutrition plan, the assessment must include key elements of the patient's clinical or medical history, current complaint, anthropometric measurements, biochemical and laboratory values, information on medication and herbal supplement use for potential food-drug interactions, plus a thorough food and nutrition intake and history. Thus, the chapters in Part 1 provide an organized way to develop the skills needed to fulfill the remainder of the nutrition care process.

## CHAPTER 1

sucrase  
synbiotic  
villi

### THE GASTROINTESTINAL TRACT

One of the primary considerations for a complete nutrition assessment is to consider the three-step model of “ingestion, digestion, and utilization.” In this model, consideration is given to each step to identify all areas of inadequacy or excess. If there is any reason why a step is altered from physical, biochemical, or behavioral-environmental causes, the astute nutrition provider must select an appropriate nutrition diagnosis for which intervention is required. Intake and assimilation of nutrients should lead to a desirable level of nutritional health.

The gastrointestinal tract (GIT) is designed to (1) digest protein, carbohydrates, and lipids from ingested foods and beverages; (2) absorb fluids, micronutrients, and trace elements; and (3) provide a physical and immunologic barrier to microorganisms, foreign material, and potential antigens

consumed with food or formed during the passage of food through the GIT. In addition, the GIT participates in many other regulatory, metabolic, and immunologic functions that affect the entire body.

The human GIT is well suited for digesting and absorbing nutrients from a tremendous variety of foods, including meats, dairy products, fruits, vegetables, grains, complex starches, sugars, fats, and oils. Depending on the nature of the diet consumed, 90% to 97% of food is digested and absorbed; most of the unabsorbed material is of plant origin. Compared with ruminants and animals with a very large cecum, humans are considerably less efficient at extracting energy from grasses, stems, seeds, and other coarse fibrous materials. Humans lack the enzymes to hydrolyze the chemical bonds that link the molecules of sugars that make up plant fibers. Fibrous foods and any

undigested carbohydrates are fermented to varying degrees by bacteria in the human colon, but only 5% to 10% of the energy needed by humans can be derived from this process (Englyst and Englyst, 2005).

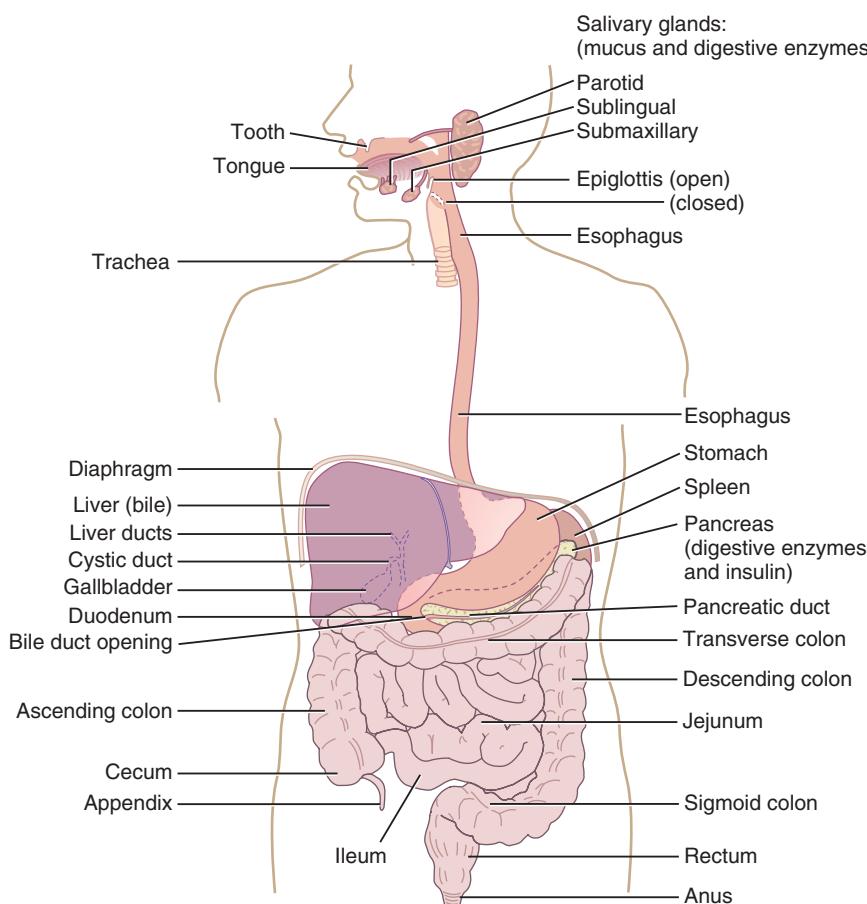

The GIT extends from the mouth to the anus and includes the oropharyngeal structures, esophagus, stomach, liver and gallbladder, pancreas, and small and large intestine. It is one of the largest organs in the body, has the greatest surface area, has the largest number of immune cells, and is one of the most metabolically active tissues in the body (Figure 1-1). The human intestine is about 7 m long and configured in a pattern of folds, pits, and fingerlike projections called **villi**. The villi are lined with epithelial cells and even smaller, cylindrical extensions called **microvilli**. The result is a tremendous increase in surface area compared with that expected from a smooth, hollow cylinder (Figure 1-2). The cells lining the intestinal tract have a life span of approximately 3 to 5 days, and then they are sloughed into the lumen and “recycled,” adding to the pool of available nutrients. The cells are fully functional only for the last 2 to 3 days as they migrate from the crypts to the distal third of the villi.

The health of the body depends on a healthy, functional GIT. Because of the unusually high metabolic activity and requirements of the GIT, the cells lining it are more susceptible than most tissues to micronutrient deficiencies; protein-energy malnutrition; and damage resulting from

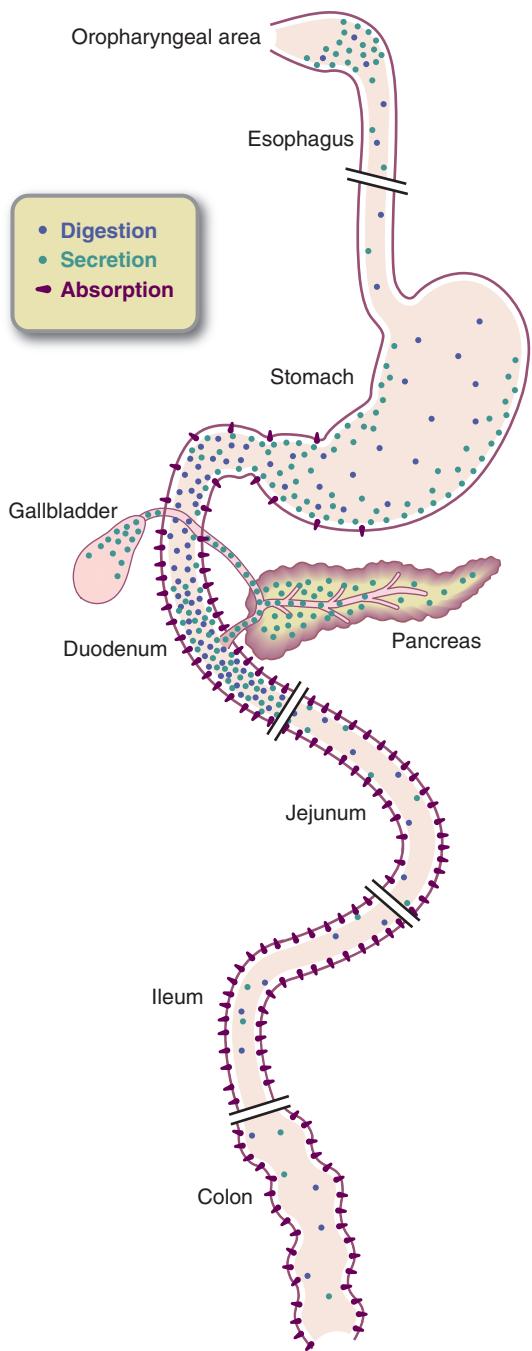

toxins, drugs, irradiation, or interruption of its blood supply. Approximately 45% of the energy requirement of the small intestine and 70% of the energy requirement of cells lining the colon are supplied by nutrients passing through its lumen. After only a few days of starvation, the GIT atrophies (i.e., the surface area decreases and secretions, synthetic functions, blood flow, and absorptive capacity are all reduced). Resumption of food intake, even with less than adequate calories, results in cellular proliferation and return of normal GI function after only a few days. Optimum function of the human GIT seems to depend on a constant supply of foods rather than on consumption of large amounts of foods interrupted by prolonged fasts.

## BRIEF OVERVIEW OF DIGESTIVE AND ABSORPTIVE PROCESSES

The sight, smell, taste, and even thought of food start the secretions and movements of the GIT. In the mouth, chewing reduces the size of food particles, which are mixed with salivary secretions that prepare them for swallowing. A small amount of starch is degraded by salivary amylase, but this overall carbohydrate digestion is minimal. The esophagus transports food and liquid from the oral cavity and pharynx to the stomach. In the stomach, food is mixed with acidic fluid and proteolytic and lipolytic enzymes. Small amounts of lipid digestion take place, and some proteins

**FIGURE 1-1** The digestive system.

**FIGURE 1-2** Sites of secretion, digestion, and absorption.

are changed in structure or partially digested to large peptides (Soybel, 2005). When food reaches the appropriate consistency and concentration, the stomach allows its contents to pass into the small intestine, where most digestion takes place. Alcohol, the exception, is absorbed through the stomach.

In the first 100 cm of small intestine, a flurry of activity occurs, resulting in the digestion and absorption of most ingested food. Here the presence of food stimulates the release of hormones that stimulate the production and release of powerful enzymes from the pancreas and small intestine and bile from the liver and gallbladder. Starches

and proteins are reduced to smaller-molecular-weight carbohydrates and small to medium-size peptides. Dietary fats are reduced from visible globules of fat to microscopic droplets of triglycerides, then to free fatty acids and monoglycerides. Enzymes from the brush border of the small intestine further reduce the remaining carbohydrates to monosaccharides and peptides to single amino acids, dipeptides, and tripeptides (Keller and Layer, 2005). Together with salivary and gastric secretions, secretions from the pancreas, small intestine, and gallbladder contribute 7 to 9 L of fluid in a day, approximately three to four times more fluid than is normally consumed orally. All but 100 to 150 mL of the total fluid entering the lumen is reabsorbed.

The movement of ingested and secreted material in the GIT is regulated primarily by peptide hormones, nerves, and enteric muscles. Along the remaining length of the small intestine, almost all the macronutrients, minerals, vitamins, trace elements, and fluid are absorbed before reaching the colon. The colon and rectum absorb most of the remaining fluid delivered from the small intestine. The colon absorbs electrolytes and only a small amount of remaining nutrients.

Most nutrients absorbed from the GIT enter the portal vein for transport to the liver, where they may be stored, transformed into other substances, or released into circulation. End products of most dietary fats are transported into the bloodstream via the lymphatic circulation.

Remaining fiber, resistant starch, sugar, and amino acids are fermented in the brush border of the colon. Fermentation of the remaining carbohydrates results in the production of short-chain fatty acids (SCFAs) and gas. SCFAs help maintain normal mucosal function, salvage a small amount of energy from some of the residual carbohydrates and amino acids, and facilitate the absorption of salt and water (Englyst and Englyst, 2005). Some of the carbohydrate and fiber resistant to digestion in the upper GIT serve as “prebiotic” material by producing SCFAs, decreasing the colonic pH, and increasing the mass of “helpful” bacteria (Macfarlane et al., 2008). Prebiotic substances support the symbiotic relationship between the GIT and its microbiological environment.

The large intestine provides temporary storage for waste products. The distal colon, rectum, and anus control defecation.

### Enzymes in Digestion

Digestion of food is accomplished by enzymatic hydrolysis. Cofactors such as hydrochloric acid, bile, and sodium bicarbonate facilitate the digestive and absorptive processes. Digestive enzymes are synthesized in specialized cells in the mouth, stomach, pancreas, and small intestine and are released into the lumen. Some enzymes are localized in the lipoprotein membranes of the mucosal cells and attach to their substrates as they enter the cell. Table 1-1 summarizes the GI enzymes and their functions in the small intestine.

Except for fiber and some carbohydrates, digestion and absorption are essentially completed in the small intestine. No digestive enzymes are secreted from the large intestine.

TABLE 1-1

**Summary of Enzymatic Digestion and Absorption**

<b>Secretion and Source</b>	<b>Enzymes</b>	<b>Substrate</b>	<b>Action and Resulting Products</b>	<b>Final Products Absorbed</b>
Saliva from salivary glands in mouth	Ptyalin (salivary amylase)	Starch	Hydrolysis to form dextrins and branched oligosaccharides	—
Gastric juice from gastric glands in stomach mucosa	Pepsin	Protein (in the presence of hydrochloric acid)	Hydrolysis of peptide bonds to form polypeptides and amino acids	—
Exocrine secretions from pancreas	Gastric lipase Lipase Cholesterol esterase	Fat, especially shorter chain Fat (in the presence of bile salts) Cholesterol	Hydrolysis to form free fatty acids Hydrolysis to form monoglycerides and fatty acids; incorporated into micelles Hydrolysis to form esters of cholesterol and fatty acids; incorporated into micelles	Fatty acids into mucosal cells; reesterified as triglycerides Cholesterol into mucosal cells; transferred to chylomicrons
	$\alpha$ -Amylase	Starch and dextrins	Hydrolysis to form dextrins and maltose	—
	Trypsin (activated trypsinogen)	Proteins and polypeptides	Hydrolysis of interior peptide bonds to form polypeptides	—
	Chymotrypsin (activated chymotrypsinogen)	Proteins and peptides	Hydrolysis of interior peptide bonds to form polypeptides	—
	Carboxypeptidase	Polypeptides	Hydrolysis of terminal peptide bonds (carboxyl end) to form amino acids	Amino acids
	Ribonuclease and deoxyribonuclease	Ribonucleic acids and (RNA) deoxyribonucleic acids (DNA)	Hydrolysis to form mononucleotides	Mononucleotides
	Elastase	Fibrous protein	Hydrolysis to form peptides and amino acids	—
Small intestine enzymes (primarily in brush border)	Carboxypeptidase, aminopeptidase, and dipeptidase	Polypeptides	Hydrolysis of carboxyl terminus, amino terminus, or internal peptide bonds	Amino acids
	Enterokinase		Activates trypsin	Dipeptides and tripeptides
	Sucrase		Hydrolysis to form glucose and fructose	Glucose and fructose
	$\alpha$ -Dextrinase (isomaltase)		Hydrolysis to form glucose	Glucose
	Maltase		Hydrolysis to form glucose	Glucose
	Lactase		Hydrolysis to form glucose and galactose	Glucose and galactose
	Nucleotidases	Nucleic acids	Hydrolysis to form nucleotides and phosphates	Nucleotides
	Nucleosidase and phosphorylase	Nucleosides	Hydrolysis to form purines, pyrimidines, and pentose phosphate	Purine and pyrimidine bases

Although water, monosaccharides, vitamins, minerals, and alcohol are usually absorbed in their basic form, often they must be unbound from other molecules or attached to carriers before absorption. Generally, the carbohydrates, lipids, and proteins must be converted to their simple constituents by digestive enzymes before they are absorbed (see Chapter 3).

## Regulators of Gastrointestinal Activity: Nerves, Neurotransmitters, and Neuropeptide Hormones

### Neural Mechanisms

GI movement, including contraction, mixing, and propulsion of luminal contents, is the result of the coordinated activity of enteric nerves, extrinsic nerves, endocrine cells, and smooth muscle. The neural mechanisms include (1) an intrinsic system consisting of two layers of nerves embedded in the gut wall and (2) an external system of nerve fibers running to and from the central and autonomic nervous systems. Mucosal receptors in the gut wall are appropriately sensitive to the composition of the **chyme** (a semiliquid substance of acid, fatty acids, and amino acids) and lumen distention (i.e., fullness) and send impulses through submucosal and mesenteric nerves.

Neurotransmitters and neuropeptides with small molecular weights signal nerves to contract or relax muscles, increase or decrease fluid secretions, or change blood flow. The GIT then largely regulates its own motility and secretory activity. However, signals from the central nervous system can override the enteric system and affect GI function. Hormones, neuropeptides, and neurotransmitters in the GIT not only affect GI function but also have an effect on other nerves and tissues in many parts of the body. Some examples of neurotransmitters released from enteric nerve endings are listed in Table 1-2. In people with GI disease (e.g., infections, inflammatory bowel disease, irritable bowel syndrome), the enteric nervous system may be overstimulated, resulting in abnormal secretion, altered

blood flow, increased permeability, and altered immune function.

Autonomic innervation is supplied by the sympathetic fibers that run along blood vessels and by the parasympathetic fibers in the vagal and pelvic nerves. In general, sympathetic neurons, which are activated by fear, anger, and stress, tend to slow transit of GI contents by inhibiting neurons affecting muscle contraction and inhibiting secretions. The parasympathetic nerves innervate specific areas of the alimentary tract. For example, the sight or smell of food stimulates vagal activity and subsequent secretion of acid from **parietal cells** scattered along the walls of the stomach. The GIT also sends signals that are perceived as colicky pain, sharp pain, nausea, urgency or gastric fullness, or gastric emptiness by way of the vagal and spinal nerves. Inflammation, dysmotility, and various types of intestinal damage may intensify these perceptions.

### Primary Neuropeptide Hormones

Regulation of the GIT involves numerous peptide hormones that can act locally or distally. These regulators can act locally in an autocrine, paracrine, or endocrine role by traveling through the blood to their target organs. More than 100 peptide hormones and hormone-like growth factors have been identified. Their actions are often complex and extend well beyond the GIT. Some of the hormones (e.g., of the cholecystokinin [CCK] and somatostatin family) also serve as neurotransmitters between neurons.

The GIT secretes more than 30 families of neuropeptide hormones and is the largest endocrine organ in the body (Rehfeld, 2004). GI hormones are involved in initiating and terminating feeding, bringing on sensations of hunger and satiety, increasing or decreasing movements of the GIT, enhancing or retarding esophageal and gastric emptying, regulating blood flow and permeability, regulating immune functions, and stimulating the growth of cells (within and beyond the GIT). Ghrelin, a neuropeptide secreted from the stomach, and motilin, a related hormone secreted from the duodenum, send a “hungry” message to the

**TABLE 1-2**

### Examples of Neurotransmitters and Their Actions

Neurotransmitter	Site of Release	Primary Action
GABA	Central nervous system	Relaxes lower esophageal sphincter.
Norepinephrine	Central nervous system, spinal cord, sympathetic nerves	Decreases motility, increases contraction of sphincters, inhibits secretions.
Acetylcholine	Central nervous system, autonomic system, other tissues	Increases motility, relaxes sphincters, stimulates secretion.
Neurotensin	GI tract, central nervous system	Inhibits release of gastric emptying and acid secretion.
Serotonin (5-HT)	GI tract, spinal cord	Facilitates secretion and peristalsis.
Nitric oxide	Central nervous system, GI tract	Regulates blood flow, maintains muscle tone, maintains gastric motor activity.
Substance P	Gut, central nervous system, skin	Increases sensory awareness (mainly pain), and peristalsis.

5-HT, 5-hydroxytryptamine; GABA,  $\alpha$ -aminobutyric acid; GI, gastrointestinal.

brain. Once food has been ingested, hormones *PYY 3-36*, CCK, glucagon-like polypeptide-1 (GLP-1), oxyntomodulin, pancreatic polypeptide, and gastrin-releasing polypeptide (bombesin) send signals to decrease hunger and increase satiety (Stanley et al., 2005). Some of the GI hormones, including some of those that affect satiety, also tend to slow gastric emptying and decrease secretions (e.g., somatostatin). Other GI hormones (e.g., motilin) increase motility.

The signaling agents of the GIT are also involved in several metabolic functions. The neuropeptides glucose-dependent insulinotropic polypeptide (GIP) and GLP-1 are called *incretin hormones* because they help lower blood sugar by facilitating insulin secretion, decreasing gastric emptying, and increasing satiety. Several of these neuropeptide hormones and analogs are used in management of obesity, inflammatory bowel disease, diarrhea, diabetes, GI malignancies, and other conditions. This area of research is critically important.

Some functions of the hormones that affect GI cell growth, deoxyribonucleic acid (DNA) synthesis, inflammation, proliferation, secretion, movement, or metabolism have not been fully identified (Kahn and Ghia, 2010).

Knowledge of major hormone functions becomes especially important when the sites of their secretion or action are diseased or removed in surgical procedures or when hormones and their analogs are used to suppress or enhance some aspect of GI function. The key GIT hormones are summarized in Table 1-3.

**Gastrin**, a hormone that stimulates gastric secretions and motility, is secreted primarily from endocrine “G” cells in the antral mucosa of the stomach. Secretion is initiated by (1) distention of the antrum after a meal; (2) impulses from the vagus nerve such as those triggered by the smell or sight of food; and (3) the presence in the antrum of secretagogues such as partially digested proteins, fermented alcoholic beverages, caffeine, or food extracts (e.g., bouillon). When the lumen gets more acidic, feedback involving other hormones inhibits gastrin release (Schubert, 2009). Gastrin binds to receptors on parietal cells and histamine-releasing cells to stimulate gastric acid, to receptors on chief cells to release pepsinogen, and to receptors on smooth muscle to increase gastric motility.

**Secretin**, the first hormone to be named, is released from “S” cells in the wall of the proximal small intestine into the

**TABLE 1-3****Functions of Major Gastrointestinal Hormones**

Hormone	Site of Release	Stimulants for Release	Organ Affected	Effect on Organ
Gastrin	Gastric mucosa, duodenum	Peptides, amino acids, caffeine	Stomach, esophagus, GIT in general Gallbladder Pancreas	Stimulates secretion of HCl and pepsinogen. Increases gastric antral motility. Increases lower esophageal sphincter tone.
		Distention of the antrum		Weakly stimulates contraction of gallbladder.
		Some alcoholic beverages, vagus nerve		Weakly stimulates pancreatic secretion of bicarbonate.
Secretin	Duodenal mucosa	Acid in small intestine	Pancreas	Increases output of $H_2O$ and bicarbonate; increases some enzyme secretion from the pancreas and insulin release.
			Duodenum	Decreases motility. Increases mucus output.
CCK	Proximal small bowel	Peptides, amino acids, fats, HCl	Pancreas	Stimulates secretion of pancreatic enzymes.
			Gallbladder	Causes contraction of gallbladder.
			Stomach Colon	Slows gastric emptying. Increases motility.
GIP	Small intestine	Glucose, fat	Stomach, pancreas	May mediate feeding behavior.
GLP-1	Small intestine	Glucose, fat	Stomach, pancreas	Stimulates insulin release. Prolongs gastric emptying. Inhibits glucagon release. Stimulates insulin release.
Motilin	Stomach, small and large bowel	Biliary and pancreatic secretions	Stomach, small bowel, colon	Promotes gastric emptying and GI motility.

CCK, Cholecystokinin; GI, gastrointestinal; GIP, glucose-dependent insulinotropic polypeptide; GIT, gastrointestinal tract; GLP-1, glucagon-like polypeptide;  $H_2O$ , water; HCl, hydrochloric acid.

bloodstream. It is secreted in response to gastric acid and digestive end products in the duodenum, stimulates the pancreas to secrete water and bicarbonate into the duodenum, and inhibits gastric acid secretion and emptying (the opposite of gastrin). Neutralized acidity protects the duodenal mucosa from prolonged exposure to acid and provides the appropriate environment for intestinal and pancreatic enzyme activity. The human receptor is found in the stomach and ductal and acinar cells of the pancreas. In different species, other organs may express secretin, including the liver, colon, heart, kidney, and brain (Chey and Chang, 2003).

Small bowel mucosal “I” cells secrete **cholecystokinin (CCK)**, an important multifunctional hormone released in response to the presence of protein and fat. Receptors for CCK are in pancreatic acinar cells, pancreatic islet cells, gastric somatostatin-releasing D cells, smooth muscle cells of the GIT, and the central nervous system. Major functions of CCK are to (1) stimulate the pancreas to secrete enzymes, some bicarbonate, and water; (2) stimulate gallbladder contraction; (3) increase colonic and rectal motility; (4) slow gastric emptying; and (5) increase satiety (Keller and Layer, 2005). CCK is also widely distributed in the brain and plays a role in neuronal functioning (Deng et al., 2010).

GLP-1 and GIP, released from the intestinal mucosa in the presence of meals rich in glucose and fat, stimulate insulin synthesis and release. GLP-1 also decreases glucagon secretion, delays gastric emptying, and may help promote satiety. GLP-1 and GIP are examples of incretin hormones, which help keep blood glucose from rising excessively after a meal (Nauck, 2009). This may explain why a glucose load received enterally results in less of an increase in blood glucose than when an equal amount of glucose is received intravenously.

**Motilin** is released by endocrine cells in the duodenal mucosa during fasting to stimulate gastric emptying and intestinal motility. Erythromycin, an antibiotic, has been shown to bind to motilin receptors; thus analogs of erythromycin and motilin have been used as therapeutic agents to treat delayed gastric emptying (De Smet et al., 2009).

**Somatostatin**, released by D cells in the antrum and pylorus, is a hormone with far-reaching actions. Its primary roles are inhibitory and antisecretory. It decreases motility of the stomach and intestine and inhibits or regulates the release of several GI hormones. Somatostatin and its analog, octreotide, are being used to treat certain malignant diseases (Van Op Den Bosch et al., 2009) as well as numerous GI disorders such as diarrhea, short bowel syndrome, pancreatitis, dumping syndrome, and gastric hypersecretion.

## Digestion in the Mouth

In the mouth, the teeth grind and crush food into small particles. The food mass is simultaneously moistened and lubricated by saliva. Three pairs of salivary glands—the parotid, submaxillary, and sublingual glands—produce approximately 1.5 L of saliva daily. A serous secretion containing **amylase** (ptyalin) begins the digestion of starch. This digestion is minimal, and the amylase becomes inactive

when it reaches the acidic contents of the stomach. Another type of saliva contains mucus, a protein that causes particles of food to stick together and lubricates the mass for swallowing. The oropharyngeal secretions also contain a lipase that is capable of digesting a minimal amount of fat.

The masticated food mass, or bolus, is passed back to the pharynx under voluntary control, but throughout the esophagus the process of swallowing (deglutition) is involuntary. **Peristalsis** then moves the food rapidly into the stomach (see Chapter 41 for detailed discussion on swallowing).

## Digestion in the Stomach

Food particles are propelled forward and mixed with gastric secretions by wavelike contractions that progress forward from the upper portion of the stomach (fundus), to the midportion (corpus), and then to the antrum and pylorus. In the stomach gastric secretions are mixed with food and beverages. An average of 2000 to 2500 mL of gastric juice is secreted daily. The gastric secretions contain hydrochloric acid (secreted by the parietal cells in the walls of the fundus and corpus), a protease, gastric lipase, mucus, intrinsic factor (a glycoprotein that facilitates vitamin B<sub>12</sub> absorption in the ileum), and the GI hormone gastrin. The protease is **pepsin**, which is also secreted from glands in the fundus and corpus. It is secreted in an inactive form, pepsinogen, which is converted by hydrochloric acid to its active form. Pepsin is active only in the acid environment of the stomach and serves primarily to change the shape and size of some of the proteins in a normal meal.

An acid-stable lipase is secreted into the stomach by chief cells. Although this lipase is considerably less active than pancreatic lipase, it contributes to the overall processing of dietary triglycerides. Gastric lipase is more specific for triglycerides composed of medium- and SCFAs, but the normal diet contains few of these fats. Lipases secreted in the upper portions of the GIT may have a relatively important role in the liquid diet of infants; but, when pancreatic insufficiency occurs, it becomes apparent that lingual and gastric lipases are not sufficient to prevent lipid malabsorption (Keller and Layer, 2005). In the process of gastric digestion, most of the food becomes semiliquid chyme, which is 50% water. Gastric secretions are also important in increasing the availability and downstream absorption of vitamin B<sub>12</sub>, calcium, iron, and zinc (Soybel, 2005).

When food is consumed, significant numbers of microorganisms are also consumed. The stomach pH is quite low, ranging from about 1 to 4. The combined actions of hydrochloric acid and proteolytic enzymes result in a significant reduction in the concentration of microorganisms ingested. Some microbes may escape and enter the intestine if consumed in sufficient concentrations or if achlorhydria, gastrectomy, GI dysfunction or disease, poor nutrition, or drugs that suppress acid secretions are present. This may increase the risk of bacterial overgrowth in the intestine.

The stomach continuously mixes and churns food and normally releases the mixture in small quantities into the small intestine. The amount emptied with each contraction of the antrum and pylorus varies with the volume and type

of food consumed, but only a few milliliters are released at a time. The presence of food in the intestine and regulatory hormones provide feedback to slow gastric emptying.

Most of a liquid meal empties within 1 to 2 hours, and most of a solid meal empties within 2 to 3 hours. When eaten alone, carbohydrates leave the stomach the most rapidly, followed by protein, fat, and fibrous food. In a meal with mixed types of foods, emptying of the stomach depends on the overall volume and characteristics of the foods. Liquids empty more rapidly than solids, large particles empty more slowly than small particles, and concentrated food tends to empty more slowly than low-calorie meals. These factors are important considerations for practitioners who counsel patients with nausea, vomiting, diabetic gastroparesis, or partial obstruction or for practitioners monitoring patients after GI surgery or malnourished patients.

The lower esophageal sphincter (LES) above the entrance to the stomach prevents reflux of gastric contents into the esophagus. The pyloric sphincter in the distal portion of the stomach helps regulate the exit of gastric contents, preventing backflow of chyme from the duodenum into the stomach. Emotional changes, food, GI regulators, and irritation from nearby ulcers may alter the performance of strictures. Certain foods and beverages may alter LES pressure, permitting reflux of stomach contents back into the esophagus (see Chapter 28).

### Digestion in the Small Intestine

The small intestine is the primary site for digestion of foods and nutrients. The small intestine is divided into the duodenum, the jejunum, and the ileum (Figure 1-2). The duodenum is approximately 0.5 m long, the jejunum is 2 to 3 m, and the ileum is 3 to 4 m. Most of the digestive process is completed in the duodenum and upper jejunum, and the absorption of most nutrients is largely complete by the time the material reaches the middle of the jejunum. The acidic chyme from the stomach enters the duodenum, where it is mixed with duodenal juices and the secretions from the pancreas and biliary tract. As a result of the secretion of bicarbonate-containing fluid from the pancreas and dilution from other secretions, acid chyme is neutralized. Enzymes of the small intestine and pancreas operate more effectively in a more neutral pH.

The entry of partially digested foods, primarily fats and protein, stimulates the release of several hormones that in turn stimulate the secretion of enzymes and fluids and affect GI motility and satiety. Bile, which is predominantly a mixture of water, bile salts, and small amounts of pigments and cholesterol, is secreted from the liver and gallbladder. Through their surfactant properties, the bile salts facilitate the digestion and absorption of lipids, cholesterol, and fat-soluble vitamins. Bile acids are also regulatory molecules; they activate the vitamin D receptor and cell-signaling pathways in the liver and GIT that alter gene expression of enzymes involved in the regulation of energy metabolism (Hylemon et al., 2009). It is now known that bile acids play an important role in hunger and satiety.

The pancreas secretes potent enzymes capable of digesting all of the major nutrients, and enzymes from the small intestine help complete the process. The primary lipid-digesting enzymes secreted by the pancreas are **pancreatic lipase** and colipase. **Proteolytic enzymes** include trypsin and chymotrypsin, carboxypeptidase, aminopeptidase, ribonuclease, and deoxyribonuclease. Trypsin and chymotrypsin are secreted in their inactive forms and are activated by enterokinase (also known as *enteropeptidase*), which is secreted when chyme contacts the intestinal mucosa. Pancreatic amylase serves to hydrolyze large starch molecules eventually into units of approximately two to six sugars. Enzymes lining the brush border of the villi further break down the carbohydrate molecules into monosaccharides before absorption. Varying amounts of resistant starches and most ingested dietary fiber escape digestion in the small intestine and may add to fibrous material available for fermentation by colonic microbes (Englyst and Englyst, 2005).

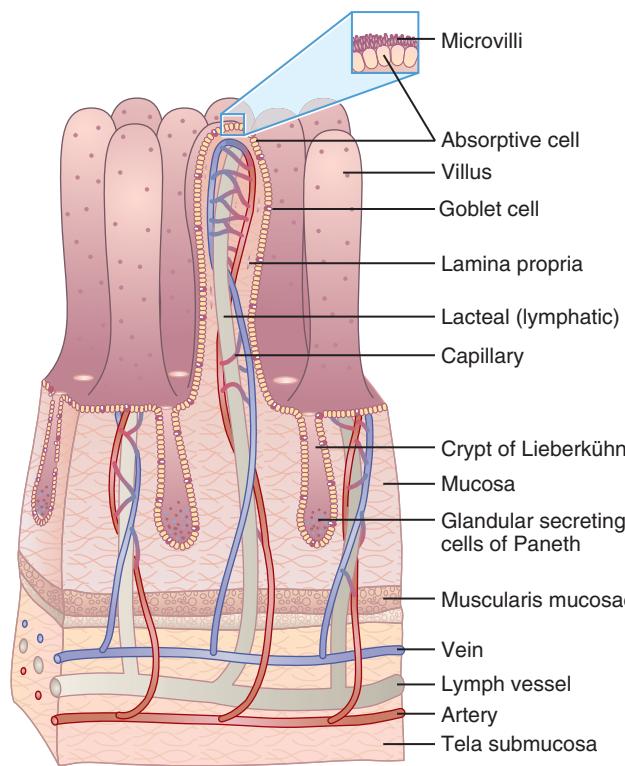

Intestinal contents move along the small intestine at a rate of 1 cm per minute, taking from 3 to 8 hours to travel through the entire intestine to the ileocecal valve; along the way, remaining substrates continue to be digested and absorbed. The ileocecal valve, like the pyloric valve, serves to limit the amount of intestinal material passed back and forth from the small intestine to the colon. A damaged or nonfunctional ileocecal valve results in the entry of significant amounts of fluid and substrate into the colon and increased chance for microbial overgrowth in the small intestine (see Chapter 28).

## THE SMALL INTESTINE: PRIMARY SITE OF NUTRIENT ABSORPTION

### Structure and Function

The primary organ of nutrient and water absorption is the small intestine, which has an expansive absorptive area. The surface area is attributable to its extensive length, as well as to the organization of the mucosal lining. The small intestine has characteristic folds in its surface called *valvulae conniventes*. These convolutions are covered with fingerlike projections called *villi* (Figure 1-3), which in turn are covered by microvilli, or the **brush border**. The combination of folds, villous projections, and microvillous border creates an enormous absorptive surface of approximately 200 to 300 m<sup>2</sup>. The villi rest on a supporting structure called the *lamina propria*. Within the lamina propria, which is composed of connective tissue, the blood and lymph vessels receive the products of digestion.

Each day, on average, the small intestine absorbs 150 to 300 g of monosaccharides, 60 to 100 g of fatty acids, 60 to 120 g of amino acids and peptides, and 50 to 100 g of ions. The capacity for absorption in the healthy individual far exceeds the normal macronutrient and caloric requirements. In the small intestine, all but 1 to 1.5 L of the 7 or 8 L of fluid secreted from the upper portions of the GIT, in addition to 1.5 to 3 L of dietary fluids, is absorbed by the time the contents reach the end of the small intestine.

**FIGURE 1-3** Structure of the villi of the human intestine showing blood and lymph vessels.

Approximately 95% of the bile salts secreted from the liver and gallbladder are reabsorbed as bile acids in the distal ileum. Without recycling bile acids from the GIT (enterohepatic circulation), synthesis of new bile acids in the liver would not keep pace with needs for adequate digestion. Bile salt insufficiency becomes clinically important in patients who have resections of the distal small bowel and diseases affecting the small intestine, such as Crohn disease, radiation enteritis, and cystic fibrosis. The distal ileum is also the site for vitamin B<sub>12</sub> (with intrinsic factor) absorption.

Emulsification of fats in the small intestine is followed by their digestion, primarily by pancreatic lipase, into free fatty acids and monoglycerides. Pancreatic lipase typically cleaves the first and third fatty acid, leaving one attached to the middle glycerol carbon. When the concentration of bile salts reaches a certain level, they form **micelles** (small aggregates of fatty acids, monoglycerides, cholesterol, bile salts, and other lipids), which are organized with the polar ends of the molecules oriented toward the watery lumen of the intestine. The products of lipid digestion are rapidly solubilized in the central portion of the micelles and carried to the intestinal brush border (Figure 1-4).

At the surface of the unstirred water layer (UWL), the slightly acidic and watery plate that forms a boundary between the intestinal lumen and the brush border membranes, the lipids detach from the micelles. Remnants of the micelles return to the lumen for further transport. The monoglycerides and fatty acids are thus left to make their way across the lipophobic UWL to the more lipid-friendly

membrane cells of the brush border. Lipids are taken up and transported through the endoplasmic reticulum and Golgi apparatus where fatty acids are re-esterified to triglyceride. Triglycerides are packaged, along with other lipids, into chylomicrons, which are released into the lymphatic circulation. Cholesterol absorption is facilitated by a protein transport system specific to cholesterol and not to other sterols (Hui et al., 2008; Lammert and Wang, 2005).

### Absorptive and Transport Mechanisms

Absorption is complex, combining the intricate process of active transport with the simple process of passive diffusion. In absorption, nutrients pass through the intestinal mucosal cells (enterocytes or colonocytes) and make their way into the venous system to the liver or into the lymphatic circulation. Diffusion involves random movement through openings in or between the membranes of the mucosal cell walls using channel proteins (**passive diffusion**) or carrier/transport proteins in **facilitated diffusion** (Figure 1-5).

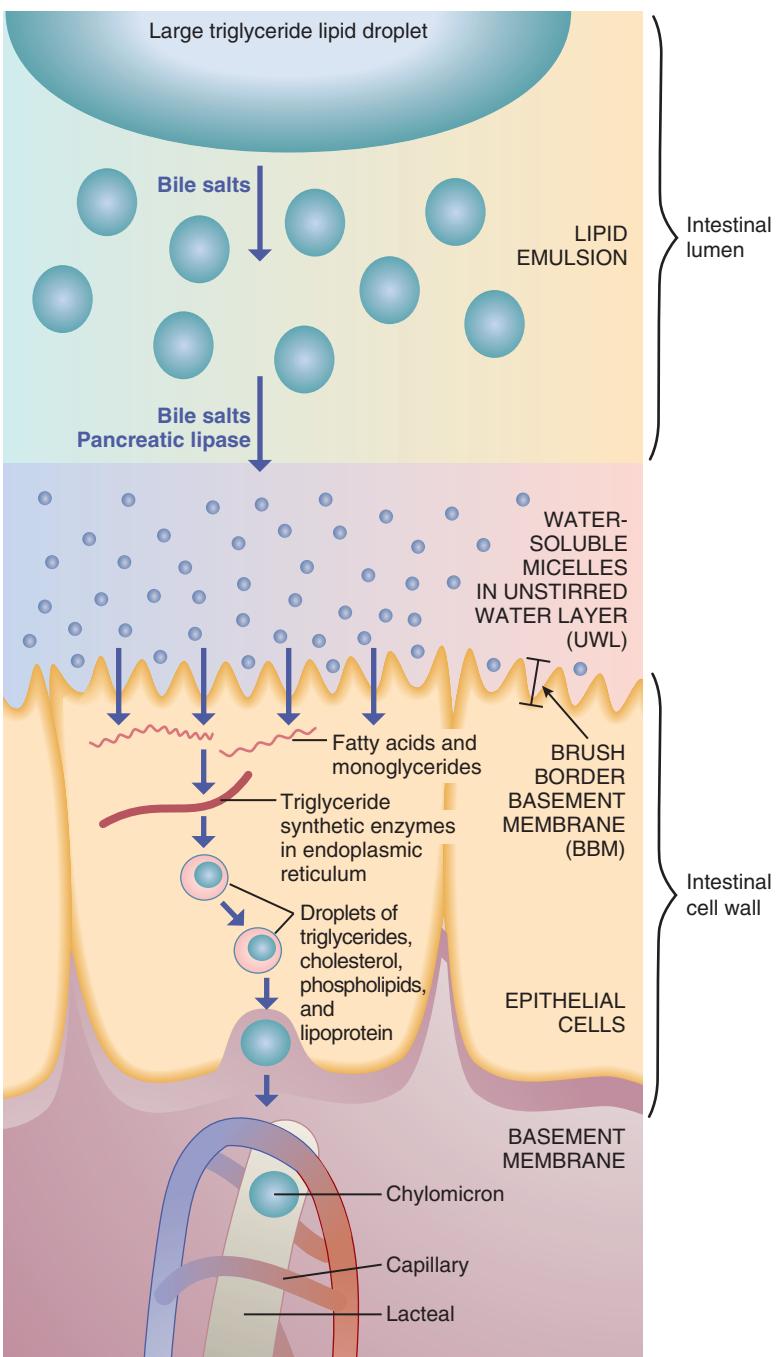

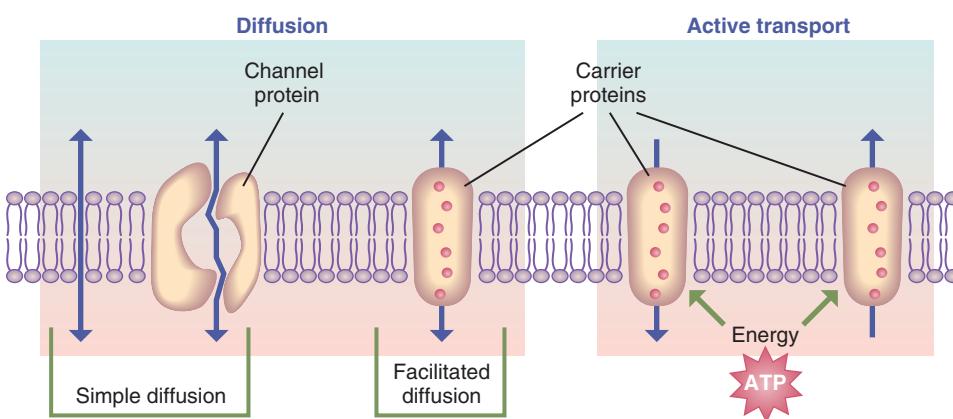

**Active transport** involves the input of energy to move ions or other substances, in combination with a transport protein, across a membrane against an energy gradient. Some nutrients may share the same carrier and thus compete for absorption. Transport or carrier systems can also become saturated, slowing the absorption of the nutrient. A notable example of such a carrier is intrinsic factor, which is responsible for the absorption of vitamin B<sub>12</sub> (see Chapters 3 and 33).

Some molecules are moved from the intestinal lumen into mucosal cells by means of pumps, which require a carrier and energy from adenosine triphosphate. The absorption of glucose, sodium, galactose, potassium, magnesium, phosphate, iodide, calcium, iron, and amino acids occurs in this manner.

**Pinocytosis** has been described as the “drinking in,” or engulfing, by the epithelial cell membrane of a small drop of intestinal contents. Pinocytosis allows large particles such as whole proteins to be absorbed in small quantities. The movement of foreign proteins across the GIT into the bloodstream, where they cause allergic reactions, may be the result of pinocytosis. The immunoglobulins from breast milk are probably absorbed through pinocytosis.

## THE LARGE INTESTINE

The large intestine is approximately 1.5 m long and consists of the cecum, colon, and rectum. Mucus secreted by the mucosa of the large intestine protects the intestinal wall from excoriation and bacterial activity and provides the medium for binding the feces together. Bicarbonate ions secreted in exchange for absorbed chloride ions help to neutralize the acidic end products produced from bacterial action. Approximately 2 L of fluids are taken in food and beverages during the day, and 7 to 9 L of fluid is secreted along the GIT. Under normal circumstances, most of that fluid is absorbed in the small intestine and approximately 1 to 1.5 L of fluid enters the large intestine. Only approximately 100 mL remain to be excreted in the feces.

**FIGURE 1-4** Summary of fat absorption.**FIGURE 1-5** Transport pathways through the cell membrane, as well as basic transport mechanisms. **ATP**, Adenosine triphosphate.

The large intestine is also the site of bacterial fermentation of remaining carbohydrates and amino acids, synthesis of a small amount of vitamins, storage, and excretion of fecal residues. Colonic contents move forward slowly at a rate of 5 cm/h, and some remaining nutrients may be absorbed.

Defecation, or expulsion of feces through the rectum and anus, occurs with varying frequency, ranging from three times daily to once every 3 or more days. Average stool weight is in the range of 100 to 200 g, and mouth-to-anus transit time may vary from 18 to 72 hours. The feces generally consist of 75% water and 25% solids, but the proportions vary greatly. Approximately two thirds of the contents of the wet weight of the stool is bacteria, with the remainder coming from GI secretions, mucus, sloughed cells, and undigested foods. A diet that includes abundant fruits, vegetables, legumes, and whole grains typically results in a shorter overall GI transit time, more frequent defecation, and larger and softer stools.

### Bacterial Action

The gut microflora make up a complex community that is estimated to involve thousands of species of microorganisms (Frank and Pace, 2008). At birth the GIT is essentially sterile, but accumulation of various microorganisms soon takes place. *Lactobacillus* organisms are the chief component of the GIT flora until an infant begins to eat solid foods. *Escherichia coli* then become predominant in the distal ileum, and the primary colonic flora are anaerobic, with species of the genus *Bacteroides* occurring most frequently. *Lactobacilli* are also present in the stools of most people who consume an ordinary mixed diet; but differences in the host's genome, dietary intake, hygiene, and medical and surgical history affect the kind of flora in the GIT (Table 1-4).

Normally relatively few bacteria remain in the stomach or small intestine after meals because bile, hydrochloric acid, and pepsin work as germicides. However, decreased gastric secretions can increase the risk of inflammation of the gastric mucosa (*gastritis*), increase the risk of bacterial overgrowth in the small intestine, or increase the numbers of microbes reaching the colon. An acid-tolerant bacterium is known to infect the stomach (*Helicobacter pylori*) and may cause gastritis and ulceration in the host (see Chapter 28).

Bacterial action is most intense in the large intestine. Following a meal, dietary fiber, resistant starches, remaining bits of amino acids, and mucus sloughed from the intestine are fermented in the colon. Colonic bacteria contribute to the formation of gases (e.g., hydrogen, carbon dioxide, nitrogen, and in some individuals methane) and SCFAs (e.g., acetic, propionic, butyric, and some lactic acids). Colonic bacteria continue the digestion of some materials that have resisted previous digestive activity. During the process, several nutrients are formed by bacterial synthesis. These nutrients are used to varying degrees by GI mucosal cells but usually contribute little to meeting the nutrient requirements of the human host. Examples of nutrients produced include vitamin K, vitamin B<sub>12</sub>, thiamin, and riboflavin.

Increased consumption of prebiotic material may lead to an increase in SCFAs and in the microbial mass—in particular, indigenous *Bifidobacteria* and *Lactobacilli* species are thought to be beneficial. Prebiotic carbohydrates typically refer to oligosaccharides from vegetables, grains, and legumes; chicory, Jerusalem artichokes, soybeans, and wheat bran are the best dietary sources. Prebiotics provide a healthy gut “ecosystem” with beneficial health effects (Roberfroid et al, 2010).

Bacterial action also may result in the formation of potentially toxic substances such as ammonia, indoles, amines, and phenolic compounds such as indolacetate, tyramine, histamine, and cresol (MacFarlane, 2008). Some of the gases and organic acids contribute to the odor of feces.

The interactions between the innate and acquired immune systems evolve based on one's genetic heritage and exposure to a myriad of environmental substances over a lifetime. Malnutrition, exposure to toxic agents, and disease may affect the relationships among the physical and immunologic components of the GIT and the tremendous number of substances that reside or pass through its lumen (Quigley, 2010). Each individual's GI immune system, therefore, has a formidable task. It must (1) mount and subsequently turn off an attack against transient invading pathogens that make their way into the GIT; (2) prevent antigenic components of peptides from producing allergic responses locally and systemically; and (3) tolerate the thousands of different species of “normal” bacteria that reside in the GIT, their secretions, and degradation into cell wall components, DNA fragments, and peptides.

Several diseases may be exacerbated by or even caused by disruption of the tenuous harmony between the GIT and the contents of its lumen. Interactions among the host immune system, host genome, diet, and GI microflora may

be linked with several infectious and inflammatory bowel diseases, allergies, immune disorders, metabolic disorders, and neoplasms (O'Keefe, 2008; Tappenden and Deutsch, 2007). In addition to the therapeutic use of antibiotics and antiinflammatory or immunosuppressive agents, attention is being given to the therapeutic potential of probiotic, prebiotic, and symbiotic products.

**Probiotics** are foods or concentrates of live organisms that contribute to a healthy microbial environment and suppress potential harmful microbes. Knowledge of their role in preventing and treating a host of GI and systemic disorders has expanded tremendously (Snelling, 2005).

**Prebiotics** are oligosaccharide components of the diet (e.g., fructo-oligosaccharides, inulin) that are the preferred energy substrates of “friendly” microbes in the GIT. When prebiotics, other sources of soluble dietary fiber, and other carbohydrates resistant to digestion are fermented by bacteria in the distal ileum and colon, they produce SCFAs that serve as fuel for the cells lining the GIT. SCFAs also serve as regulatory agents for several GI and host functions (Roberfroid et al, 2010).

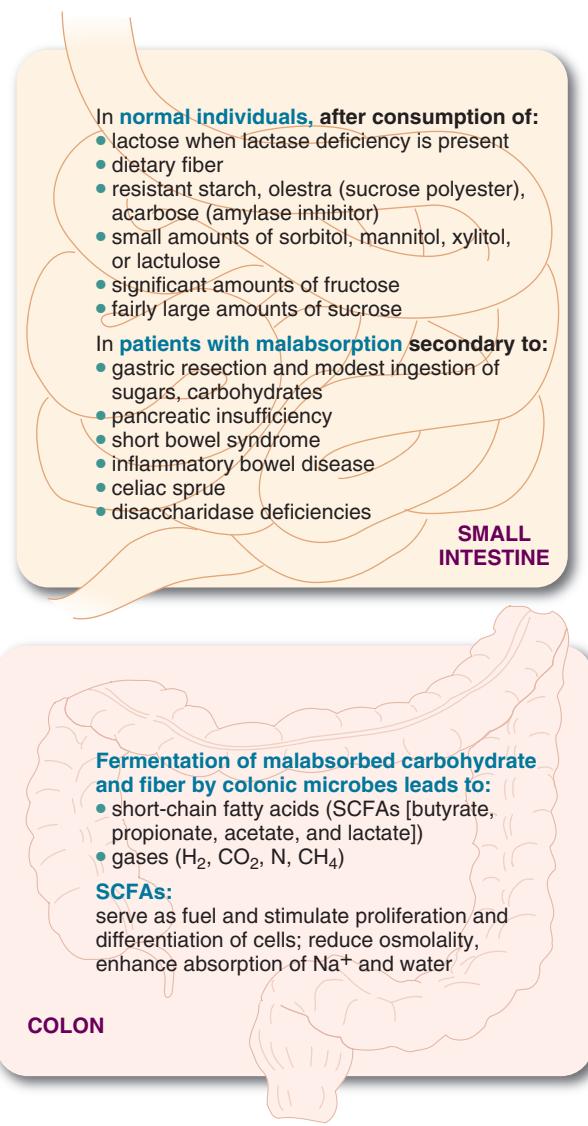

**Symbiotics** are a combination of probiotics and prebiotics. Symbiotics are long-chain, inulin-type fructans as compared with short-chain derivatives. These fructans, extracted from chicory roots, are prebiotic food ingredients that are fermented to lactic acid and SCFAs in the gut lumen. Symbiotics may be useful for early prevention or treatment of allergic disease (van de Pol et al, 2011.)

### Colonic Salvage of Malabsorbed Energy Sources and Short-Chain Fatty Acids

Normally, varying amounts of some small-molecular-weight carbohydrates and amino acids remain in the chyme after leaving the small intestine. Accumulation of these small molecules could become osmotically important were it not for the action of bacteria in the colon. The disposal of residual substrates through production of SCFAs is called **colonic salvage** (Figure 1-6). SCFAs produced in fermentation are rapidly absorbed and take water with them. They also serve as fuel for the colonocytes and gut microbes, stimulate colonocyte proliferation and differentiation, enhance the absorption of electrolytes and water, and reduce the osmotic load of malabsorbed sugars. SCFAs may also help slow the movement of GI contents and participate in several other regulatory functions.

The ability to salvage carbohydrates is limited in humans. Colonic fermentation normally disposes of 20 to 25 g of carbohydrate over 24 hours. Excess amounts of carbohydrate and fermentable fiber in the colon can cause increased gas production, abdominal distention, bloating, pain, increased flatulence, decreased colonic pH, or even diarrhea. Over time, adaptation seems to occur in individuals consuming diets high in fiber that are resistant to human digestive enzymes. Current recommendations are for the consumption of approximately 24 to 38 g of dietary fiber per day from fruits, vegetables, legumes, seeds, and whole grains for (1) maintaining the health of the cells lining the colon, (2) preventing excessive intracolonic

### SITUATIONS OF INCREASED CARBOHYDRATE MALABSORPTION WITH COLONIC FERMENTATION

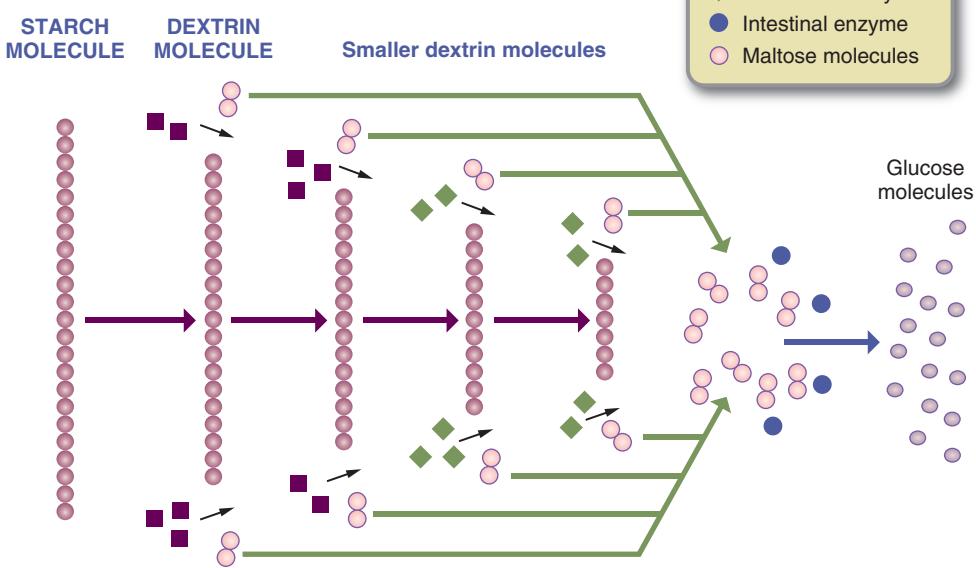

**FIGURE 1-6** Colonic fermentation of malabsorbed carbohydrates and fiber.

pressure, (3) preventing constipation, and (4) maintaining a stable and healthful microbial population.

### Digestion and Absorption of Specific Types of Nutrients Carbohydrates and Fiber

Most dietary carbohydrates are consumed in the form of starches, disaccharides, and monosaccharides. Starches, or polysaccharides, usually make up the greatest proportion of carbohydrates. Starches are large molecules composed of straight or branched chains of sugar molecules that are joined together, primarily in 1-4 or 1-6 linkages. Most of

**FIGURE 1-7** The gradual breakdown of large starch molecules into glucose by digestion enzymes.

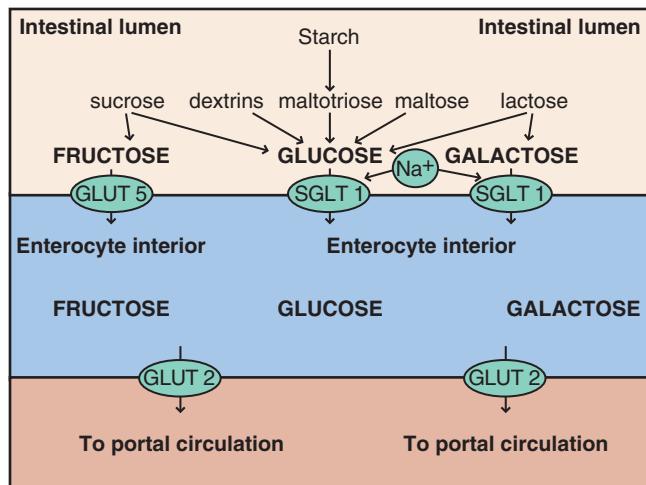

the dietary starches are *amylopectins*, the branching polysaccharides, and *amylose*, the straight chain-type polymers.

Dietary fiber is also largely made of chains and branches of sugar molecules, but in this case the hydrogens are positioned on the beta (opposite) side of the oxygen in the link instead of the alpha side. That humans have significant ability to digest starch, but not most fiber, exemplifies the “stereospecificity” of enzymes.

In the mouth, the enzyme salivary amylase (ptyalin) operates at a neutral or slightly alkaline pH and starts the digestive action by hydrolyzing a small amount of the starch molecules into smaller fragments (Figure 1-7). Amylase deactivates after contact with hydrochloric acid. If digestible carbohydrates remained in the stomach long enough, acid hydrolysis could eventually reduce most of them into monosaccharides. However, the stomach usually empties before significant digestion can take place. By far, most carbohydrate digestion occurs in the proximal small intestine.

Pancreatic amylase breaks the large starch molecules at 1-4 linkages to create maltose, maltotriose, and “alpha-limit” dextrans remaining from the amylopectin branches. Enzymes from the brush border of the enterocytes further break the disaccharides and oligosaccharides into monosaccharides. For example, **maltase** from the mucosal cells breaks down the disaccharide maltose into two molecules of glucose. These outer-cell membranes also contain the enzymes **sucrase**, **lactase**, and isomaltase (or  $\alpha$ -dextrinase), which act on sucrose, lactose, and isomaltose, respectively (Figure 1-8).

The resultant monosaccharides (i.e., glucose, galactose, and fructose) pass through the mucosal cells and into the bloodstream via the capillaries of the villi, where they are carried by the portal vein to the liver. At low concentrations, glucose and galactose are absorbed by active transport,

**FIGURE 1-8** Starch, sucrose, maltotriose, and galactose are digested to their constituent sugars. Glucose and galactose are transported through the apical brush border membrane of the enterocyte by a sodium-dependent transporter, glucose (galactose) cotransporter; and fructose is transported by glucose transporter (GLUT) 5. Glucose, fructose, and galactose are transported across the serosal membrane by the sodium-independent transporter, GLUT2.

primarily by a sodium-dependent transporter called the glucose (galactose) cotransporter. At higher luminal concentrations of glucose, glucose transporter (GLUT) 2 becomes a primary facilitative transporter into the intestinal cell. Fructose is more slowly absorbed and uses GLUT5 and the facilitative transporter from the lumen. GLUT2 is used to transport both glucose and fructose across the intestinal cell membranes into the blood (Kellett and Brot-Laroche, 2005).

The sodium-dependent transport of monosaccharides is the reason why sodium-glucose drinks are used to rehydrate infants with diarrhea or athletes who have lost too much fluid. Glucose is transported from the liver to the tissues, although some glucose is stored in the liver and muscles as glycogen. Most of the fructose, as in the case of galactose, is transported to the liver, where it is converted to glucose. Consumption of large amounts of lactose (especially in individuals with a lactase deficiency), fructose, stachyose, raffinose, or alcohol sugars (e.g., sorbitol, mannitol, or xylitol) can result in considerable amounts of these sugars passing unabsorbed into the colon (Beyer et al., 2005) and may cause increased gas and loose stools. Fructose is found naturally in many fruits (e.g., in sucrose and high-fructose corn syrup) but is likely to produce symptoms only if consumed as the single monosaccharide or if the food has an abundance of fructose compared with glucose (as in the case of apple juice).

Some forms of carbohydrates (i.e., cellulose, hemicellulose, pectin, gum, and other forms of fiber) cannot be digested by humans because neither their salivary nor pancreatic amylase has the ability to split the linkages connecting the constituent sugars. These carbohydrates pass relatively unchanged into the colon, where they are partially fermented by bacteria in the colon. However, unlike humans, cows and other ruminants can subsist on high-fiber food because of the bacterial digestion of these carbohydrates that takes place in the rumen. Other resistant starches and sugars are also less well digested or absorbed by humans; thus their consumption may result in significant amounts of starch and sugar in the colon. The resistant starches and some types of dietary fiber are fermented into SCFAs and gases. Starches resistant to digestion tend to include plant foods with a high protein and fiber content such as those from legumes and whole grains. One form of dietary fiber, lignin, is made of cyclopentane units and is neither readily soluble nor fermentable.

## Proteins

Protein intake in the Western world ranges from approximately 50 to 100 g daily, and a good deal of the protein consumed is from animal sources. Additional protein is added all along the GIT from GI secretions and cells sloughed from GI tissues. The GIT is one of the most active synthetic tissues in the body, and the life span of enterocytes migrating from the crypts of the villi until they are shed is only 3 to 4 days. The number of cells shed daily is in the range of 10 to 20 billion cells. The latter accounts for an additional 50 to 60 g of protein that is digested and “recycled” and contributes to the daily supply. In general, animal proteins are more efficiently digested than plant proteins, but human GI physiology allows for very effective digestion and absorption of large amounts of ingested protein sources.

Protein digestion begins in the stomach, where some of the proteins are split into proteoses, peptones, and large polypeptides. Inactive pepsinogen is converted into the enzyme pepsin when it contacts hydrochloric acid and other pepsin molecules. Unlike any of the other proteolytic

enzymes, pepsin digests collagen, the major protein of connective tissue. Most protein digestion takes place in the upper portion of the small intestine, but it continues throughout the GIT (Soybel, 2005). Any residual protein fractions are fermented by colonic microbes.

Contact between chyme and the intestinal mucosa stimulates release of enterokinase, an enzyme that transforms inactive pancreatic trypsinogen into active trypsin, the major pancreatic protein-digesting enzyme. Trypsin in turn activates the other pancreatic proteolytic enzymes. Pancreatic trypsin, chymotrypsin, and carboxypeptidase break down intact protein and continue the breakdown started in the stomach until small polypeptides and amino acids are formed.

Proteolytic peptidases located on the brush border also act on polypeptides, breaking them down into amino acids, dipeptides, and tripeptides. The final phase of protein digestion takes place in the brush border, where some of the dipeptides and tripeptides are hydrolyzed into their constituent amino acids by peptide hydrolases.

End products of protein digestion are absorbed as both amino acids and small peptides. Several transport molecules are required for the different amino acids, probably because of the wide differences in the size, polarity, and configuration of the different amino acids. Some of the transporters are sodium- or chloride-dependent, and some are not. Considerable amounts of dipeptides and tripeptides are also absorbed into intestinal cells using a peptide transporter, a form of active transport (Daniel, 2004). Absorbed peptides and amino acids are transported to the liver via the portal vein for metabolism by the liver and are released into the general circulation.

The presence of antibodies to many food proteins in the circulation of healthy individuals indicates that immunologically significant amounts of large intact peptides escape hydrolysis and can enter the portal circulation. The exact mechanisms that cause a food to become an allergen are not entirely clear, but these foods tend to be high in protein, to be relatively resistant to complete digestion, and to produce an immunoglobulin response (see Chapter 27). With new technology, it is possible to map and characterize allergenic peptides; this will eventually lead to safe immunotherapy treatments (Lin et al., 2009).

Almost all protein is absorbed by the time it reaches the end of the jejunum, and only 1% of ingested protein is found in the feces. Small amounts of amino acids may remain in the epithelial cells and are used for synthesis of new proteins, including intestinal enzymes and new cells.

## Lipids

Approximately 97% of dietary lipids are in the form of triglycerides, and the rest are in the form of phospholipids and cholesterol. Only small amounts of fat are digested in the mouth with lingual lipase and in the stomach from the action of gastric lipase (tributyrylase). Gastric lipase hydrolyzes some triglycerides, especially short-chain triglycerides (such as those found in butter), into fatty acids and glycerol. However, most fat digestion takes place in the small

intestine as a result of the emulsifying action of bile salts and hydrolysis by pancreatic lipase. As in the case of carbohydrates and protein, the capacity for digestion and absorption of dietary fat is in excess of ordinary needs.

Entrance of fat and protein into the small intestine stimulates the release of CCK and enterogastrone, which inhibit gastric secretions and motility, thus slowing the delivery of lipids. As a result, a portion of a large, fatty meal may remain in the stomach for 4 hours or longer. In addition to its many other functions, CCK stimulates biliary and pancreatic secretions. The combination of the peristaltic action of the small intestine and the surfactant and emulsification action of bile reduces the fat globules into tiny droplets, thus making them more accessible to digestion by the most potent lipid-digesting enzyme, pancreatic lipase (Keller and Layer, 2005).

Bile is a liver secretion composed of bile acids (primarily conjugates of cholic and chenodeoxycholic acids with glycine or taurine), bile pigments (which color the feces), inorganic salts, some protein, cholesterol, lecithin, and many compounds such as detoxified drugs that are metabolized and secreted by the liver. From its storage organ, the gallbladder, approximately 1 L of bile is secreted daily in response to the stimulus of food in the duodenum and stomach.

The free fatty acids and monoglycerides produced by digestion form complexes with bile salts called *micelles*. The micelles facilitate passage of the lipids through the watery environment of the intestinal lumen to the brush border (see Figure 1-4). The micelles release the lipid components and are returned to the gut lumen. Most of the bile salts are actively reabsorbed in the terminal ileum and returned to the liver to reenter the gut in bile secretions. This efficient recycling process is known as the **enterohepatic circulation**. The pool of bile acids may circulate from 3 to 15 times per day, depending on the amount of food ingested.

In the mucosal cells the fatty acids and monoglycerides are reassembled into new triglycerides. A few are further digested into free fatty acids and glycerol and then reassembled to form triglycerides. These triglycerides, along with cholesterol, fat-soluble vitamins, and phospholipids, are surrounded by a lipoprotein coat, forming chylomicrons (see Figure 1-4). The lipoprotein globules pass into the lymphatic system instead of entering portal blood and are transported to the thoracic duct and emptied into the systemic circulation at the junction of the left internal jugular and left subclavian veins. The chylomicrons are then carried through the bloodstream to several tissues, including liver, adipose tissue, and muscle. In the liver, triglycerides from the chylomicrons are repackaged into very low-density lipoproteins and transported primarily to the adipose tissue for metabolism and storage.

The fat-soluble vitamins A, D, E, and K are also absorbed in a micellar fashion, although water-soluble forms of vitamins A, E, and K supplements and carotene can be absorbed in the absence of bile acids.

Under normal conditions approximately 95% to 97% of ingested fat is absorbed into lymph vessels. Because of their shorter length and thus increased solubility, fatty acids of 8

to 12 carbons (i.e., medium-chain fatty acids) can be absorbed directly into colonic mucosal cells without the presence of bile and micelle formation. After entering mucosal cells, they are able to go directly without esterification into the portal vein, which carries them to the liver.

Increased motility, intestinal mucosal changes, pancreatic insufficiency, or the absence of bile can decrease absorption of fat. When undigested fat appears in the feces, the condition is known as *steatorrhea* (see Chapter 29). Medium-chain triglycerides (MCTs) have fatty acids 8 to 12 carbons long; MCTs are clinically valuable for individuals who lack necessary bile salts for long-chain fatty acid metabolism and transport. Supplements for clinical use are normally provided in the form of oil or a dietary beverage with other macronutrients and micronutrients.

For the nutrition care process, several nutrition diagnoses can be identified. The following list provides examples:

#### Common or Possible Nutrition Diagnoses Related to Digestion or Metabolism

- Altered GI function
- Imbalance of nutrients
- Altered nutrient utilization
- Altered nutritional laboratory results
- Inadequate or excessive fluid intake
- Food-drug interaction

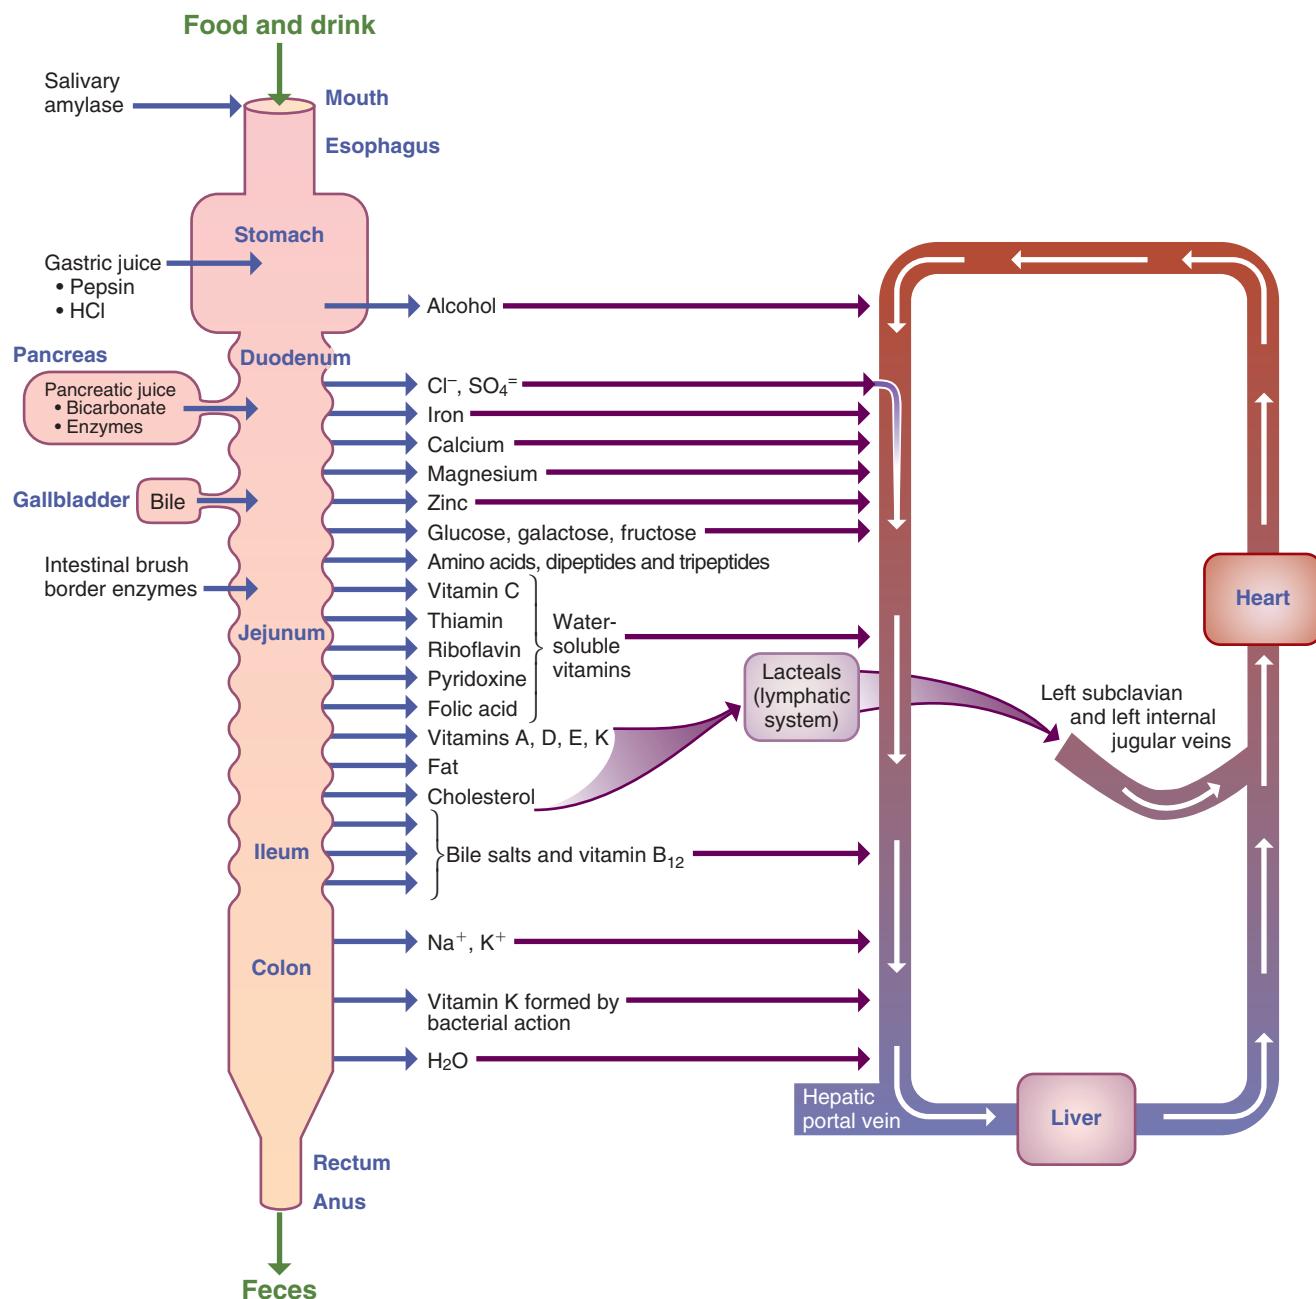

#### Vitamins and Minerals

Vitamins and minerals from foods are made available as macronutrients and are digested and absorbed across the mucosal layer, primarily in the small intestine (Figure 1-9). Besides adequate passive and transporter mechanisms, various factors affect the bioavailability of vitamins and minerals, including the presence or absence of other specific nutrients, acid or alkali, phytates, and oxalates. Each day approximately 8 to 9 L of fluid is secreted from the GIT and serves as a solvent, a vehicle for chemical reactions, and a medium for transfer of several nutrients.

At least some vitamins and water pass unchanged from the small intestine into the blood by passive diffusion, but several different mechanisms might be used to transport individual vitamins across the GI mucosa. Drugs are absorbed by a number of mechanisms, but often by passive diffusion. Thus drugs may share or compete with mechanisms for the absorption nutrients into intestinal cells (see Chapter 9).

Mineral absorption is more complex, especially the absorption of the cation minerals. These cations, such as selenium, are made available for absorption by the process of **chelation**, in which a mineral is bound to a ligand—usually an acid, an organic acid, or an amino acid, so that it is in a form absorbable by intestinal cells.

Iron and zinc absorption share several characteristics in that the efficiency of absorption partly depends on the needs of the host. They also use at least one transport protein, and each has mechanisms to increase absorption when stores are inadequate. Because phytates and oxalates from plants

**FIGURE 1-9** Sites of secretion and absorption in the gastrointestinal tract.

impair the absorption of both iron and zinc, absorption is better when animal sources are consumed. The absorption of zinc is impaired with disproportionately increased amounts of magnesium, calcium, and iron. Calcium absorption into the enterocyte occurs through channels in the brush border membrane, where it is bound to a specific protein carrier for transportation across the basolateral membrane. The process is regulated by the presence of vitamin D. Phosphorus is absorbed by a sodium phosphorus cotransporter, which is also regulated by vitamin D or low phosphate intake.

The GIT is the site of important interactions among minerals. Supplementation with large amounts of iron or zinc may decrease the absorption of copper. In turn, the

presence of copper may lower iron and molybdenum absorption. Cobalt absorption is increased in patients with iron deficiency, but cobalt and iron compete and inhibit one another's absorption. These interactions are probably the result of an overlap of mineral absorption mechanisms.

Minerals are transported in blood bound to protein carriers. The protein binding is either specific (e.g., transferrin, which binds with iron, or ceruloplasmin which binds with copper) or general (e.g., albumin, which binds with a variety of minerals). A fraction of each mineral is also carried in the serum as amino acid or peptide complexes. Specific protein carriers are usually not completely saturated; the reserve capacity may serve as a buffer against excessive exposure.

Toxicity from minerals usually results only after this buffering capacity is exceeded.

## CHAPTER 2

Carol S. Ireton-Jones, PhD, RD, LD,  
CNSD, FACN

# Intake: Energy

### KEY TERMS

activity thermogenesis (AT)  
basal energy expenditure (BEE)  
basal metabolic rate (BMR)  
direct calorimetry  
energy expenditure  
estimated energy requirement (EER)  
excess postexercise oxygen consumption (EPOC)  
facultative thermogenesis  
fat-free mass (FFM)  
high-metabolic-rate organ (HMRO)

indirect calorimetry (IC)  
kilocalorie (kcal)  
metabolic equivalents (METs)  
nonexercise activity thermogenesis (NEAT)  
obligatory thermogenesis  
physical activity level (PAL)  
resting energy expenditure (REE)  
resting metabolic rate (RMR)  
respiratory quotient (RQ)  
thermic effect of food (TEF)  
total energy expenditure (TEE)

Energy may be defined as “the capacity to do work.” The ultimate source of all energy in living organisms is the sun. Through the process of photosynthesis, green plants intercept a portion of the sunlight reaching their leaves and capture it within the chemical bonds of glucose. Proteins, fats, and other carbohydrates are synthesized from this basic carbohydrate to meet the needs of the plant. Animals and humans obtain these nutrients and the energy they contain by consuming plants and the flesh of other animals.

The body makes use of the energy from dietary carbohydrates, proteins, fats, and alcohol; this energy is locked in chemical bonds within food and is released through metabolism. Energy must be supplied regularly to meet needs for the body’s survival. Although all energy eventually takes the form of heat, which dissipates into the atmosphere, unique cellular processes first make possible its use for all of the

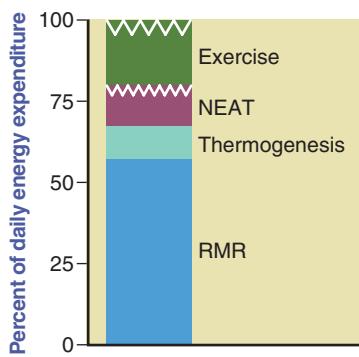

tasks required for life. These processes involve chemical reactions that maintain body tissues, electrical conduction of the nerves, mechanical work of the muscles, and heat production to maintain body temperature.

### ENERGY REQUIREMENTS

*Energy requirements* are defined as the dietary energy intake that is required for growth or maintenance in a person of a defined age, gender, weight, height, and level of physical activity. In children and pregnant or lactating women, energy requirements include the needs associated with the deposition of tissues or the secretion of milk at rates consistent with good health (Institute of Medicine, 2002, 2005). In ill or injured people, the stressors have an effect by increasing or decreasing **energy expenditure** (Joffe, 2009).

Body weight is one indicator of energy adequacy or inadequacy. The body has the unique ability to shift the fuel mixture of carbohydrates, proteins, and fats to accommodate energy needs. However, consuming too much or too

Sections of this chapter were written by Rachel Johnson, PhD, RD and Carol D. Frary, MS, RD for the previous edition of this text.

**FIGURE 2-1** The components of total energy expenditure: activity, diet-induced thermogenesis, and basal or resting metabolic rate.

little energy over time results in body weight changes. Thus body weight reflects adequacy of energy intake, but it is not a reliable indicator of macronutrient or micronutrient adequacy. Additionally, because body weight is affected by body composition, a person with a higher lean mass to body fat mass or body fat mass to lean mass may require differing energy intakes compared with the norm or “average” person.

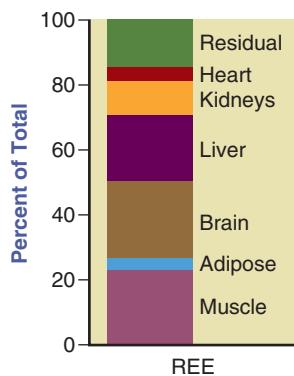

## COMPONENTS OF ENERGY EXPENDITURE

Energy is expended by the human body in the form of **basal energy expenditure (BEE)**, thermic effect of food (TEF), and activity thermogenesis (AT). These three components make up a person’s daily **total energy expenditure (TEE)** (Figure 2-1).

### Basal and Resting Energy Expenditure

BEE, or **basal metabolic rate (BMR)**, is the minimum amount of energy expended that is compatible with life. An individual’s BEE reflects the amount of energy used during 24 hours while physically and mentally at rest in a thermo-neutral environment that prevents the activation of heat-generating processes, such as shivering. Measurements of BEE should be done before an individual has engaged in any physical activity (preferably on awakening from sleep) and 10 to 12 hours after the ingestion of any food, drink, or nicotine. The BEE remains remarkably constant on a daily basis, typically representing 60% to 70% of TEE (see Figure 2-1).

**Resting energy expenditure (REE)**, or **resting metabolic rate (RMR)**, is the energy expended in the activities necessary to sustain normal body functions and homeostasis. These activities include respiration and circulation, the synthesis of organic compounds, and the pumping of ions across membranes. It includes the energy required by the central nervous system and for the maintenance of body temperature. For practical reasons the BEE is now rarely measured. REE measurements are used in its place, which in most cases are higher than the BEE by 10% to 20%

**FIGURE 2-2** Proportional contribution of organs and tissues to calculated resting energy expenditure. (Modified and used with permission from Gallagher D et al: Organ-tissue mass measurement allows modeling of REE and metabolically active tissue mass, Am J Physiol Endocrinol Metab 275:E249, 1998. Copyright American Physiological Society.)

(Institute of Medicine, 2002, 2005). The terms *REE* and *RMR* and *BEE* and *BMR* can be used interchangeably, but *REE* and *BEE* are used in this chapter.

### Factors Affecting Resting Energy Expenditure

Numerous factors cause the REE to vary among individuals, but body size and composition have the greatest effect. See Chapter 4 for discussion of methods used to determine body composition.

**Age.** Because REE is highly affected by the proportion of lean body mass (LBM), it is highest during periods of rapid growth, especially the first and second years of life (Butte et al., 2000). The additional energy required for synthesizing and depositing body tissue is approximately 5 kcal/g of tissue gained (Roberts and Young, 1988). Growing infants may store as much as 12% to 15% of the energy value of their food in the form of new tissue. As a child becomes older, the energy requirement for growth is reduced to approximately 1% of TEE. After early adulthood there is a decline in REE of 1% to 2% per kilogram of fat-free mass (FFM) per decade (Keys et al., 1973; Van Pelt, 2001). Fortunately, exercise can help maintain a higher LBM and a higher REE. Decreases in REE with increasing age may be partly related to age-associated changes in the relative size of LBM components (Gallagher et al., 2006).

**Body Composition.** **Fat-free mass (FFM)**, or LBM, comprises the majority of metabolically active tissue in the body and is the primary predictor of REE. FFM contributes to approximately 80% of the variations in REE (Bosy-Westphal et al., 2004). Because of their greater FFM, athletes with greater muscular development have approximately a 5% higher resting metabolism than nonathletic individuals. Organs in the body contribute to heat production (Figure 2-2). Approximately 60% of REE can be accounted for by the heat produced by **high-metabolic-rate organs (HMRGs)**, that is, the liver, brain, heart, spleen, and kidneys (Gallagher et al., 1998). Indeed, differences in FFM

between ethnic groups may be related to the total mass of these HRMOs (Gallagher et al., 2006). Relatively small individual variation in HMRO mass significantly affects REE (Javed et al., 2010).

**Body Size.** Larger people generally have higher metabolic rates than smaller people, but tall, thin people have higher metabolic rates than short, wide people. For example, if two people weigh the same but one person is taller, the taller person has a larger body surface area and a higher metabolic rate (Cereda, 2009). The amount of LBM is highly correlated with total body size. For example, obese children have higher REEs than nonobese children, but, when REE is adjusted for body composition, FFM, and fat mass, no REE differences are found (Byrne, 2003).

**Climate.** The REE is affected by extremes in environmental temperature. People living in tropical climates usually have REEs that are 5% to 20% higher than those living in temperate areas. Exercise in temperatures greater than 86° F imposes a small additional metabolic load of approximately 5% from increased sweat gland activity. The extent to which energy metabolism increases in extremely cold environments depends on the insulation available from body fat and protective clothing (Dobratz et al., 2007).

**Gender.** Gender differences in metabolic rates are attributable primarily to differences in body size and composition. Women, who generally have more fat in proportion to muscle than men, have metabolic rates that are approximately 5% to 10% lower than men of the same weight and height. However, with aging, this difference becomes less pronounced (Poehlman, 1993).

**Hormonal Status.** Hormones affect metabolic rate. Endocrine disorders, such as hyperthyroidism and hypothyroidism, increase or decrease energy expenditure, respectively. Stimulation of the sympathetic nervous system during periods of emotional excitement or stress causes the release of epinephrine, which promotes glycogenolysis and increased cellular activity. Ghrelin and peptide YY are gut hormones involved in appetite regulation and energy homeostasis (Larson-Meyer et al., 2010). The metabolic rate of women fluctuates with the menstrual cycle. During the luteal phase (i.e., the time between ovulation and the onset of menstruation), metabolic rate increases slightly (Ferraro, 1992). During pregnancy, growth in uterine, placental, and fetal tissues, along with the mother's increased cardiac workload, contributes to gradual increases in BEE (Butte et al., 2004).

**Temperature.** Fevers increase REE by approximately 7% for each degree of increase in body temperature more than 98.6° F or 13% for each degree more than 37° C as noted by classic studies (Hardy and DuBois, 1937). Studies in hospitalized patients have demonstrated increases in energy expenditure during fever as well as during cooling, varying according to the patient's condition (Bruder et al., 1998).

**Other Factors.** Caffeine, nicotine, and alcohol use stimulate metabolic rate. Caffeine intakes of 200 to 350 mg in men or 240 mg in women may increase mean REE by 7% to 11% and 8% to 15%, respectively (Compher et al., 2006). Nicotine use increases REE by approximately 3% to

4% in men and by 6% in women; alcohol consumption increases REE in women by 9% (Compher et al., 2006). Under conditions of stress and disease, energy expenditure may increase or decrease, based on the clinical situation. Energy expenditure may be higher in people who are obese (Dobratz et al., 2007), but depressed during starvation or chronic dieting and in people with anorexia nervosa (Sedlet and Ireton-Jones, 1989).

## Thermic Effect of Food

The **thermic effect of food (TEF)** is the increase in energy expenditure associated with the consumption, digestion, and absorption of food. The TEF accounts for approximately 10% of TEE (Institute of Medicine, 2002). The TEF may also be called *diet-induced thermogenesis, specific dynamic action*, or the *specific effect of food*. TEF can be separated into obligatory and facultative (or adaptive) subcomponents. **Obligatory thermogenesis** is the energy required to digest, absorb, and metabolize nutrients, including the synthesis and storage of protein, fat, and carbohydrates. Adaptive or **facultative thermogenesis** is the “excess” energy expended in addition to the obligatory thermogenesis and is thought to be attributable to the metabolic inefficiency of the system stimulated by sympathetic nervous activity.

The TEF varies with the composition of the diet, with energy expenditure increasing directly after food intake, particularly after consumption of a meal higher in protein compared with a meal higher in fat (Tentolouris et al., 2008). Fat is metabolized efficiently, with only 4% wastage, compared with 25% wastage when carbohydrate is converted to fat for storage. These factors are thought to contribute to the obesity-promoting characteristics of fat (Prentice, 1995). Although the extent of TEF depends on the size and macronutrient content of the meal, TEF decreases after ingestion over 30 to 90 minutes. Furthermore, the macronutrient oxidation rate is not different in lean and obese individuals (Tentolouris et al., 2008).

Spicy foods enhance and prolong the effect of the TEF. Meals with chili and mustard may increase the metabolic rate as much as 33% over that after an unspiced meal, and this effect may last for more than 3 hours (McCrory et al., 1994). Caffeine, capsaicin, and different teas such as green, white, and oolong tea may also increase energy expenditure and fat oxidation (Hursel and Westerterp-Plantenga, 2010). The role of TEF in weight management is discussed in Chapter 22.

Actual measurement of the TEF is appropriate only for research purposes. Thus to measure the TEF, it would be necessary to determine BEE and the energy expended in excess of BEE every 30 minutes for at least 5 hours after a meal. For practical purposes, it is calculated as no more than an additional 10% of the REE added to the sum of the REE and the activity thermogenesis.

## Activity Thermogenesis

Beyond REE and TEF, energy is expended in activity, either exercise related or part of daily work and movement.

Although it can be broken down into two categories, for most individuals, additional kilocalories/kcals are allocated for the more general term “activity,” which includes **activity thermogenesis (AT)** and **nonexercise activity thermogenesis (NEAT)**. AT is the energy expended during sports or fitness exercise; the energy expended during activities of daily living is referred to as NEAT (Levine and Kotz, 2005). The contribution of physical activity is the most variable component of TEE, which may be as low as 100 kilocalories (kcal)/day in sedentary people or as high as 3000 kcal/day in athletes. NEAT represents the energy expended during the work day and during leisure-type activities (e.g., shopping, fidgeting, even gum chewing), which may account for vast differences in energy costs among people (Levine and Kotz, 2005); see Appendix 28.

Individual AT varies considerably, depending on body size and the efficiency of individual habits of motion. The level of fitness also affects the energy expenditure of voluntary activity because of variations in muscle mass. AT tends to decrease with age, a trend that is associated with a decline in FFM and an increase in fat mass (Roubenoff et al., 2000). In general, men have a greater skeletal muscle than women, which may account for their higher AT (Janssen et al., 2000).

**Excess postexercise oxygen consumption (EPOC)** affects energy expenditure. The duration and magnitude of physical activity increase EPOC, resulting in an elevated metabolic rate even after exercise has ceased (Bahr et al., 1992). Habitual exercise does not cause a significantly prolonged increase in metabolic rate per unit of active tissue, but it has been shown to cause an 8% to 14% higher metabolic rate in men who are moderately and highly active, respectively, because of their increased FFM (Horton and Geissler, 1994). These differences seem to be related to the person, not to the activity.

## Measurement of Energy Expenditure

The standard unit for measuring energy is the *calorie*, which is the amount of heat energy required to raise the temperature of 1 ml of water at 15° C by 1° C. Because the amount of energy involved in the metabolism of food is fairly large, the **kilocalorie (kcal)**, 1000 calories, is used to measure it. A popular convention is to designate kilocalorie by *Calorie* (with a capital C). In this text, however, *kilocalorie* is abbreviated *kcal*. The *joule* (J) measures energy in terms of mechanical work and is the amount of energy required to accelerate with a force of 1 Newton (N) for a distance of 1 m; this measurement is widely used in countries other than the United States. One kcal is equivalent to 4.184 kilojoules (kJ).

Because various methods are available to measure human energy expenditure, it is important to gain an understanding of the differences in these methods and how they can be applied in practical and research settings.

### Direct Calorimetry

**Direct calorimetry** is possible only with very specialized and expensive equipment. An individual is monitored in a

**FIGURE 2-3** Measuring resting metabolic rate using a ventilated hood system. (Courtesy of MRC Mitochondrial Biology Unit, Cambridge, England.)

room-type structure (a whole-room calorimeter) that permits a moderate amount of activity. It includes equipment that monitors the amount of heat produced by the individual inside. Direct calorimetry provides a measure of energy expended in the form of heat but provides no information on the kind of fuel being oxidized. The method is also limited by the confined nature of the testing conditions. Hence the measurement of TEE using this method is not representative of a free-living (i.e., engaged in normal daily activities) individual in a normal environment because physical activity within the chamber is limited. High cost, complex engineering, and scarcity of appropriate facilities around the world also limit the use of this method.

### Indirect Calorimetry

**Indirect calorimetry (IC)** is a more commonly used method for measuring energy expenditure. An individual's oxygen consumption and carbon dioxide production are quantified over a given period. The **Weir equation (1949)** and a constant respiratory quotient value of 0.85 are used to convert oxygen consumption to REE. The equipment varies but usually involves an individual breathing into a mouthpiece (with nose clips), a mask that covers the nose and mouth, or a ventilated hood that captures all expired carbon dioxide (Figure 2-3). Ventilated hoods are useful for short- and long-term measurements.

IC measurements are achieved through the use of equipment called a *metabolic measurement cart* or *monitor*. There are various types of metabolic measurement carts, varying from larger equipment that measures oxygen consumption and carbon dioxide production only to equipment that also has the capability of providing pulmonary function and exercise testing parameters. These larger carts are more expensive because of the expanded capabilities, including measurement interface for IC measurements of hospitalized patients who are ventilator dependent. Metabolic carts are

often used at hospitals to assess energy requirements and are most typically found in the intensive care unit (Ireton-Jones, 2010). Individuals and patients who are spontaneously breathing may have their energy expenditure measured with smaller “handheld” indirect calorimeters designed specifically for measuring oxygen consumption while using a static value for carbon dioxide production (St-Onge, 2004). These have easy mobility and relatively low equipment cost.

A strict protocol should be followed before performing IC measurement. For “normal” healthy people, a minimum of a 5-hour fast after meals and snacks is recommended. Caffeine should be avoided for at least 4 hours and alcohol and smoking for at least 2 hours. Testing should occur no sooner than 2 hours after moderate exercise; following vigorous resistance exercise, a 14-hour period is advised (Compher et al., 2006). To achieve a steady-state measurement, there should be a rest period of 10 to 20 minutes before the measurement is taken. An IC measurement duration of 10 minutes with the first 5 minutes deleted and the remaining 5 minutes having a coefficient of variation less than 10% indicates a steady-state measurement (Compher et al., 2006). When the measurement conditions listed here are met and a steady state is achieved, energy expenditure can be measured at any time during the day.

Energy expenditure can be measured for ill or injured individuals as well. Equipment used for the patient who is ventilator dependent may be different from that used for the ambulatory individual; however, a protocol specifying the conditions of measurement should be used for these patients as well (Ireton-Jones, 2010). When these conditions are met, IC can be applied for measuring the energy expenditure of acute or critically ill inpatients, outpatients, or healthy individuals.

## Respiratory Quotient

When oxygen consumption and carbon dioxide production are measured, **respiratory quotient (RQ)** may be calculated as noted in the following equation. The RQ indicates the fuel mixture being metabolized. The RQ for carbohydrate is 1 because the number of carbon dioxide molecules produced is equal to the number of oxygen molecules consumed.

$$\text{RQ} = \text{volume of CO}_2 \text{ expired/volume of O}_2 \text{ consumed (VO}_2/\text{VCO}_2)$$

### RQ values:

1 = carbohydrate

0.85 = mixed diet

0.82 = protein

0.7 = fat

$\leq 0.65$  = ketone production

RQs greater than 1 are associated with net fat synthesis; carbohydrate (glucose) intake or total caloric intake that is excessive, whereas a very low RQ may be seen under conditions of inadequate nutrient intake (Elia and Livesey, 1988; Ireton-Jones and Turner, 1987; McClave et al., 2003).

Although RQ has been used to determine the efficacy of nutrition support regimens for hospitalized patients, McClave found that changes in RQ failed to correlate to percent calories provided or required, indicating low sensitivity and specificity that limits the efficacy of RQ as an indicator of overfeeding or underfeeding. It is appropriate to use RQ as a marker of test validity (to confirm measured RQ values are in physiologic range) and a marker for respiratory tolerance of the nutrition support regimen.

## Other Methods of Measuring Energy Expenditure

**Doubly Labeled Water:** The doubly labeled water (DLW) technique for measuring TEE is considered the gold standard for determining energy requirements and energy balance in humans. The method was first applied to humans in 1982, and since that time scientists have developed a database that is used to develop recommendations for energy intake (Institute of Medicine, 2002; 2005). The DLW method is based on the principle that carbon dioxide production can be estimated from the difference in the elimination rates of body hydrogen and oxygen. After administering an oral loading dose of water labeled with deuterium oxide ( $^2\text{H}_2\text{O}$ ) and oxygen-18 ( $\text{H}_2^{18}\text{O}$ )—hence the term *doubly labeled water*—the  $^2\text{H}_2\text{O}$  is eliminated from the body as water, and the  $\text{H}_2^{18}\text{O}$  is eliminated as water and carbon dioxide. The elimination rates of the two isotopes are measured for 10 to 14 days by periodic sampling of body water from urine, saliva, or plasma. The difference between the two elimination rates is a measure of carbon dioxide production. Carbon dioxide production can then be equated to TEE using standard IC techniques for the calculation of energy expenditure.

The DLW technique has numerous characteristics that make it a useful method for measuring TEE in various populations (Friedman and Johnson, 2002). First, it provides a measure of energy expenditure that incorporates all the components of TEE, REE, TEF, and AT. The administration is easy, and the person is able to engage in typical activities of daily living throughout the measurement period. Therefore the technique provides a measure of the person's usual daily TEE, which is beneficial for those such as infants, young children, older adults, and disabled individuals who cannot easily withstand the rigorous testing involved in the measurement of oxygen consumption during various activities. DLW also provides a method by which more subjective estimates of energy intakes (e.g., diet recalls, records) and energy expenditure (e.g., physical activity logs) can be validated (Schoeller, 1990). Most important, the method is accurate and has a precision of 2% to 8% (Plasqui and Westerterp, 2007).

The DLW technique is clearly most applicable as a research tool; the stable isotopes are expensive, and expertise is required to operate the highly sophisticated and costly mass spectrometer for the analysis of the isotope enrichments. These disadvantages make the DLW technique impractical for daily use by clinicians. However, DLW research studies have provided the data used to develop

some prediction equations to estimate total energy requirements (Institute of Medicine, 2002; 2005). These equations should be used only as a guide or starting point, after which the person must be monitored closely and interventions developed to promote optimal nutrition status. As with most equations, these apply to healthy individuals, not to those who are ill, injured, or requiring intensive nutrition support (Wells et al., 2002).

### Measuring Activity-Related Energy Expenditure

**Doubly Labeled Water.** The caloric value of AT can be estimated by using the DLW method in conjunction with IC. After the postprandial REE (which includes a measure of the TEF) has been measured using IC, an estimated AT can be determined by subtracting the postprandial REE from the TEE that was measured using DLW (Goran et al., 1995). This method is generally used only in research settings but can be used to validate other, more practical and easily administered methods of measuring physical activity.

**Uniaxial Monitors.** Uniaxial monitors measure the degree and intensity of movement in a vertical plane. Resembling a pager worn on the hip, the uniaxial monitor is a portable device designed for children and adults to estimate activity-related energy expenditure. Among adults, the uniaxial monitor was found to be an effective tool for measuring energy expenditure when compared with the DLW technique (Gretebeck et al., 1991; 1992). It may be acceptable for estimates of activity-related energy expenditure in groups of people, but it has limited use with individuals.

A triaxial monitor has also been used to measure energy related to activity (Philips Research, Eindhoven, The Netherlands). It more efficiently measures multidirectional movement by employing three uniaxial monitors. In a review of numerous articles, Plasqui and Westerterp (2007) found that a triaxial monitor correlated with energy expenditure measured using DLW technique. Application of an easily accessible and useable monitor allows determination of real activity levels, thereby reducing errors related to overreporting or underreporting of actual energy expenditure for weight management.

### Physical Activity Questionnaire

Physical activity questionnaires (PAQs) are the simplest and least expensive tools for gaining information about an individual's activity level (Winters-Hart et al., 2004.) DLW allows researchers to determine the validity of these questionnaires. The Seven-Day Recall and the Yale Physical Activity Survey are two questionnaires that are validated (Bonnefoy et al., 2001). The Baecke questionnaire and an adapted version of the Tecumseh Community Health Study questionnaire are useful for determining whether a group or an individual is active or inactive (Philippaerts et al., 1999). Reporting errors are common among PAQs, which can lead to discrepancies between calculated energy expenditure and that determined by DLW (Neilson et al., 2008). For normal individuals, this may account for slowed weight loss or gain and, as such, a need to modify caloric intake.

## ESTIMATING ENERGY REQUIREMENTS

### Equations for Estimating Resting Energy Expenditure

Over the years several equations have been developed to estimate the REE. Equations are available that allow the estimation of REE as derived from measurement using IC in adults. Until recently, the Harris-Benedict equations were some of the most widely used equations to estimate REE in normal and ill or injured individuals (Harris and Benedict, 1919). The Harris-Benedict formulas have been found to overestimate REE in normal weight and obese individuals by 7% to 27% (Frankenfield, 2003). A study comparing measured REE with estimated REE using the Mifflin-St. Jeor equations, Owen equations, and Harris-Benedict equations for both males and females found that the Mifflin-St. Jeor equations were most accurate in estimating REE in both normal weight and obese people (Frankenfield et al., 2003; Owen et al., 1986; Owen et al., 1987). The Mifflin-St Jeor equations were developed from measured REE using IC in 251 males and 247 females; 47% of these individuals had a body mass index (BMI) between 30 and 42 kg/m<sup>2</sup> (Mifflin et al., 1990). These equations are as follows:

#### Mifflin-St. Jeor Equations

Males: kcal/day = 10 (wt) + 6.25 (ht) - 5 (age) + 5

Females: kcal/day = 10 (wt) + 6.25 (ht) - 5 (age) - 161

Weight = actual body weight in kilograms;

Height = centimeters; Age = years

Although the Harris-Benedict equations have been applied to ill and injured people, these equations, as well as those of Mifflin, were developed for use in "normal" healthy individuals, and their application to any other population is questionable. For energy requirements for critically ill patients, see Chapter 39.

### Estimating Energy Requirements from Energy Intake

Traditionally, recommendations for energy requirements were based on self-recorded estimates (e.g., diet records) or self-reported estimates (e.g., 24-hour recalls) of food intake. However, it is now well accepted that these methods do not provide accurate or unbiased estimates of an individual's energy intake. The percentage of people who underestimate or underreport their food intake ranges from 10% to 45%, depending on the person's age, gender, and body composition. Underestimating tends to increase as children age, is worse among women than men, and is more prevalent and severe among obese people (Johnson, 2000).

Multiple online programs are available whereby an individual can enter the food and quantity consumed into a program that will estimate the macronutrient and micronutrient content. These programs allow users to enter data and receive a summary report, often with a detailed report provided to the health professional as well. Widely available

programs include Food Prodigy and the MyPlate Tracker from the United States Department of Agriculture.

### Energy Requirements Prediction Equations

The National Academy of Sciences, Institute of Medicine, and Food and Nutrition Board, in partnership with Health Canada, developed the estimated energy requirements for men, women, children, and infants and for pregnant and lactating women (Institute of Medicine, 2002; 2005). The **estimated energy requirement (EER)** is the average dietary

energy intake that is predicted to maintain energy balance in a healthy adult of a defined age, gender, weight, height, and level of physical activity consistent with good health. In children and pregnant and lactating women, the EER is taken to include the energy needs associated with the deposition of tissues or the secretion of milk at rates consistent with good health. Table 2-1 lists average dietary reference intake (DRI) values for energy in healthy, active people of reference height, weight, and age for each life-stage group (Institute of Medicine, 2002; 2005).

**TABLE 2-1**

### Intensity and Effect of Various Activities on Physical Activity Level in Adults\*

Physical Activity	METs <sup>†</sup>	Δ PAL/10 min <sup>‡</sup>	Δ PAL/hr <sup>‡</sup>
<b>Daily Activities</b>			
Lying quietly	1	0	0
Riding in a car	1	0	0
Light activity while sitting	1.5	0.005	0.03
Watering plants	2.5	0.014	0.09
Walking the dog	3	0.019	0.11
Vacuuming	3.5	0.024	0.14
Doing household tasks (moderate effort)	3.5	0.024	0.14
Gardening (no lifting)	4.4	0.032	0.19
Mowing lawn (power mower)	4.5	0.033	0.20
<b>Leisure Activities: Mild</b>			
Walking (2 mph)	2.5	0.014	0.09
Canoeing (leisurely)	2.5	0.014	0.09
Golfing (with cart)	2.5	0.014	0.09
Dancing (ballroom)	2.9	0.018	0.11
<b>Leisure Activities: Moderate</b>			
Walking (3 mph)	3.3	0.022	0.13
Cycling (leisurely)	3.5	0.024	0.14
Performing calisthenics (no weight)	4	0.029	0.17
Walking (4 mph)	4.5	0.033	0.20
<b>Leisure Activities: Vigorous</b>			
Chopping wood	4.9	0.037	0.22
Playing tennis (doubles)	5	0.038	0.23
Ice skating	5.5	0.043	0.26
Cycling (moderate)	5.7	0.045	0.27
Skiing (downhill or water)	6.8	0.055	0.33
Swimming	7	0.057	0.34
Climbing hills (5-kg load)	7.4	0.061	0.37
Walking (5 mph)	8	0.067	0.40
Jogging (10-min mile)	10.2	0.088	0.53
Skipping rope	12	0.105	0.63

Modified from Institute of Medicine of The National Academies: Dietary reference intakes for energy, carbohydrate, fiber, fat, fatty acids, protein, and amino acids, Washington, DC, 2002, The National Academies Press.

*MET*, Metabolic equivalent; *PAL*, physical activity level.

\*PAL is the physical activity level that is the ratio of the total energy expenditure to the basal energy expenditure.

<sup>†</sup>METs are multiples of an individual's resting oxygen uptakes, defined as the rate of oxygen ( $O_2$ ) consumption of 3.5 ml of  $O_2/min/kg$  body weight in adults.

<sup>‡</sup>The Δ PAL is the allowance made to include the delayed effect of physical activity in causing excess postexercise oxygen consumption and the dissipation of some of the food energy consumed through the thermic effect of food.

Supported by DLW studies, prediction equations have been developed to estimate energy requirements for people according to their life-stage group. Box 2-1 lists the EER prediction equations for people of normal weight. TEE prediction equations are also listed for various overweight and obese groups, as well as for weight maintenance in obese girls and boys. All equations have been developed to maintain current body weight (and promote growth when appropriate) and current levels of physical activity for all subsets of the population; they are not intended to promote weight loss (Institute of Medicine, 2002; 2005).

The EER incorporates age, weight, height, gender, and level of physical activity for people ages 3 years and older. Although variables such as age, gender, and feeding type (i.e., breast milk, formula) can affect TEE among infants and young children, weight has been determined as the sole predictor of TEE needs (Institute of Medicine, 2002; 2005). Beyond TEE requirements, additional calories are required for infants and young children and children ages 3 through 18 to support the deposition of tissues needed for growth, and for pregnant and lactating women; thus the EER among these subsets of the population is the sum of TEE plus the caloric requirements for energy deposition.

The prediction equations include a physical activity (PA) coefficient for all groups except infants and young children (see Box 2-1). PA coefficients correspond to four **physical activity level (PAL)** lifestyle categories: sedentary, low active, active, and very active. Because PAL is the ratio of TEE to BEE, the energy spent during activities of daily living, the sedentary lifestyle category has a PAL range of 1 to 1.39. PAL categories beyond sedentary are determined according to the energy spent by an adult walking at a set pace (Table 2-2). The walking equivalents that correspond to each PAL

category for an average-weight adult walking at 3 to 4 mph are 2, 7, and 17 miles per day, respectively (Institute of Medicine, 2002; 2005).

## Estimated Energy Expended in Physical Activity

Energy expenditure in physical activity can be estimated using either the method shown in Appendix 28, which represents energy spent during common activities and incorporates body weight and the duration of time for each activity as variables, or using information in the DRI tables (see tables on inside front cover), which represents energy spent by adults during various intensities of physical activity—energy that is expressed as metabolic equivalents (METs) (Institute of Medicine, 2002; 2005).

## Estimating Energy Expenditure of Selected Activities Using Metabolic Equivalents

**Metabolic equivalents (METs)** are units of measure that correspond with a person's metabolic rate during selected physical activities of varying intensities and are expressed as multiples of REE (Institute of Medicine, 2002; 2005). An MET value of 1 is the oxygen metabolized at rest (3.5 mL of oxygen per kilogram of body weight per minute in adults) and can be expressed as 1 kcal/kg of body weight per hour (Ainsworth et al., 1993). Thus the energy expenditure of adults can be estimated using MET values (1 MET = 1 kcal/kg/hour). For example, an adult who weighs 65 kg and is walking moderately at a pace of 4 mph (which is a MET value of 4.5) would expend 293 calories in one hour ( $4.5 \text{ kcal} \times 65 \text{ kg} \times 1 = 293$ ).

To estimate a person's energy requirements using the Institute of Medicine EER equations, it is necessary to identify a PAL value for that person. A person's PAL value can be affected by various activities performed throughout the day and is referred to as the *change in physical activity level* ( $\Delta$  PAL). To determine  $\Delta$  PAL, take the sum of the  $\Delta$  PALs for each activity performed for 1 day from the DRI tables (Institute of Medicine, 2002; 2005). To calculate the PAL value for 1 day, take the sum of activities and add the BEE (1) plus 10% to account for the TEF ( $1 + 0.1 = 1.1$ ). For example, to calculate an adult woman's PAL value, take the sum of the  $\Delta$  PAL values for activities of daily living, such as walking the dog (0.11) and vacuuming (0.14) for 1 hour each, sitting for 4 hours doing light activity (0.12), and then performing moderate to vigorous activities such as walking for 1 hour at 4 mph (0.20) and ice skating for 30 minutes (0.13) for a total of (0.7). To that value include the BEE adjusted for the 10% TEF (1.1) for the final calculation ( $0.7 + 1.1 = 1.8$ ). For this woman the PAL value (1.8) falls within an active range. The PA coefficient that correlates with an active lifestyle for this woman is 1.27.

To calculate the EER for an adult woman, use the EER equation for women 19 years and older (BMI 18.5–25 kg/m<sup>2</sup>); see Box 2-1 (Institute of Medicine, 2002; 2005). The following calculation estimates the EER for a 30-year-old

**TABLE 2-2**

**Physical Activity Level Categories and Walking Equivalence\***

PAL Category	PAL Values	Walking Equivalence (miles/day at 3-4 mph)
Sedentary	1-1.39	
Low active	1.4-1.59	1.5, 2.2, 2.9 for PAL = 1.5
Active	1.6-1.89	3, 4.4, 5.8 for PAL = 1.6 5.3, 7.3, 9.9 for PAL = 1.75
Very active	1.9-2.5	7.5, 10.3, 14 for PAL = 1.9 12.3, 16.7, 22.5 for PAL = 2.2 17, 23, 31 for PAL = 2.5

*PAL*, Physical activity level.

\*In addition to energy spent for the generally unscheduled activities that are part of a normal daily life. The low, middle, and high miles/day values apply to relatively heavyweight (120-kg), midweight (70-kg), and lightweight (44-kg) individuals, respectively.

**BOX 2-1****Estimated Energy Expenditure\* Prediction Equations at Four Physical Activity Levels†****EER for Infants and Young Children 0-2 Years (Within the 3rd-97th Percentile for Weight-for-Height)****EER = TEE<sup>‡</sup> Energy deposition**

0-3 months ( $89 \times \text{Weight of infant [kg]} - 100$ ) + 175 (kcal for energy deposition)

4-6 months ( $89 \times \text{Weight of infant [kg]} - 100$ ) + 56 (kcal for energy deposition)

7-12 months ( $89 \times \text{Weight of infant [kg]} - 100$ ) + 22 (kcal for energy deposition)

13-35 months ( $89 \times \text{Weight of child [kg]} - 100$ ) + 20 (kcal for energy deposition)

**EER for Boys 3-8 Years (Within the 5th-85th Percentile for BMI<sup>§</sup>)****EER = TEE<sup>‡</sup> Energy deposition**

$\text{EER} = 88.5 - 61.9 \times \text{Age (yr)} + \text{PA} \times (26.7 \times \text{Weight [kg]} + 903 \times \text{Height [m]}) + 20$  (kcal for energy deposition)

**EER for Boys 9-18 Years (Within the 5th-85th Percentile for BMI)****EER = TEE Energy deposition**

$\text{EER} = 88.5 - 61.9 \times \text{Age (yr)} + \text{PA} \times (26.7 \times \text{Weight [kg]} + 903 \times \text{Height [m]}) + 25$  (kcal for energy deposition)

in which

PA = Physical activity coefficient for boys 3-18 years:

PA = 1 if PAL is estimated to be  $\geq 1 < 1.4$  (Sedentary)

PA = 1.13 if PAL is estimated to be  $\geq 1.4 < 1.6$  (Low active)

PA = 1.26 if PAL is estimated to be  $\geq 1.6 < 1.9$  (Active)

PA = 1.42 if PAL is estimated to be  $\geq 1.9 < 2.5$  (Very active)

**EER for Girls 3-8 Years (Within the 5th-85th Percentile for BMI)****EER = TEE Energy deposition**

$\text{EER} = 135.3 - 30.8 \times \text{Age (yr)} + \text{PA} \times (10 \times \text{Weight [kg]} + 934 \times \text{Height [m]}) + 20$  (kcal for energy deposition)

**EER for Girls 9-18 Yr (Within the 5th-85th Percentile for BMI)****EER = TEE + Energy deposition**

$\text{EER} = 135.3 - 30.8 \times \text{Age (yr)} + \text{PA} \times (10 \times \text{Weight [kg]} + 934 \times \text{Height [m]}) + 25$  (kcal for energy deposition)

in which

PA = Physical activity coefficient for girls 3-18 years:

PA = 1 (Sedentary)

PA = 1.16 (Low active)

PA = 1.31 (Active)

PA = 1.56 (Very active)

**EER for Men 19 Years and Older (BMI 18.5-25 kg/m<sup>2</sup>)****EER = TEE**

$\text{EER} = 662 - 9.53 \times \text{Age (yr)} + \text{PA} \times (15.91 \times \text{Weight [kg]} + 539.6 \times \text{Height [m]})$

in which

PA = Physical activity coefficient:

PA = 1 (Sedentary)

PA = 1.11 (Low active)

PA = 1.25 (Active)

PA = 1.48 (Very active)

**EER for Women 19 Years and Older (BMI 18.5-25 kg/m<sup>2</sup>)****EER = TEE**

$\text{EER} = 354 - 6.91 \times \text{Age (yr)} + \text{PA} \times (9.36 \times \text{Weight [kg]} + 726 \times \text{Height [m]})$

in which

PA = Physical activity coefficient:

PA = 1 (Sedentary)

PA = 1.12 (Low active)

PA = 1.27 (Active)

PA = 1.45 (Very active)

**EER for Pregnant Women**

14-18 years: EER = Adolescent EER + Pregnancy energy deposition

First trimester = Adolescent EER + 0 (Pregnancy energy deposition)

Second trimester = Adolescent EER + 160 kcal (8 kcal/wk  $\times$  20 wk) + 180 kcal

Third trimester = Adolescent EER + 272 kcal (8 kcal/wk  $\times$  34 wk) + 180 kcal

19-50 years: = Adult EER + Pregnancy energy deposition

First trimester = Adult EER + 0 (Pregnancy energy deposition)

Second trimester = Adult EER + 160 kcal (8 kcal/wk  $\times$  20 wk) + 180 kcal

Third trimester = Adult EER + 272 kcal (8 kcal/wk  $\times$  34 wk) + 180 kcal

**EER for Lactating Women**

14-18 years: EER = Adolescent EER + Milk energy output – Weight loss

First 6 months = Adolescent EER + 500 – 170 (Milk energy output – Weight loss)

Second 6 months = Adolescent EER + 400 – 0 (Milk energy output – Weight loss)

19-50 years: EAR = Adult EER + Milk energy output – Weight loss

First 6 months = Adult EER + 500 – 70 (Milk energy output – Weight loss)

Second 6 months = Adult EER + 400 – 0 (Milk energy output – Weight loss)

## Estimated Energy Expenditure Prediction Equations at Four Physical Activity Levels—cont'd

### **Weight Maintenance TEE for Overweight and At-Risk for Overweight Boys 3-18 Years (BMI >85th Percentile for Overweight)**

$$\text{TEE} = 114 - 50.9 \times \text{Age (yr)} + \text{PA} \times (19.5 \times \text{Weight [kg]} + 1161.4 \times \text{Height [m]})$$

in which

PA = Physical activity coefficient:

PA = 1 if PAL is estimated to be  $\geq 1.0 < 1.4$  (Sedentary)

PA = 1.12 if PAL is estimated to be  $\geq 1.4 < 1.6$  (Low active)

PA = 1.24 if PAL is estimated to be  $\geq 1.6 < 1.9$  (Active)

PA = 1.45 if PAL is estimated to be  $\geq 1.9 < 2.5$  (Very active)

### **Weight Maintenance TEE for Overweight and At-Risk for Overweight Girls 3-18 Years (BMI >85th Percentile for Overweight)**

$$\text{TEE} = 389 - 41.2 \times \text{Age (yr)} + \text{PA} \times (15 \times \text{Weight [kg]} + 701.6 \times \text{Height [m]})$$

in which

PA = Physical activity coefficient:

PA = 1 if PAL is estimated to be  $\geq 1 < 1.4$  (Sedentary)

PA = 1.18 if PAL is estimated to be  $\geq 1.4 < 1.6$  (Low active)

PA = 1.35 if PAL is estimated to be  $\geq 1.6 < 1.9$  (Active)

PA = 1.60 if PAL is estimated to be  $\geq 1.9 < 2.5$  (Very active)

### **Overweight and Obese Men 19 Years and Older (BMI $\geq 25 \text{ kg/m}^2$ )**

$$\text{TEE} = 1086 - 10.1 \times \text{Age (yr)} + \text{PA} \times (13.7 \times \text{Weight [kg]} + 416 \times \text{Height [m]})$$

in which

PA = Physical activity coefficient:

PA = 1 if PAL is estimated to be  $\geq 1 < 1.4$  (Sedentary)

PA = 1.12 if PAL is estimated to be  $\geq 1.4 < 1.6$  (Low active)

PA = 1.29 if PAL is estimated to be  $\geq 1.6 < 1.9$  (Active)

PA = 1.59 if PAL is estimated to be  $\geq 1.9 < 2.5$  (Very active)

### **Overweight and Obese Women 19 Years and Older (BMI $\geq 25 \text{ kg/m}^2$ )**

$$\text{TEE} = 448 - 7.95 \times \text{Age (yr)} + \text{PA} \times (11.4 \times \text{Weight [kg]} + 619 \times \text{Height [m]})$$

where

PA = Physical activity coefficient:

PA = 1 if PAL is estimated to be  $\geq 1 < 1.4$  (Sedentary)

PA = 1.16 if PAL is estimated to be  $\geq 1.4 < 1.6$  (Low active)

PA = 1.27 if PAL is estimated to be  $\geq 1.6 < 1.9$  (Active)

PA = 1.44 if PAL is estimated to be  $\geq 1.9 < 2.5$  (Very active)

### **Normal and Overweight or Obese Men 19 Years and Older (BMI $\geq 18.5 \text{ kg/m}^2$ )**

$$\text{TEE} = 864 - 9.72 \times \text{Age (yr)} + \text{PA} \times (14.2 \times \text{Weight [kg]} + 503 \times \text{Height [m]})$$

in which

PA = Physical activity coefficient:

PA = 1 if PAL is estimated to be  $\geq 1 < 1.4$  (Sedentary)

PA = 1.12 if PAL is estimated to be  $\geq 1.4 < 1.6$  (Low active)

PA = 1.27 if PAL is estimated to be  $\geq 1.6 < 1.9$  (Active)

PA = 1.54 if PAL is estimated to be  $\geq 1.9 < 2.5$  (Very active)

### **Normal and Overweight or Obese Women 19 Years and Older (BMI $\geq 18.5 \text{ kg/m}^2$ )**

$$\text{TEE} = 387 - 7.31 \times \text{Age (yr)} + \text{PA} \times (10.9 \times \text{Weight [kg]} + 660.7 \times \text{Height [m]})$$

in which

PA = Physical activity coefficient:

PA = 1 if PAL is estimated to be  $\geq 1 < 1.4$  (Sedentary)

PA = 1.14 if PAL is estimated to be  $\geq 1.4 < 1.6$  (Low active)

PA = 1.27 if PAL is estimated to be  $\geq 1.6 < 1.9$  (Active)

PA = 1.45 if PAL is estimated to be  $\geq 1.9 < 2.5$  (Very active)

From Institute of Medicine, Food and Nutrition Board: Dietary reference intakes for energy, carbohydrate, fiber, fat, fatty acids, cholesterol, protein, and amino acids, Washington, DC, 2002, The National Academies Press, [www.nap.edu](http://www.nap.edu).

BMI, Body mass index; EER, estimated energy requirement; PA, physical activity; PAL, physical activity level; TEE, total energy expenditure.

\*EER is the average dietary energy intake that is predicted to maintain energy balance in a healthy adult of a defined age, gender, weight, height, and level of physical activity consistent with good health. In children and pregnant and lactating women, the EER includes the needs associated with the deposition of tissues or the secretion of milk at rates consistent with good health.

<sup>†</sup>PAL is the physical activity level that is the ratio of the total energy expenditure to the basal energy expenditure.

<sup>‡</sup>TEE is the sum of the resting energy expenditure, energy expended in physical activity, and the thermic effect of food.

<sup>§</sup>BMI is determined by dividing the weight (in kilograms) by the square of the height (in meters).

active woman who weighs 65 kg, is 1.77 m tall, with a PA coefficient (1.27):

$$\text{EER} = 354 - 6.91 \times \text{Age (yr)} + \text{PA} \times (9.36 \times \text{Weight [kg]} + 726 \times \text{Height [m]})$$

$$\text{EER} = 354 - (6.91 \times 30) + 1.27 \times ([9.36 \times 65] + [726 \times 1.77])$$

$$\text{EER} = 2551 \text{ kcal}$$

A simplified way of predicting physical activity additions to REE is through the use of estimates of the level of physical activity, which are then multiplied by the measured or predicted REE. To estimate TEE for minimal activity, increase REE by 10% to 20%; for moderate activity, increase REE by 25% to 40%; for strenuous activity, increase REE by 45% to 60%. These levels are ranges used in practice and can be considered “expert opinion” rather than evidence-based at this time.

### Physical Activity in Children

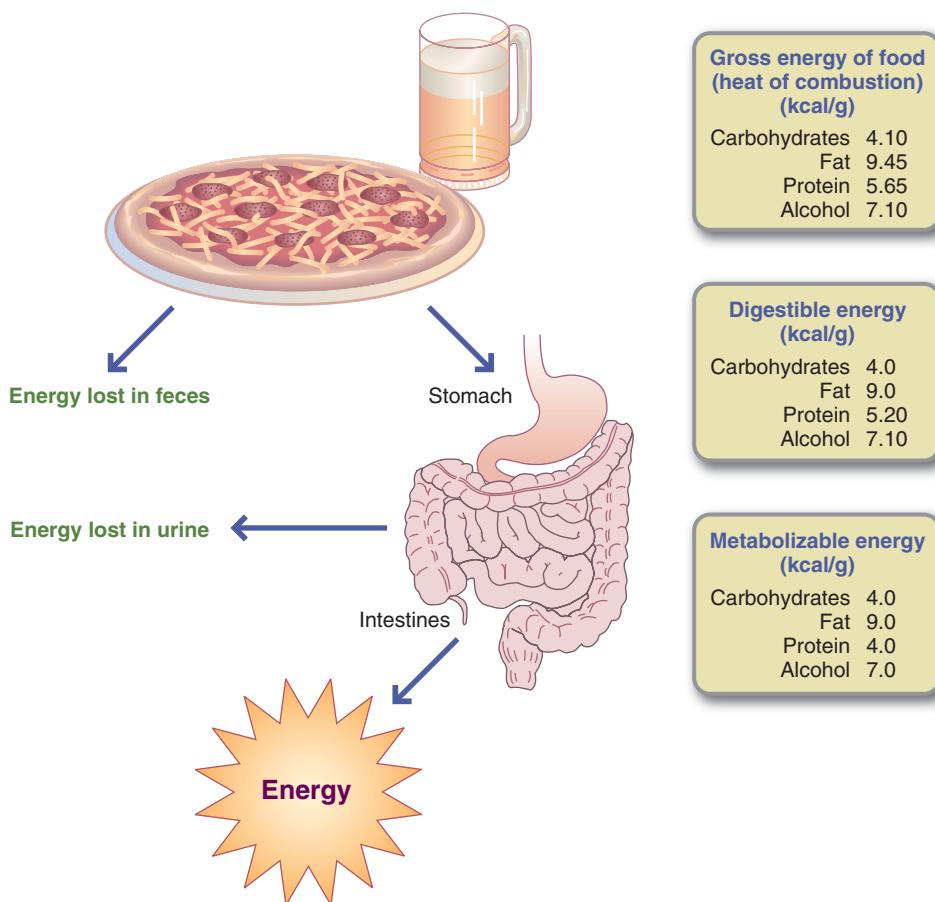

Energy spent during various activities and the intensity and impact of selected activities can also be determined for children and teens (see Box 2-1) (Institute of Medicine, 2002; 2005).

## CALCULATING FOOD ENERGY

The total energy available from a food is measured with a bomb calorimeter. This device consists of a closed container in which a weighed food sample, ignited with an electric spark, is burned in an oxygenated atmosphere. The container is immersed in a known volume of water, and the rise in the temperature of the water after igniting the food is used to calculate the heat energy generated.

Not all of the energy in foods and alcohol is available to the body's cells because the processes of digestion and absorption are not completely efficient. In addition, the nitrogenous portion of amino acids is not oxidized but is excreted in the form of urea. Therefore the biologically available energy from foods and alcohol is expressed in values rounded off slightly below those obtained using the calorimeter. These values for protein, fat, carbohydrate, and alcohol (Figure 2-4) are 4, 9, 4, and 7 kcal/g, respectively. Fiber is “unavailable carbohydrate” that resists digestion and absorption; its energy intake is minimal.

Although the energy value of each nutrient is known precisely, only a few foods, such as oils and sugars, are made up of a single nutrient. More commonly, foods contain a

**FIGURE 2-4** Energy value of food.

mixture of protein, fat, and carbohydrate. For example, the energy value of one medium (50-g) egg calculated in terms of weight is derived from protein (13%), fat (12%), and carbohydrate (1%) as follows:

$$\text{Protein: } 13\% \times 50 \text{ g} = 6.5 \text{ g} \times 4 \text{ kcal/g} = 26 \text{ kcal}$$

$$\text{Fat: } 12\% \times 50 \text{ g} = 6 \text{ g} \times 9 \text{ kcal/g} = 54 \text{ kcal}$$

$$\text{Carbohydrate: } 1\% \times 50 \text{ g} = 0.05 \text{ g} \times 4 \text{ kcal/g} = 2 \text{ kcal}$$

$$\text{Total} = 82 \text{ kcal}$$

The energy value of alcoholic beverages can be determined using the following equation (Gastineau, 1976): Alcohol kcal = Amount of beverage (oz) × Proof × 0.8 kcal/proof/1 oz. *Proof* is the proportion of alcohol to water or other liquids in an alcoholic beverage. The standard in the United States defines 100-proof as equal to 50% of ethyl alcohol by volume. To determine the percentage of ethyl alcohol in a beverage, divide the proof value by 2. For example, 86-proof whiskey contains 43% ethyl alcohol. The latter part of the equation—0.8 kcal/proof/1 oz—is the factor that accounts for the caloric density of alcohol (7 kcal/g) and the fact that not all of the alcohol in liquor is available for energy. For example, the number of kilocalories in 1 1/2 oz of 86-proof whiskey would be determined as follows:

$1 \frac{1}{2} \text{ oz} \times 86\% \text{ proof} \times 0.8 \text{ kcal/proof/1 oz} = 103 \text{ kcal}$ . Energy values of foods based on chemical analyses may be obtained from the U.S. Department of Agriculture (USDA) Nutrient Data Laboratory website or from *Bowes and Church's Food Values of Portions Commonly Used* (Pennington and Douglass, 2009). Many computer software programs that use the USDA nutrient database as the standard reference are also available and there are many online websites that can be used. See Appendixes 38 and 44.

ascorbic acid  
beta-glucans (glucopyranose)  
beriberi  
bioavailability  
bioflavonoids  
biotin  
calbindins  
calcitriol  
carnitine  
carotenoids  
ceruloplasmin  
cellulose  
chiral carbon  
cholecalciferol  
cholesterol  
chylomicrons  
cobalamin  
coenzyme Q<sub>10</sub> (CoQ<sub>10</sub>)  
conjugated linoleic acid (CLA)  
cretinism  
deamination  
denaturation  
dextrans  
diacylglycerols (diglycerides)  
dietary fiber  
disaccharides  
essential amino acids  
ferritin  
folate  
free radicals  
fructans  
fructose  
functional fiber  
galactose  
glucose tolerance factor (GTF)  
glutathione peroxidase (GSH-Px)  
glycemic index  
glycemic load  
glycogen  
glycolipids  
goiter  
goitrogens  
heme iron  
hemoglobin  
 hemosiderin  
hepcidin  
hydrogenation  
hydroxyapatite  
hypercarotenodermia  
isoprenoid  
ketone  
lactose  
lecithin (phosphatidylcholine)  
lignin  
limiting amino acid  
macrominerals  
maltose  
meat-fish-poultry (MFP) factor  
medium-chain triglycerides (MCTs)  
menadione  
menaquinones  
metallothionein  
microminerals

**monoacylglycerols (monoglycerides)**  
**monosaccharides**  
**monounsaturated fatty acids (MFAs)**

**vitamin**  
**vitamin K**  
**xerophthalmia**

## MACRONUTRIENTS

### CARBOHYDRATES

Carbohydrates are manufactured by plants and are a major source of energy, composing approximately half the total calories in the diet. Carbohydrates are composed of carbon, hydrogen, and oxygen in a ratio of C:O:H<sub>2</sub>. Important dietary carbohydrates can be categorized as (1) monosaccharides, (2) disaccharides and oligosaccharides, and (3) polysaccharides.

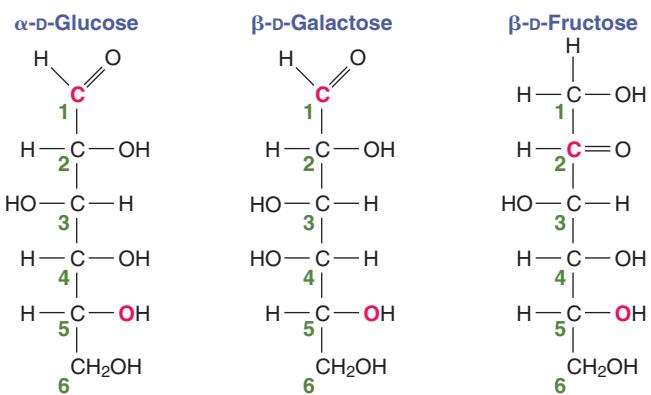

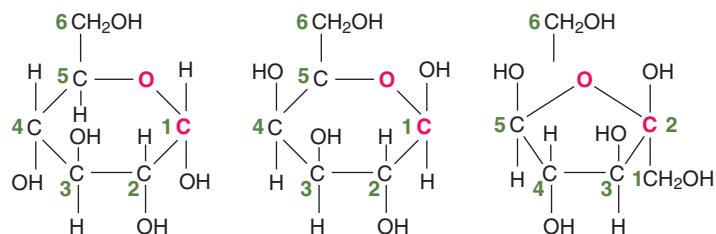

#### Monosaccharides

**Monosaccharides** do not normally occur as free molecules in nature but as basic components of disaccharides and polysaccharides. Only a small number of the many monosaccharides found in nature can be absorbed and used by humans. Monosaccharides can have three to seven carbons, but the most important are the six-carbon hexoses: glucose, galactose, and fructose. These hexoses all have the same chemical formula but differ importantly from one another. These differences result from small but significant differences in their chemical structure, some resulting from the presence of **chiral carbons** with four different atoms or groups attached. These groups can occur in different positions (isomers): glucose and galactose (Figure 3-1). The most important monosaccharide is  $\alpha$ -D-glucose. *Blood sugar* refers to glucose. Because the brain depends on a regular, predictable supply, the body has highly adapted physiologic mechanisms to maintain adequate blood glucose levels.

**Fructose** is the sweetest of all monosaccharides (Table 3-1). *High-fructose corn syrup* is intensely sweet, inexpensive, and manufactured enzymatically by changing the glucose in cornstarch to fructose. Epidemiologic evidence suggests that high-fructose diets (including intake from sweetened beverages) may contribute to obesity and other health conditions, such as the metabolic syndrome. Both galactose and fructose are metabolized in the liver by incorporation into metabolic pathways for glucose, but fructose bypasses a major control enzyme in the glycolytic pathway (Figure 3-2). **Galactose** is produced from lactose by hydrolysis during the digestive process. Infants born with an inability to metabolize galactose have galactosemia (see Chapter 44).

#### Disaccharides and Oligosaccharides

Although a wide variety of disaccharides exist in nature, the three most important **disaccharides** in human nutrition are sucrose, lactose, and maltose. These sugars are formed from monosaccharides joined by a glycosidic linkage between the active aldehyde or **ketone** carbon and a specific hydroxyl on another sugar (Figure 3-3). **Sucrose** occurs naturally in many foods and is also an additive in commercially processed items; it is consumed in large amounts by most Americans. *Invert sugar* is also a natural form of sugar (unlinked glucose and fructose in a 1:1 ratio) that is used commercially because it is sweeter than equal concentrations of sucrose. Invert sugar forms smaller crystals than sucrose and is

**HEXOSES****RING STRUCTURE**

**FIGURE 3-1** The three monosaccharides of importance in humans differ from each other in how they are handled metabolically even though they have very similar structures. They are isomers of one another.

preferred in the preparation of candies and icings. *Honey* is an invert sugar. *Lactose* is made almost exclusively in the mammary glands of lactating animals. *Maltose* is seldom found naturally in the food supply but is formed by hydrolysis of starch polymers during digestion and is also consumed as an additive in numerous food products. **Oligosaccharides** are small (3–10 monosaccharide units), readily water soluble, and often sweet (Roberfroid, 2005). Enzymes found in the brush border of the intestine (see Chapter 1) break bonds between molecules in disaccharides and are specific to the particular bond. Larger molecules with linkages that are different are not digestible and are classified as **dietary fiber** (American Dietetic Association, 2008).

**TABLE 3-1****Sweetness of Sugars and Sugar Substitutes**

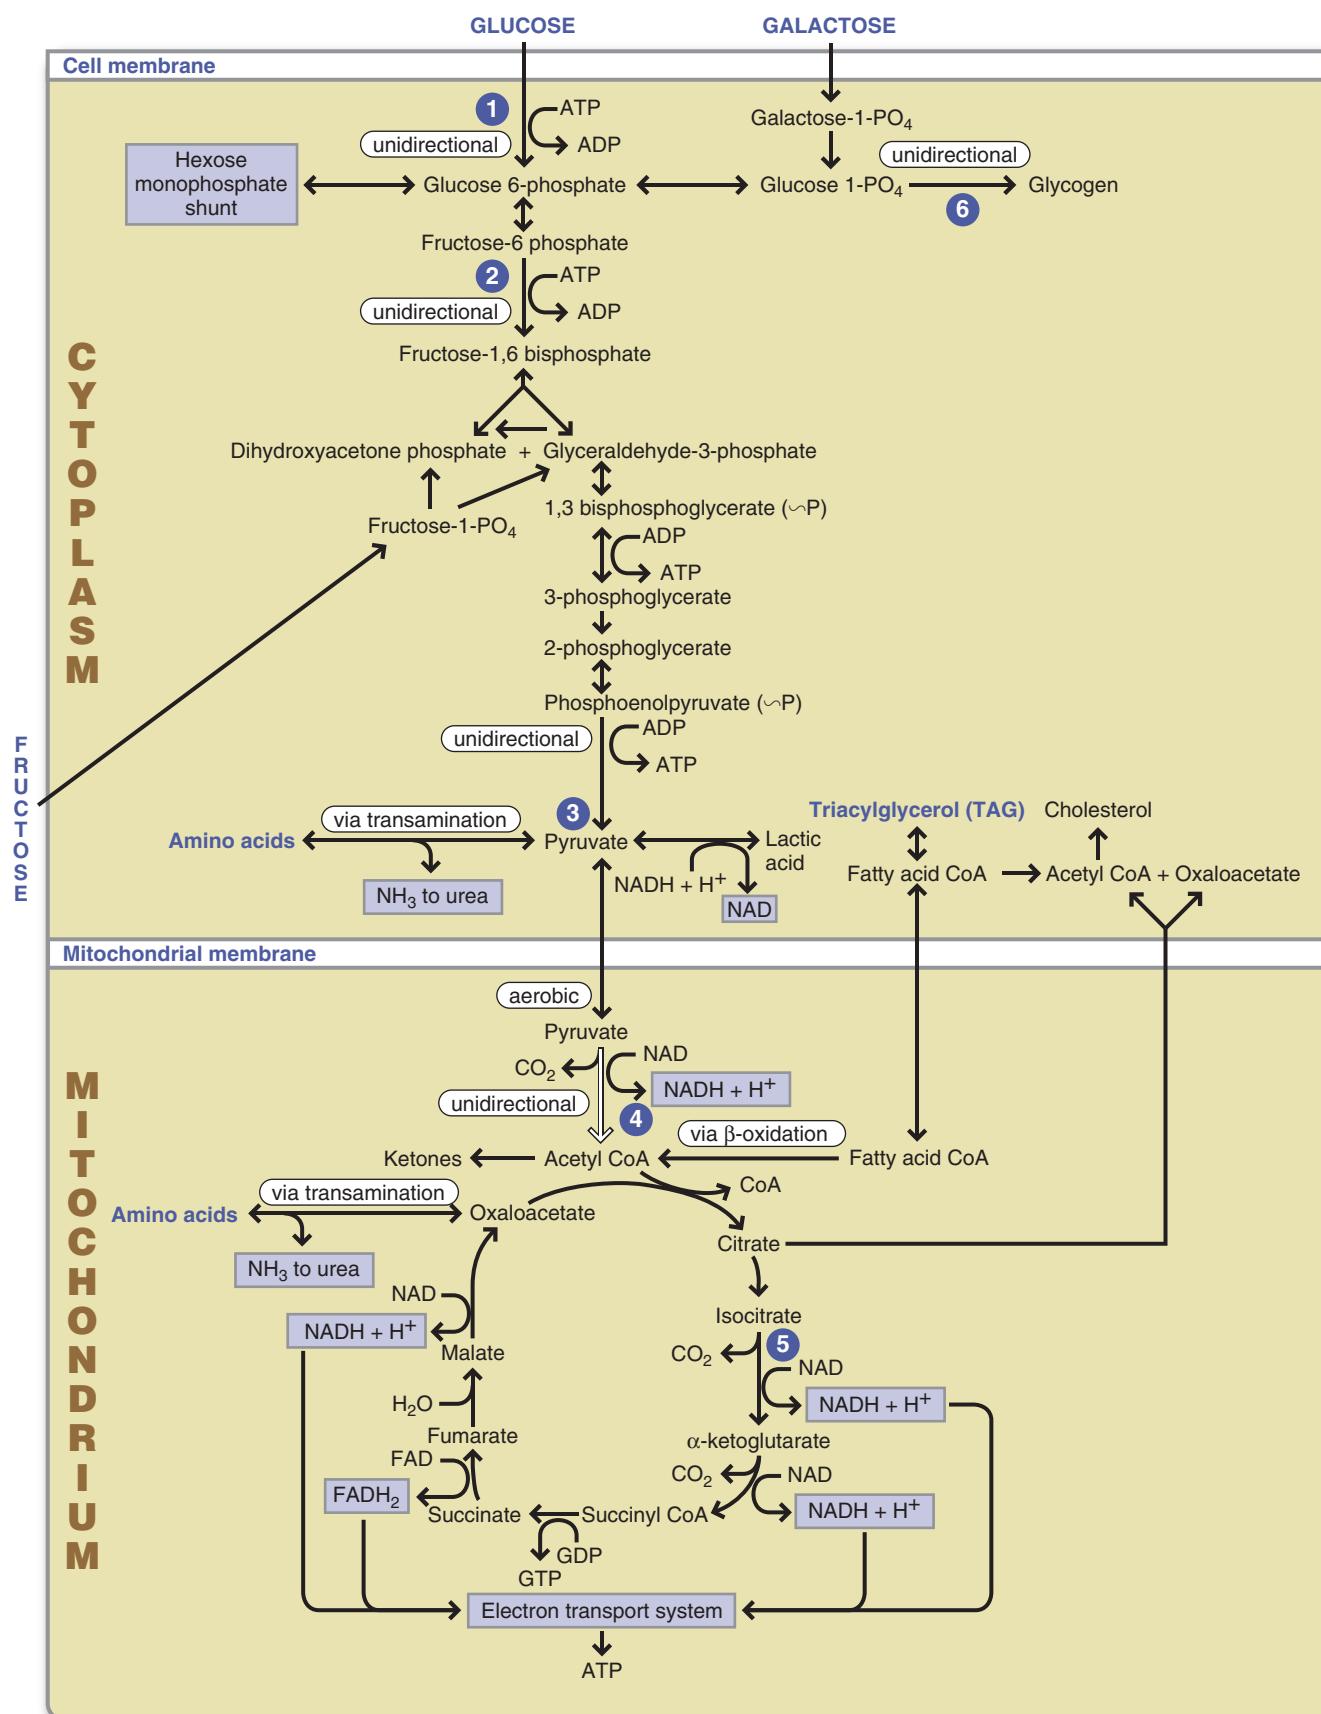

Substance	Sweetness Value (% equivalent to sucrose)
<b>Natural Sugar or Sugar Product</b>	
Levulose, fructose	173
Invert sugar	130
Sucrose	100
Xylitol	100
Glucose	74
Sorbitol	60
Mannitol	50
Galactose	32
Maltose	32
Lactose	16
<b>Sugar Substitutes</b>	
Cyclamate—banned in United States	30
Aspartame (Equal)*—FDA approved	180
Acesulfame-K (Sunette)—FDA approved	200
Stevia (Rebiana, Truvia, Purvia)—FDA approved	300
Saccharin (Sweet 'n Low)—FDA approved	300
Sucralose (Splenda)—FDA approved	600
Neotame (NutraSweet)*—FDA approved	8000

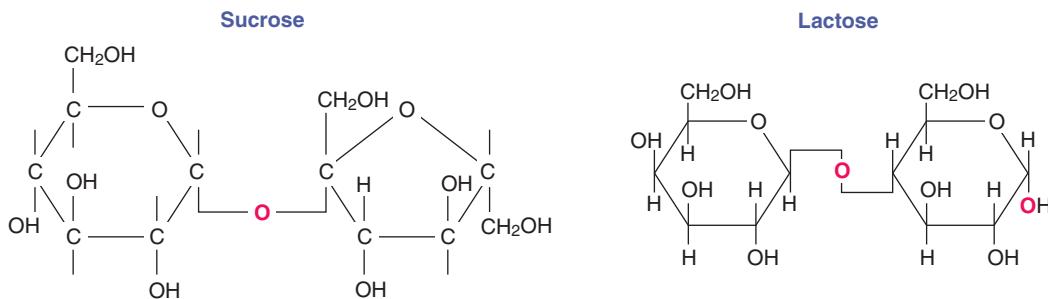

\*Nutritive (has calories).

Note: In the United States, six sugar substitutes have been approved for use; stevia, aspartame, sucralose, neotame, acesulfame potassium, and saccharin. Hundreds of new sweeteners are evaluated each year. New sweeteners on the market, such as Swerve and Just Like Sugar, are considered equal in sweetness to sugar.

For more information, see FDA website at: <http://www.fda.gov/Food/FoodIngredientsPackaging/ucm094211.htm#qanatural>, accessed 1-14-11.

**FIGURE 3-2** Overview of macronutrient metabolism. 1, Hexokinase/glucokinase (liver) reaction: uses adenosine triphosphate (ATP), is reversed by glucose 6-phosphatase in gluconeogenesis. 2, Phosphofructokinase reaction: modulated by ATP, positively modified by adenosine monophosphate and adenosine diphosphate (ADP), uses ATP, and is reversed by specific phosphatase in gluconeogenesis. 3, Pyruvate kinase reaction: second example of substrate level phosphorylation of ADP → ATP is not reversible and must be bypassed for gluconeogenesis. 4, Pyruvate dehydrogenase enzyme complex reaction: unidirectional and cannot be reversed. 5, Dehydrogenase reaction: similar to pyruvate dehydrogenase, characterizes the removal of hydrogens in the Krebs cycle. 6, Glycogenesis uses a glycogenic primer reaction and then glycogen synthetase and branching enzymes to synthesize glycogen. The reactions are not reversible. Glycogen is catabolized by a highly controlled phosphorylase. *ADP*, Adenosine diphosphate; *ATP*, adenosine triphosphate; *cAMP*, cyclic adenosine monophosphate. (Courtesy Margie Gallagher, PhD, RD, East Carolina University.)

**FIGURE 3-3** Disaccharides of importance in humans: sucrose (glucose and fructose) and lactose (glucose and galactose).

## Polysaccharides

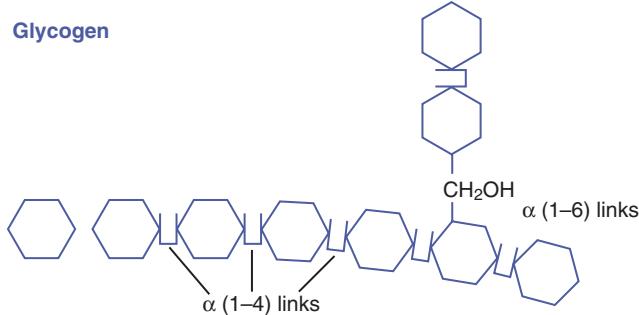

**Polysaccharides** are carbohydrates with more than 10 monosaccharide units. Plants store these carbohydrates as *starch* granules formed by linking glucose in straight chains and branching into a complex granular structure. Plants make two types of starch, amylose and amylopectin. **Amylose** is a smaller, linear molecule that is less than 1% branched whereas **amylopectin** is highly branched. Because of its larger size, amylopectin is more abundant in the food supply, especially in grains and starchy tubers.

Starches from corn, arrowroot, rice, potato, tapioca, and other plants are glucose polymers with the same chemical composition. Their unique character, taste, texture, and absorbability are determined by the relative numbers of glucose units in straight (amylase) and branched configurations (amylopectin) and the degree of accessibility to digestive enzymes.

Raw starch from raw potato or grains is poorly digested. Moist cooking causes the granules to swell, gelatinizes the starch, softens and ruptures the cell wall, and makes the starch more digestible by pancreatic amylase. Starch that remains intact throughout cooking, recrystallizes after cooling, resists enzyme breakdown, and yields limited amounts of glucose for absorption is known as **resistant starch**. **Waxy starch**, from corn and rice strains bred for more branched amylopectin chains, forms a smooth paste in water that gels only with a high concentration. Once a gel forms, the product remains thick during freezing and thawing, making it an ideal thickener for commercially frozen fruit pies, sauces, and gravies. **Modified food starch** is chemically or physically modified to change its viscosity, ability to gel, and other texture properties. Pregelatinized starch, dried on hot drums and made into a porous powder, is rapidly rehydrated with cold liquid. This starch rapidly thickens and is used in instant puddings, salad dressings, pie fillings, gravies, and baby food.

**Dextrins** result from the digestive process and are large, linear glucose polysaccharides of intermediate lengths cleaved from high amylose starch by  $\alpha$ -amylase. **Limit dextrins** are cleaved from amylopectin containing branch points and are subsequently digested into glucose by the mucosal enzyme isomaltase.

In contrast to plants, animals use carbohydrates primarily to maintain blood glucose concentrations between feedings.

**FIGURE 3-4** Glycogen is a branched glucose polymer similar to amylopectin, but the branches in glycogen are shorter and more numerous.

To ensure a readily available supply, liver and muscle cells store carbohydrate as **glycogen** (Figure 3-4). Glycogen is stored hydrated with water; thus the water makes glycogen large, cumbersome, and unsuitable for long-term energy storage. The 70-kg “average” man stores only an 18-hour fuel supply as glycogen, compared with a 2-month supply stored as fat. If all human energy stores were glycogen, humans would need to weigh 60 additional pounds (Alberts et al., 2002). Approximately 150 g of glycogen is stored in muscle, which can be increased fivefold with physical training (see Chapter 24) but is not available to maintain blood glucose directly. It is the glycogen store in the human liver (approximately 90 g) that is involved in the hormonal control of blood sugar.

The recommended amount of digestible carbohydrate required in the diet ranges between 45% and 65% of total calories (Institute of Medicine [IOM], Food and Nutrition Board, 2002). The percent carbohydrate of selected foods is given in Table 3-2. The Dietary Guidelines for Americans recommend that consumers select fruits, vegetables, and whole grains for higher fiber intake while decreasing sugar-added food choices (United States Department of Agriculture [USDA], 2005).

## Dietary Fiber and Functional Fiber

Dietary fiber refers to intact plant components that are not digestible by gastrointestinal (GI) enzymes, whereas **functional fiber** refers to nondigestible carbohydrates that

**TABLE 3-2****Carbohydrate Content of Foods**

Food	Carbohydrate (g/100 g)
<b>Sugar</b>	
Concentrated Sweets	
Sugar: Cane, beet, powdered, brown, maple	99.5 90-96
Candies	70-95
Honey (extracted)	82
Syrup: Table blends, molasses	55-75
Jams, jellies, marmalades	70
Carbonated, sweetened beverages	10-12
<b>Fruits</b>	
Prunes, apricots, figs (cooked, unsweetened)	12-31
Bananas, grapes, cherries, apples, pears	15-23
Fresh: Pineapples, grapefruits, oranges, apricots, strawberries	8-14
<b>Milk</b>	
Skim	6
Whole	5
<b>Starch</b>	
Grain products	
Starches: Corn, tapioca, arrowroot	86-88
Cereals (dry): Corn, wheat, oat, bran	68-85
Flour: Corn, wheat (sifted)	70-80
Popcorn (popped)	77
Cookies: Plain, assorted	71
Crackers, saltines	72
Cakes: Plain, without icing	56
Bread: White, rye, whole wheat	48-52
Macaroni, spaghetti, noodles, rice (cooked)	23-30
Cereals (cooked): Oat, wheat, grits	10-16
<b>Vegetables</b>	
Boiled: Corn, white and sweet potatoes, lima and dried beans, peas	15-26
Beets, carrots, onions, tomatoes	5-7
Leafy: Lettuce, asparagus, cabbage, greens, spinach	3-4

have been extracted or manufactured from plants. Both of these types of fiber have been shown to have beneficial physiologic functions in the GI tract and in reducing risk of certain disease states. These fibers and their functions are summarized in Table 3-3.

*Homopolysaccharides* contain repeating units of the same molecule. An example is **cellulose**, which cannot be hydrolyzed by amylase enzymes. Cellulose is the most abundant organic compound in the world, constituting 50% or more

of all the carbon in vegetation. The long cellulose molecule folds back on itself and is held in place by hydrogen bonding, thus giving cellulose fibrils great mechanical strength but limited flexibility. Cellulose is found in carrots and other vegetables. Other homopolymers called **beta-glucans (glucopyranose)** occur with branching, which makes them more soluble; examples include oats and barley.

*Heteropolysaccharides* are made by modifying the basic cellulose structure to form compounds with different water solubilities. **Hemicellulose** is a glucose polymer substituted with different sugar molecules that have different water solubilities. The predominant sugar is used to name the hemicellulose (e.g., xylan, galactan, mannan, arabinose, galactose). **Pectins** and **gums** contain sugars and sugar alcohols that make these molecules more water soluble. The galacturonic acid structure of pectin absorbs water and forms a gel that it is widely used for making jams and jellies. The galacturonic acid backbone has rhamnose units inserted at intervals and side chains of arabinose and galactose. Pectin is found in apples, citrus fruit, strawberries, and other fruits. **Gums and mucilages** (e.g., guar gum) are similar to pectin, except their galactose units are combined with other sugars (e.g., glucose) and polysaccharides. Gums are found in plant secretions and seeds. The specific textural qualities of gums and mucilages are commercially useful when added to processed foods such as ice cream.

**Fructans** include *fructooligosaccharides (FOSs)*, *inulin*, *inulin-type fructans*, and *oligofructose* and are composed of fructose polymers, often linked with an initial glucose. Inulin is a diverse group of fructose polymers widely distributed in plants as a storage carbohydrate. Oligofructose is a subgroup of inulin with fewer than 10 fructose units. All are poorly digested in the upper GI tract and thus supply only approximately 1 kcal/g (Roberfroid, 2005). Fructans contain fructose; have a sweet, clean flavor; and are half as sweet as sucrose. Major sources of fructans include wheat, onions, garlic, bananas, and chicory; other sources include tomatoes, barley, rye, asparagus, and Jerusalem artichokes. Inulin compounds are widely used to improve the flavor and sweetness of low-calorie foods and to improve the stability and acceptability of fat-reduced foods. Because they are not absorbed in the proximal intestine, fructans have been used as a sugar replacement for diabetic patients.

**Prebiotics** are nondigestible food substances that selectively stimulate the growth or activity of beneficial bacterial species already resident in the colon (*probiotics*) and are beneficial to the host. Various prebiotics, including inulin, inulin-type fructans, and FOSs, stimulate the growth of intestinal bacteria, principally *bifidobacteria*. Fructans (synthesized or extracted) have prebiotic properties and are considered to be functional fiber (Roberfroid, 2007). Functional fiber is commonly added to liquid nutrition supplements and tube feeding formulas.

*Algal polysaccharides* (e.g., carrageenan) are extracted from seaweed and algae and are used as thickening and stabilizing agents in infant formulas, ice cream, milk pudding, and sour cream products. Algal polysaccharides are used commercially because they form weak gels with proteins and

**TABLE 3-3****Types, Composition, Sources, and Functions of Fibers**

Type of Fiber	Major Chemical Components	Sources	Major Functions
<b>Less Soluble Fiber</b>			
Cellulose	Glucose ( $\beta$ -1-4 linkages)	Whole wheat, bran, vegetables	Increase water-holding capacity, thus increasing fecal volume and decreasing gut transit time
Hemicellulose	Xylose, mannose, galactose	Bran, whole grains	
Lignin	Phenols	Fruits and edible seeds, mature vegetables	Fermentation produces short-chain fatty acids associated with decreased risk of tumor formation
<b>More Soluble Fibers</b>			
Gums	Galactose and glucuronic acid	Oats, legumes, guar, barley	Cause gel formation, thus decrease gastric emptying, slow digestion, gut transit time, and glucose absorption
Pectins	Polygalacturonic acid	Apples, strawberries, carrots, citrus	Also binds minerals, lipids, and bile acids increasing excretion of each, thus decreasing serum cholesterol
<b>Functional Fibers*</b>			
Chitin	Glucopyranose	Supplement from crab or lobster shells	Reduces serum cholesterol
Fructans (including inulin)	Fructose polymers	Extracted from natural sources: chicory, onions, etc.	Prebiotic that stimulates growth of beneficial bacteria in gut, used as fat replacer
$\beta$ -glucans	Glucopyranose	Oat and barley bran	Reduces serum cholesterol
Algal polysaccharides (carrageenan)		Isolated from algae and seaweed	Gel forming—used as thickeners, stabilizers (can be toxic)
Polydextrose, polyols	Glucose and sorbitol, etc.	Synthesized	Used as a bulking agent or sugar substitute
Psyllium		Extracted from psyllium seeds	Has a high water-binding capacity (choking hazard)

\*Isolated or extracted.

stabilize food mixtures, preventing suspended ingredients from settling. Tobacman (2001) demonstrated that carrageenan damages human cells in culture and destroys human mammary myoepithelial cells at concentrations as low as 0.00014%. With its wide use in commercial foods and uncertainty about the extent of human sensitivity, further investigation of carrageenan is needed.

Polydextrose and other polyols are synthetic polymers of *sugar alcohols* that are used as sugar substitutes in foods. They are not digestible, contribute to increased fecal bulk, and may be fermented in the small intestine. They are not yet classified as functional fibers (IOM, Food and Nutrition Board, 2002).

**Lignin** is a woody fiber found in the stems and seeds of fruits and vegetables and the bran layer of cereals. It is not a carbohydrate but is a polymer composed of phenylpropyl alcohols and acids. The phenyl groups contain conjugated

double bonds, which make them excellent antioxidants. Flaxseed lignin also has phytoestrogen activity and can mimic estrogen at its receptors on reproductive organs and bone.

**Role of Fiber in Digestion and Absorption**

The role of fiber in the GI tract varies based on its solubility. Nonabsorbable oligosaccharides and fibers have a significant effect on human physiology. Insoluble fibers such as cellulose increase the water-holding capacity of undigested material, increase fecal volume, increase numbers of stools per day, and decrease GI transit time. On the other hand, soluble fibers form gels, slow GI transit time, bind other nutrients such as cholesterol and minerals, and decrease their absorption. Certain nondigestible oligosaccharides (NDOs), which are fermented by intestinal bacteria, stimulate the intestinal absorption and retention

of minerals such as calcium, magnesium, zinc, and iron (Scholz-Ahrens et al., 2001).

Serum lipid concentrations can be modified by both insoluble cellulose and lignin or by soluble pectin and psyllium. They bind fecal bile acids and increase excretion of bile acid-derived cholesterol, thereby reducing lipid absorption. Fermentable oligosaccharides and dietary fiber are converted by intestinal bacteria to **short-chain fatty acids (SCFAs)**, which lower blood lipids. Evidence for the hypocholesterolemic effect of soluble fibers—including FOSs, synthetic polydextrose and polyols, viscous pectin, guar gum, oat bran, psyllium husk, beans, legumes, and fruits and vegetables—is conflicting. Effects vary with the type and amount of fiber (American Dietetic Association, 2008.) Prebiotic modulation by fiber is by fermentation into the SCFAs, acetate, butyrate, and propionate. SCFAs are readily absorbed by the intestinal and colonic mucosa. They enhance sodium and water absorption, colonic blood flow, colonocyte proliferation, GI hormone production, metabolic energy production, and they stimulate the autonomic nervous system via specific receptors in the colon (Tazoe et al., 2008). More than 70% of the fuel for colonocytes is the SCFA butyrate (4C), derived primarily from starch. Propionate (3C) is absorbed and cleared by the liver for hepatic lipid or glucose metabolism. Acetate (2C), produced from undigested carbohydrate, is rapidly metabolized into carbon dioxide by peripheral tissues as a substrate for lipid and cholesterol synthesis (Cummings et al., 2001).

The roles of fiber in the physiology of the GI tract are complex. The adequate intake (AI) of total fiber is set at 38 g/day for men and 25 g/day for women (IOM, Food and Nutrition Board, 2002). Americans' mean intake of fiber is currently less than half this. In addition to fiber, other non-nutrient components of plants, including tannins, saponins, lectins, and phytates, interact with nutrients, and may reduce their absorption. **Phytic acid** or **phytate**, a six-carbon ring with phosphate bound to each carbon, is found in the seed coat of grains and legumes and can bind metal ions, especially calcium, copper, iron, and zinc. Excess phytate can reduce starch hydrolysis if it binds with calcium, which catalyzes the action of amylase.

### Glucose Absorption and the Glycemic Index

Dietary carbohydrates are digested into glucose, fructose, and galactose through the actions of  $\alpha$ -amylase and brush-border digestive enzymes in the upper GI tract. The ability to digest carbohydrates is modified by the relative availability of the starch to enzyme action, the activity of digestive enzymes at the mucosal brush border, and the presence of other dietary factors (such as fat) that slow stomach emptying. Nonabsorbable oligosaccharides and viscous dietary fibers, such as pectins,  $\beta$ -glucans, and gums dilute enzyme concentration. Thus a diet rich in whole foods, such as fruits, vegetables, legumes, nuts, and minimally processed grains, slows the pace of glucose absorption.

Once digested, glucose is actively absorbed across the intestinal cell and transferred to the portal blood for transport to the liver (see Chapter 1). The liver removes

approximately 50% of absorbed glucose for oxidation and storage as glycogen. Galactose (absorbed actively) and fructose (absorbed by facilitated diffusion) are also taken up by the liver and incorporated into glucose metabolic pathways. Glucose exits the liver, enters the systemic circulation, and is available for insulin-dependent uptake by peripheral tissues. Major regulators of blood glucose concentration after a meal are the amount and digestibility of ingested carbohydrate, absorption and degree of liver uptake, insulin secretion, and sensitivity of peripheral tissues to insulin action.

The **glycemic index** is used to rank carbohydrates by their ability to raise blood glucose levels as compared with a reference food. Riccardi et al. (2008) concluded that foods with a low glycemic index have consistently shown beneficial effects on blood glucose control in both the short and long term in diabetic patients. The glycemic index of a diet has a predictable effect on blood glucose levels. However, the Institute of Medicine (IOM) declined to set an upper limit for the glycemic index in the 2002 recommendations because it is difficult to separate the other factors that contribute to blood glucose levels. A metaanalysis by Livesey et al. (2008) concluded that although consumption of diets with reduced glycemic index were followed by positive health markers, fiber (unavailable carbohydrate) was equally important. The **glycemic load** of a food is the glycemic index of the carbohydrate divided by 100 and multiplied by its amount of available carbohydrate content (i.e. carbohydrates minus fiber) in grams. The glycemic load and dietary fiber also have important implications for individuals manifesting the metabolic syndrome. Published data on the glycemic index of individual foods, using white bread and glucose as reference foods, have been consolidated for the convenience of users. Use of the glycemic index to modify diets and prevent and control chronic disease is still under investigation.

### Carbohydrate Regulation of Blood Lipids

Carbohydrate-induced hypertriglyceridemia can result from consuming a high-carbohydrate diet. The body regulates macronutrient levels to provide adequate fuel for body tissues. The brain uses the most of the approximately 200 g of glucose required per day. When blood glucose level falls to less than 40 mg/dL, counterregulatory hormones release macronutrients from stores. When blood glucose level rises to more than 180 mg/dL, glucose is spilled into the urine. High intakes of carbohydrate trigger large releases of insulin for compensatory responses, including insulin-dependent glucose uptake by muscle or fat and active synthesis of glycogen and fat. Blood glucose then drops to a normal range. Approximately 2 hours after a meal, intestinal absorption is complete, but insulin effects persist and blood glucose falls. The body interprets this hypoglycemic state as starvation and secretes counterregulatory hormones to release free fatty acids from fat cells (Ludwig, 2002). Fatty acids are packed into transport lipoproteins (very-low-density lipoproteins [VLDLs]) in the liver, thereby elevating serum triglycerides.

## FATS AND LIPIDS

### Lipid Structures and Functions

Fats and lipids constitute approximately 34% of the energy in the human diet. Because fat is energy rich and provides 9 kcal/g of energy, humans are able to obtain adequate energy with a reasonable daily consumption of fat-containing foods. Dietary fat is stored in *adipose* cells. The ability to store and use large amounts of fat enables humans to survive without food for weeks and sometimes months. Some fat deposits are not used effectively during a fast; they are classified as *structural fat*. Structural fat pads hold the body organs and nerves in position, protecting them against traumatic injury and shock. Fat pads on the palms and buttocks

protect the bones from mechanical pressure. A subcutaneous layer of fat insulates the body, preserving body heat and maintaining body temperature.

Dietary fat is essential for the digestion, absorption, and transport of the fat-soluble vitamins and phytochemicals such as carotenoids and lycopene. Dietary fat depresses gastric secretions, slows gastric emptying, and stimulates biliary and pancreatic flow, thereby facilitating digestion. Fat also conveys important textural properties to foods such as ice creams (smoothness) and baked goods (tenderness—caused by “shortening” strands of gluten). **Box 3-1** lists the fat content of some common foods.

Unlike carbohydrates, lipids are not polymers; they are small molecules extracted from animal and plant tissues.

### BOX 3-1

#### Fat Content of Some Common Foods

##### **0 g**

Most fruits and vegetables

Nonfat milk

Nonfat yogurt

Plain pasta and rice

Angel food cake

Popcorn, air popped, un buttered

Soft drinks

Jam or jelly

##### **1 to 3 g**

Popcorn, oil popped, un buttered, 1 cup

Low-calorie salad dressing, 1 tbsp

Baked beans,  $\frac{1}{2}$  cup

Soup, chicken noodle, canned, 1 cup

Whole-wheat bread, 1 slice

Dinner roll, 1

Waffle, frozen, 4 inch, 1

Coleslaw,  $\frac{1}{2}$  cup

Flounder or sole, baked, 3 oz

Chicken, without skin, baked or roasted, 3 oz

Tuna, canned in water, 3 oz

Cheese, cottage, 2% fat,  $\frac{1}{2}$  cup

Ice milk, soft serve,  $\frac{1}{2}$  cup

##### **4 to 6 g**

Low-fat yogurt, 1 cup

Cheese, mozzarella, part skim, 1 oz

Chicken, baked or roasted with skin, 3 oz

Egg, scrambled, 1

Turkey, roasted, 3 oz

Granola, 1 oz

Muffin, bran, 1 small

Pizza, cheese,  $\frac{1}{4}$  of 12 inch

Burrito, bean, 1

Brownie, with nuts, 1 small

Margarine or butter, 1 tsp

Popcorn, oil popped, buttered, 1 cup

French dressing, regular, 1 tbsp

##### **7 to 10 g**

Cheese, cheddar, 1 oz

Milk, whole, 1 cup

Bologna, beef, 1 slice

Sausage, 1 patty

Steak, sirloin, broiled, 3 oz

Potatoes, French fried, 10

Chow mein, chicken, 1 cup

Chocolate candy bar, 1 oz

Corn chips, 1 oz

Doughnut, cake type, plain, 1

Mayonnaise, 1 tbsp

##### **15 g**

Hot dog, beef, 2 oz

McDonald's Chicken McNuggets, 6 pieces

Peanut butter, 2 tbsp

Pork chop, broiled, 3 oz

Sunflower seeds, dry roasted,  $\frac{1}{4}$  cup

Avocado,  $\frac{1}{2}$  medium

Chop suey, beef and pork, 1 cup

Cinnamon roll, 1

##### **20 g**

Lasagna with meat, 1 medium piece

Macaroni and cheese, homemade, 1 cup

Peanuts, dry roasted,  $\frac{1}{4}$  cup

Ground beef, broiled, 3 oz

##### **25 g**

Polish sausage, 3 oz

Cheeseburger, large

Pie, pecan,  $\frac{1}{8}$  of 9 inch

Chicken pot pie, frozen, baked, 1 pie

Quiche, bacon,  $\frac{1}{8}$  pie

Lipids are composed of a heterogeneous group of compounds characterized by their insolubility in water; they are classified into three major groups (Box 3-2). Figure 3-5 shows some important lipid structures.

## Fatty Acids

Fatty acids are rarely free in nature and almost always are linked to other molecules by their *hydrophilic* carboxylic acid head group. Fatty acids occur primarily as unbranched hydrocarbon chains with an even number of carbons and are classified according to the number of carbons, the number of double bonds, and the position of the double bonds in the chain. Chain length and extent of saturation contribute to the melting temperature of a fat. In general, fats with shorter fatty acid chains or more double bonds are liquid at room temperature. Saturated fats, especially those with long chains, are solid at room temperature. A fat such as coconut oil, which is also highly saturated, is semiliquid at room temperature because the predominant fatty acids are short (8 to 14 carbons). Some manufacturers cool oil and filter out solidified lipid particles before sale; the resulting “winterized” oil remains clear when refrigerated. In general, SCFAs are considered to have 4 to 6 carbons, medium-chain fatty acids to have 8 to 14, and long-chain fatty acids (LCFAs), to have 16 to 20 or more.

## BOX 3-2

### Classification of Lipids

#### Simple Lipids

##### Fatty Acids

Neutral fats: Esters of fatty acids with glycerol

Monoglycerides, diglycerides, triglycerides

Waxes: Esters of fatty acids with high-molecular-weight alcohols

Sterol esters (e.g., cholesterol ester)

Nonsterol esters (e.g., retinyl palmitate  
[vitamin A esters])

#### Compound Lipids

Phospholipids: Compounds of phosphoric acid, fatty acids, and a nitrogenous base

Glycerophospholipids (e.g., lecithins, cephalins, plasmalogens)

Glycosphingolipids (e.g., sphingomyelins, ceramide)

Glycolipids: Compounds of fatty acids, monosaccharides, and a nitrogenous base (e.g., cerebrosides, gangliosides)

Lipoproteins: Particles of lipid and protein

#### Miscellaneous Lipids

Sterols (e.g., cholesterol, vitamin D, bile salts)

Vitamins A, E, K

From Examples of current and proposed ingredients for fats. J Am Diet Assoc 92:472, 1992.

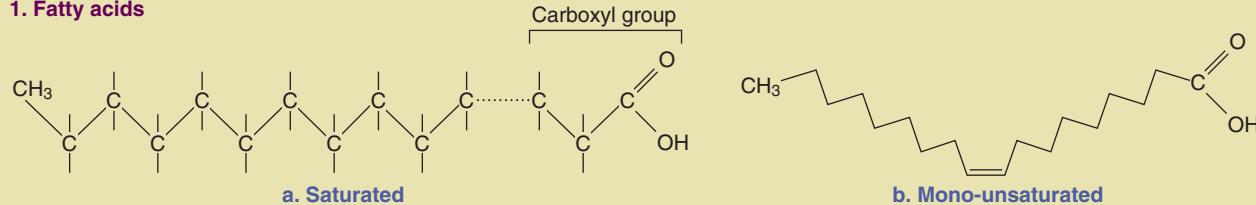

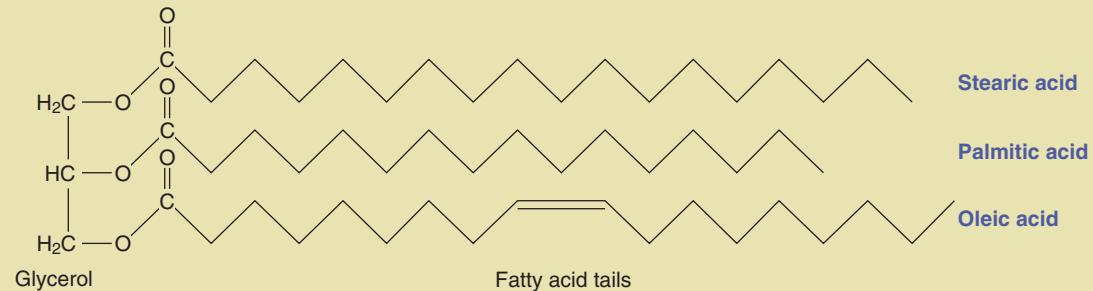

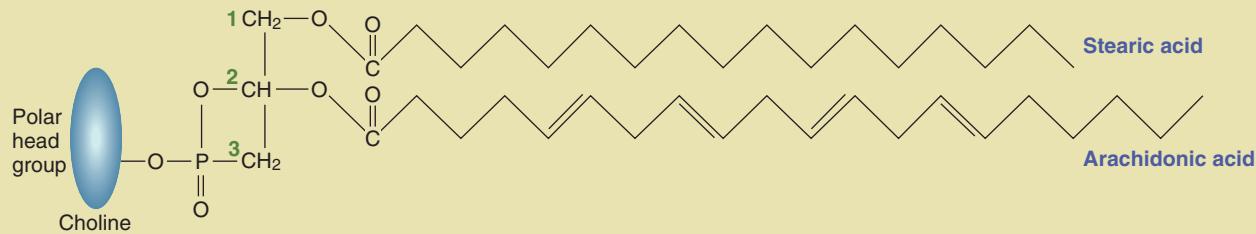

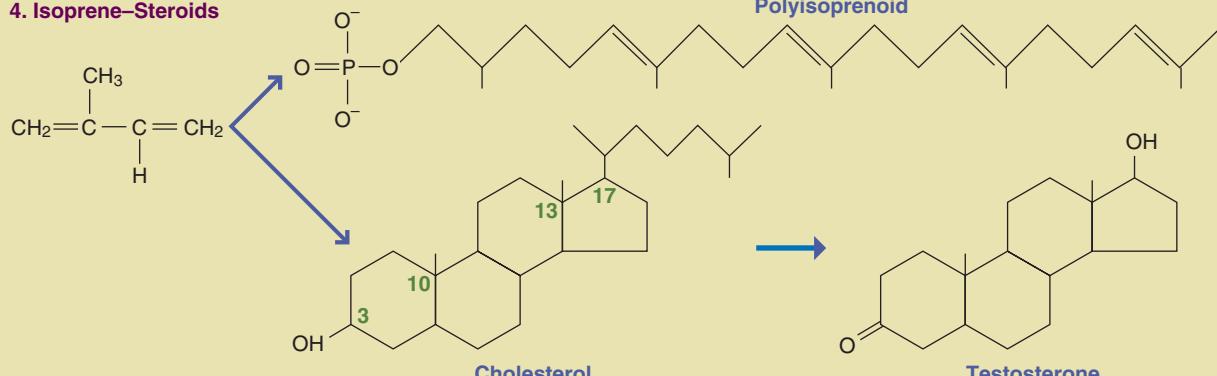

In a **saturated fatty acid (SFA)**, all carbon binding sites not linked to another carbon are linked to hydrogen and are therefore saturated. There are no double bonds between carbons. **Monounsaturated fatty acids (MFAs)** contain only one double bond, and **polyunsaturated fatty acids (PUFAs)** contain two or more double bonds. In MFAs and PUFAs one or more pairs of hydrogen have been removed, and double bonds form between adjacent carbons. Because fatty acids with double bonds are vulnerable to oxidative damage, humans and other warm-blooded organisms store fat predominantly as saturated palmitic fatty acid (C16:0) and stearic fatty acid (C18:0). Cell membranes must be stable and flexible. To achieve this requirement, membrane phospholipids contain one SFA and one highly PUFA, the most abundant of which is arachidonic acid (C20:4). Commonly occurring fatty acids and a typical food source are listed in Table 3-4.

Fatty acids are also characterized by the location of their double bonds. Two notation conventions are used to describe the location of the double bonds (Table 3-5). Omega notation is used in this chapter. In omega notation, a lowercase omega ( $\omega$ ) or  $n$  is used to refer to the placement of the first double bond counting from the methyl end (the fatty acid's omega number). Thus arachidonic acid (20:4  $\omega$ -6 or 20:4  $n$ -6), the major highly polyunsaturated fat in membranes of land animals, is an **omega-6 ( $\omega$ -6) fatty acid**. It has 20 carbons and four double bonds, the first of which is six carbons from the terminal methyl group. Eicosapentaenoic acid (EPA) (20:5  $\omega$ -3 or 20:5  $n$ -3) is found in marine organisms and is an **omega-3 ( $\omega$ -3) fatty acid**. It has five double bonds, the first of which is three carbons from the terminal methyl group. Sources of the longer EPA and docosahexaenoic acid (DHA)  $\omega$ -3 fatty acids are primarily marine, such as cod liver oil, mackerel, salmon, and sardines (Table 3-6).

#### Essential Fatty Acids and the Omega-6/Omega-3 Ratio

Only plants (including marine phytoplankton) can synthesize  $\omega$ -6 and  $\omega$ -3 fatty acids. Humans and other animals can only place double bonds as low as the  $\omega$ -9 carbon and cannot produce their own  $\omega$ -6 and  $\omega$ -3 fatty acids. But humans can desaturate and elongate linoleic acid (18:2  $n$ -6) to arachidonic acid (20:4  $n$ -6) and alpha-linoleic acid (ALA) (C18:3  $\omega$ -3) to EPA (C20:5  $\omega$ -3) and DHA (C22:6  $\omega$ -3). Therefore both linoleic (18:2  $n$ -6) and ALA (C18:3  $\omega$ -3) acids are essential in the diet (IOM, Food and Nutrition Board, 2002).

An *essential fatty acid* refers to the families of  $\omega$ -6 and  $\omega$ -3 fatty acids. Yet it is the longer-chain fatty acids made from them that are components of cell membranes and are precursors of eicosanoids such as prostaglandins, thromboxanes, and leukotrienes. *Eicosanoids* act as localized (paracrine) hormones and have multiple local functions. They can alter the size and permeability of the blood vessels, alter the activity of platelets and contribute to blood clotting, and modify the processes of inflammation

**1. Fatty acids****2. Triglycerides****3. Phospholipids (lecithin)****4. Isoprene–Steroids****FIGURE 3-5** Structures of physiologically important fats and lipids.

(Figure 3-6). Derivatives of  $\omega$ -3 fatty acids from dietary sources or fish oil can have beneficial effects in a number of disease states (Freemantle et al., 2006; McCowen and Bis-trian, 2005), including improved brain function during aging. Roles for  $\omega$ -3 fatty acids are discussed in chapters related to cardiovascular disease, arthritis and inflammatory conditions, and neurologic disorders.

An imbalance between dietary  $\omega$ -3 and  $\omega$ -6 fatty acids contributes to a wide range of disease states (Wertz, 2009). Excess amounts of  $\omega$ -6 fatty acids in the diet saturate the enzymes that desaturate and elongate both  $\omega$ -3 and  $\omega$ -6 fatty acids; this prevents conversion of ALA into EPA and DHA (Kris-Etherton, 2000). The optimal  $\omega$ -6/ $\omega$ -3 ratio has been estimated to be 2:1 to 3:1, four times lower than

**TABLE 3-4****Common Fatty Acids**

Common Name	Systematic Name	Number of Carbon Atoms*	Number of Double Bonds	Typical Fat Source
<b>Saturated Fatty Acids</b>				
Butyric	Butanoic	4	0	Butterfat
Caproic	Hexanoic	6	0	Butterfat
Caprylic	Octanoic	8	0	Coconut oil
Capric	Decanoic	10	0	Coconut oil
Lauric	Dodecanoic	12	0	Coconut oil, palm kernel oil
Myristic	Tetradecanoic	14	0	Butterfat, coconut oil
Palmitic	Hexadecanoic	16	0	Palm oil, animal fat
Stearic	Octadecanoic	18	0	Cocoa butter, animal fat
Arachidic	Eicosanoic	20	0	Peanut oil
Behenic	Docosanoic	22	0	Peanut oil
<b>Unsaturated Fatty Acids</b>				
Caproleic	9-Decenoic	10	1	Butterfat
Lauroleic	9-Dodecenoic	12	1	Butterfat
Myristoleic	9-Tetradecenoic	14	1	Butterfat
Palmitoleic	9-Hexadecenoic	16	1	Some fish oils, beef fat
Oleic	9-Octadecenoic	18	1	Olive oil, canola oil
Elaidic	9-Octadecenoic	18	1	Butterfat
Vaccenic	11-Octadecenoic	18	1	Butterfat
Linoleic	9, 12-Octadecadienoic	18	2	Most vegetable oils, especially safflower, corn, soybean, cottonseed
Linolenic	9, 12, 15-Octadecatrienoic	18	3	Soybean oil, canola oil, walnuts, wheat germ oil, flaxseed oil
Gadoleic	11-Eicosaenoic	20	1	Some fish oils
Arachidonic	5, 8, 11, 14-Eicosatetraenoic	20	4	Lard, meats
—	5, 8, 11, 14, 17-EPA	20	5	Some fish oils, shellfish
Erucic	13-Docosenoic	22	1	Canola oil
—	4, 7, 10, 13, 16, 19-DHA	22	6	Some fish oils, shellfish

DHA, Docosahexaenoic acid; EPA, eicosapentaenoic acid.

the current intake; therefore it is recommended that humans consume more ω-3 fatty acids from vegetable and marine sources. ALA is found in flaxseed (57%), canola oil (8%), soybean oil (7%), and green leaves in a few plants such as purslane.

**Trans-Fatty Acids**

In natural unsaturated fatty acids, the two carbons participating in a double bond each bind a hydrogen on the *same* side of the bond (the *cis*-isomer form), causing the fatty acid to bend (see Figure 3-5). The more double bonds per fatty acid, the more bends in the molecule. **Hydrogenation** of unsaturated fatty acids is a chemical process that adds hydrogen to oils to form a stable, solid fat such as margarine. Hydrogen can be added both in the natural *cis* position (with two hydrogens on the same side of the double bond) and in the *trans* position (with one hydrogen on opposite sides of the double bond). Membrane function depends on the three-dimensional configuration of membrane fatty acids found in phospholipids. The *cis* double bonds in the membrane bend, allowing the fatty acids to pack loosely, thus making the membrane fluid. Because proteins embedded in a membrane float or sink, depending on the membrane's fluidity, membrane viscosity is important for membrane protein function.

**Trans-fatty acids** do not bend; they pack into the membrane as tightly as if they were fully saturated. *Trans*-fatty

**FIGURE 3-6** Eicosanoid synthesis after phospholipid cleavage in the biomembrane. Injury, inflammation, and other stimuli cleave the highly unsaturated fatty acid at the C-2 position of the membrane phospholipid. Arachidonic acid or eicosapentaenoic acid is the major fatty acid released; the pathway entered depends on the degree to which the target tissue expresses the enzyme. The cyclooxygenase pathway leads to prostaglandin, thromboxane, and prostacyclin synthesis. The lipoxygenase pathway, which is common in the lungs and bronchi, leads to leukotriene synthesis and subsequent bronchoconstriction. Note the point at which steroid and nonsteroidal antiinflammatory drugs act.

acids inhibit the desaturation and elongation of linoleic and ALA, which are critical for fetal brain and organ development. Major sources of *trans*-fatty acids in the American diet are chemically hydrogenated margarine, shortening, commercial frying fats, high-fat baked goods, and salty snacks containing these fats. Butter and animal fat can also contain *trans*-fatty acids from bacterial fermentation in the rumen of cows and sheep.

Higher intakes of *trans*-fatty acids are associated with increased risk for coronary heart disease, cancer, type 2 diabetes, and allergies, possibly because of their potential to influence membrane fluidity (Micha and Mozaffarin, 2009). The U.S. Department of Agriculture Dietary Guidelines for Americans (2005) recommends limiting intake of *trans*-fatty acids and SFAs to as little as possible.

### Conjugated Linoleic Acid

**Conjugated linoleic acids (CLAs)** are positional and geometric isomers of linoleic acid, not separated by a methylene group as occurs in linoleic acid. These isomers are minor components of the lipids from meat and dairy products. CLA isomers are metabolized in the body through different metabolic pathways with different physiologic outcomes. Eighty percent of CLA is the *cis*-9, *trans*-11 isomer. Another notable isomer is *trans*-10, *cis*-12, which is more efficiently oxidized and has different biological outcomes. The *cis*-9, *trans*-11 isomer appears to be responsible for the anticarcinogenic effect of CLAs; the *trans*-10, *cis*-12 isomer reduces body fat and alters blood lipids. Both isomers seem to be responsible for insulin resistance in humans. CLAs are of interest because of these anticarcinogenic, antidiabetogenic, and antiatherogenesis effects. Studies on CLA supplementation demonstrate reduction in body fat percentage and body mass (Baddini et al., 2009; Churruca et al., 2009).

### Triglycerides

The body forms **triglycerides (triacylglycerols TAG)** by joining three fatty acids to a glycerol side chain (see Figure 3-5, 2), thereby neutralizing reactive fatty acids and making triglycerides water insoluble (hydrophobic). The hydroxyl group on each fatty acid is bound to a hydroxyl group on glycerol, releasing water and forming an ester linkage. Neutral fats can be safely transported in the blood and stored in fat cells (adipocytes) as an energy reserve. Different fatty acids can make up a single triglyceride and depend on the dietary fatty acids and the amount of synthesis taking place. Storage triglycerides from land animals are predominately saturated because SFAs are relatively inert and not susceptible to oxidative damage during storage. Cold-water creatures must maintain their fatty acids in liquid form even at low temperatures; therefore triglycerides in fish oils and marine-derived fats contain longer (C20 and C22), highly unsaturated fatty acids.

### Phospholipids

**Phospholipids** are derivatives of phosphatidic acid, a triglyceride modified to contain a phosphate group at the

third position (see Figure 3-5, 3). Phosphatidic acid is esterified into a nitrogen-containing molecule, usually choline, serine, inositol, or ethanolamine, and named for its nitrogenous base (e.g., phosphatidylcholine, phosphatidylserine). Membrane phospholipids usually contain one SFA (C16 to C18) at C-1 and a highly PUFA (C16 to C20) at C-2, usually one of the essential fatty acids. ALA (C18:3  $\omega$ -3), arachidonic acid (C20:4  $\omega$ -6), and  $\omega$ -3 substitutes can be cleaved from the lipid bilayer to provide substrate for synthesis of prostaglandins and other mediators of cell activity.

Because it is polar at physiologic pH, the phosphate-containing portion of the molecule forms hydrogen bonds with water, whereas the two fatty acids have hydrophobic interactions with other fatty acids (Figure 3-6). The polar head groups face outward into the aqueous external and cytoplasmic fluids, whereas the centrally placed fatty acid tails participate in hydrophobic interactions at the membrane center. The barrier formed by this lipid bilayer can be crossed only by very small lipid soluble molecules (e.g., oxygen, carbon dioxide, and nitrogen) and to a limited extent by small, uncharged polar molecules such as water and urea.

**Lecithin (phosphatidylcholine)** is a major phospholipid, and it is the primary component of lipid in the membrane lipid bilayer. Lecithin is also a major component of lipoproteins (i.e., VLDLs, low-density lipoproteins [LDLs], and high-density lipoproteins [HDLs]) used to transport fats and cholesterol. Lecithin is made by the body with arachidonic acid. Because all cells contain lecithin as a lipid bilayer component, animal products, especially liver and egg yolks, are rich sources of lecithin. Plant products such as soybeans, peanuts, legumes, spinach, and wheat germ are also rich sources. Lecithin is widely distributed in the food supply and is added to food products such as margarine, ice cream, snack crackers, and confections as a stabilizer.

### Sphingolipids, Alcohols, Waxes, Isoprenoids, and Steroids

All organisms produce small amounts of complex lipids with specialized, critical functions. Many of these lipids do not contain glycerol and are built from two-carbon **acetyl coenzyme A (acetyl CoA)** units. **Sphingolipids** are lipid esters attached to a sphingosine base rather than a glycerol. They are widely distributed in the nervous systems of animals and the membranes of plants and lower eukaryotes such as yeast. Sphingomyelin includes the nitrogenous base choline and makes up more than 25% of the myelin sheath, the lipid-rich structure that protects and insulates cells of the central nervous system. In addition to phosphatidylcholine, sphingomyelin is found in all membranes. Sphingolipidoses comprise a group of genetic lipid-storage diseases in which normal sphingolipid degradation is blocked. Tay-Sachs disease is an example of such a lipid-storage disease.

**Long-chain alcohols** are metabolic by-products of lipids. The feces contain cetyl alcohol, a by-product of palmitic

acid. Beeswax is rich in the alcohol myricyl palmitate. Waxes consist of LCFA s bound to long-chain alcohols. These molecules are almost completely water insoluble and are often used as water repellants, as they are in the feathers of birds and on the leaves of plants.

**Isoprenoids**, activated derivatives of isoprene, are an extraordinarily large and diverse group of lipids built from one or more five-carbon units. Isoprene contains alternating single and double (conjugated) bonds, an arrangement that can quench free radicals by accepting or donating electrons. *Terpene* is a generic term for all compounds synthesized from isoprene precursors and includes essential oils of plants (e.g., turpentine from trees and limonene from lemons). Plant pigments that transfer electrons in photosynthesis are also isoprenoids and include lycopene (the red pigment in tomatoes), carotenoids (the yellow and orange pigments in squash and carrots), and the yellow and green chlorophyll group. Fat-soluble vitamins A, D, E, and K and the electron transducer coenzyme Q have isoprenoid structures. Vitamin E, lycopene, and β-carotene are effective antioxidants; non-nutritive phytochemicals with antioxidant function also have an isoprenoid structure.

**Steroids** constitute a class of lipids derived from a four-membered saturated ring (see Figure 3-5, 4). **Cholesterol** is the basis for all steroid derivatives made in the body, including glucocorticoids (cortisone) and mineralocorticoids (aldosterone), which are made in the adrenal gland; androgens (testosterone) and estrogens (estradiol), which are made in the testes and ovaries, respectively; and bile acids, which are made in the liver. Vitamin D hormone is made when ultraviolet rays from the sun cleave cholesterol in subcutaneous fat to form cholecalciferol ( $D_3$ ). Synthetic vitamin D is made by irradiating the plant steroid ergosterol to form ergocalciferol ( $D_2$ ).

Cholesterol also plays an important role in membrane function. The rigid, four-ringed cholesterol molecule is bound into the hydrophobic membrane by its hydroxyl group. The stiff, planar rings spread apart and partially immobilize the fatty acid chains near the polar region. At the same time, the nonpolar hydrocarbon tail contributes to greater fluidity in the interior of the membrane. Plasma membranes contain large amounts of cholesterol—up to one molecule for every phospholipid molecule.

**Glycolipids** include the cerebrosides and gangliosides, which are composed of a sphingosine base and very long-chain (22C) fatty acids. Cerebrosides contain galactose; gangliosides also contain glucose and a complex compound containing an amino sugar. Structurally both compounds are components of nerve tissue and cell membranes, where they play a role in lipid transport.

## Synthetic Lipids

**Medium-chain triglycerides (MCTs)** are SFAs with a chain length of between 6 and 12 carbons. Although MCTs occur naturally in milk fat, coconut oil, and palm kernel oil, they are also produced commercially (MCT oil) as a by-product

of margarine production. MCT oils provide 8.25 kcal/g and are of value in a number of clinical situations because they are short enough to be water soluble, require less bile salt for solubilization, are not reesterified in the enterocyte, and are transported as free fatty acids, bound to albumin, through the portal system. Because the portal blood flow rate is approximately 250 times faster than the lymph flow, MCTs are digested quickly and not likely to be affected by intestinal factors that inhibit fat absorption. They are not stored in adipose tissue but are oxidized to acetic acid.

**Structured lipids** include MCT oil esterified with a desired fatty acid such as linoleic acid or an ω-3 lipid. The combined product is absorbed faster than the long-chain triglyceride alone. Clinically, structured lipids have a role in parenteral and enteral formulas, such as to enhance immune function or athletic performance.

**Fat replacers** (Table 3-7) are structurally different from fats and do not provide readily absorbable nutrients. Their commercial importance is that they imitate the texture and other sensations of fat, especially in the mouth. Fat replacers differ in their macronutrient base and the extent to which they mimic the characteristics of fat. The caloric value of these substitutes varies between 5 kcal/g (e.g., caprenin) and 0 kcal/g (e.g., olestra, carrageenan). Most fat replacers are derived from plant polysaccharides such as gums, cellulose, dextrins, fiber, maltodextrins, starches, and polydextrose. Olestra is a sucrose polyester in which sucrose is esterified with six to eight fatty acids to form esters. The fatty acid chains range in length from 12 to 24 carbons and are derived from edible oils such as soybean, cottonseed, and corn oils. The product has the physical properties of natural dietary fats. Because they are nonabsorbable, sucrose polyesters do not contribute calories to the diet.

Protein-based fat replacers alter the texture of a product in various ways. Microparticulated proteins can act like small ball bearings, providing a fatlike feeling in the mouth. These replacers contribute between 1.3 and 4 kcal/g and augment the protein content of the food. Note that some of these proteins can stimulate an allergic or antigenic response in susceptible individuals (see Chapter 27).

Fat sources can be modified to reduce GI absorption and caloric availability. **Monoacylglycerols (monoglycerides)** and **diacylglycerols (diglycerides)** are used as emulsifiers and contribute to the sensory properties of fat but have fewer calories (approximately 5 kcal/g). Salatrim has SFA and LCFA triglyceride molecules and contains 5 kcal/g because of reduced absorability. Concerns about the long-term effects of fat substitutes are that they may bind essential fatty acids and fat-soluble vitamins and contribute to their malabsorption or have negative effects on fundamental energy intake regulatory mechanisms (McKiernan et al., 2008). However, under most circumstances they appear to be safe, effective, and feasible alternatives for controlling fat and energy in diets (American Dietetic Association, 2005).

**TABLE 3-7****Examples of Fat Replacers and Their Functions and Properties**

<b>Class of Fat Replacers</b>	<b>Trade Names</b>	<b>Applications</b>	<b>Functional Properties</b>

**Recommendations for Lipid Intake**

Recommendations for lipid intake must take into account the documented physiologic and health effects of various lipid components, as well as the worldwide obesity epidemic. For example, SFAs are known to increase LDLs and HDLs, whereas PUFAs decrease the “bad” and “good” lipoproteins. The 2005 Dietary Guidelines for Americans (USDA) recommended the consumption of less than 10% of calories as SFA. SFAs and MFAs, especially those in olive oil, that are similarly thermally stressed do not produce these toxic products. Saturated fat and partially hydrogenated oils have fewer oxygen-binding sites and thereby have increased stability and a longer shelf life; however, their intake is associated with greater risk of cardiovascular disease. On the other hand, too much PUFA can also be dangerous. Double bonds are highly reactive and bind oxygen to form peroxides when exposed to air or heat. When subjected to routine frying or cooking, PUFAs can generate high levels of toxic aldehyde products that promote cardiovascular disease and cancer.

**Alcohol (Ethyl Alcohol)**

Alcohol has 7 kcal/g and no nutrient value. It is able to permeate all membranes and is absorbed quickly and easily. It is metabolized primarily by the liver enzyme alcohol dehydrogenase (ADH) to acetaldehyde and then to acetyl-CoA, where it can be used to synthesize fat or enter the tricarboxylic acid (TCA) cycle. ADH requires both thiamin and niacin to function. When the amount of alcohol in the cell exceeds the capacity of ADH to metabolize it or when niacin (as NAD<sup>+</sup>) is depleted, the microsomal ethanol oxidizing system (MEOS) will also metabolize alcohol to acetaldehyde. Chronic alcohol consumption induces both ADH and certain enzymes in the MEOS system. Because the MEOS system is also responsible for the metabolism of many drugs, chronic ingestion of large amounts of alcohol can alter drug responses in unpredictable ways. For example, overall alcoholism leading to induction of the MEOS causes a person to be tolerant not only of alcohol but other drugs as well. But if at any

given time the MEOS is saturated with alcohol, drugs are not metabolized at the expected rate and a drug overdose can occur. In addition the production of acetaldehyde in these pathways may be toxic in itself, leading to cirrhosis of the liver.

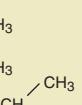

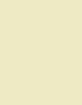

**AMINO ACIDS AND PROTEIN**

Whereas plant structures are composed primarily of carbohydrates, the body structure of humans and animals is built on protein. **Proteins** differ molecularly from carbohydrates and lipids in that they contain nitrogen. Primary roles for proteins in the body include structural protein, enzymes, hormones, transport, and immunoproteins. Proteins are composed of amino acids (Figure 3-7) linked by **peptide bonds** (Figure 3-8).

The sequence of the amino acids determines the ultimate structure and function of the protein and is determined by the genetic code stored in the cell nucleus as deoxyribonucleic acid (DNA). As illustrated in Figure 3-9 and in Chapter 5, protein synthesis is a complex process through which the protein pattern is copied from DNA to ribonucleic acid (RNA). The pattern for protein synthesis is carried to the rough endoplasmic reticulum via messenger RNA (mRNA). New proteins are built by attaching amino acids as dictated by the mRNA in a precise linear sequence. When the protein has been built, it detaches from the message and is ready to be used or further processed for use (see Chapter 5).

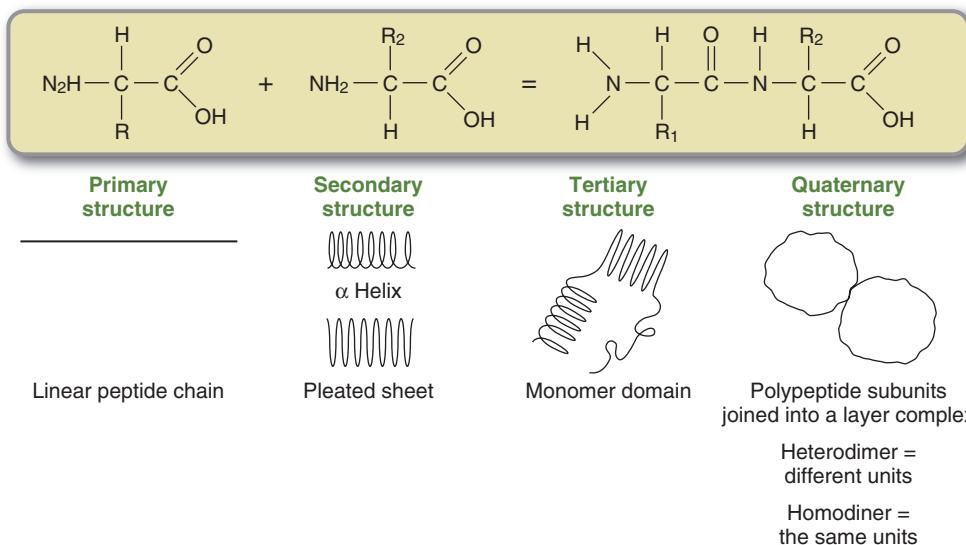

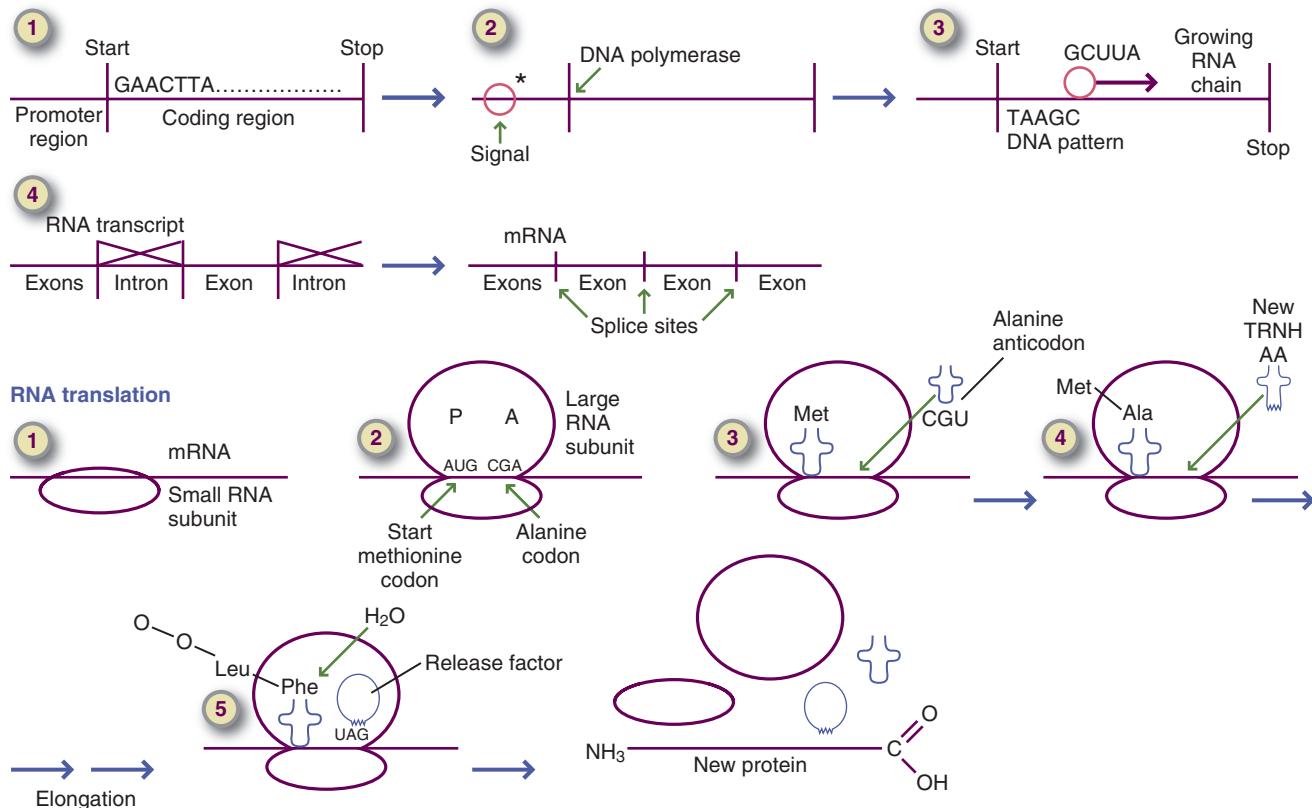

Proper folding of the completed linear amino acid chain is essential for a protein to perform its unique functions. The linear sequence of individual amino acids dictates the configuration of the mature protein. R groups protrude from the newly synthesized peptide chain and are in position to react with each other. Folding is accomplished through hydrogen bonding, ionic bonding, and hydrophobic and other interactions between individual R groups on each amino acid. For example, a negative charge on one amino acid R group forms an attraction with a positive charge on another, forming a precise, three-dimensional structure. Proteins have the following four levels of structure:

All amino acids have the same general structure  in which R is different for each.

FUNCTIONAL TYPE	AMINO ACID (abbr.)	R GROUP	CHARACTERISTICS OF THE AMINO ACID
Aliphatic	Glycine (Gly) G	H	Tiny R group (H), which allows hairpin bends in the peptide chains
	Alanine (Ala) A	CH <sub>3</sub>	Can be deaminated to pyruvate and used for glucose synthesis
	Valine (Val) V*		Branched-chain amino acids; metabolized in muscle
	Leucine (Leu) L*		Branched-chain amino acids more hydrophobic; muscle metabolism
	Isoleucine (Ile) I*		Branched-chain amino acids most hydrophobic; muscle metabolism
Sulfur	Cysteine (Cys) C**		Essential for glutathione synthesis; synthesis limited in chronic diseases
	Methionine (Met) M*	—CH <sub>2</sub> —CH <sub>2</sub> —S—CH <sub>2</sub>	Converted to S-adenosylmethionine (SAM), the universal methyl donor, and cysteine
Hydroxyl	Serine (Ser) S	—CH <sub>2</sub> —OH	Hydroxyl group phosphorylated to activate and inactivate protein
	Threonine (Thr) T*	—CH <sub>2</sub> —OH—CH <sub>3</sub>	Also site for regulatory phosphorylation
Aromatic	Phenylalanine (Phe) F*	—CH <sub>2</sub> — 	Converted to tyrosine for synthesis of norepinephrine, epinephrine, and dopamine
	Tyrosine (Tyr) Y	—CH <sub>2</sub> — 	Converted to neurotransmitters norepinephrine, epinephrine, and dopamine
	Tryptophan (Trp) W*	—CH <sub>2</sub> — 	Converted to neurotransmitter serotonin and to niacin
Cyclic	Proline (Pro) P		Allows triple helix; proline in collagen to be hydroxylated for cross-linkage
Basic	Lysine (Lys) K*	—CH <sub>2</sub> —CH <sub>2</sub> —CH <sub>2</sub> —CH <sub>2</sub> —NH <sub>3</sub> <sup>+</sup>	Site for hydroxylation in proteins; hydrophylic; used in signaling
	Histidine (His) H**		Hydrophilic, binds zinc in signaling proteins
	Arginine (Arg) R	—CH <sub>2</sub> —CH <sub>2</sub> —CH <sub>2</sub> —NH—C(=O)—NH <sub>2</sub>	Formed in the urea cycle; essential for synthesis of nitric oxide signaling pathway
Acidic	Aspartic acid (Asp) D	—CH <sub>2</sub> —C(=O)—O <sup>-</sup>	Takes a second nitrogen to form asparagine (Asn) N—CH <sub>2</sub> —C(=O)—NH <sub>2</sub>
	Glutamic acid (Glu) E	—CH <sub>2</sub> —CH <sub>2</sub> —C(=O)—O <sup>-</sup>	Takes a second nitrogen to form glutamine (Gln) Q—CH <sub>2</sub> —CH <sub>2</sub> —C(=O)—NH <sub>2</sub>

**FIGURE 3-7** Structures and functions of the 20 amino acids required by humans. All amino acids have the same general structure, but the R group is different for each. Amino acids are abbreviated using a three-letter and single-letter code. Amino acids marked with an asterisk (\*) are essential; those marked with double asterisks (\*\*) are essential for infants and those with certain chronic diseases.

1. **Primary structure:** Peptide bonds are formed between sequential amino acids according to directions on mRNA. The completed protein is a linear chain of amino acids.
2. **Secondary structure:** Attractions between R groups of amino acids create helices and pleated sheet structures.
3. **Tertiary structure:** Helices and pleated sheets are folded into compact domains. Small proteins have one domain, and large proteins have multiple domains.
4. **Quaternary structure:** Individual polypeptides can serve as subunits in the formation of larger

**The peptide bond****FIGURE 3-8** The peptide bond and protein folding.**DNA transcription****FIGURE 3-9** Summary of deoxyribonucleic acid transcription and ribonucleic acid translation in the eukaryotic cell.

assemblies, or complexes. Subunits are bound together by numerous weak, noncovalent interactions; sometimes they are stabilized by disulfide bonds. For example, four hemoglobin monomers are joined to form the tetramer hemoglobin molecule.

Protein structure is a critical component of protein function. The active and catalytic sites at which protein action occurs are formed by juxtaposing functional groups from nearby but occasionally distant R groups. If the linear protein sequence is altered, as in genetic diseases, the protein is unable to form active sites, and its activity may be reduced or eliminated entirely.

### Essential Amino Acids

Synthesis of proteins requires the presence of all necessary amino acids during the process. Chemically, **amino acids** are carboxylic acids with an amino group attached to the  $\alpha$ -carbon. All amino acids have this same general structure; the side chain is also attached to the  $\alpha$ -carbon (the R group), which dictates the identity and function of each amino acid. Note that the  $\alpha$ -carbon is a chiral carbon, and isomers can be formed. The L-isomer is functional in the human body. Many amino acids can be synthesized from carbon skeletons produced as intermediates in the major metabolic pathways by a process called **transamination**, which adds an amino group from another amino acid without actually producing a free amino group. Transamination is an important process because it allows for the production of **nonessential amino acids** from metabolic intermediates

while using free amino groups, so that they are not left to produce toxic ammonia. For example, pyruvate formed during glycolysis is easily converted to the amino acid alanine by adding an amino group via the enzyme alanine aminotransaminase. On the other hand, **essential amino acids** have carbon skeletons that humans cannot synthesize in adequate amounts and therefore must obtain from the diet (Table 3-8). Protein can also be an energy source. Proteins contain 5 kcal/g; removal of the amino group and the formation and excretion of urea (**deamination**) has a metabolic cost of 1 kcal/g. Therefore the resulting carbon skeleton product can be used for energy at the rate of 4 kcal/g. These carbon skeletons can also be used to produce glucose. When the diet is low in carbohydrate or an individual is starving, protein is the only good source of de novo synthesis of glucose available; this process is called *gluconeogenesis*. Oxaloacetate is moved out of the mitochondria and converted to phosphoenolpyruvate (PEP) (see Figure 3-2). From PEP, the glycolytic pathway can be reversed because all the enzymes with the exception of phosphofructokinase and glucokinase are reversible. Both of these enzymes can be reversed by specific phosphatase enzyme when there is a need for blood glucose. Because glucokinase is found primarily in the liver, it is only reversed there, making the liver the primary site for gluconeogenesis. Amino acids that produce carbon skeletons that can be converted to glucose are called *glucogenic amino acids*. Only two of the 20 amino acids cannot be used to produce at least some glucose. These amino acids are lysine and threonine. They produce products that are converted to ketones and used for energy; thus they are known as *ketogenic amino acids*.

**TABLE 3-8**

#### Estimates of Amino Acid Requirements

Amino Acid	Requirements (mg/kg/day) by Age-Group			
	Infants, Age 3-4 mo*	Children, Age ~2 yr <sup>†</sup>	Children, Age 10-12 yr <sup>‡</sup>	Adults <sup>§</sup>
Histidine	28	Not determined	Not determined	8-12
Isoleucine	70	31	28	10
Leucine	161	73	44	14
Lysine	103	64	44	12
Methionine plus cystine	58	27	22	13
Phenylalanine plus tyrosine	125	69	22	14
Threonine	87	37	28	7
Tryptophan	17	12.5	3.3	3.5
Valine	93	38	25	10
Total without histidine	714	352	216	84

Modified from World Health Organization: Energy and protein requirements report of a joint FAO/WHO/UNU expert consultation, Technical Report Series 724, p 65, Geneva, 1985, WHO.

\*Based on amounts of amino acids in human milk or cow's milk formulas fed at levels that supported good growth.

<sup>†</sup>Based on achievement of nitrogen balance sufficient to support adequate lean tissue gain (16 mg nitrogen/kg/day).

<sup>‡</sup>Based on upper range of requirement for positive nitrogen balance.

<sup>§</sup>Based on highest estimate of requirement to achieve nitrogen balance.

According to current recommendations, a healthy adult human requires 0.8 g of protein per kilogram of healthy body weight (IOM, Food and Nutrition Board, 2002). To obtain this quantity of protein, humans benefit when dietary protein makes up approximately 10% to 15% of total energy intake. Protein requirements increase during times of stress and disease. Protein-rich foods are obtained primarily from animal flesh or animal products such as eggs and milk. Most plant foods are relatively poor sources of protein, with the exception of legumes and beans.

## Dietary Protein Quality

Because the synthesis of proteins for the body depends on the availability of all necessary amino acids, the quality of a dietary protein depends on its amino acid makeup and their bioavailability. A number of methods have been used to measure the quality of proteins based on these properties. More than 50 years ago, Block and Mitchel (1946) determined that a protein's biologic value could be determined by the essential amino acid profile compared with human requirements. The essential amino acid that occurred in the least concentration compared with human requirement was the **limiting amino acid**, from which a "chemical score" of protein quality could be calculated.

Protein quality is also determined by measuring the amount of protein actually used by an organism; *net protein utilization* (NPU) is the one method of doing so. Dietary protein is equated with its metabolic products by measuring nitrogen in the diet and biologic samples and converting it to the amount of protein on the basis of the formula (nitrogen [grams]  $\times$  6.25 = protein [grams]). The gain in nitrogen is compared with the nitrogen intake, and the proportion of nitrogen retained in the body is computed to obtain the NPU. The NPU ranges from approximately 40 to 94, with protein from animal products scoring higher and protein from vegetables scoring lower. However, care must be taken when using animals in trials for determining the quality of a protein for humans.

The World Health Organization (WHO) and the U.S. Food and Drug Administration (FDA) have adopted a **protein digestibility corrected amino acid score (PDCAAS)** as the official assay for evaluating protein quality in humans. The PDCAAS is based on amino acid requirements of children ages 2 to 5 years and represents the **amino acid score** after correcting for digestibility. After being corrected for digestibility, proteins that provide amino acids equal to or in excess of requirements receive a PDCAAS of 1. Gilani et al. (2008) have identified the need for more accurate, standardized methods that include bioactive peptides.

Digestibility is a major factor affecting protein quality and is affected by multiple factors. Meat preparation procedures often involve wine or vinegar marinades and moist heat to tenderize tough cuts of meat through **denaturation**. Proteins are kept in their functional three-dimensional structure by hydrogen and ionic interactions; these bonds loosen in the presence of acid, salt, and heat. Because they

denature proteins, these methods also soften gristle, or connective tissue proteins, and release muscle proteins from their attachments, thereby making all proteins more available to digestive enzymes.

Vegetable protein is less efficient than animal protein; it is encased in carbohydrate and is less available to digestive enzymes. Some plants contain enzymes that interfere with protein digestion and require heat inactivation before consumption. For example, soybeans contain a trypsinase that inactivates trypsin, the major protein-digesting enzyme in the intestine. Although research suggests that plant protein may benefit blood pressure control, little has been published regarding protein sources in diets of U.S. adults and factors influencing these choices (Lin et al., 2010). Protein source frequencies in the lifestyle-changing PREMIER trial were poultry, dairy, refined grains and beef; animal protein was two thirds of intake, and one third was from plant protein, varying by sex, race, age, and body weight status (Lin et al., 2010).

Food processing can damage amino acids and reduce their digestive availability in several ways. Mild heat treatment in the presence of reducing milk sugars (glucose and galactose) during processing causes a loss of available lysine. Lactose reacts with lysine side chains and renders them unavailable. This *browning* (the *Maillard reaction*) causes significant lysine loss at high temperatures. Under severe heating conditions in the presence (or even absence) of sugars or oxidized lipids, all amino acids in food proteins become resistant to digestion. When protein is exposed to severe treatment with alkali, the amino acids lysine and cysteine can react together and form a potentially toxic lysinoalanine. Exposure to sulfur dioxide and other oxidative conditions can result in loss of methionine. Thermal processing and low-moisture storage of proteins can also result in reductive binding of vitamin B<sub>6</sub> to lysine residues, thereby inactivating the vitamin. Therefore proper handling of protein foods is necessary to maintain their integrity and usefulness.

As noted, if the amino acid profile of a food does not match human needs, those in short supply are "limiting." The quality of dietary protein can be improved by combining protein sources with different limiting amino acids. Diets based on a single plant food staple do not foster optimal growth because the diet does not have enough of the limiting amino acid to provide substrates for protein synthesis. If another plant protein that contains an excess of the limiting amino acid is added to the diet, the protein combination is *complemented*; essential amino acids are adequate to support human protein synthesis. The concept of complementary proteins is important for populations without animal protein intake or at risk from insufficiently diverse foods. Complementary foods that, when eaten together, provide all of the essential amino acids are shown in Table 3-9. It is not necessary to eat complementary amino acids during a single meal, but they should be eaten within the same day (American Dietetic Association, 2009). Children, pregnant women, and nursing mothers who have vegan diets need to plan their

diets carefully to include a mixture of amino acid-containing foods.

### Nitrogen Balance

Homeostatic regulations control the concentrations of specific amino acids in the amino acid pool and the rate at which muscle and plasma proteins are synthesized and broken down. Body protein synthesis and turnover are regulated. In healthy individuals the amount of protein taken in is balanced by protein used for body maintenance and excreted in feces, in urine, and from skin, resulting in a zero protein balance (Figure 3-10). This balance reflects homeostatic regulations within tissues.

**TABLE 3-9**

#### Food Combinations Providing All Essential Amino Acids

Excellent Combinations*	Examples
Grains and legumes	Rice and beans, pea soup and toast, lentil curry and rice
Grains and dairy	Pasta and cheese, rice pudding, cheese sandwich
Legumes and seeds	Garbanzo beans and sesame seeds; hummus as dip, falafel, or soup

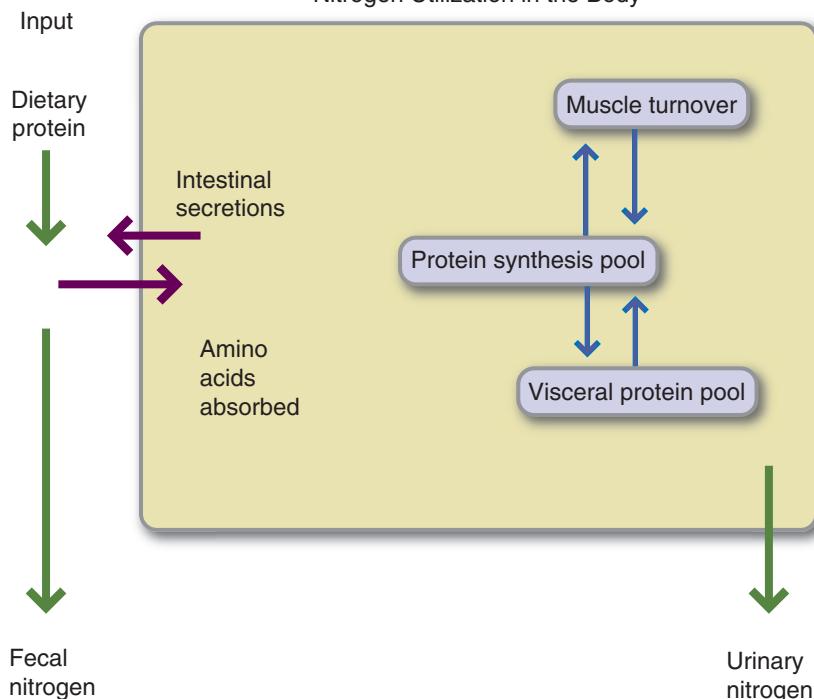

\*Other combinations, such as dairy and seeds, dairy and legumes, grains and seeds, are less effective because the chemical scores are similar and not effectively complementary.

For food lists containing high protein, see <http://www.nal.usda.gov/fnic/foodcomp/Data/SR18/nutrlst/sr18w203.pdf>

Muscle mass (*somatic protein*) is maintained with the circulating amino acid pool such that similar quantities of muscle protein are destroyed and rebuilt daily. Muscle mass can be estimated using the creatinine/height index and the midarm muscle circumference. Amino acids are also required for synthesis of *visceral proteins* by the liver and other tissues. A person with an infection or a traumatic injury excretes more nitrogen than is ingested; inflammatory cytokines cause nitrogen loss and negative nitrogen balance under these conditions. The pregnant woman and her growing child use ingested protein for growth and to retain more protein than is lost daily (positive nitrogen balance).

Nitrogen in the form of ammonia ( $\text{NH}_3$ ) is highly toxic, easily crosses membranes, and cannot be allowed to travel unbound throughout the body. In the fed state, pyruvate and other carbon skeletons take up nitrogen (via transamination) and transport it to the liver as nonessential amino acids, usually alanine and glutamic acid (from  $\alpha$ -ketoglutarate). When these amino acids reach the liver, they are deaminated or transaminated back into the carbon skeleton. A deaminated ammonia ion is combined with carbon dioxide in the presence of high-energy phosphate and magnesium by the enzyme *carbamoyl phosphate synthase* to form carbamoyl phosphate, the first intermediate of the urea cycle. A second amino group enters the urea cycle via aspartic acid. Thus with each urea molecule formed, two excess amino groups can be excreted. **Urea** makes up 90% of urinary nitrogen in the fed state. Arginine, one of the basic amino acids is also a product of the urea cycle. Arginine is required for formation of nitric oxide and other mediators of the inflammatory response (Gropper et al., 2005). Although classified as a *nonessential amino acid*, arginine may be essential for critically ill individuals.

**Nitrogen Utilization in the Body**

**FIGURE 3-10** Nitrogen use in the body.

Protein supplies nitrogen in the form of amino acids, according to the formula (nitrogen [grams] = protein [grams] ÷ 6.25). Dietary protein and protein from endogenous secretions are available for absorption across the gastrointestinal tract. More than 95% of protein is normally absorbed and enters the synthetic pool. Muscle proteins and visceral (i.e., plasma) proteins are broken down and built up daily. Nitrogen is converted to urea and excreted in the urine. Minor amounts of nitrogen are lost in the menstrual flow and the normal secretions and turnover of skin and its appendages. In a healthy individual, nitrogen intake equals nitrogen losses; the person is in zero protein balance. (Modified from Crim MC, Munro HN: Proteins and amino acids. In Shils ME et al., editors: *Modern nutrition in health and disease*, Philadelphia, 1994, Lea & Febiger.)

## MACRONUTRIENT USE AND STORAGE IN THE FED STATE

Absorbed carbohydrates are transported as plasma glucose in the portal vein. An increase in the glucose level in the portal vein stimulates pre-formed insulin secretion from the pancreas. One of the most dramatic effects of insulin is its effects on the glucose transporters (GLUT 4) in insulin-dependent adipose and muscle. However, the liver is the first organ to receive portal blood glucose. The liver takes up approximately 50% of absorbed glucose via noninsulin-dependent transporters (GLUT 2) and immediately phosphorylates glucose into glucose-6-phosphate using the high-capacity enzyme glucokinase, thereby retaining glucose in the liver cells (see Figure 3-2).

Insulin enhances the oxidation of glucose in the glycolytic pathway by increasing the activity of glucokinase. *Pyruvate dehydrogenase* is also stimulated, increasing glycolysis and acetyl CoA production in both the liver and the muscle to generate adenosine triphosphate (ATP). In addition, insulin increases glycogen synthase activity in the liver and muscle, maximizing glucose storage as glycogen storage under fed conditions. Muscle glycogen is used within the muscle cell to provide ATP for muscle contraction. Its concentration in the muscle depends on the physical activity of the individual and can be greatly increased by physical training.

Liver glycogen serves as a reservoir, providing a readily available supply of glucose to maintain blood glucose levels during the fasting state. If carbohydrate intake exceeds the body's oxidative and storage capacities, the cells convert carbohydrate into fat. Elevated insulin levels increase the activity of fatty acid and triglyceride synthesis enzymes such as acetyl CoA carboxylase in the liver, lipoprotein lipase (LPL) in the adipose tissue, and fatty acid synthetase.

Because they are fat soluble, lipids cannot be transported unbound through the aqueous media of the body. Absorbed fatty acids and monoglycerides are reesterified into triglycerides within mucosal cells, and the fat-soluble center is surrounded with a thin layer of protein and phospholipid for transport. The protein component includes apoproteins (Apo) B, A, C, and E with specific functions. The resulting **chylomicrons** contain only 2% protein; the rest are triglycerides (84%), cholesterol, and phospholipids. The lipid-rich particles leave the mucosal cells and travel through lymphatic channels to the thoracic duct that empties into the right side of the heart. Rapid blood flow in the heart prevents the large, lipid-rich chylomicrons from forming clumps and fat emboli. Chylomicrons transport dietary fat and are found in blood only after meals, making the plasma appear milky after a high-fat meal.

Chylomicrons leave the heart through the aorta and are dispersed into the general circulation and transported to the adipocytes. The enzyme LPL is expressed on the membrane of endothelial cells lining capillaries in the region of the adipocytes. LPL is activated by lipoprotein-bound Apo C to bind chylomicrons and cleave triglycerides, releasing fatty

acids and monoglycerides that cross the fatty lipid membrane, enter the adipocytes, and become reesterified into triglyceride for safe and hydrophobic storage. Note that insulin, the predominant hormone in the fed state, activates LPL and facilitates fat storage. The chylomicron remnant, relieved of some of its triglyceride content, is bound to liver receptors and recycled.

The liver receives fat from numerous sources: chylomicron remnants, circulating fatty acids, uptake of intermediate lipoproteins and other lipoproteins, and endogenous synthesis. The liver reestifies fat from all sources and forms VLDLs, which are richer in cholesterol compared with chylomicrons but still contain a large proportion of triglycerides. VLDLs also contain Apo B, E, and C and adsorb Apo A as they circulate. In the fed state numerous VLDLs are formed and transported to the adipocytes, where triglycerides are again hydrolyzed, reesterified, and stored. Even in fasting, VLDLs are formed to carry endogenous lipids.

Dietary cholesterol is transported via chylomicrons and VLDLs but is not removed by LPL. After LPL has cleaved the maximum triglyceride from VLDLs, the remnant remaining is called an *intermediate-density lipoprotein*. Once the maximum triglyceride is removed, the lipoprotein is known as an *LDL* and primarily carries cholesterol. Although LDLs can be taken up by the liver on receptors for Apo B and Apo E, they are first taken up by specific LDL receptors that bind these cholesterol-rich particles. After uptake, endocytic vesicles containing LDL fuse with a lysosome. The digestive enzymes in the lysosome break down the protein and phospholipids, leaving free cholesterol. Free cholesterol regulates cholesterol synthesis and LDL uptake within the cell by inhibiting 3-hydroxy-3-methylglutaryl (HMG) CoA reductase, the rate-limiting enzyme for cholesterol synthesis from acetyl CoA. It downregulates cellular synthesis of the LDL receptor and reduces receptor expression on the membrane. Free cholesterol also increases the esterification of cholesterol for storage.

Cholesterol is removed from the cell membrane and other lipoproteins by HDLs. HDL particles are formed in the liver and other tissues as disk-shaped lipoproteins. They circulate in the bloodstream and accumulate free cholesterol, which they esterify with fatty acid from their phosphatidylcholine (lecithin) structure. The ability of HDLs to function as a cholesterol transporter depends on the activity of their copper-dependent enzyme lecithin-cholesterol acyltransferase, which esterifies cholesterol and stores it in its hydrophobic center. When it has accumulated sufficient lipid to become spherical, HDL is taken up by the liver and recycled. Recycled cholesterol is used for bile acid synthesis, stored in subcutaneous tissue, formed into vitamin D, or secreted as VLDL.

The LDLs that remain in circulation too long are susceptible to oxidative damage and macrophage scavenging. Macrophages are large cells that engulf other particles. They are distributed throughout the body, play a major role in immune defense, and inhabit the arteries, where they serve as a surveillance mechanism against foreign and

microbial agents in the blood. Although macrophages do not recognize and ingest normal lipoproteins, they do recognize as foreign those lipoproteins that have undergone oxidation. Macrophages ingest oxidized LDLs and accumulate ingested fat within their cytoplasm, giving them a foamy appearance (thus the name *foam cells*). LDL ingestion activates macrophages and stimulates them to secrete mediators that trigger multiple inflammatory and proliferative cascades, some of which lead to atherosclerosis.

## MACRONUTRIENT CATABOLISM IN THE FASTED STATE

The body has a remarkable ability to withstand food deprivation, allowing humans to survive cycles of feast and famine. Adaptive changes allow the body to access stored macronutrients to provide for routine activities.

Individuals with protein-energy malnutrition (PEM) or protein-calorie malnutrition (PCM) can have varying symptoms, determined by the cause of the malnutrition. Starvation of both protein and calories leads to *marasmus* at one end of the PEM continuum. At the opposite end is protein deprivation that occurs in individuals who are consuming carbohydrates almost entirely. *Kwashiorkor* is the Ghanaian word for the disease that develops when a mother's first child is weaned from protein-rich breast milk to a protein-poor carbohydrate food source. The condition is caused by severe protein deficiency and hypoalbuminemia. In adults, the correct term is *protein-energy malnutrition*, not the pediatric term, *kwashiorkor*. The starving adult has simply "malnutrition" described more fully in Chapter 14.

Glucose is an obligate nutrient for the brain and nervous system, red and white blood cells, and other glucose-requiring tissues. To maintain function, the blood glucose level must be maintained within a normal range at all times. During early fasting, glucose is obtained from glycogen by the action of the hormones glucagon and epinephrine; these stores are depleted in 18 to 24 hours. At this point, new glucose must be synthesized using protein as a substrate. The catabolic hormones epinephrine, thyroxine, and glucagon stimulate the release of muscle protein and other available substrates for gluconeogenesis. The most common amino acid substrate for gluconeogenesis is alanine; when its nitrogen is removed, alanine becomes pyruvate. Note that glycogen is never totally depleted, even during long-term starvation. A small amount of pre-formed glycogen is carefully guarded as a primer for glycogen resynthesis.

As fasting is prolonged and the body adapts to starvation conditions, liver gluconeogenesis decreases from producing 90% of the glucose to less than 50%, with the remainder being supplied by the kidney. Although the muscle and brain are unable to release free glucose, the muscle can release pyruvate and lactate for gluconeogenesis in the *Cori cycle*. Muscles also release glutamine and alanine. These amino acids can be deaminated or transaminated into  $\alpha$ -ketoglutarate or pyruvate, respectively, and converted

into oxaloacetate, then to glucose. During prolonged fasting the kidney requires ammonia to excrete acidic metabolic products. Muscle-derived glutamine is used for this purpose; deaminated glutamine ( $\alpha$ -ketoglutarate) can then be used to produce glucose. Thus, during starvation, glucose production by the kidney increases while production by the liver decreases.

In addition to glucose, a reliable energy source is required during fasting. The best source is fat that is stored in adipocytes and used primarily by muscles, including the heart muscle, to make ATP. Fatty acid release and use require low insulin levels and an increase of the antiinsulin hormones glucagon, cortisone, epinephrine, and growth hormone. Antiinsulin hormones activate the hormone-sensitive lipase enzyme on the adipocyte membrane. This enzyme cleaves stored triglycerides, releasing fatty acids and glycerol from fat cells. Fatty acids travel to the liver bound to serum albumin and easily enter the liver cells. Once inside the cell, fatty acids enter the liver mitochondria via the carnitine acyltransferase transport system, which carries fatty acid **carnitine** esters across the mitochondrial membrane. Once inside the mitochondria, acetyl CoA is formed from fatty acid CoA via the process of  $\beta$ -oxidation. During starvation, excess acetyl CoA molecules accumulate in the liver because the liver is able to obtain all necessary energy from the process of  $\beta$ -oxidation and form ketones, which then enter the bloodstream and act as a source of energy for the muscles, thus sparing protein.

Adaptation to starvation depends on ketone production. As the blood ketone level rises during fasting, the brain and nervous system, although obligate glucose consumers, begin to use ketones as an energy source. Because the brain is using a fuel other than glucose, the demand on muscle protein for gluconeogenesis declines, thereby reducing the rate of muscle catabolism. Reduced muscle catabolism reduces the amount of ammonia received by the liver. Liver synthesis of urea decreases precipitously, reflecting the slower rate of muscle protein deamination. If the fast extends for weeks, the rate of urea synthesis and excretion is minimized. In an individual who has adapted to starvation, urea is excreted from the kidney at approximately the same rate as uric acid.

Thus, in an individual who is adapting to starvation, protein losses are minimized and lean body mass spared. Although fat cannot be converted into glucose, it does provide fuel for the muscle and brain as ketones. As long as water is available, a normal-weight individual can fast for a month. Relatively normal nutritional indices, immune function, and other system function are maintained. However, when fat stores are exhausted, protein is used, and death is the ultimate consequence.

In certain cases of trauma and sepsis, the individual is not able to adapt to fasting or starvation. If an individual who is fasting develops an infection, inflammatory mediators such as interleukin-1 and tumor necrosis factor stimulate insulin secretion and prevent the development of mild ketosis. Without ketones the brain and other tissues continue to depend on glucose, thereby limiting the person's ability to

adapt to starvation. Muscle mass erodes to provide glucose substrates. A fasting person with an infection rapidly develops a negative nitrogen balance. When 50% of the protein stores is exhausted, recovery from infection is poor.

Adaptation to starvation is also not possible for those with protein malnutrition because the carbohydrate intake stimulates insulin production. Insulin is a storage hormone that prevents fat stores from being accessed for fuel. It also inhibits fat from being formed into ketones, thereby limiting adaptation to starvation. Insulin secretion inhibits muscle breakdown. Protein cannot be used to make albumin and other visceral proteins. Edema results because albumin exerts osmotic pressure in the vessels. If the albumin concentration is low, fluid remains in the extracellular spaces and causes edema. Compromised neural function or GI absorption, decreased cardiac output, immune function, fatigue, and other symptoms of malnutrition result from inadequate protein synthesis, inadequate ATP production, and fluid accumulation in the tissues.

Nonadapted malnutrition is dangerous. Not only can unremitting protein loss become life threatening by compromising the muscles of the heart and respiratory system, but it also compromises the immune system. The individual becomes susceptible to a vicious cycle of infections, diarrhea, additional nutrient loss, an even weaker immune system, and finally opportunistic infections and death. Iatrogenic, or “physician-induced,” malnutrition was

recognized long ago as a danger for hospitalized patients and remains so to this day (Kruizenga et al., 2005). Often lung failure occurs from weakened respiratory muscles. Pneumonia yields the mortal blow, yet malnutrition is the actual underlying cause.

## MICRONUTRIENTS: VITAMINS

The discovery of vitamins gave birth to the field of nutrition. The term **vitamin** came to describe a group of essential micronutrients that generally satisfy the following criteria: (1) organic compounds (or class of compounds) distinct from fats, carbohydrates, and proteins; (2) natural components of foods, usually present in minute amounts; (3) not synthesized by the body in amounts adequate to meet normal physiologic needs; (4) essential in minute amounts for normal physiologic function (i.e., maintenance, growth, development, and reproduction); and (5) cause a specific deficiency syndrome by their absence or insufficiency.

The elucidation of these compounds was an exciting and convoluted story (see *Focus On: Pellagra, Politics, and the Poor*).

**Vitamers** are the multiple forms (all isomers and active analogs) of vitamins. Although the vitamins have few close chemical similarities, their metabolic functions have classically been described in one of four general categories: membrane stabilizers, hydrogen ( $H^+$ ) and electron donors and

### © FOCUS ON

#### Pellagra, Politics, and the Poor

The history of niacin and pellagra is an example of the complicated search for the vitamins. Even though oranges and lemons were used as early as 1601 on the ships of the East India Company to prevent scurvy, the idea that a chemical in the diet could prevent certain diseases eluded the scientific and medical communities for hundreds of years. Pellagra was among these diseases. In 1915, 11,000 deaths from pellagra were reported in the southern United States. By 1917, more than 170,000 cases developed in the South. The situation was so grave that the Public Health Service sent Joseph Goldberger to investigate the deaths. He determined that a nutrient deficiency was the cause of the disease and that it could be cured by a diet containing high-quality protein. In fact, he showed that he could eliminate the disease simply by improving the diet. In 1918, Goldberger published these findings. Considering these facts, why in 1927 were 120,000 cases reported in the South? Between 1927 and 1930 27,103 deaths were recorded.

Why were there so many deaths from a disease that was entirely preventable? Several factors contributed to the situation. First, Pasteur's germ theory of disease was sweeping the scientific community. It was thought that scurvy, beriberi, and

rickets were each caused by a microbe rather than by the lack of a nutrient. The antiberiberi actions of whole-grain rice were thought to be caused by a pharmacologic substance that acted against an unknown bacterium rather than a substance that served as a nutrient (thiamin). Even after Goldberger showed that pellagra was not contagious, doubts persisted. The problem was further complicated because (1) high-quality protein does not contain niacin—it contains the **tryptophan** precursor; and (2) the isolation of individual vitamins from the B-complex isolate took many years of painstaking laboratory research. Many more years passed before tryptophan was recognized as an important precursor of niacin.

More significant factors contributed to the numerous deaths from pellagra. The southern United States in the 1940s (with more than 2000 deaths per year) and early 1950s (with more than 500 deaths per year) were afflicted by economic and social factors. All who died from pellagra were poor and got poorer in the Great Depression of the late 1920s and 1930s. Pellagra primarily affected black Americans. In the South, people died from a lack of food, whereas in other parts of the country, farmers burned or threw away food because they could not sell the excess.

acceptors, hormones, and coenzymes. Their functions in human health are much broader and often include roles in gene expression. Subclinical or even less than optimum levels of some vitamins can contribute to disease states that are not normally associated with vitamin status. A number of vitamins and minerals have roles in prevention of the symptoms of deficiency diseases.

Subclinical deficiencies may have important effects on development of chronic disease. For example, folate and B<sub>12</sub> are critical for both DNA synthesis and repair; low intake levels are common in the general population and in the elderly. Folate also has a role in maintaining the stability of DNA. Individuals who are homozygous for the gene that controls key folate-metabolizing enzymes have decreased risk of colorectal cancer. Similarly, riboflavin and niacin status affect cancer risk by playing an important role in response to DNA damage and genomic stability (Kirkland, 2003). More substantial evidence supports riboflavin's role in iron metabolism.

Vitamin D is essential for healthy bones and is protective against bone diseases. Vitamin D also protects against certain types of cancers, multiple sclerosis, and type 1 diabetes (Grant and Holick, 2005). Vitamins A and D and calcium deficits predispose individuals to certain types of cancers, chronic inflammatory and autoimmune diseases, metabolic syndrome, and hypertension (Peterlik and Cross, 2005). Multiple nutrients have also been implicated in the development of osteoporosis (Nieves, 2005) and lung disease (Romieu, 2005). The widespread deficit of these nutrients in the American population is a major challenge for preventive medicine. As the roles of vitamins and minerals in preventing secondary disease become clear, recommended daily intakes may need to be revised for some populations. Currently, data cannot support the benefits of vitamin or mineral supplements to prevent cancer or chronic disease (Lin et al, 2009). An adequate dietary intake is essential, in conjunction with a variety of macronutrients and phytochemicals.

## THE FAT-SOLUBLE VITAMINS

The fat-soluble vitamins are absorbed passively and must be transported with dietary lipid. They tend to be found in the lipid portions of the cell such as membranes and lipid droplets. Fat-soluble vitamins need fat for proper absorption and are generally excreted with the feces via enterohepatic circulation.

### Vitamin A

*Vitamin A (retinoids)* refers to three pre-formed compounds that exhibit metabolic activity: the alcohol (retinol), the aldehyde (retinal or retinaldehyde), and the acid (retinoic acid) (Table 3-10). Stored retinol is often esterified to a fatty acid, usually retinyl-palmitate, which is usually found complexed with food proteins. The active forms of vitamin A exist only in animal products.

In addition to pre-formed vitamin A found in animal products, plants contain a group of compounds known as

**carotenoids**, which can yield retinoids when metabolized in the body. Although several hundred carotenoids exist in foods naturally as antioxidants, only a few have significant vitamin A activity. The most important of these is β-carotene. The amount of vitamin A available from dietary carotenoids depends on how well they are absorbed and how efficiently they are converted to retinol. Absorption varies greatly (from 5% to 50%) and is affected by other dietary factors such as the digestibility of the proteins complexed with the carotenoids and the level and type of fat in the diet.

### Absorption, Transport, and Storage

Before either vitamin A or its carotenoid provitamins can be absorbed, proteases in the stomach and small intestine must hydrolyze proteins that are usually complexed with these compounds. In addition, retinyl esters must be hydrolyzed in the small intestine by lipases to retinol and free fatty acids (Figure 3-11, A). Retinoids and carotenoids are incorporated into micelles along with other lipids for passive absorption into the mucosal cells of the small intestine. Once in the intestinal mucosal cells, retinol is bound to a cellular retinol-binding protein (CRBP) and reesterified, primarily by lecithin retinol acyl transferase into retinyl esters. Carotenoids and retinyl esters are then incorporated into chylomicrons for transport into the lymph and eventually the bloodstream. They may also be cleaved into retinal, which is then reduced to retinol and reesterified into retinyl esters to be incorporated into chylomicrons (Figure 3-11, B).

The liver plays an important role in vitamin A transport and storage (Figure 3-11, C). Chylomicron remnants deliver retinyl esters to the liver. These esters are immediately hydrolyzed into retinol and free fatty acids. **Retinol** in the liver has three major metabolic fates. First, retinol may be bound to CRBP, which controls free retinol concentrations that can be toxic in the cell. Second, retinol may be reesterified to form retinyl palmitate for storage. Approximately 50% to 80% of the vitamin A in the body is stored in the liver. Adipose tissue, lungs, and kidneys also store retinyl esters in specialized cells called *stellate cells*. This storage capacity buffers the effects of highly variable patterns of vitamin A intake and is particularly important during periods of low intake when a person is at risk for developing a deficiency.

Finally, retinol may be bound to *retinol-binding protein (RBP)*. Retinol bound to RBP leaves the liver and enters the blood, where the *transthyretin (TTR)* protein attaches and forms a complex to transport retinol in the blood to the peripheral tissues. Because hepatic RBP synthesis depends on adequate protein, protein deficiency affects retinol levels along with vitamin A deficiency. Thus individuals with PCM typically have low circulating retinol levels that may not respond to vitamin A supplementation until protein deficiency is also corrected.

The retinol-RBP-TTR complex delivers retinol to other tissues via cell surface receptors. Retinol is transferred from RBP to CRBP with the subsequent release of Apo RBP into binding protein and TTR to the blood. Apo RBP is

**TABLE 3-10****Vitamins, Vitamers, and Their Functions**

<b>Group</b>	<b>Vitamers</b>	<b>Provitamins</b>	<b>Physiologic Functions</b>
Vitamin A	Retinol Retinal Retinoic acid	$\beta$ -carotene Cryptoxanthin	Visual pigments; cell differentiation; gene regulation
Vitamin D	Cholecalciferol (D <sub>3</sub> ) Ergocalciferol (D <sub>2</sub> )		Ca homeostasis; bone metabolism
Vitamin E	$\alpha$ -tocopherol $\gamma$ -tocopherol Tocotrienols		Membrane antioxidant
Vitamin K	Phylloquinones (K <sub>1</sub> ) Menaquinones (K <sub>2</sub> ) Menadione (K <sub>3</sub> )		Blood clotting; Ca metabolism
Vitamin C	Ascorbic acid		Reductant in hydroxylations in biosynthesis of collagen and carnitine and in the metabolism of drugs and steroids
Vitamin B <sub>1</sub>	Dehydroascorbic acid Thiamin		Coenzyme for decarboxylations of 2-keto acids and transketolations
Vitamin B <sub>2</sub> Niacin	Riboflavin Nicotinic acid Nicotinamide		Coenzyme in redox reactions of fatty acids and the TCA cycle Coenzymes for several dehydrogenases
Vitamin B <sub>6</sub>	Pyridoxol Pyridoxal Pyridoxamine		Coenzymes in amino acid metabolism
Folate	Folic acid Pteroylmonoglutamate Polyglutamyl folacins		Coenzymes in single-carbon metabolism
Biotin	Biotin		Coenzyme for carboxylations
Pantothenic acid	Pantothenic acid		Coenzyme in fatty acid metabolism
Vitamin B <sub>12</sub>	Cobalamin		Coenzyme in metabolism of propionate, amino acids, and single carbon fragments

TCA, Tricarboxylic acid.

eventually metabolized and excreted by the kidney. In addition to CRBP, cellular retinoic acid-binding proteins (CRABPs) bind retinoic acid in the cell and serve to control retinoic acid concentrations similar to the way CRBP controls retinol concentrations.

### Metabolism

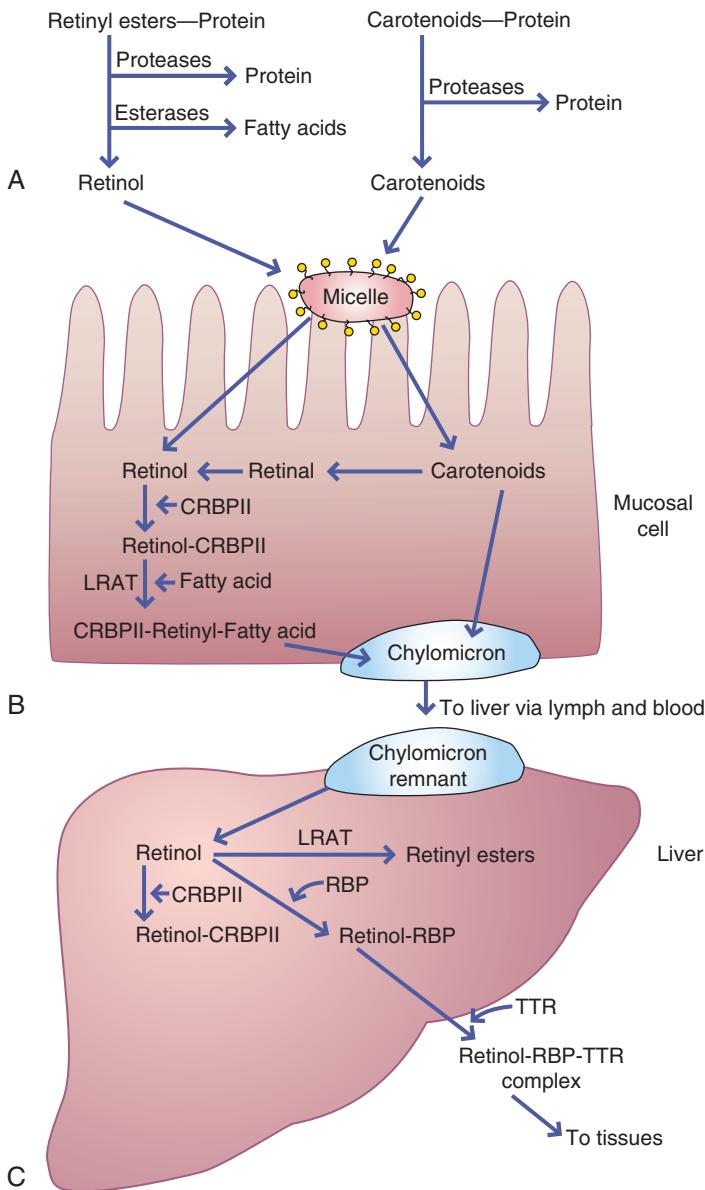

In addition to being esterified for storage, the transport form of retinol can also be oxidized into retinal and then into retinoic acid or conjugated into retinyl glucuronide or phosphate. After retinoic acid is formed, it is converted to forms that are readily excreted. Chain-shortened and oxidized forms of vitamin A are excreted in the urine; intact forms are excreted in the bile and feces.

### Functions

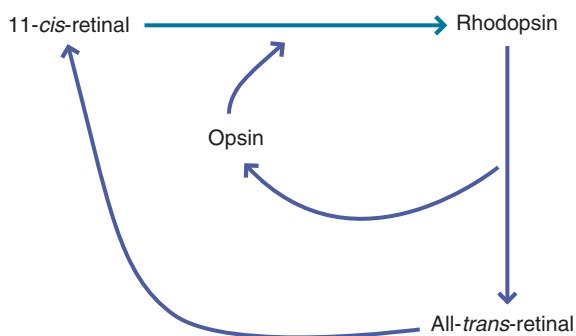

Vitamin A has essential but separate roles in vision and various systemic functions, including normal cell differentiation and cell surface function (e.g., cell recognition),

growth and development, immune functions, and reproduction.

Retinal is a structural component of the visual pigments of the rod and cone cells of the retina and is essential to photoreception. The 11-*cis* isomer, 11-*cis*-retinal, constitutes the photosensitive group of various visual pigment proteins (i.e., the opsins—rhodopsin in the rods and iodopsin in the cones). Photoreception results from light-induced isomerization of 11-*cis*-retinal to the completely all-*trans* form. For example, in the rod, rhodopsin progresses through a series of reactions leading to the dissociation of “bleached” rhodopsin into all-*trans*-retinal and opsin, a reaction that is coupled to nervous stimulation of the visual centers of the brain. All-*trans*-retinal can then be converted back enzymatically to 11-*cis*-retinal for subsequent binding to opsin (Figure 3-12). The movement of retinal into designated sites in the retina is controlled by the proteins and interphotoreceptor retinal-binding protein, which serves a similar function.

**FIGURE 3-11** Retinol and carotenoids. **A**, Digestion. **B**, Absorption. **C**, Transport. *CRBPII*, Cellular retinol-binding protein II; *RBP*, retinol-binding protein; *TTR*, transthyretin.

**FIGURE 3-12** The visual cycle.

Although the systemic functions of vitamin A are not completely understood, they can be separated into two major categories. First, retinoic acid acts as a hormone to affect gene expression (see Chapter 5). Within the cell, CRABP transports retinoic acid to the nucleus. In the nucleus, retinoic acid and 9-cis-retinoic acid bind to retinoic acid receptors or retinoid receptors on the gene (Figure 3-13). Subsequent interactions allow stimulation or inhibition of transcription of specific genes, thus affecting protein synthesis and many body processes. Only a few of these processes are known, and they include morphogenesis in embryonic development and epithelial cell function (including differentiation and production of keratin proteins). The second major role of vitamin A in systemic functions involves glycoprotein synthesis. In a series of reactions, retinol forms retinyl-phosphomannose and then transfers the mannose to the glycoprotein. Glycoproteins are important for normal cell surface functions such as cell aggregation and cell recognition. This role in glycoprotein synthesis may also account for the importance of vitamin A in cell growth because it may increase glycoprotein synthesis for cell receptors that respond to growth factors. Vitamin A (retinol) is also essential for normal reproduction, bone development and function, and immune system function, although its actions in these roles are currently unclear.

Although a consistent body of epidemiologic evidence indicates that higher blood levels of carotenoids reduce the risk of several chronic diseases, the only clear function of the carotenoids is as provitamin A (IOM, Food and Nutrition Board, 2001). β-Carotene can act as an antioxidant. Its other properties include retinoid-dependent signaling, gap junction communications, regulation of cell growth, and induction of enzymes (Stahl et al., 2002).

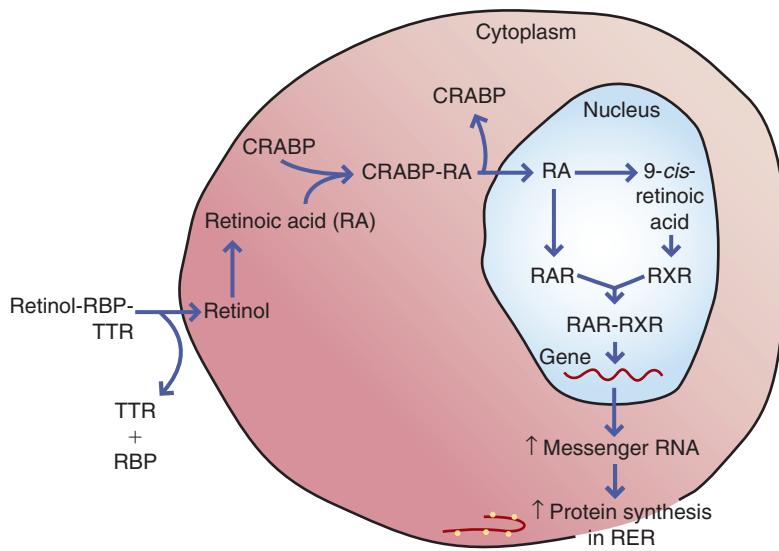

### Dietary Reference Intakes Measurement

The vitamin A content of foods is measured as **retinol activity equivalents (RAEs)**. One RAE equals the activity of 1 mcg of retinol (1 mcg of retinol is equal to 3.33 International Units) (Box 3-3). The efficiency of β-carotene absorption is lower (14%) than previously believed (33%). In developed countries, 12 mcg of β-carotene is equal to 1 RAE, and 24 mcg of other carotenoids equal 1 RAE. The rate in developing countries is less efficient, requiring at least 21 molecules of β-carotene to get 1 molecule of vitamin A (Sommer, 2008).

Dietary reference intakes (DRIs) have been determined for vitamin A and are expressed in micrograms per day (mcg/day). The AI for infants is based on the amount of retinol in human milk. The DRIs for adults are based on levels that provide adequate blood levels and liver stores and are adjusted for differences in average body size. Increased amounts of the vitamin during pregnancy and lactation allow for fetal storage and the vitamin A in breast milk.

No DRIs have been established for the carotenoids. Indeed, while supplementation may be harmful, increased

### BOX 3-3

#### Vitamin A Activity

1 RAE =

1 mcg of retinol

12 mcg of β-carotene (from food)

3.33 IU of vitamin A activity (on a label)\*

For example: 5000 IU vitamin A (supplement or food label) =

1500 RAE = 1500 mcg of retinol

Data from Institute of Medicine, Food and Nutrition Board: Dietary reference intakes for vitamin A, vitamin K, arsenic, boron, chromium, copper, iodine, iron, manganese, molybdenum, nickel, silicon, vanadium, and zinc, Washington, DC, 2001, National Academies Press.

RAE, Retinol activity equivalent.

\*The vitamin A activity on a food or supplement label is stated in international units (IU), a term outdated scientifically but still required legally on labels.

consumption of fruits and vegetables containing carotenoids is clearly beneficial (IOM, Food and Nutrition Board, 2001).

#### Sources

Pre-formed vitamin A exists only in foods of animal origin, either in storage areas such as the liver or in the fat of milk and eggs. Very high concentrations of vitamin A are found in cod and halibut liver oils. Nonfat milk in the United States, which by U.S. law can contain 0.1% fat, is routinely fortified with retinol. Provitamin A carotenoids are found in dark green, leafy and yellow-orange vegetables and fruit; deeper colors are associated with higher carotenoid levels. In much of the world, carotenoids supply most of the dietary vitamin A. The American food supply provides roughly equal amounts of pre-formed vitamin A and provitamin A carotenoids. Carrots, greens, spinach, orange juice, sweet

potatoes, and cantaloupe are rich sources of provitamin A. In many of these foods, vitamin A bioavailability is limited by binding of carotenoids to proteins; this can be overcome by cooking, which disrupts the protein association and frees the carotenoid. Table 3-11 and Appendix 47 list the vitamin A content of selected foods.

#### Deficiency

Primary deficiencies of vitamin A result from inadequate intakes of pre-formed vitamin A or provitamin A carotenoids. Secondary deficiencies can result from malabsorption caused by insufficient dietary fat, biliary or pancreatic insufficiency, impaired transport from abetalipoproteinemia, liver disease, PEM, or zinc deficiency.

An early sign of vitamin A deficiency is impaired vision from the loss of visual pigments. This manifests clinically as **night blindness**, or nyctalopia. This impairment of dark adaptation (the ability to adapt from being in a bright light or glare to being in darkness [e.g., while driving at night or moving from a brightly lighted to a dark room]), results from the failure of the retina to regenerate rhodopsin. Individuals with night blindness have poor visual discriminatory abilities and may not be able to see in dim light or at twilight. In addition to measuring plasma retinol levels, dark adaptation testing is one of the recommended methods for testing for vitamin A adequacy (IOM, Food and Nutrition Board, 2001).

Subsequent vitamin A deficiency leads to impaired embryonic development or spermatogenesis, spontaneous abortion, anemia, impaired immunocompetence (reduced numbers and mitogenic responsiveness of T lymphocytes), and fewer osteoclasts in bone. Vitamin A deficiency also leads to the keratinization of the mucous membranes that line the respiratory tract, alimentary canal, urinary tract, skin, and epithelium of the eye. Clinically these conditions manifest as poor growth, blindness caused by xerophthalmia, corneal ulceration, or occlusion of the optic foramina from periosteal overgrowth of the cranium. **Xerophthalmia**

**TABLE 3-11****Vitamin A Content of Selected Foods**

Food	RAE*
Turkey, 1 cup	15,534
Sweet potato, baked, 1 small	7,374
Carrots, raw, 1 cup	5,553
Spinach, cooked, 1 cup	6,882
Squash, butternut, 1 cup	2,406
Mixed vegetables, frozen, 1 cup	2,337
Apricots, canned, 1 cup	1,329
Cantaloupe, 1 cup	1,625
Broccoli, cooked, 1 cup	725
Brussel sprouts, 1 cup	430
Tomatoes, 1 cup	450
Peaches, canned, 1 cup	283

**DRLs**

Infants and young children, AI = 400-500 RAE/day, depending on age  
 Older children and adolescents, RDA = 600-900 RAE/day, depending on age  
 Adults, RDA = 700-900 RAE/day, depending on gender  
 Pregnant, RDA = 750-770 RAE/day, depending on age  
 Lactating, RDA = 1200-1300 RAE/day, depending on age

\*1 RAE = 1 mcg of retinol; RAE from plant sources calculated based on 12 mcg β-carotene = 1 RAE.

involves atrophy of the periocular glands, hyperkeratosis of the conjunctiva, softening of the cornea (keratomalacia), and blindness. The condition is now rare in the United States (usually associated with malabsorption), but it is more common in developing countries. In fact, vitamin A deficiency is the most significant cause of blindness in the developing world, and an estimated 250 million children are at risk. Between 250,000 and 500,000 cases of blindness from vitamin A deficiency occur annually. Millions of preschool children have xerophthalmia, and two thirds of those newly diagnosed die within months of going blind because of enhanced susceptibility to infections.

Vitamin A deficiency produces characteristic changes in skin texture involving follicular hyperkeratosis (phryno-derma). Blockage of the hair follicles with plugs of keratin causes the distinctive “goose flesh” or “toad skin”; and the skin becomes dry, scaly, and rough. At first the forearms and thighs are affected, but in advanced stages the whole body is affected (Figure 3-14). Loss of mucous membrane integrity increases susceptibility to bacterial, viral, or parasitic infections. The deficiency also leads to impairments in cell-mediated immunity, ultimately increasing the risk for infection, particularly respiratory infections.

**FIGURE 3-14** Follicular hyperkeratosis. Dry, bumpy skin associated with vitamin A or linoleic acid (essential fatty acid) deficiency. Linoleic acid deficiency may also result in eczematous skin, especially in infants. (From Taylor KB, Anthony LE: Clinical nutrition, New York, 1983, McGraw-Hill.)

Acute vitamin A deficiency is treated with large oral doses of vitamin A. When the deficiency is part of concomitant PEM, the malnutrition must be treated for the patient to benefit from vitamin A treatment. The signs and symptoms of deficiency respond to vitamin A supplementation in approximately the same order as they appear; night blindness responds very quickly, whereas the skin abnormalities may take several weeks to resolve. Massive, intermittent dosing with large doses of vitamin A has been used in developing countries. Treatments with single doses of 60,000 RAE of vitamin A have reduced child mortality by 35% to 70% (IOM, Food and Nutrition Board, 2001). However, Gogia and Sachdev (2009) recently concluded that there is no reduction in risk of infant mortality associated with neonatal vitamin A supplementation.

**Toxicity**

Persistent large doses of vitamin A (>100 times the required amount) overcome the capacity of the liver to store the vitamin, produce intoxication, and eventually lead to liver disease. This intoxication is marked by high plasma levels of retinyl esters associated with lipoproteins. Hypervitaminosis A in humans is characterized by changes in the skin and mucous membranes (Box 3-4). Dry lips (cheilitis) are a common initial sign, followed by dryness of the nasal mucosa and eyes. More advanced signs include dryness, erythema, scaling and peeling of the skin, hair loss, and nail fragility. Headache, nausea, and vomiting have also been reported. Animals with hypervitaminosis A frequently have bone abnormalities involving overgrowth of periosteal bone. An increased incidence of hip fractures was found in women with high vitamin A intakes (Feskanich et al., 2002).

Acute hypervitaminosis A can be induced by single doses of retinol greater than 200 mg (200,000 RAEs) in adults or

**BOX 3-4****Signs of Vitamin A Toxicity**

Serum vitamin A of 75-2000 RAE/100 mL

Bone pain and fragility

Hydrocephalus and vomiting (infants and children)

Dry, fissured skin

Brittle nails

Hair loss (alopecia)

Gingivitis

Cheilosis

Irritability

Fatigue

Hepatomegaly and abnormal liver function

Ascites and portal hypertension

RAE, Retinol activity equivalent.

depends on the amount of melanin in the skin, clothing type, blockage of effective rays by window glass, and use of sunscreens. Holick (2004) described sensible sun exposure as 5 to 10 minutes of exposure of the arms and legs or the hands, arms, and face, two or three times per week. This type of casual exposure seems to provide sufficient vitamin D to last through the winter months except in those unable or unwilling to go outside. For these individuals who get sun exposure in the summer and who live in the United States, the present level of fortification of foods with vitamin D has been thought to be adequate. However, 40% of all Americans may be vitamin-D deficient (Pietras et al., 2009).

Two sterols—one in the lipids of animals (7-dehydrocholesterol) and one in plants (ergosterol)—can serve as precursors of vitamin D. Each of these can undergo photolytic ring opening when exposed to ultraviolet irradiation. Ring opening of 7-dehydrocholesterol yields a provitamin form of 7-dehydrocholesterol, which yields **cholecalciferol**, or vitamin D<sub>3</sub> (Table 3-12). Ergosterol ring opening yields ergocalciferol, or vitamin D<sub>2</sub>. Vitamin D<sub>2</sub> requires further metabolism to yield the metabolically active form of 1,25-dihydroxyvitamin D (1,25[OH]<sub>2</sub>D<sub>3</sub>; **calcitriol**), vitamin D<sub>3</sub> (Figure 3-15). In this form, vitamin D<sub>3</sub> plays an important role in the maintenance of calcium homeostasis and healthy bones and teeth, as well as influencing hundreds of genes.

**Absorption, Transport, and Storage**

Dietary vitamin D is incorporated with other lipids into micelles and absorbed with lipids into the intestine by passive diffusion. Inside the absorptive cells, the vitamin is incorporated into chylomicrons, and enters the lymphatic system and finally the plasma, where it is delivered to the liver by chylomeric remnants or to the specific carrier vitamin D-binding protein (DBP), or transcalciferin. The efficiency of this absorption process is approximately 50%. Vitamin D synthesized in the skin from cholesterol enters the capillary system and is transported by DBP and delivered to the peripheral tissues. Little vitamin D is stored in the liver.

**Metabolism**

Vitamin D must be activated by two sequential hydroxylations. The first occurs in the liver and yields 25-hydroxyvitamin D<sub>3</sub> (25-hydroxycholecalciferol), the predominant circulating form. The second hydroxylation is carried out by the enzyme  $\alpha$ -1-hydroxylase in the kidney and yields 1,25(OH)<sub>2</sub>D<sub>3</sub>, the most active form. The activity of  $\alpha$ -1-hydroxylase is increased by parathyroid hormone (PTH) in the presence of low plasma concentrations of calcium, yielding increased production of 1,25(OH)<sub>2</sub>D<sub>3</sub> (calcitriol). The enzyme decreases when calcitriol levels increase (see Figure 3-15). In supplements and fortified foods, vitamin D is available as D-2 (ergocalciferol) and D-3 (cholecalciferol), yet controversy persists as to the overall effectiveness of D-2 supplementation and whether it can influence the serum level of D-3 (Stiff, 2009).

greater than 100 mg (100,000 RAEs) in children. Chronic hypervitaminosis A can result from chronic intakes (usually from misuse of supplements) greater than at least 10 times the AI (i.e., 4000 RAEs/day for an infant or 7000 RAEs/day for an adult). Dramatic stories in the literature describe reddening and exfoliation of the skin of Arctic explorers and fishermen who feasted on polar bear or halibut liver, both extremely high in vitamin A.

Retinoids can be toxic to embryos exposed in the womb. This is particularly true for 13-*cis*-retinoic acid (Accutane), a form very effective in treating severe cystic acne but that can cause craniofacial, central nervous system, cardiovascular, and thymic malformations in the fetus. Fetal malformations have also been linked to daily exposures of 6000 to 7500 RAEs of vitamin A from supplements, and pregnant women are advised against exceeding 3000 RAEs/day of vitamin A.

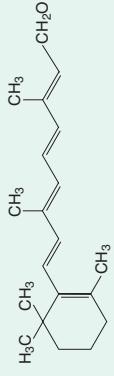

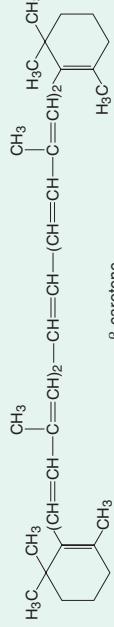

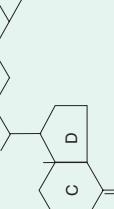

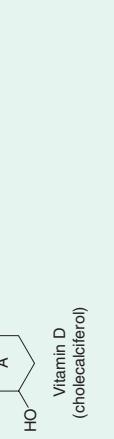

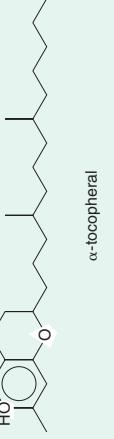

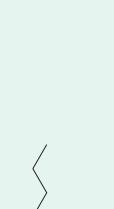

The toxicities of carotenoids are low, and daily intakes of as much as 30 mg of  $\beta$ -carotene have no side effects other than the accumulation of the carotenoid in the skin and consequent yellowing. However, high doses of  $\beta$ -carotene have been implicated as playing a role in some types of lung cancer, especially in smokers. **Hypercarotenodermia** differs from jaundice in that the former affects only the skin, leaving the sclera (white) of the eye clear. Hypercarotenodermia is reversible if excessive carotene intake is decreased.

**Vitamin D (Calciferol)**

Vitamin D is known as the “sunshine vitamin” because modest exposure to sunlight should be sufficient for most people to produce their own vitamin D using ultraviolet light and cholesterol in the skin. Because the vitamin can be produced in the body, has specific target tissues, and does not have to be supplied in the diet, it performs as a steroid hormone.

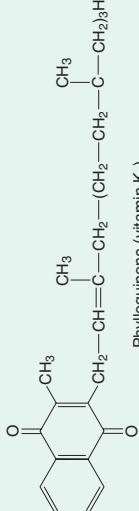

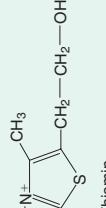

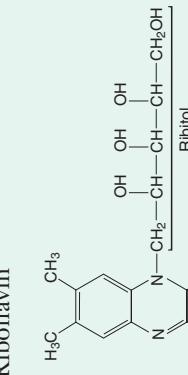

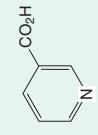

Brief and casual exposure of the face, arms, and hands to sunlight should be promoted. Ultraviolet light penetration

**TABLE 3-12**  
**Summary of Vitamins**

Fat-Soluble Vitamins	RDA for Adults	Sources	Stability	Comments
Vitamin A (retinol; $\alpha$ -, $\beta$ -, $\gamma$ -carotene)	M: 900 RAE F: 700 RAE	Liver, kidney, milk fat, fortified margarine, egg yolk, yellow and dark-green leafy vegetables, apricots, cantaloupe, peaches	Stable in presence of light, heat, and usual cooking methods. Destroyed by oxidation, drying, very high temperature, ultraviolet light.	Essential for normal growth, development, and maintenance of epithelial tissue. Essential for the integrity of night vision. Helps promote normal bone development and influences normal tooth formation. Functions as antioxidant. Toxic in large quantities.
All-trans-retinal				
				
				
Vitamin D (calciferol)	M & F 600 IU/day. Over age 70, 800 IU/day.	Vitamin D-fortified milk, irradiated foods, some in milk fat, liver, egg yolk, salmon, tuna fish, sardines	Stable in presence of heat and oxidation.	Is a prohormone. Essential for normal growth and development; important for formation and maintenance of normal bones and teeth. Influences absorption and metabolism of phosphorus and calcium. Toxic in large quantities.
				
				
Vitamin D (cholecalciferol)	M: 15 $\alpha$ -TE F: 15 $\alpha$ -TE	Wheat germ, vegetable oils, green leafy vegetables, milk fat, egg yolk, nuts	Stable in presence of heat and acids. Destroyed by rancid fats, alkali, oxygen, lead, iron salts, and ultraviolet irradiation.	Is a strong antioxidant. May help prevent oxidation of unsaturated fatty acids and vitamin A in intestinal tract and body tissues. Protects red blood cells from hemolysis. Role in reproduction (in animals). Role in epithelial tissue maintenance and prostaglandin synthesis.
				
Vitamin E (tocopherols and tocotrienols)

**TABLE 3-12**  
**Summary of Vitamins—cont'd**

<b>Summary of Vitamins—cont'd</b>	<b>RDA for Adults</b>	<b>Sources</b>	<b>Stability</b>	<b>Comments</b>
Vitamin K (phylloquinone and menaquinone)  Phylloquinone (vitamin K <sub>1</sub> )	M: 120 mcg F: 90 mcg AI	Liver, soybean oil, other vegetable oils, green leafy vegetables, wheat bran	Resistant to heat, oxygen, and moisture. Destroyed by alkali and ultraviolet light.	Aids in production of prothrombin, a compound required for normal clotting of blood. Involved in bone metabolism. Toxic in large amounts.
<b>Water-Soluble Vitamins</b>				
Thiamin 	M: 1.2 mg F: 1.1 mg	Pork liver, organ meats, legumes, whole-grain and enriched cereals and breads, wheat germ, potatoes	Unstable in presence of heat, alkali, or oxygen. Heat stable in acid solution.	As part of cocarboxylase, aids in removal of CO <sub>2</sub> from α-keto acids during oxidation of carbohydrates. Essential for growth, normal appetite, digestion, and healthy nerves.
Riboflavin 	M: 1.3 mg F: 1.1 mg	Milk and dairy foods, organ meats, green leafy vegetables, enriched cereals and breads, eggs	Stable in presence of heat, oxygen, and acid. Unstable in presence of light (especially ultraviolet) or alkali.	Essential for growth. Plays enzymatic role in tissue respiration and acts as a transporter of hydrogen ions. Coenzyme forms FMN and FAD.
Niacin (nicotinic acid and nicotinamide) 	M: 16 mg NE F: 14 mg NE	Fish, liver, meat, poultry, many grains, eggs, peanuts, milk, legumes, enriched grains	Stable in presence of heat, light, oxidation, acid, and alkali.	As part of enzyme system, aids in transfer of hydrogen and acts in metabolism of carbohydrates and amino acids. Involved in glycolysis, fat synthesis, and tissue respiration.
Nicotinic acid (niacin)				

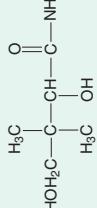

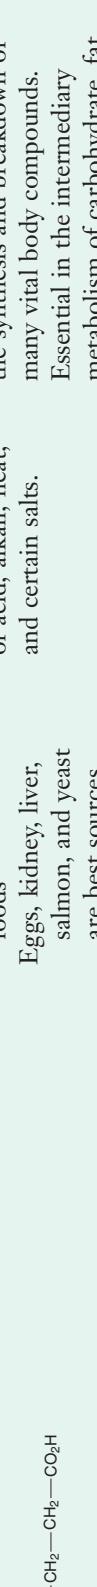

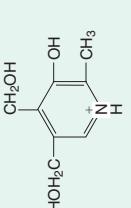

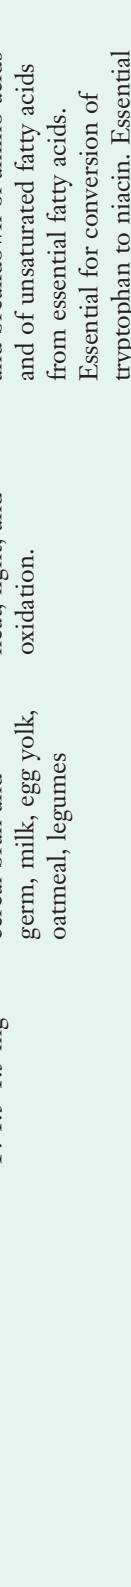

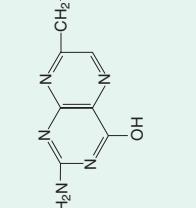

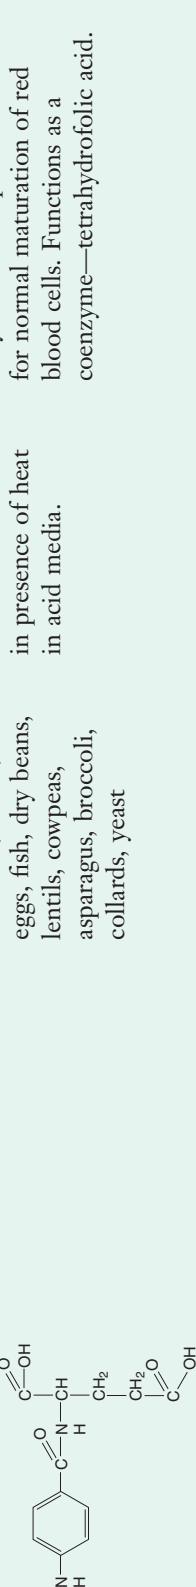

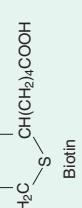

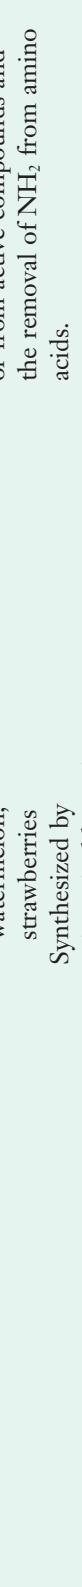

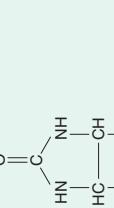

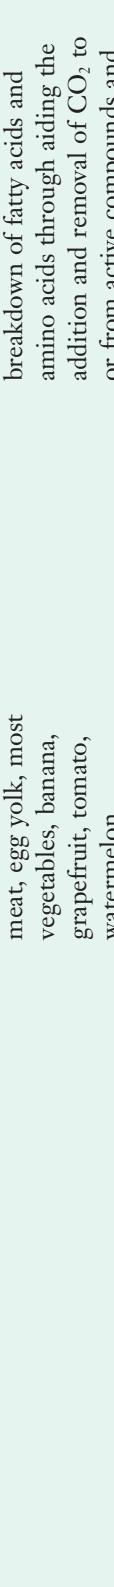

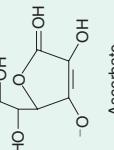

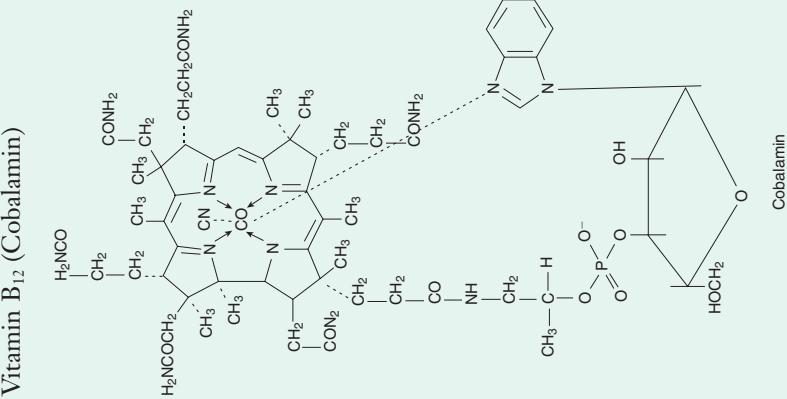

Pantothenic acid 	5 mg AI  	All plant and animal foods Eggs, kidney, liver, salmon, and yeast are best sources. Possibly synthesized by intestinal bacteria.	Unstable in presence of acid, alkali, heat, and certain salts. Stable in presence of heat, light, and oxidation.	As part of coenzyme A, functions in the synthesis and breakdown of many vital body compounds. Essential in the intermediary metabolism of carbohydrate, fat, and protein.
Vitamin B <sub>6</sub> (pyridoxine, pyridoxal, and pyridoxamine) 	M: 1.3-1.7 mg F: 1.3-1.5 mg  	Pork, glandular meats, cereal bran and germ, milk, egg yolk, oatmeal, legumes	Stable in presence of heat, light, and oxidation.	As a coenzyme, aids in the synthesis and breakdown of amino acids and of unsaturated fatty acids from essential fatty acids. Essential for conversion of tryptophan to niacin. Essential for normal growth.
Pyridoxine (PN) 	400 mcg  	Green leafy vegetables, organ meats (liver), lean beef, wheat, eggs, fish, dry beans, lentils, cowpeas, asparagus, broccoli, collards, yeast	Stable in presence of sunlight when in solution. Unstable in presence of heat in acid media.	Essential for biosynthesis of nucleic acids—especially important in early fetal development. Essential for normal maturation of red blood cells. Functions as a coenzyme—tetrahydrofolic acid.
Folate (folic acid, folacins) 	30 mcg AI  	Liver, mushrooms, peanuts, yeast, milk, meat, egg yolk, most vegetables, banana, grapefruit, tomato, watermelon, strawberries Synthesized by intestinal bacteria.	Stable under most conditions.	Essential component of enzymes. Involved in synthesis and breakdown of fatty acids and amino acids through aiding the addition and removal of CO <sub>2</sub> to or from active compounds and the removal of NH <sub>2</sub> from amino acids.
Biotin 	30 mcg AI  			Continued

TABLE 3-12

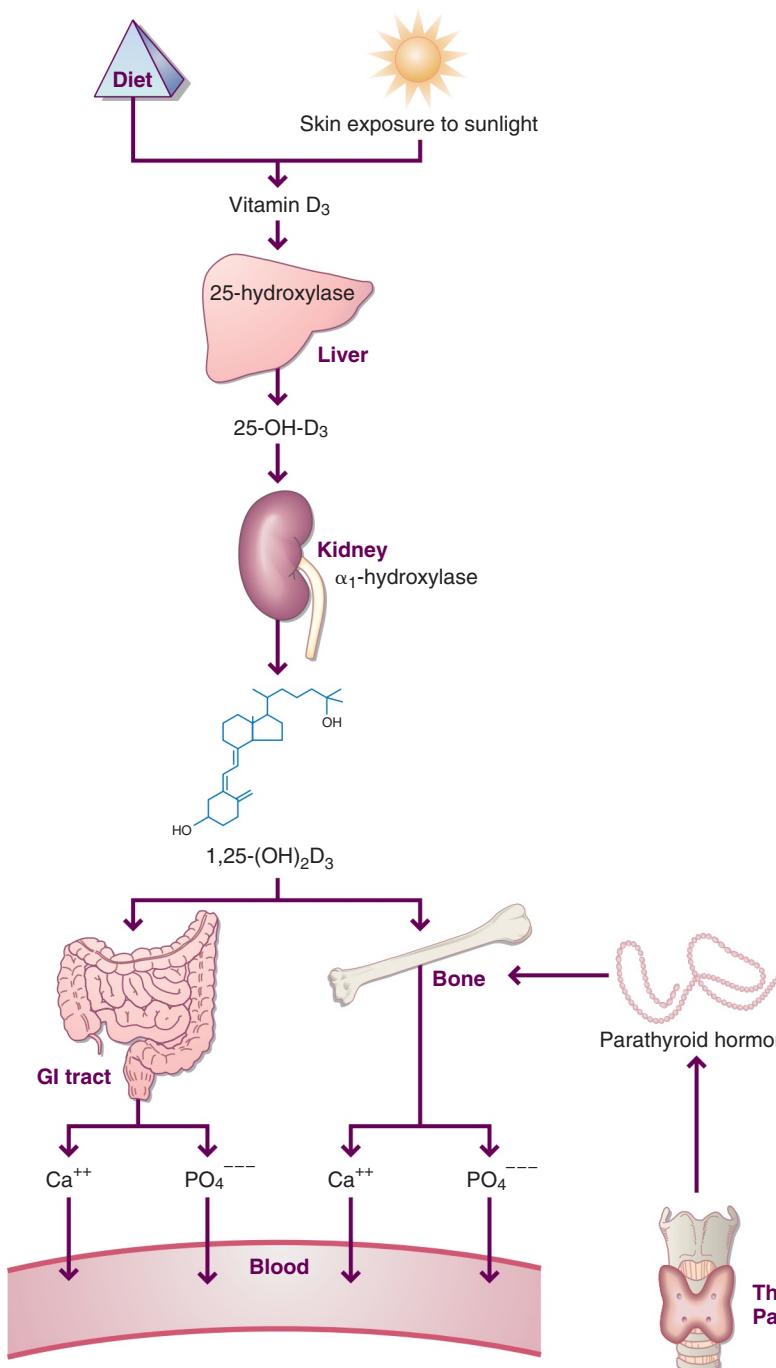

## Summary of Vitamins—cont'd

	RDA for Adults	Sources	Stability	Comments
Vitamin C (ascorbic acid) 	M: 90 mg F: 75 mg	Acerola (West Indian cherry-like fruit), citrus fruit, tomato, melon, peppers, greens, raw cabbage, guava, strawberries, pineapple, potato, kiwi	Unstable in presence of heat, alkali, and oxidation, except in acids. Destroyed by storage.	Maintains intracellular cement substance with preservation of capillary integrity. Cosubstrate in hydroxylations requiring molecular oxygen. Important in immune responses, wound healing, and allergic reactions. Increases absorption of nonheme iron.
Vitamin B <sub>12</sub> (Cobalamin)	2.4 mcg	Liver, kidney, milk and dairy foods, meat, eggs  Vegans require supplement.	Slowly destroyed by acid, alkali, light, and oxidation.	Involved in the metabolism of single-carbon fragments. Essential for biosynthesis of nucleic acids and nucleoproteins. Role in metabolism of nervous tissue. Involved with folate metabolism. Related to growth.

Cobalamin

$\alpha$ -TE,  $\alpha$ -Tocopherol equivalents; AI, adequate intake; F, female; EAD, flavin adenine dinucleotide; FMN, flavin adenine mononucleotide; M, male; NE, niacin equivalents; RAE, retinol activity equivalents; RDAs, recommended dietary allowance.

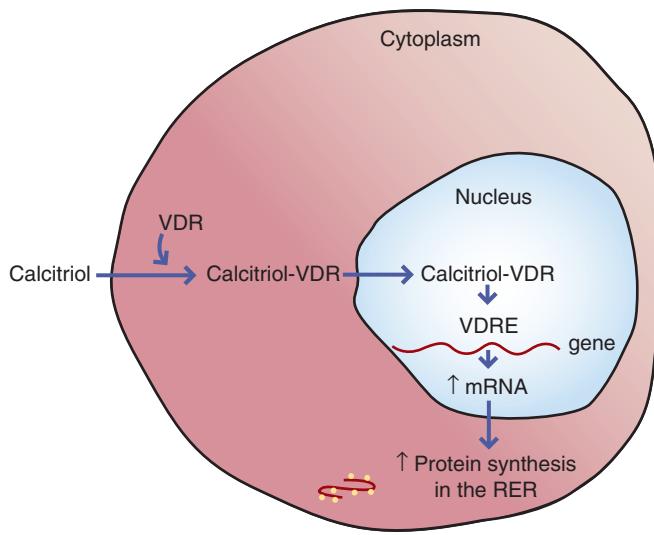

**FIGURE 3-15** Metabolism and function of vitamin D. Vitamin D<sub>3</sub> (cholecalciferol) changes into its biologically active forms: 25-(OH)D<sub>3</sub> and 1,25-(OH)<sub>2</sub>D<sub>3</sub>(calcitriol). Calcitriol increases calcium and phosphate absorption in the intestine, increases calcium and phosphate resorption in bone, and acts on the kidney to decrease calcium loss in urine.

## Functions

Calcitriol (1,25[OH]<sub>2</sub>D<sub>3</sub>) functions primarily like a steroid hormone. Its major actions involve interaction with cell membrane receptors and nuclear vitamin D receptor (VDR) proteins to affect gene transcription in a wide variety of tissues. When calcitriol binds to VDR proteins in the nucleus, the affinity of the VDR proteins for specific promoter regions of the genes—vitamin D response elements (VDRE)—increases, allowing the VDR-calcitriol complex to bind to the VDRE. Once the VDR-calcitriol complex is attached to the VDRE region, transcription for specific

mRNAs for specific proteins is either promoted or inhibited (Figure 3-16).

More than 50 genes are known to be regulated by vitamin D (Omdahl et al., 2002). Although most of the genes regulated by vitamin D are unrelated to mineral metabolism, this is its most widely recognized function. Vitamin D maintains calcium and phosphorus homeostasis in three major ways. First, through gene expression, calcitriol in the small intestine enhances the active transport of calcium across the gut, which stimulates synthesis of calcium-binding proteins (including calbindin) in the mucosal brush border. These

**FIGURE 3-16** Role of vitamin D in gene expression. *RER*, Rough endoplasmic reticulum; *VDR*, vitamin D receptor protein; *VDRE*, vitamin D response elements.

proteins then increase calcium absorption. Phosphate absorption is also increased by enhancing acid phosphatase activity, which cleaves phosphate esters and allows increased phosphorus absorption. Second, PTH, along with calcitriol or estrogen, moves calcium and phosphorus from the bone to maintain normal blood levels. The process most probably involves increased osteoclast activity, increased numbers of new osteoclasts through cell differentiation, or both. Third, in the kidney, calcitriol increases renal tubular reabsorption of calcium and phosphate. These activities are coordinated to maintain plasma calcium concentrations within a narrow range. Calcitonin is secreted by the thyroid to counter the activity of calcitriol and PTH; it suppresses bone mobilization and increases the renal excretion of calcium and phosphate.

Calcitriol plays important roles in cell differentiation, proliferation, and growth in the skin, muscles, pancreas, nerves, parathyroid gland, and immune system. It influences the onset of conditions as diverse as multiple sclerosis (Simon et al., 2010), cardiovascular disease (Artaza et al., 2009), proteinuria, and diabetic nephropathy (Agarwal, 2009). Vitamin D has paracrine functions through local activation by 1-alpha-hydroxylase and thus maintains immunity, vascular function, and cardiomyocyte health; it reduces inflammation and insulin resistance (Agarwal, 2009). Randomized, controlled trials are needed to determine whether vitamin D supplements during pregnancy and early in life might protect against these disorders.

### Dietary Reference Intakes

The preferred units for quantification of vitamin D are micrograms (mcg) of vitamin D<sub>3</sub>. Both vitamins D<sub>2</sub> and D<sub>3</sub> are used to quantify total vitamin D. International Units (IU) are still used on some labels. Vitamin D<sub>3</sub> in 1 IU equals 0.025 mcg of vitamin D<sub>3</sub>, and 1 mcg of vitamin D<sub>3</sub> equals 40 IU of vitamin D<sub>3</sub>.

The DRIs for vitamin D are a mix of RDA and AIs, set to meet the body's needs when a person has inadequate exposure to sunlight. The tolerable upper intake levels (ULs) are set at those considered to pose no risk of adverse effects. Although 2.5 mcg (100 IU) of vitamin D daily is sufficient to prevent vitamin D-deficiency rickets, higher levels are recommended (AI = 400 IU/day for infants; RDA = 600 IU/day for children) during skeletal development. Adults require continual bone remodeling and adequate calcium and phosphorus homeostasis. The RDA for adults 71 years and older is 800 IU/day.

The UL for vitamin D for infants is 1000–1500 IU/day, 2500–3000 IU/day for children, and 2000–2500 IU/day for adults.

The normal adult is presumed to obtain sufficient vitamin D from exposure to sunlight and incidental ingestion through small amounts in foods. However, increasing evidence suggests that vitamin D status is low (Parks and Johnson, 2005; Pettifor, 2005) and increasing vitamin D intake has been recommended. However, recently the IOM, Food and Nutrition Board (2010) reported that vitamin D deficiencies were likely overestimated and set the RDA for normal individuals at 600 IU.

Pietras et al. (2009) and Holick and Chen (2008) have recommended that the AI for vitamin D be increased (800–1000 IU) in normal individuals and much higher for treatment of individuals with bone disease and a vitamin D deficiency. Supplemental vitamin D is especially appropriate for individuals consistently shielded from sunlight, such as those who are housebound, live in northern latitudes or areas with high atmospheric pollution, wear clothing that completely covers the body, or work at night and stay indoors during the day.

Milk continues to be a food of choice for vitamin D fortification because of its calcium content. Soy milks and other nondairy milks are now often fortified with the same amount of vitamin D and calcium found in cow's milk. However, milk and infant formulas may not always contain the amount stated on the label; fortification of other foods such as pasta and orange juice should be considered (Holick, 2006; 2007). Caution is necessary to avoid overfortification and under-fortification; a unified fortification monitoring program is needed (Calvo et al., 2004).

### Sources

Vitamin D<sub>3</sub> exists naturally in animal products, and the richest sources are fish liver oils. It is found in only small and highly variable amounts in butter, cream, egg yolk, and liver. Human milk and unfortified cow's milk tend to be poor sources of vitamin D<sub>3</sub>, providing only 0.4 to 1 mcg/L. However, approximately 98% of all fluid milk sold in the United States is fortified with vitamin D<sub>2</sub> (usually 10 mcg [400 IU/qt]), as is most dried whole milk, evaporated milk, some margarines, butters, soy milks, certain cereals, and all infant formula products. Vitamin D is very stable and does not deteriorate when foods are heated or stored for long periods (Table 3-13; see also Appendix 51).

**TABLE 3-13****Vitamin D Content of Selected Foods**

Food	IUs per serving IUs = International Units
Cod liver oil, 1 tablespoon	1360
Salmon (sockeye), cooked, 3 ounces	794
Mackerel, cooked, 3 ounces	388
Tuna fish, canned in water, drained, 3 ounces	154
Milk, nonfat, reduced fat, and whole, vitamin D-fortified, 1 cup	115-124
Orange juice fortified with vitamin D, 1 cup (check product labels, as amount of added vitamin D varies)	100
Yogurt, fortified with 20% of the DV for vitamin D, 6 ounces (more heavily fortified yogurts provide more of the DV)	80
Margarine, fortified, 1 tablespoon	60
Sardines, canned in oil, drained, 2 sardines	46
Liver, beef, cooked, 3.5 ounces	46
Ready-to-eat cereal, fortified with 10% of the DV for vitamin D, 0.75-1 cup (more heavily fortified cereals might provide more of the DV)	40
Egg, 1 whole (vitamin D is found in yolk)	25
Cheese, Swiss, 1 ounce	6
<b>DRI*</b>	
Infants	10 mcg (400 IU)
Children and adolescents	15 mcg (600 IU)
Adults	15 mcg (600 IU)
Adults > age 70	20 mcg (800 IU)
Pregnant	15 mcg (600 IU)
Lactating	15 mcg (600 IU)

**Deficiency**

Vitamin D deficiency manifests as rickets in children and as osteomalacia in adults. Vitamin D deficiency can also precipitate and exacerbate osteoporosis and fractures in adults and is associated with increased risk of common cancers, autoimmune diseases, hypertension, and infectious diseases (Holick and Chen, 2008). Inadequate vitamin D intake is

prevalent around the world, regardless of age or health status (Pietras et al., 2009). A level of 30 ng/mL is considered the minimum level for sufficient serum 25-hydroxy vitamin D (Holick, 2007).

**Rickets.** **Rickets** is a disease involving impaired mineralization of growing bones. It is the result not only of deprivation of vitamin D, but of deficiencies of calcium and phosphorus. Rickets is characterized by structural abnormalities of the weight-bearing bones (e.g., tibia, ribs, humerus, radius, ulna) as in Figure 3-17. Bone pain, muscular tenderness, hypocalcemic tetany, and soft, pliable, rachitic bones occur. This results in bowed legs, “knock knees,” beaded ribs (the rachitic rosary), pigeon breast, and frontal bossing of the skull. Radiography reveals enlarged epiphyseal growth plates manifested as enlarged wrists and ankles resulting from their failure to mineralize and continue growth. Increased plasma and serum levels of alkaline phosphatase occur when released by the affected osteoblasts.

Historically, rickets has afflicted poor children in industrialized cities where exposure to sunlight is limited. In North America the vitamin D supplementation of foods virtually eliminated the disease. However, the incidence of vitamin D-dependent rickets is increasing again. The children most at risk have dark skin and are breastfed for long periods without exposure to sunlight or vitamin D supplements (Holick, 2006). Rickets can also develop in children with chronic problems of lipid malabsorption and in those undergoing long-term anticonvulsant therapy (which reduces the circulating levels of 1,25[OH]<sub>2</sub>D<sub>3</sub>).

Rickets caused strictly by vitamin D deprivation can be treated effectively with oral preparations of the vitamin or natural sources rich in the vitamin. Vitamin D concentrates of fish-liver oil may be prescribed; 1 teaspoon (4 mL) of cod-liver oil contains 9 mcg (360 IU) of vitamin D. For those with calcium deficiency-related or hypophosphatemic vitamin D-refractory rickets, vitamin D treatment alone may not be effective, and active vitamin D metabolites such as 25-(OH)D<sub>3</sub> or 1,25(OH)<sub>2</sub>D<sub>3</sub>, or a synthetic analog become necessary.

**Osteomalacia.** Osteomalacia develops in adults whose epiphyseal closures make that portion of the bone resistant to vitamin D deficiency. Therefore the disease involves generalized reductions in bone density and the presence of pseudofractures, especially of the spine, femur, and humerus. Patients experience muscular weakness with associated increase in fall risk as well as bone pain and have a greater risk of fractures, particularly of the wrist and pelvis. These nonspecific symptoms can lead to misdiagnosis of osteomalacia as fibromyalgia, chronic fatigue syndrome, or depression (Holick, 2007).

Prevention of osteomalacia is usually possible with an adequate consumption of vitamin D, calcium, and phosphorus in the diet. It has been estimated that as little as 10 to 15 minutes of sun exposure on a clear summer day two or three times a week is sufficient to prevent osteomalacia among most older adults. Osteomalacia can be treated effectively with vitamin D<sub>3</sub> in doses of 25 to 125 mcg (1000 to

**FIGURE 3-17** Severely bowed legs caused by rickets, an indication of vitamin D and calcium deficiencies in children. Rickets is a disorder of cartilage cell growth and enlargement of epiphyseal growth plates. (*From Latham MC et al: Scope manual on nutrition, Kalamazoo, Mich., 1980, The Upjohn Company.*)

1250 IU/day); in those whose conditions are complicated by lipid malabsorption, daily doses as large as 1250 mcg (12,500 IU) have been used.

**Osteoporosis.** Osteoporosis differs from osteomalacia; it involves diminished bone mass but with retention of a normal histologic appearance. Osteoporosis is a multifactorial disease involving impaired vitamin D metabolism and function, often associated with low or decreasing estrogen levels. It is the most common bone disease of postmenopausal women, but it also develops in older men. Chronic use of the active form  $1,25(\text{OH})_2\text{D}_3$  by women can delay the onset and show some reversal of the signs and symptoms of osteoporosis.

### Toxicity

Excessive intake of vitamin D can produce intoxication characterized by elevated serum calcium (hypercalcemia) and phosphorus (hyperphosphatemia) levels and ultimately the calcification of soft tissues (calcinosis), including the kidney, lungs, heart, and even the tympanic membrane of the ear, which can result in deafness. Patients often complain of headache and nausea (Box 3-5). Infants given excessive amounts of vitamin D may have GI upset, bone fragility, and retarded growth.

Hypervitaminosis D is progressive; individuals seem to vary in their susceptibility to the condition. The UL for

### BOX 3-5

#### Signs of Vitamin D Toxicity

- Excessive calcification of bone
- Kidney stones
- Metastatic calcification of soft tissues (kidney, heart, lung, and tympanic membrane)
- Hypercalcemia
- Headache
- Weakness
- Nausea and vomiting
- Constipation
- Polyuria
- Polydipsia

vitamin D is 1000 IU/day for infants up to age 6 months; 1500 IU/day for infants 6 to 12 months; 2500 IU/day for ages 1-3 years; 3000 IU/day for children aged 4-8 years. Infants and small children are most susceptible to hypervitaminosis D. In children aged 9 through all older age groups, the IU is 4000 IU/day.

### Vitamin E

Vitamin E has a fundamental role in protecting the body against the damaging effects of reactive oxygen species that are formed metabolically or encountered in the environment. Vitamin E includes two classes of biologically active substances: (1) the **tocopherols** and (2) the related but less biologically active compounds, the tocotrienols. The vitamins are named according to the position and number of methyl groups on their ring systems. The most important of these is  $\alpha$ -tocopherol (see Table 3-12) in the natural D-isomer form.

### Absorption, Transport, and Storage

Vitamin E is absorbed in the upper small intestine by micelle-dependent diffusion; its use depends on the presence of dietary fat and adequate biliary and pancreatic function. The esterified forms of vitamin E found in supplements are more stable and can be absorbed only after hydrolysis by esterases at the duodenal mucosa. However, esters of natural and synthetic  $\alpha$ -tocopherol are digested equally well (IOM, Food and Nutrition Board, 2000a). The absorption of vitamin E is highly variable, and efficiencies range from 20% to 70%. Absorbed vitamin E is incorporated into chylomicrons and transported into the general circulation via lymph. Vitamin E delivered to the liver is incorporated into VLDLs using a transport protein specific for vitamin E. In the plasma, tocopherol is also partitioned into LDLs and HDLs, where it may protect the lipoproteins from oxidation.

The cellular uptake of vitamin E can occur either as a receptor-mediated process (in which LDLs deliver the vitamin into the cell) or as a process mediated by lipoprotein lipase (LPL) as vitamin E is released from chylomicrons and

VLDLs by the action of LPL. Within the cell, intracellular transport of the tocopherol requires an intracellular tocopherol-binding protein. In most nonadipose cells, vitamin E is located almost exclusively in membranes. In adipose tissues it is not readily mobilized.

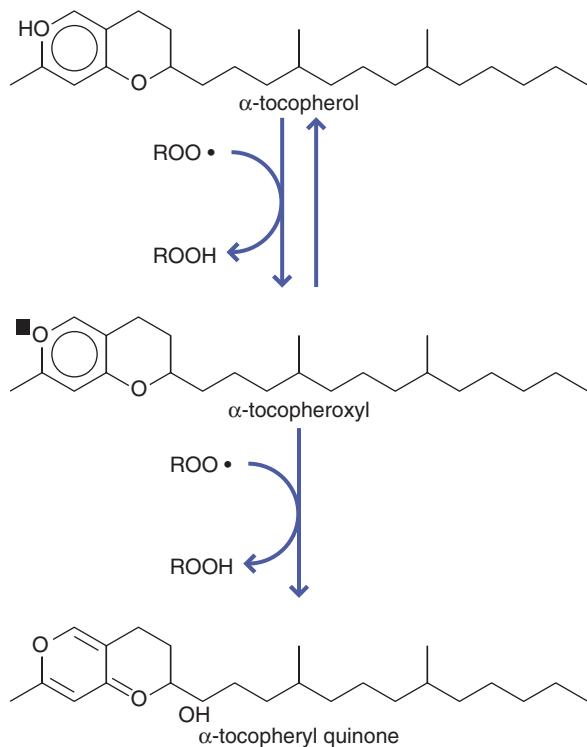

## Metabolism

The metabolism of vitamin E is limited. It is primarily oxidized into the biologically inactive tocopheryl quinone, which can be reduced to tocopheryl hydroquinone. Glucuronic acid conjugates of the hydroquinone are secreted in the bile, making excretion in the feces the major route of elimination of the vitamin. With usual intakes of vitamin E, a very small portion is excreted in the urine as water-soluble, side-chain metabolites (tocopheronic acid and tocopheronolactone).

## Functions

Vitamin E is the most important lipid-soluble **antioxidant** in the cell. Located in the lipid portion of cell membranes, it protects unsaturated phospholipids of the membrane from oxidative degradation from highly reactive oxygen species and other **free radicals**. Vitamin E performs this function through its ability to reduce such radicals into harmless metabolites by donating a hydrogen to them (**Figure 3-18**), which is called *free radical scavenging*.

As a membrane free radical scavenger, vitamin E is an important component of the cellular antioxidant defense

**FIGURE 3-18** Mechanism of vitamin E scavenging oxygen-centered free radicals. (From Combs GF: The vitamins: fundamental aspects in nutrition and health, ed 2, Orlando, 1998, Academic Press.)

system, which involves other enzymes (e.g., superoxide dismutases [SODs], glutathione peroxidases [GSH-Pxs], glutathione reductase [GR], catalase, thioredoxin reductase [TR]), and nonenzymatic factors (e.g., glutathione, uric acid), many of which depend on other essential nutrients. For example, GSH-Px and TR depend on adequate selenium status; SODs depend on adequate copper, zinc, and manganese statuses; and the activity of GR depends on adequate riboflavin status. Therefore the antioxidant function of vitamin E can be affected by the levels of many other nutrients.

This antioxidant function suggests that vitamin E and related nutrients may collectively be important in protecting the body against and treating conditions related to oxidative stress. However, care must be taken in making broad statements regarding these antioxidant effects. Although vitamin E is known to inhibit processes related to the development of atherosclerosis, clinical trials using supplements have given variable results, mostly negative (Weinberg, 2005). Recent evidence has indicated that vitamin E also functions in regulation of cell signaling processes and gene expression, particularly of drug metabolizing enzymes (Brigelius-Flohe, 2005).

## Dietary Reference Intakes

Vitamin E is quantified in terms of  $\alpha$ -tocopherol equivalents ( $\alpha$ -TEs); 1 mg of R,R,R- $\alpha$ -tocopherol is defined as 1  $\alpha$ -TE, and 1 mg of the synthetic all-rac- $\alpha$ -tocopherol is defined as 0.5  $\alpha$ -TE. Although outdated, International Units of vitamin E are still found on food labels. An International Unit of vitamin E is equal to 0.67 mg of RRR- $\alpha$ -tocopherol and 1 mg of all-rac- $\alpha$ -tocopherol (IOM, Food and Nutrition Board, 2000a). The DRIs for vitamin E have been established (IOM, Food and Nutrition Board 2000a) with AIs for infants and recommended dietary allowances (RDAs) for children and adults based solely on the  $\alpha$ -tocopherol form of the vitamin because other forms are not converted to  $\alpha$ -tocopherol in humans. The need for vitamin E depends in part on the amount of PUFAs consumed. For Americans, typical intakes are approximately 0.4 mg  $\alpha$ -TE/mg of PUFAs; because the United States does not have significant vitamin E deficiency problems, this ratio is thought to be adequate.

## Sources

Tocopherols and tocotrienols are synthesized only by plants; plant oils are the best sources of them, with  $\alpha$ - and  $\gamma$ -tocopherols being the forms in most common foods. Nearly two thirds of the vitamin E in the typical American diet is supplied by salad oils, margarines, and shortenings, approximately 11% by fruits and vegetables, and approximately 7% by grains and grain products. Table 3-14 and Appendix 49 list the vitamin E content of selected foods (IOM, Food and Nutrition Board, 2000a).

The free alcohol forms of vitamin E (e.g., tocopherols) are fairly stable but can be destroyed by oxidation. Vitamin E esters (e.g., tocopheryl acetate) are very stable, even in oxidizing conditions. Because the vitamers E are insoluble

**TABLE 3-14****Vitamin E Content of Selected Foods**

Food	$\alpha$ -TE (mg)
Raisin bran, 1 cup	13.50
Almonds, 1 oz	7.33
Sunflower oil, 1 tbsp	5.59
Mixed nuts 1 oz	3.10
Canola oil, 1 tbsp	2.39
Asparagus, 1 cup	2.16
Peanut oil, 1 tbsp	2.12
Corn oil, 1 tbsp	1.94
Olive oil, 1 tbsp	1.94
Apricots, canned, sweetened, ½ cup	1.55
Margarine, 1 tbsp	1.27
Flounder, 3 oz	0.56
Cashews, 1 oz	0.26
Baked beans, canned with pork, 1 cup	0.25

DRIs	
Infants	4-5 $\alpha$ -TE (mg)/day, depending on age
Young children	6-7 $\alpha$ -TE (mg)/day, depending on age
Older children and adolescents	11-15 $\alpha$ -TE (mg)/day, depending on age
Adults	15 $\alpha$ -TE (mg)/day
Pregnant	15 $\alpha$ -TE (mg)/day
Lactating	19 $\alpha$ -TE (mg)/day

From U.S. Department of Agriculture, Agricultural Research Service: Nutrient Database for Standard Reference, Release 18, Data Laboratory home page: <http://www.nal.usda.gov/fnic/foodcomp/Data/SR18/nutrlst/sr18w323.pdf>; accessed 2011.

$\alpha$ -TE,  $\alpha$ -Tocopherol equivalents; DRI, dietary reference intake.

in water, they are not lost by cooking in water but can be destroyed by deep-fat frying.

### Deficiency

The clinical manifestations of vitamin E deficiency vary considerably. In general, the targets of deficiency are the neuromuscular, vascular, and reproductive systems. Vitamin E deficiency, which may take 5 to 10 years to develop, manifests with loss of deep tendon reflexes, impaired vibratory and position sensation, changes in balance and coordination, muscle weakness, and visual disturbances (Sokol, 2001). Symptoms in humans have occurred only in those with lipid malabsorption attributable to diseases such as biliary atresia or exocrine pancreatic insufficiency or with lipid transport abnormalities like abetalipoproteinemia.

At the cellular level, a deficiency of vitamin E is accompanied by an increase in lipid peroxidation of the cell membrane. Because of this, vitamin E-deficient cells exposed to an oxidant stress experience more rapid injury and necrosis.

Because there is limited transplacental movement of vitamin E, newborn infants have low tissue concentrations of vitamin E and premature infants may be at risk for vitamin E deficiency (see Chapter 43).

### Toxicity

Vitamin E is one of the least toxic of the vitamins. Humans and animals seem to be able to tolerate relatively high intakes—at least 100 times the nutritional requirement. The UL for vitamin E in adults is 1000 mg/day. However, in very high doses, vitamin E can decrease the body's ability to use other fat-soluble vitamins. Animals fed excessive amounts of vitamin E have impaired bone mineralization, hepatic vitamin A storage, and blood coagulation (Traber, 2008). In the last few years, conflicting data regarding high-dose supplementation of vitamin E and increased mortality of patients with cardiovascular disease, inflammatory joint diseases, and cancer have been noted. A causal relationship of vitamin E supplementation and increased mortality is questionable and should have further study (Gerss and Kopcke, 2009).

### Vitamin K

Scientists now know that **vitamin K** plays a role in blood clotting, bone formation, and regulation of multiple enzyme systems (Denisova and Booth, 2005). Naturally occurring forms of vitamin K are the phylloquinones (the vitamin K<sub>1</sub> series), which are synthesized by green plants, and the **menaquinones** (the vitamin K<sub>2</sub> series), which are synthesized by bacteria. Both of these natural forms have a 2-methyl-1,4-naphthoquinone ring and alkylated side chains (see Table 3-12). The synthetic compound **menadione** (vitamin K<sub>3</sub>) has no side chain but can be alkylated in the liver to produce menaquinones. Menadione is twice as potent biologically as the naturally occurring forms vitamins K<sub>1</sub> and K<sub>2</sub>.

### Absorption, Transport, and Storage

The phylloquinones (K<sub>1</sub>) are absorbed by an energy-dependent process in the small intestine. However, the menaquinones (K<sub>2</sub>) and menadione (K<sub>3</sub>) are absorbed in the small intestine and colon by passive diffusion. Like the other fat-soluble vitamins, absorption depends on a minimum amount of dietary fat and on bile salts and pancreatic juices. The absorbed vitamers K are incorporated into chylomicrons in the lymph and taken to the liver, where they are incorporated into VLDLs and subsequently delivered to the peripheral tissues by LDLs.

Vitamin K is found in low concentrations in many tissues, where it is localized in cellular membranes. Because of the metabolism of the vitamin, tissues show mixtures of vitamers K even when a single form is consumed. Most tissues contain phylloquinones and menaquinones.

### Metabolism

Phylloquinones can be converted to menaquinones by successive bacterial dealkylation and realkylation before absorption. Side-chain shortening and oxidation produce

metabolites that are excreted in the feces via the bile, frequently as glucuronic acid conjugates, and catabolize phylloquinones and menaquinones. Menadione is metabolized more rapidly; it is excreted primarily in the urine as a phosphate, sulfate, or glucuronide derivative.

## Functions

Vitamin K is essential for the posttranslational carboxylation of glutamic acid residues in proteins to form carboxyglutamate ([GLA] residues); the residues bind calcium. In the process of generating residues, vitamin K is oxidized to an epoxide. It is restored to its hydroquinone form by the enzyme epoxide reductase (Figure 3-19). This process is known as the *vitamin K cycle*. The vitamin K cycle can be disrupted by coumarin-type drugs such as warfarin and dicumarol, which is the basis for their anticoagulant activities. Patients taking these anticoagulant drugs do not need to eliminate vitamin K from their diets but should maintain a consistent level of vitamin K intake.

Four plasma-clotting GLA proteins have been identified, including thrombin, which is necessary for the conversion of fibrinogen to fibrin in blood clotting. In addition, at least three proteins are found in calcified tissues (osteocalcin being one) and at least one protein is found in calcified atherosclerotic tissue (atherocalcin).

Vitamin K regulates enzymes involved in sphingolipid metabolism in the brain, as well as other enzyme systems (Denisova and Booth, 2005). Vitamin K may also play roles in age-related bone loss, cardiovascular disease, and regulation of inflammation (Booth, 2009).

## Dietary Reference Intakes

Although the various vitamers K vary widely in their biopotencies, no standardization of means exists for accommodating these differences when quantifying the amounts of the vitamin K in foods or diets. Each vitamer is expressed in terms of its mass in micrograms of vitamin K. The DRIs for vitamin K are given as AIs, and no UL has been determined. However, it should not be assumed that high vitamin K consumption has adverse effects because data on such effects are very limited.

## Sources

Vitamin K is found in large amounts in green leafy vegetables, usually at levels greater than 100 mcg/100 g.

(Table 3-15; see also Appendix 50). The amounts of the vitamin in dairy products, meats, and eggs tend to vary, ranging from 0 to 50 mcg/g, and fruits and cereals usually contain approximately 15 mcg/g. Breast milk tends to be low in vitamin K and does not provide enough of the vitamin for infants younger than 6 months of age. Products that contain plant oils can be a good source of phylloquinone.

TABLE 3-15

## Vitamin K Content of Selected Foods

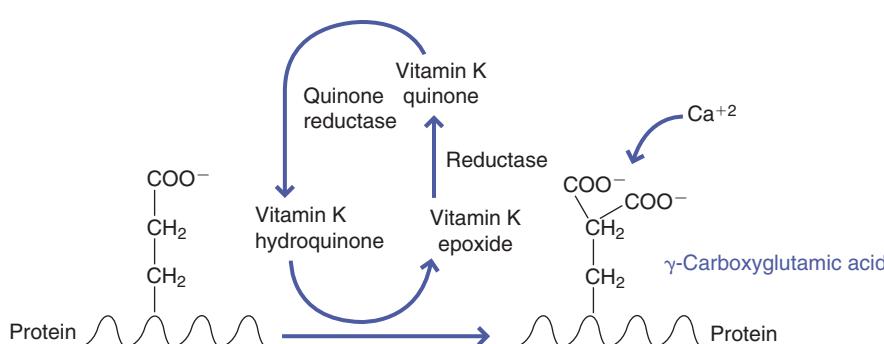

<b>Food</b>	<b>Content (mcg)</b>
Spinach, frozen, cooked, 1 cup	1027
Broccoli, cooked, 1 cup	220
Asparagus, cooked, 1 cup	144
Cabbage, cooked, 1 cup	73
Green beans, raw, 1 cup	47
Carrot, raw, 1 cup	14
Lettuce, iceberg, 1 cup	13
Avocado, raw, 1 oz	6
Turkey, cooked, 3 oz	0.03
Potato, baked, 1 medium	0.5

DRI Dietary reference intake

**FIGURE 3-19** Function and regeneration of vitamin K in the production of  $\gamma$ -carboxyglutamic acid.

Meat, dairy, and fast foods do contain small amounts of menaquinone, which could be physiologically significant (Elder et al., 2006).

The analytic task of determining the vitamers K in foods is formidable; tabulated vitamin K values for food are often inaccurate. Nevertheless, the absence of evidence of a significant vitamin K deficiency in the general population indicates that adequate amounts of the vitamin can normally be obtained by foods or produced by enteric microflora. Vitamin K is not destroyed by ordinary cooking methods, nor is it lost in cooking water, but it is sensitive to light and alkalis.

### Deficiency

The predominant sign of vitamin K deficiency is hemorrhage, which in severe cases can cause fatal anemia. The underlying condition is hypoprothrombinemia, characterized by prolonged clotting time. Vitamin K deficiencies are rare among humans but have been associated with lipid malabsorption, destruction of intestinal flora in those receiving chronic antibiotic therapy, and liver disease. Newborn infants, particularly those who are premature or exclusively breastfed, are susceptible to hypoprothrombinemia during the first few days of life. Poor placental transfer of vitamin K and failure to establish a vitamin K-producing intestinal microflora are problematic. Hemorrhagic disease in the newborn is treated prophylactically by administering menadione intramuscularly at birth.

In older adults, low intakes of vitamin K have been associated with increased incidence of hip fractures. Vitamin K<sub>1</sub> and alendronate are more cost-effective than either risedronate or strontium ranelate; but further research is required because it is unlikely that the present prescribing policy (i.e., alendronate as first-line treatment) will be altered (Stevenson et al., 2009).

### Toxicity

Neither the phylloquinones nor the menaquinones have shown any adverse effects by any route of administration. However, menadione can be toxic; excessive doses have produced hemolytic anemia in rats and severe jaundice in infants.

## THE WATER-SOLUBLE VITAMINS

Thiamin, riboflavin, niacin, vitamin B<sub>6</sub>, pantothenic acid, biotin, folic acid, vitamin B<sub>12</sub>, and vitamin C are referred to as the *water-soluble vitamins*. Solubility in water is one of the only characteristics that they share. Because they are water soluble, these vitamins tend to be absorbed by simple diffusion when ingested in large amounts and by carrier-mediated processes when ingested in smaller amounts. They are distributed in the aqueous phases of the cell (i.e., the cytoplasm and mitochondrial matrix space) and are essential cofactors or cosubstrates of enzymes involved in various aspects of metabolism. Most are not stored in appreciable amounts, making regular consumption a necessity. The water-soluble

vitamins are transported by carriers and are excreted in the urine.

### Thiamin

**Thiamin** (see Table 3-12) plays essential roles in carbohydrate metabolism and neural function. The vitamin must be activated by phosphorylation into thiamin triphosphate, or cocarboxylase, which serves as a coenzyme in energy metabolism and the synthesis of pentoses. Thiamin's role in neural function is unclear, but it probably does not act as a coenzyme (Gropper et al., 2005).

### Absorption, Transport, and Storage

Thiamin is absorbed from the proximal small intestine by active transport in low doses and passive diffusion in high doses (>5 mg/day). Active transport is inhibited by alcohol consumption, which interferes with transport of the vitamin, and by folate deficiency, which interferes with the replication of enterocytes. The mucosal uptake of thiamin is coupled to its phosphorylation into thiamin diphosphate (ThDP); activated ThDP is carried to the liver by the portal circulation.

Approximately 90% of circulating thiamin is carried as ThDP by erythrocytes, although small amounts exist primarily as free thiamin and thiamin monophosphate (ThMP) bound chiefly to albumin. Uptake by cells of peripheral tissues occurs by passive diffusion and active transport. Tissues retain thiamin as phosphate esters, mostly bound to proteins. Tissue levels of thiamin vary, with no appreciable storage of the vitamin.

### Metabolism

Thiamin is phosphorylated in many tissues by specific kinases into the diphosphate and triphosphate esters. Each of these esters can be catabolized by a phosphorylase to yield ThMP. Small amounts of some 20 other excretory metabolites are also produced and excreted in the urine.

### Functions

The major functional form of thiamin is ThDP, which is a coenzyme for several dehydrogenase enzyme complexes essential in the metabolism of pyruvate and other  $\alpha$ -keto acids. Thiamin is essential for the oxidative decarboxylation of  $\alpha$ -keto acids, including the oxidative conversion of pyruvate to acetyl CoA, which enters the TCA, or Krebs, cycle to generate energy. It is also required for the conversion of  $\alpha$ -ketoglutarate and the 2-ketocarboxylates derived from the amino acids methionine, threonine, leucine, isoleucine, and valine. ThDP also serves as the coenzyme for transketolase, which catalyzes 2-carbon fragment exchange reactions in the oxidation of glucose by the hexose monophosphate shunt.

### Dietary Reference Intakes

Thiamin is expressed quantitatively in terms of its mass, usually in milligrams. The DRIs for thiamin include AIs for infants and the newly defined RDAs. In general, the RDAs are based on levels of energy intake because of the direct

role of thiamin in energy metabolism, whereas the AIs for infants are based on the thiamin levels typically found in human milk.

## Sources

Thiamin is widely distributed in many foods, but in low concentrations. The richest sources are yeasts and liver; however, cereal grains are the most important source of the vitamin (Table 3-16). Although whole grains are typically rich in thiamin, most of it is removed during milling and refining. In the United States most refined grain products are supplemented with thiamin and other B vitamins. Plant foods contain thiamin predominantly in the free form, whereas almost all of the thiamin in animal products exists as the more efficient ThDP.

Thiamin can be destroyed by heat, oxidation, and ionizing radiation, but it is stable when frozen. Cooking losses of the vitamin tend to vary widely, depending on cooking time, pH, temperature, quantity of water used and discarded, and whether the water is chlorinated. Thiamin can be destroyed by sulfites added in processing; by thiamin-degrading enzymes (thiaminases) in raw fish, shellfish, and some bacteria; and by certain heat-stable factors in plants such as ferns, tea, and betel nuts.

## Deficiency

Thiamin deficiency is characterized by anorexia and weight loss, as well as cardiac and neurologic signs (Table 3-17). In

humans thiamin deficiency eventually results in **beriberi**, with mental confusion, muscular wasting, edema (wet beriberi), peripheral neuropathy, tachycardia, and cardiomegaly. The nonedematous (dry beriberi) disease is usually associated with energy deprivation and inactivity, whereas the wet form is usually associated with a high carbohydrate intake along with strenuous physical exertion. The latter is characterized by edema caused by biventricular heart failure with pulmonary congestion. Without ThDP, pyruvate cannot be converted to acetyl CoA and enter the TCA cycle, and energy deprivation of the heart muscle results in heart failure.

Historically, beriberi has been endemic among the poor in areas of the world where polished white rice is the major

**TABLE 3-17**

### Clinical Features of Thiamin Deficiency

Deficiency Type	Features
Early stage of deficiency	Anorexia Indigestion Constipation Malaise Heaviness and weakness of legs Tender calf muscles “Pins and needles” and numbness in legs Anesthesia of skin, particularly at the tibia Increased pulse rate and palpitations Edema of legs, face, trunk, and serous cavities
Wet beriberi	Tense calf muscles Fast pulse Distended neck veins High blood pressure Decreased urine volume Worsening of early-stage polyneuritis Difficulty walking Wernicke-Korsakoff syndrome: possible Encephalopathy <ul style="list-style-type: none"> <li>• Loss of immediate memory</li> <li>• Disorientation</li> <li>• Nystagmus (jerky movements of eyes)</li> <li>• Ataxia (staggering gait)</li> </ul>
Dry beriberi	Acute <ul style="list-style-type: none"> <li>• Decreased urine output</li> <li>• Excessive crying; thin and plaintive whining</li> <li>• Cardiac failure</li> </ul> Chronic <ul style="list-style-type: none"> <li>• Constipation and vomiting</li> <li>• Fretfulness</li> <li>• Soft, toneless muscles</li> <li>• Pallor of skin with cyanosis</li> </ul>
Infantile beriberi (2-5 mo of age)	

**TABLE 3-16**

### Thiamin Content of Selected Foods

Food	Content (mg)
Fortified ready to eat cereal, 1 cup	Up to 9.90
Pork chop, lean, 3 oz	1.06
Ham, lean, 3 oz	0.82
Sunflower seeds, shelled, 1 oz	0.59
Bagel, plain, 4 inch	0.53
Tuna sushi, 6-inch roll	0.46
Green peas, 1 cup	0.45
Beans, baked, 1 cup	0.13
Pasta, spaghetti, cooked, 1 cup	0.29
Rice, white, enriched, cooked, 1 cup	0.26
Potato, mashed, 1 cup	0.23
Doughnut, yeast, 1	0.22
Orange juice, from frozen concentrate, 6 fl oz	0.2

#### DRI Range

0.2-1.4 mg/day, depending on age and gender

From U.S. Department of Agriculture, Agricultural Research Service: Nutrient Database for Standard Reference, Release 18, Data Laboratory home page: <http://www.nal.usda.gov/fnic/foodcomp/Data/SR18/nutrlist/sr18w404.pdf>; accessed 2011.

DRI, Dietary reference intake.

staple food and where people also consume raw fish and other sources of thiaminase. Such conditions usually produce not only beriberi but also multiple nutritional deficiencies. Beriberi has also been reported in infants (infantile beriberi) who were fed formulas that were not supplemented with thiamin; deterioration is sudden and characterized by cardiac failure and cyanosis. Beriberi responds to thiamin treatment, particularly if neural damage and cardiac involvement are not great.

Frank thiamin deficiency is not common in the United States because of the thiamin supplementation of rice and other refined cereal products. Subclinical thiamin deficiency develops in those with alcoholism who tend to have inadequate thiamin intake and impaired absorption of the vitamin. In addition, thiamin is required for the metabolism and detoxification of alcohol, so those with alcoholism need more. Some older Americans are at risk for thiamin deficiency because of their poor diets and long-term use of diuretics for high blood pressure or heart failure. In addition, patients who have had gastric bypass may be at risk for deficiency and should be monitored carefully (Welch et al., 2010).

Deficient individuals may have Wernicke-Korsakoff syndrome, the signs of which range from mild confusion to coma. Beginning around 1900, investigators began to recognize a relationship between Korsakoff's psychosis, delirium tremens, peripheral polyneuropathy, and Wernicke encephalopathy (Lanska, 2009).

Others who are deficient in thiamin have an inherited abnormal transketolase incapable of normal ThDP binding. Biochemical changes that reflect thiamin status occur well before the appearance of overt symptoms. Thus thiamin status can be assessed by determining erythrocyte transketolase activity, measuring blood or serum levels of thiamin or measuring urinary thiamin excretion levels (see Appendix 30).

### Toxicity

Little information exists about the toxic potential of thiamin, although massive doses (1000 times greater than nutritional needs) of commercial thiamin hydrochloride suppress the respiratory center and cause death (IOM, Food and Nutrition Board, 2000b). Parenteral doses of thiamin at 100 times the recommended levels have produced headache, convulsions, muscular weakness, cardiac arrhythmia, and allergic reactions.

### Riboflavin

**Riboflavin** is essential for the metabolism of carbohydrates, amino acids, and lipids and supports antioxidant protection. It carries out these functions as the coenzymes flavin adenine dinucleotide (FAD) and flavin adenine mononucleotide (FMN). Because of its fundamental roles in metabolism, riboflavin deficiencies are first evident in tissues that have rapid cellular turnover such as the skin and epithelia.

### Absorption, Transport, and Storage

Riboflavin is absorbed in the free form by a carrier-mediated process in the proximal small intestine. Because most foods contain the vitamin in its coenzyme forms, FMN and FAD, absorption occurs only after the hydrolytic cleavage of free riboflavin from its various flavoprotein complexes by various phosphatases. Riboflavin absorption is a carrier-mediated process that requires ATP. The mucosal uptake of free riboflavin depends on its phosphorylation into FMN.

Riboflavin is transported in the plasma as free riboflavin and FMN, both of which are mainly bound to plasma albumin. A specific riboflavin-binding protein has also been identified and is thought to function in the transplacental movement of the vitamin. Riboflavin is transported in its free form into cells by a carrier-mediated process, and then it is converted to FMN or FAD. Their protein binding prevents diffusion out of the cell and makes them resistant to catabolism. Although small amounts of the vitamin are found in the liver and kidney, it is not stored in any useful amount and therefore must be supplied in the diet regularly.

### Metabolism

Riboflavin is converted to its coenzyme forms by ATP-dependent phosphorylation to yield riboflavin-5'-phosphate, or FMN, by the enzyme flavokinase. Most FMN is then converted to FAD by FAD-pyrophosphorylase. Both steps are regulated by the thyroid hormones adrenocorticotrophic hormone and aldosterone.

Most excess riboflavin is excreted as such in the urine. However, free riboflavin can be glycosylated in the liver, and the glycosylated metabolite is excreted. Riboflavin may also have a direct metabolic function. It can also be catabolized by oxidation, demethylation, and hydroxylation of its ring system to yield products that are excreted in the urine with free riboflavin.

### Functions

The flavin coenzymes FMN and FAD accept pairs of hydrogen atoms forming  $\text{FMNH}_2$  or  $\text{FADH}_2$ . As such they can participate in either one- or two-electron redox reactions. FMN and FAD serve as prosthetic groups of several flavoprotein enzymes that catalyze oxidation-reduction reactions in the cells and function as hydrogen carriers in the mitochondrial electron transport system. FMN and FAD are also coenzymes of dehydrogenases (such as in the TCA cycle) that catalyze initial fatty acid oxidation and several steps in glucose metabolism.

FMN is required for the conversion of pyridoxine (PN; vitamin  $\text{B}_6$ ) to its functional form, pyridoxal phosphate (PLP). FAD is required for the biosynthesis of the vitamin niacin from the amino acid tryptophan. In other cellular roles, mechanisms dependent on riboflavin and nicotinamide adenine dinucleotide phosphate (NADPH) seem to combat oxidative damage to the cell. Nutritional supplements that include riboflavin may protect against cataracts (Jacques et al., 2005).

## Dietary Reference Intakes

The DRIs for riboflavin include AIs for infants and newly defined RDAs. In general, the RDAs are based on the amount required to maintain normal tissue reserves based on urinary excretion, red blood cell riboflavin contents, and erythrocyte GR activity. Riboflavin requirements are higher during pregnancy and lactation so that they can meet the needs of increased tissue synthesis and the losses of riboflavin secreted in breast milk.

## Sources

Riboflavin, measured in milligrams in foods, is widely distributed in foods in a form bound to proteins as FMN and FAD. Rapidly growing, green leafy vegetables are rich in the vitamin; however, meats and dairy products are the most important contributors to the American diet (Table 3-18). More than half of the vitamin is lost when flour is milled; however, most breads and cereals are enriched with riboflavin and contribute appreciably to the total daily intake.

Riboflavin is stable when heated but can be readily destroyed by alkali and exposure to ultraviolet irradiation. Very little of the vitamin is destroyed during the cooking and processing of foods; however, because of its sensitivity to alkali, the practice of adding baking soda to soften dried peas or beans destroys much of their riboflavin content.

**TABLE 3-18**

### Riboflavin Content of Selected Foods

Food	Content (mg)
Liver, beef, 3 oz	2.91
Fortified ready to eat cereal, 1 cup	Up to 1.70
Milk, 2% fat, 1 cup	0.45
Yogurt, fruit flavored, low fat, 1 cup	0.40
Clams, canned, 3 oz	0.36
Cheese, cottage, 1 cup	0.37
Egg, 1	0.25
Custard, baked, $\frac{1}{2}$ cup	0.25
Pork, roast loin, 3 oz	0.27
Bagel, plain, 1	0.22
Hamburger, lean, broiled medium, 3.5 oz	0.21
Spinach, fresh, cooked, $\frac{1}{2}$ cup	0.21
Chicken, dark meat, 3 oz	0.21
Broccoli, 1 cup	0.19
Cheese, American, 1 oz	0.10
Banana, 1	0.09

#### DRI Range

0.3-1.6 mg/day, depending on age and gender

From U.S. Department of Agriculture, Agricultural Research Service: Nutrient Database for Standard Reference, Release 18, Data Laboratory home page: <http://www.nal.usda.gov/fnic/foodcomp/Data/SR18/nutrlst/sr18w405.pdf>; accessed 2011.

DRI, Dietary reference intake.

Wax-lined paper containers protect milk against riboflavin loss from exposure to sunlight.

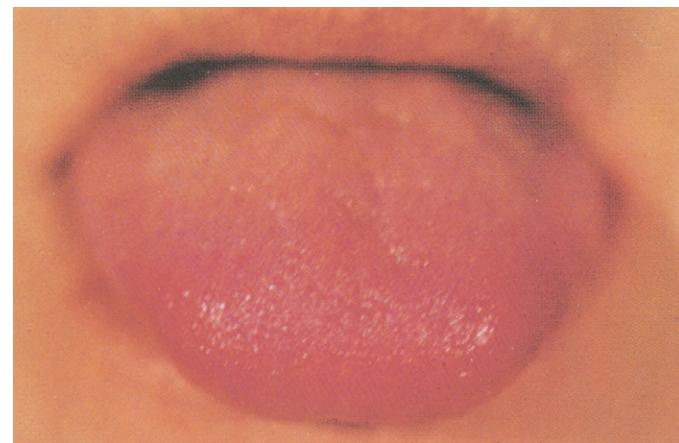

## Deficiency

Riboflavin deficiency becomes manifest after several months of deprivation of the vitamin. The initial symptoms include photophobia; tearing; burning and itching of the eyes; loss of visual acuity; and soreness and burning of lips, mouth, and tongue. More advanced symptoms include fissuring of the lips (*cheilosis*) and cracks in the skin at the corners of the mouth (*angular stomatitis*). It may manifest as a greasy eruption of the skin in the nasolabial folds, scrotum, or vulva; a purple, swollen tongue (Figure 3-20); capillary overgrowth around the cornea of the eye; and peripheral neuropathy (Box 3-6).

Riboflavin has been implicated in cataract formation when multiple vitamin deficiencies are present (Jacques et al., 2005). Phototherapy for infants with hyperbilirubinemia often leads to riboflavin deficiency (by photodestruction of the vitamin) if the therapy does not also include riboflavin supplementation. Otherwise riboflavin deficiencies usually occur in combination with deficiencies of other water-soluble vitamins such as thiamin and niacin, especially in those who are malnourished. The B vitamins and several gene polymorphisms that affect DNA synthesis and methylation have shown a small, inverse association between riboflavin and gastric cancer risk (Eussen et al., 2010). Riboflavin status is measured by assessment of the activity of erythrocyte GR. This enzyme requires FAD and converts oxidized glutathione to reduced glutathione.

## Toxicity

Riboflavin is not known to be toxic; high oral doses are considered essentially nontoxic. However, high doses are not beneficial.

**FIGURE 3-20** Magenta tongue, a sign of riboflavin deficiency. In contrast, a person with an iron deficiency often has a pale tongue; and vitamin B-complex deficiency results in a beefy, red-colored tongue. (From McLaren DS: Colour atlas of nutritional diseases, England, 1981, Yearbook Medical Publishers.)

**BOX 3-6****Signs of Possible Riboflavin Deficiency**

- Soreness and burning of lips, mouth, and tongue\*
- Cheilosis\*
- Angular stomatitis\*
- Glossitis\*
- Purplish or magenta tongue\*
- Hypertrophy or atrophy of tongue papillae\*
- Seborrheic dermatitis of nasolabial folds, vestibule of nose, and sometimes the ears and eyelids, scrotum, and vulva
- Ocular pathologic conditions (sometimes)
  - Inflammation of conjunctiva
  - Superficial vascularization of cornea
  - Ulcerations of cornea
  - Photophobia
- Anemia—normocytic and normochromic
- Neuropathy

Modified from Goldsmith GA: Riboflavin deficiency. In Rivlin RS, editor: Riboflavin, New York, 1975, Plenum Press.

\*Tongue and mouth changes are difficult to differentiate from those caused by niacin, folic acid, thiamin, vitamin B<sub>6</sub>, or vitamin B<sub>12</sub> deficiency.

**Niacin**

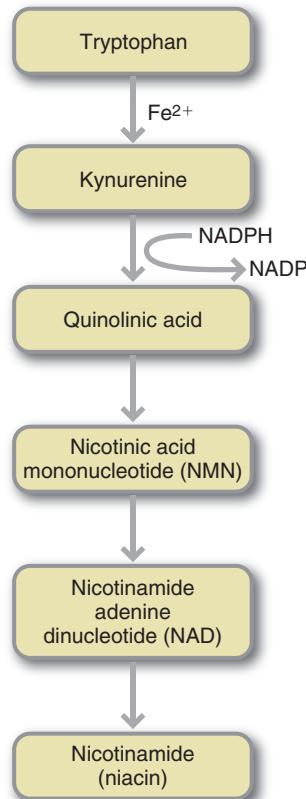

**Niacin** is the generic term for nicotinamide (Nam) and nicotinic acid (NA). It functions as a component of pyridine nucleotide coenzymes nicotinamide adenine dinucleotide (NAD) and NADPH, which are essential in all cells for energy production and metabolism. NAD and NADPH are the reduced forms of NAD and NADP; they carry a hydrogen ion. Niacin was first identified as a result of the search for the cause and cure of pellagra, a disease common in Spain and Italy in the eighteenth century and that devastated the southern United States in the early twentieth century.

**Biosynthesis, Absorption, Transport, and Storage**

Niacin can be synthesized from the essential amino acid tryptophan. Even though this process is not efficient, dietary tryptophan intake is important to the overall niacin status of the body (Figure 3-21).

Niacin in many foods, particularly those from animal sources, consists mostly of the coenzyme forms NAD and NADPH, each of which must be digested to release the absorbed forms, Nam and NA. Many foods derived from plants, particularly grains, contain niacin in covalently bound complexes with small peptides and carbohydrates that are not released during digestion. These forms (niacytin) are not biologically available but can become bioavailable through alkaline hydrolysis. Thus the Central American tradition of soaking maize in lime water before preparing tortillas effectively increases the bioavailability of niacin in what otherwise would be considered a low-niacin food.

Ultimately Nam and NA are absorbed in the stomach and small intestine by carrier-mediated facilitated diffusion.

**FIGURE 3-21** Synthesis of niacin from tryptophan. NADPH, Nicotinamide adenine dinucleotide phosphate in the reduced form.

Both are transported in the plasma in free solution, and each is taken up by most tissues through passive diffusion. Some tissues like erythrocytes, kidney, and brain require a transport system for NA. Niacin is retained in tissues as NAD but may also be converted to NADPH.

**Metabolism**

The de novo synthesis of NAD and NADPH occurs from quinolinic acid, a metabolite of the essential amino acid tryptophan. The conversion of tryptophan to niacin depends on such factors as the amount of tryptophan and niacin ingested and PN status (B<sub>6</sub>); therefore the body must have adequate levels of riboflavin and, to a lesser extent, vitamin B<sub>6</sub>. Humans are moderately efficient at this conversion, and 60 mg of tryptophan is considered equal to 1 mg of niacin.

NAD and NADPH can be produced from NA and Nam obtained from the diet. Nam is deaminated to yield NA. Then two ribose phosphates are attached to the nitrogen in the pyridine ring. Next, adenosine is attached to the ribose. Finally, an amino group is added to the acid group, forming an amide and yielding NAD. NAD can be phosphorylated in the hexose monophosphate shunt to yield NADPH.

NAD and NADPH are catabolized by hydrolysis to yield Nam, which can be deaminated into NA or methylated to

yield 1-methylnicotinamide. Dietary protein deficiency changes the profile of urinary metabolites, presumably because of changes in the amount of tryptophan converted to niacin.

## Functions

The coenzymes NAD and NADPH are the most central electron carriers of cells, playing essential roles as cosubstrates of more than 200 enzymes for the metabolism of carbohydrates, fatty acids, and amino acids. In general, NAD and NADPH facilitate hydrogen transport by two-electron transfers, which use the hydride ion ( $H^+$ ) as the carrier but play very different roles in metabolism. The NAD-dependent reactions are involved in intracellular respiration (e.g., beta-oxidation, TCA cycle function [see Figure 3-2], and the electron transport system). NADPH, on the other hand, is important for biosynthetic (e.g., fatty acid, sterol) pathways.

Because of its fundamental role in metabolism, niacin may play an important role in mechanisms for DNA repair and gene stability (Kirkland, 2003). Nam, the amide form, participates in the cellular energy metabolism that directly affects normal physiology, influences oxidative stress, and modulates multiple pathways tied to both cellular survival and death; it is a robust cytoprotectant that holds great potential for multiple disease entities (Maiese et al., 2009). It may have roles in Alzheimer disease, Parkinson disease, aging, diabetes, cancer, and cerebral ischemia (Li et al., 2006).

## Dietary Reference Intakes

Niacin is expressed in total milligrams of niacin or niacin equivalents (NEs), which are calculated from the pre-formed niacin content plus 1/60 of the tryptophan content. The DRIs established for niacin include AIs for infants, RDAs, and the tolerable UL. Requirements are directly related to energy intake because of niacin's role in energy-producing reactions in metabolism; they are expressed as NEs from pre-formed niacin and tryptophan.

## Sources

Significant amounts of niacin are found in many foods; lean meats, poultry, fish, peanuts, and yeasts are particularly rich sources. Niacin exists predominantly as protein-bound NA in plant tissues and as Nam, NAD, and NADPH in animal tissues. Milk and eggs contain small amounts of niacin, but they are excellent sources of tryptophan, giving them significant NE contents. The amount of niacin in foods depends on the total milligrams of niacin (NA and Nam) plus 1/60 of the tryptophan content. Table 3-19 lists the pre-formed niacin content of various foods. Many tables of food nutrient composition list only pre-formed niacin and underestimate the total niacin equivalencies of other foods.

## Deficiency

Niacin deficiency begins with muscular weakness, anorexia, indigestion, and skin eruptions. Severe deficiency of niacin leads to **pellagra**, which is characterized by dermatitis,

**TABLE 3-19**

**Pre-formed Niacin Content of Selected Foods\***

Food	Content (mg)
Ready-to-eat cereals	Up to 26.43
Chicken, ½ breast	14.73
Tuna, canned in water, 3 oz	11.29
Rice, white, 1 cup	7.75
Mushrooms, cooked, 1 cup	6.96
Beef, ground regular, cooked	4.55
Ham, canned, 3 oz	4.28
Peanuts, dry roasted, 1 oz	3.83
Coffee, 2 fl oz	3.12
Egg bagel, 4 inch	3.06
Pizza with pepperoni	3.05
Noodles, 1 cup	2.68

DRI Range
2-18 mg/day, depending on age and gender

From U.S. Department of Agriculture, Agricultural Research Service: Nutrient Database for Standard Reference, Release 18, Data Laboratory home page: <http://www.nal.usda.gov/fnic/foodcomp/Data/SR18/nutrlst/sr18w406.pdf>; accessed 2011.

DRI, Dietary reference intake.

\*These data do not take into account niacin available from food via synthesis from tryptophan.

dementia, and diarrhea (“the three Ds”); tremors; and a beefy red, sore tongue. The dermatologic changes are usually the most prominent. Skin that has been exposed to the sun develops cracked, pigmented, scaly dermatitis (Figure 3-22). Central nervous system involvement symptoms include confusion, disorientation, and neuritis. Digestive abnormalities cause irritation and inflammation of the mucous membranes of the mouth and the GI tract. Untreated pellagra can cause death, which is often referred to as “the fourth D.”

Patients with pellagra may also show clinical signs of riboflavin deficiency, highlighting the metabolic interrelationships of these vitamins. Patients with pellagra are likely to have very poor diets that not only provide little niacin but also lack protein and other nutrients. The most reliable method for assessing niacin status is the measurement of the urinary excretion of the methylated metabolites methylnicotinamide and methylpyridone carboxamide.

## Toxicity

In general, niacin toxicity is low. However, high doses of 1 to 2 g of NA three times per day—dosages that have been used in attempts to lower blood cholesterol concentrations (Malik and Kashyap, 2003)—can have untoward side effects. The main side effect is a histamine release that causes flushing and may be harmful to those with asthma or peptic ulcer disease. Nam does not have this effect. High doses of niacin can also be toxic to the liver; risks are greater with

**FIGURE 3-22** Pellagra. Pigmented keratotic scaling lesions caused by niacin deficiency. The lesions are especially prominent in areas exposed to the sun, such as the hands, forearms, neck, and legs. (From Latham MC et al: *Scope manual on nutrition*, Kalamazoo, Mich., 1980, The Upjohn Company.)

time-released forms of the vitamin. Megavitamin use should be monitored carefully because high doses act as drugs and not nutritional supplements (Kamanna, 2009; Kamanna and Kashyap, 2008).

## Pantothenic Acid

**Pantothenic acid** is widely distributed in foods; clinical deficiency is rare. The vitamin has critical roles in metabolism. It is an integral part of CoA, which is essential in energy production from the macronutrients, and acyl-carrier protein (ACP), which is used in synthesis reactions.

## Absorption, Transport, and Storage

Pantothenic acid exists in foods mostly as CoA and ACP. Therefore absorption requires hydrolysis to phosphopantetheine and then conversion to pantothenic acid. Pantothenic acid is absorbed by both passive diffusion and active transport in the jejunum. It is transported in the free acid form in solution in the plasma and taken up by diffusion into erythrocytes, which carry most of the vitamin in the blood. Pantothenic acid is taken up by cells of peripheral tissues by a sodium-dependent active transport process in some tissues and by facilitated diffusion in others. Within the cell, the vitamin is converted to CoA, which is its predominant form in most tissues, particularly the liver, adrenals, kidney, brain, heart, and testes.

## Metabolism

All tissues are capable of synthesizing CoA from pantothenic acid. This multienzyme process takes place in four steps. First pantothenic acid is phosphorylated to yield 4'-

phosphopantothenic acid. Then it is condensed with cysteine to yield 4'-phosphopantethenoylcysteine. Next phosphopantethenoylcysteine is decarboxylated to yield 4'-phosphopantetheine, which is finally converted to CoA. ACP contains 4'-phosphopantetheine that is transferred from CoA to bind to the Apo acetyl carrier protein, forming ACP.

CoA and ACP are degraded to yield free pantothenic acid and other metabolites. The vitamin is excreted mainly in the urine as free pantothenic acid but also as 4'-phosphopantethenate. An appreciable amount (some 15% of the daily intake) is oxidized completely and excreted through the lungs as carbon dioxide.

## Functions

CoA and ACP function metabolically as carriers of acyl groups. CoA is critical in the formation of acetyl CoA, which condenses with oxaloacetate and enters the TCA cycle to release energy. It is also the compound in the first steps of the synthesis of fatty acids or cholesterol or in the acetylation of alcohols, amines, and amino acids. It also activates fatty acids before their incorporation into triglycerides and acts as an acyl donor for proteins. ACP is a component of the multienzyme complex fatty acid synthase, which is necessary for fatty acid synthesis.

## Dietary Reference Intakes

Pantothenic acid is measured in milligrams. DRIs are expressed as AIs. No estimated average requirements (EARs) or RDAs have been established.

## Sources

Pantothenic acid is present in all plant and animal tissues. The most important sources in mixed diets are meats (particularly liver and heart). Mushrooms, avocados, broccoli, egg yolks, yeast, skim milk, and sweet potatoes are also good sources of the vitamin (Table 3-20). Pantothenic acid is fairly stable during ordinary cooking and storage, although the vitamin can be lost in frozen meats during thawing. Because it is localized in the outer layers of grains, approximately half of the vitamin is lost in the milling of flour.

## Deficiency

Pantothenic acid deficiency results in impairments in lipid synthesis and energy production. Because the vitamin is so widely distributed in foods, deficiencies are rare. However, pantothenic acid deficiency has been observed among severely malnourished humans. Symptoms include paresthesia in the toes and soles of the feet, burning sensations in the feet, depression, fatigue, insomnia, and weakness (IOM, Food and Nutrition Board, 2000b).

## Toxicity

The toxicity of pantothenic acid is negligible; no adverse effects after ingestion of large doses of the vitamin have been reported in any species. Massive doses (e.g., 10 g/day)

**TABLE 3-20****Pantothenic Acid Content of Selected Foods**

Food	Content (mg)
Fortified dry cereal, 1 cup	Up to 10.65

<i>DRI</i> , Dietary reference intake.	

administered to humans have produced only mild intestinal distress and diarrhea.

### Vitamin B<sub>6</sub> (Pyridoxine)

Vitamin B<sub>6</sub> is the general term for numerous 2-methyl-3, 5-dihydroxymethylpyridine derivatives exhibiting the biologic activity of **pyridoxine (PN)**, the alcohol derivative. The biologically active analogs are the aldehyde pyridoxal (PL) and the amine pyridoxamine (PM). All three compounds are converted to the metabolically active coenzyme form PLP, which is primarily involved in the metabolism of amino acids.

### Absorption, Transport, and Storage

Vitamin B<sub>6</sub> is absorbed by passive diffusion of the dephosphorylated forms PN, PL, or PM—primarily in the jejunum and ileum. Absorption is driven by phosphorylation to form PLP and pyridoxamine phosphate (PMP) and then by protein binding of each of these metabolites in the intestinal mucosa and blood.

The predominant form of the vitamin in the blood is PLP, most of which is derived from the liver after metabolism by hepatic flavoenzymes. Small amounts of free PN are also found in the circulation, but most is PLP bound to albumin. However, PLP must be dephosphorylated to PL to be taken up by the cells. On uptake, PL is again phosphorylated to PLP and PMP, with the greatest levels being found in liver, brain, kidney, spleen, and muscle, where they are bound to proteins. Muscle is

the largest depot, containing 80% to 90% of the total body vitamin stores in the form of PLP bound to glycogen phosphorylase.

### Metabolism

The vitamers of B<sub>6</sub> are readily metabolically interconverted by phosphorylation-dephosphorylation, oxidation-reduction, and amination-deamination reactions. The limiting step during this metabolism is catalyzed by the FMN enzyme PLP oxidase. Thus riboflavin deficiency can reduce the conversions of PN and PM to the active coenzyme PLP. In the liver PLP is dephosphorylated and oxidized by FAD- and NAD-dependent enzymes to yield 4-pyridoxic acid and other inactive metabolites that are excreted in the urine.

### Functions

The metabolically active form (PLP) is a coenzyme for numerous enzymes in the metabolism of amino acids. PLP is the cofactor for more than 100 enzyme-catalyzed reactions in the body, including many involved in the synthesis or catabolism of neurotransmitters (Clayton, 2006). It also has roles in the metabolism of glycogen, sphingolipids, heme, and steroids. These roles relate to the ability of the PLP aldehyde group to react with α-amino groups of the amino acid and thus to stabilize the other bonds on the bound carbon. Thus vitamin B<sub>6</sub> is essential for various amino acid transaminases, decarboxylases, racemases, and isomerases.

Vitamin B<sub>6</sub> is needed for the biosynthesis of the neurotransmitters serotonin, epinephrine, norepinephrine, and γ-aminobutyric acid; the vasodilator and gastric secretagogue histamine; and the porphyrin precursors of heme. The vitamin is also required for the metabolic conversion of tryptophan to niacin, the release of glucose from glycogen, the biosynthesis of sphingolipids in the myelin sheaths of nerve cells, and the modulation of steroid hormone receptors.

### Dietary Reference Intakes

The DRIs for vitamin B<sub>6</sub> include AIs for infants, the redefined RDAs, and the UL for children and adults. In general, needs for vitamin B<sub>6</sub> increase with increasing intake of protein.

### Sources

The vitamin is obtained from two exogenous sources: a dietary source absorbed in the small intestine and a bacterial source synthesized in significant quantities by the normal microflora of the large intestine; the carrier-mediated process for PN uptake by mammalian colonocytes is under study (Said et al., 2008).

Vitamin B<sub>6</sub> is widely distributed in foods, occurring in greatest concentrations in meats, whole-grain products (especially wheat), vegetables, and nuts (Table 3-21). Vitamin B<sub>6</sub> derived from animal sources tends to have superior bioavailability. Much of the vitamin B<sub>6</sub> in foods is bound

**TABLE 3-21****Pyridoxine Content of Selected Foods**

Food	Content (mg)
Ready-to-eat cereals	Up to 3.6

DRI, Dietary reference intake.	

covalently to proteins or glycosylated. PN in some plants (e.g., potatoes, spinach, beans, and other legumes) is often glycosylated and has a low bioavailability.

### Deficiency

Deprivation of vitamin B<sub>6</sub> leads to metabolic abnormalities resulting from insufficient production of PLP. These manifest clinically as dermatologic and neurologic changes such as weakness, sleeplessness, peripheral neuropathies, cheilosis, glossitis, stomatitis, and impaired cell-mediated immunity. Inadequate levels of PLP in the brain cause neurologic dysfunction, particularly epilepsy; treatment with PN or PLP can be lifesaving (Clayton, 2006).

Because of the widespread distribution of the vitamin in foods, cases of vitamin B<sub>6</sub> deficiency are relatively rare. However, deficiency may be precipitated by medications like the antitubercular drug isoniazid that interfere with vitamin B<sub>6</sub> metabolism. An increased requirement for PN or PLP is also found with inborn errors affecting the B<sub>6</sub> pathways, celiac disease with malabsorption, and renal dialysis with increased losses of B<sub>6</sub> vitamers (Clayton, 2006).

### Toxicity

Many of the signs of vitamin B<sub>6</sub> toxicity resemble those of deficiency. Toxicity from diet is relatively low. High-dose PN or PLP may have deleterious side effects, particularly peripheral neuropathy (Clayton, 2006). Indeed, a man using 9.6 g/day developed severe sensorimotor neuropathy (Gdynia et al., 2008). With over-the-counter

use of B<sub>6</sub> for everything from carpal tunnel to premenstrual syndrome, health providers must ask about the frequency of use and the quantity of vitamins consumed, including those considered to be nontoxic because of water solubility.

### Folate

**Folate** refers generally to pteroylmonoglutamic acid and its derived compounds. The reduced compound, tetrahydrofolic acid (FH<sub>4</sub>), functions metabolically as a carrier for single-carbon moieties. Each carrier form is named according to the moiety it carries and each can be used in single-carbon synthesis reactions.

### Absorption, Transport, and Storage

Dietary folates are absorbed only as the monoglutamate forms of 5-methyltetrahydrofolic acid and 5-formyltetrahydrofolic acid. Absorption occurs by active transport mainly in the jejunum, but the vitamin can also be absorbed by passive diffusion when ingested in large amounts. Because most folate in foods is present in polyglutamate forms (more than one glutamate residue attached), absorption requires hydrolysis to the monoglutamate form in the brush border and intracellular mucosa.

The bioavailability of folates from fruit, vegetables, and liver is approximately 80% that of folic acid; therefore consumption of a diet rich in food folate can improve the folate status of a population more efficiently than was previously thought (Winkels et al., 2007). Although folic acid has historically been used as the reference folate in human intervention studies, using the reference of 5-methyltetrahydrofolic acid is more desirable and realistic (Wright et al., 2009).

Folate taken up by the intestinal mucosal cell is reduced to FH<sub>4</sub>, which can either be transferred to the portal circulation or converted to 5-methyl-FH<sub>4</sub> before entering the circulation. Only monoglutamate derivatives found in plasma are taken up by the cells using an energy-dependent process with a specific folate-binding protein or a carrier-mediated process. Within cells, FH<sub>4</sub> is methylated to 5-methyl-FH<sub>4</sub>, which is retained intracellularly by binding to intracellular macromolecules. There is additional conversion to folyl polyglutamates. The liver is the most important depot for folate, containing approximately half of the total body store as polyglutamates of 5-methyl-FH<sub>4</sub> and 10-formyl-FH<sub>4</sub>. Tissues with high rates of cell division like the intestinal mucosa tend to have low concentrations of 5-methyl-FH<sub>4</sub> and high concentrations of 10-formyl-FH<sub>4</sub>, whereas 5-methyl-FH<sub>4</sub> predominates in tissues with low rates of cell division.

### Metabolism

Folates are metabolized in three ways: reduction of the pterin ring by the enzyme reductase in the kidney and liver; reactions of the polyglutamyl side chain by the enzyme polyglutamate synthetase, which add the amino acid glutamate; and acquisition of single-carbon moieties at certain positions on the pterin ring.

Folate is metabolically activated by conversion to one of several derivatives with single-carbon units substituted at the N-5 or N-10 (or both) positions of the pterin ring. The main source of the single-carbon fragments is via serine hydroxymethyltransferase, which uses the dispensable amino acid serine and the single-carbon donor to produce 5,10-methylene-FH<sub>4</sub>. Other enzymes also yield other single-carbon metabolites: 5-methyl-FH<sub>4</sub>, 5,10-methenyl-FH<sub>4</sub>, 5-formimino-FH<sub>4</sub>, 5-formyl-FH<sub>4</sub>, and 10-formyl-FH<sub>4</sub>.

Tissue folates turn over by cleavage of their pteridine and paraaminobenzoyl polyglutamate moieties. The latter are further degraded to a variety of water-soluble side-chain metabolites that are excreted in the urine and bile (Figure 3-23).

## Functions

FH<sub>4</sub>, with its moieties attached, functions as an enzyme cosubstrate in many synthesis reactions in the metabolism of amino acids and nucleotides by donating or accepting single carbon units. For example, it functions in new synthesis and repair of DNA by transferring formate (as 5,10-methenyl-FH<sub>4</sub>) for purine synthesis and formaldehyde (as 5,10-methylene-FH<sub>4</sub>) for thymidylate synthesis. It is required for the conversion of histidine to glutamic acid, impairments of which result in accumulation of the intermediary product, formiminoglutamic acid, which must be excreted in the urine.

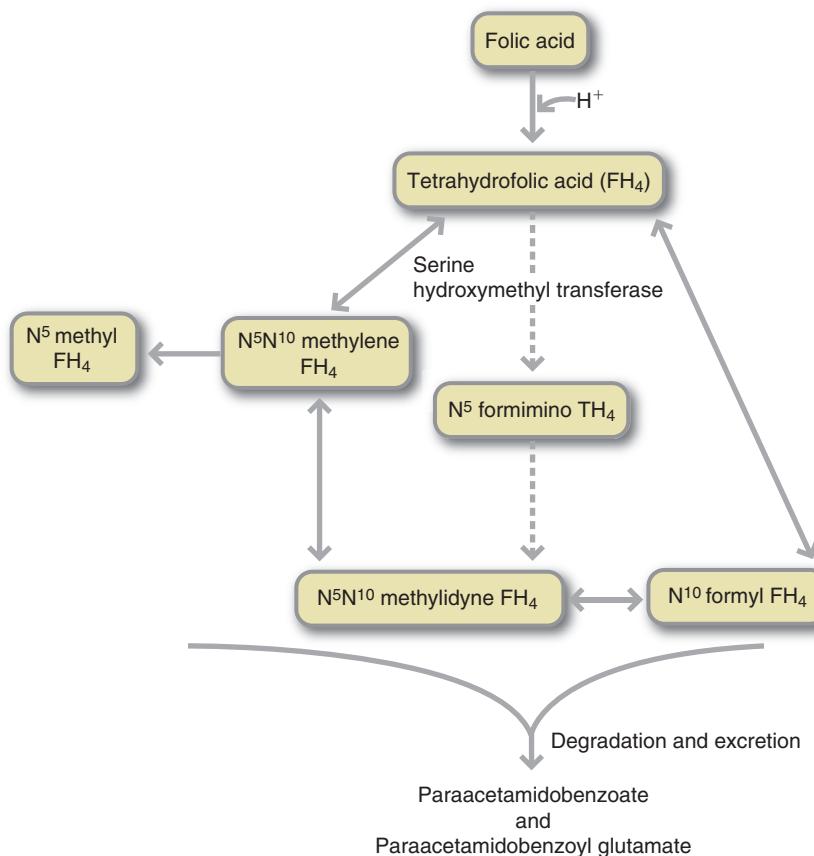

FH<sub>4</sub> provides labile methyl groups (as 5-methyl-FH<sub>4</sub>) for the synthesis of methionine from homocysteine. This conversion also requires vitamin B<sub>12</sub>, which passes the methyl group from 5-methyl-FH<sub>4</sub> to homocysteine; therefore deficiencies of either folate or vitamin B<sub>12</sub> can lead to elevated serum homocysteine levels (homocystinemia). Folate deficiency was initially recognized clinically as a macrocytic anemia in the 1920s, and only clearly separated from pernicious anemia by the mid-twentieth century (Lanska, 2009). Because of this interrelationship, deprivation of vitamin B<sub>12</sub> alone can produce a functional secondary folate deficiency by interrupting the regeneration of FH<sub>4</sub>, effectively trapping the vitamin as 5-methyl-FH<sub>4</sub>—a process called the *methyl-folate trap*. For synthesis and repair of DNA, both folate and B<sub>12</sub> have pivotal roles in maintaining gene stability.

Finally, folate is essential for the formation of red and white blood cells in the bone marrow and for their maturation and is a single-carbon carrier in the formation of heme. The role of folate in normal cell division makes it particularly important in embryogenesis. Periconceptual folate supplementation can reduce the risk of serious birth defects, including cleft palate and neural tube defects.

## Dietary Reference Intakes

The DRIs for folate are expressed as dietary folate equivalents (DFEs), which is an attempt to account for known differences in the bioavailability of folates noted previously.

**FIGURE 3-23** Metabolism of folates.

One DFE equals 1 mcg of food folate, which is equal to 0.6 mcg of folic acid consumed with food or 0.5 mcg of synthetic folic acid taken as a supplement on an empty stomach. The DRIs for folate include AIs for infants and RDAs for children and adults. The DRIs for women include increased amounts for women who could become pregnant. Although low folate stores are found in approximately 10% of the population, they are not accompanied by overt signs of deficiency.

### Sources

Folates exist as reduced folyl polyglutamates (of mostly 5-methyl-FH<sub>4</sub> and 10-formyl-FH<sub>4</sub>) in various foods of plant and animal origin. Rich sources include liver, mushrooms, green leafy vegetables (“foliage” such as spinach, asparagus, and broccoli). Lean beef, potatoes, whole-wheat bread, orange juice, and dried beans are good sources (Table 3-22). Although controversial because folic acid can mask a B<sub>12</sub> deficiency (Osterhues et al., 2009), the United States began fortification of wheat products in 1998. These products are now major sources of folate.

Folate exists in 150 different forms, and their bioavailability varies widely. The reduced forms in foods are easily oxidized. Losses of 50% to 90% typically occur during storage, cooking, or processing at high temperatures. The bioavailability in foods varies considerably because of inherent differences among its forms, the presence or absence of conjugase inhibitors and folate binders, and the nutritional

status of the host. Deficiencies of iron and vitamin C can also impair folate use. Analysis of foods for their folate content is complex and difficult, and values in tables of food composition are often too low.

### Deficiency

Deficiencies of folate result in impaired biosynthesis of DNA and RNA, thus reducing cell division. This is most apparent in rapidly multiplying cells such as red blood cells, leukocytes, epithelial cells of the stomach, intestine, vagina, and uterine cervix. In blood this is characterized by megaloblastic, macrocytic anemia with large, immature erythrocytes that have excessive amounts of hemoglobin. Initial signs of deficiency in humans include nuclear hypersegmentation of circulating polymorphonuclear leukocytes followed by megaloblastic anemia and then general weakness, depression, and polyneuropathy. Dermatologic lesions and poor growth are also symptoms.

Folate-responsive homocystinemia is related to the role of folate in regeneration of methionine from homocysteine, is a condition associated with elevated risk for occlusive vascular disease, and is prevalent among apparently healthy Americans. Other studies suggest a role for lowering homocysteine in Alzheimer disease, Parkinson disease, amyotrophic lateral sclerosis (ALS), and other neuropsychiatric disorders. This suggests that subclinical folate deficiencies may be more common than previously thought.

There are genetic predispositions for neural tube defects, including both infant and maternal gene polymorphisms for enzymes involved in folate-dependent homocysteine metabolism; the genotype of the mother, the genotype of the unborn child, and environmental factors (e.g., folate intake) can all affect the risk for neural tube defects (Lanska, 2009). Well-designed randomized trials established that folate supplementation prevents more than 70% of neural tube defects (Lanska, 2009). Results from these trials convinced the American government to establish fortification mandates by adding folate to wheat flour.

Where there are genetic polymorphisms in the folate pathway, the bioavailable form (L-methylfolate) can be obtained by prescription for use in pregnancy, cancer prevention, and many neuropsychiatric disorders. Nearly one third of gene-variant cancer associations are statistically significant for variants in genes that encode for metabolizing enzymes; the *MTHFR* gene allele for the C>T phenotype is linked with gastric cancer, for example (Dong et al., 2008). Folate status is assessed by measuring the erythrocyte folate concentration, sometimes in conjunction with plasma homocysteine concentrations and testing for genetic alleles. The interrelationships of B<sub>12</sub>, folate, and homocysteine continue to intrigue researchers (Varela-Moreiras et al., 2009). Elevated homocysteine levels and low serum folate may play a role in several conditions, including cognitive changes in aging.

High doses of folate may have a positive benefit by reducing arsenic toxicity in genetically susceptible persons. Arsenic-contaminated groundwater is a global environmental health concern known to promote skin and bladder

**TABLE 3-22**

**Dietary Folate Equivalents (DFE) of Selected Foods**

DRI, Dietary reference intake.

cancers. Arsenic metabolism involves methylation by a folate-dependent process, so folate supplementation may be helpful in excreting more arsenic (Kile and Ronnenberg, 2008).

### Toxicity

No adverse effects of high oral doses of folate have been reported in animals, although parenteral administration of amounts some 1000 times the dietary requirement produce epileptiform seizures in the rat. It has been suggested that high levels of folate may render zinc unavailable through the formation of nonabsorbable complexes in the gut, and studies have shown that folate treatment can exacerbate the teratogenic effects of nutritional zinc deficiency in animals. As noted previously, high supplemental doses of folate can mask a B<sub>12</sub> deficiency if dietary B<sub>12</sub> is insufficient.

### Vitamin B<sub>12</sub> (Cobalamin)

The term *vitamin B<sub>12</sub>* (Table 3-23) refers to the family of **cobalamin** compounds containing the porphyrin-like, cobalt-centered corrin nucleus. This family includes analogs containing cobalt-bound methyl groups (methylcobalamin), 5'-deoxyadenosyl groups (adenosylcobalamin), hydroxyl (OH<sup>-</sup>) groups (hydroxocobalamin), nitrito groups (nitritocobalamin), or water (aquacobalamin). Of the several cobalamin compounds that exhibit vitamin B<sub>12</sub> activity, cyanocobalamin and hydroxycobalamin are the most active.

### Absorption, Transport, and Storage

Vitamin B<sub>12</sub> is bound to protein in food and must be released from it by pepsin digestion in the stomach. The vitamin then combines with R proteins (cobalophilins) in the stomach and moves into the small intestine, where the R proteins are hydrolyzed and intrinsic factor (IF), a specific binding protein for B<sub>12</sub> produced in the stomach, binds the cobalamin. Most vitamin B<sub>12</sub> is absorbed by this active transport, and IF is essential to the process. Only approximately 1% can be absorbed by simple diffusion even in high amounts. IF can bind any of the four cobalamins in an IF-vitamin B<sub>12</sub> complex by which the vitamin is taken into the enterocyte by a process involving binding to a specific membrane receptor on the ileal brush border (Figure 3-24). After absorption, cobalamin binds to the plasma R proteins known as transcobalamins (TCs): TCI, TCII, and TCIII. TCII is the main transporter protein for newly absorbed cobalamins as they circulate to peripheral tissues (Gropper et al., 2005). Cellular uptake of vitamin B<sub>12</sub> seems to be mediated by a specific TC receptor that internalizes the TC-vitamin complex. After lysosomal degradation of TC, the free vitamin is released for binding to vitamin B<sub>12</sub>-dependent enzymes.

In adequately nourished individuals, vitamin B<sub>12</sub> is stored in appreciable amounts ( $\approx$ 2000 mcg) mainly in the liver, which typically accumulates a substantial store—some 5 to 7 years' worth—mostly in the form of adenosylcobalamin. Enterohepatic circulation of the vitamin also contributes to these stores.

### Metabolism

Vitamin B<sub>12</sub> is metabolically active only as derivatives that have either a 5''-deoxyadenosine or a methyl group attached covalently to the corrin ring cobalt atom. These conversions are accomplished by vitamin B<sub>12</sub> coenzyme synthetase and 5-methyl-FH<sub>4</sub>:homocysteine methyltransferase, respectively. Little or no metabolism of the corrinoid ring system occurs, and the vitamin is excreted intact by renal and biliary routes. Only the free plasma cobalamins, not the adenosylated or methylated forms, are available for excretion.

### Functions

Vitamin B<sub>12</sub> functions in two coenzyme forms: adenosylcobalamin (with methylmalonyl-CoA mutase and leucine mutase) and methylcobalamin (with methionine synthetase). These forms of the vitamin play important roles in the metabolism of propionate, amino acids, and single carbons, respectively. Because these steps are essential for normal metabolism of cells in the GI tract, bone marrow, and nervous tissue, a deficiency of the vitamin is marked by increases in plasma and urinary levels of methylmalonic acid, aminoisopropane, homocysteine and losses of FH<sub>4</sub> (via the methyl folate trap).

### Dietary Reference Intakes

Vitamin B<sub>12</sub> is expressed in micrograms. The DRIs for vitamin B<sub>12</sub> include AIs for infants and defined RDAs. The

**TABLE 3-23**

#### Vitamin B12 Content of Selected Foods

Food	Content (mcg)
Liver, beef, 3.5 oz	70.66

B<sub>12</sub>-R: B<sub>12</sub>, R Protein complex; B<sub>12</sub>-IF: B<sub>12</sub>, intrinsic factor complex; B<sub>12</sub>-TCII: B<sub>12</sub>, transcobalamin II complex.

adult RDA provides for substantial body stores because of the prevalences of achlorhydria and atrophic gastritis associated with losses of IF production and of pernicious anemia in those older than 60 years of age.

### Sources

Vitamin B<sub>12</sub> is synthesized by bacteria, but the vitamin produced from the microflora in the colon is not absorbed. The richest sources of the vitamin are liver and kidney, milk, eggs, fish, cheese, and muscle meats (see Table 3-23). Foods of plant origin contain the vitamin only through contamination or bacterial synthesis.

Many people believe that fermented foods contain sufficient vitamin B<sub>12</sub> to meet their needs; however, this theory is not supported by analysis. Individuals consuming strictly vegetarian (vegan) diets, particularly after 5 to 6 years, typically have lower circulating levels of vitamin B<sub>12</sub> unless they use supplemental forms. This is not true for ovolactovegetarians whose diets include food sources of vitamin B<sub>12</sub>.

Because the vitamin is found in food bound to protein, approximately 70% of its activity is retained during the cooking of most foods. However, appreciable amounts of the vitamin can be lost when milk is pasteurized or evaporated.

### Deficiency

Vitamin B<sub>12</sub> deficiency causes impaired cell division, particularly in the rapidly dividing cells of the bone marrow and intestinal mucosa, through arrested synthesis of DNA. The ensuing reduction in mitotic rate results in abnormally large cells and a characteristic megaloblastic anemia. The anemia of B<sub>12</sub> deficiency relates to a secondary folate deficiency because of the methyl folate trap (see “Folate” earlier in this chapter). Folate supplementation alleviates the anemia

caused by B<sub>12</sub> deficiency; however, other symptoms progress unless B<sub>12</sub> is provided. Cobalamin deficiency also produces neurologic abnormalities that develop much later than the anemia, with nerve demyelination commencing peripherally and proceeding centrally. Symptoms include numbness, tingling and burning of the feet, stiffness and generalized weakness of the legs, neurologic disorders including impaired mentation, and depression. If prolonged, deficiency causes permanent nerve damage. Finally, B<sub>12</sub> deficiency symptoms may include a waxy, lemon-yellow tint to the skin and eyes; and a smooth, beefy, red tongue.

Poor vitamin B<sub>12</sub> status occurs from a low dietary intake of the vitamin from animal-source foods and from malabsorption. Deficiency occurs in 15% of seniors older than age 65 (Andrés et al., 2007). Food-bound cobalamin malabsorption is due to gastric atrophy in the older adults, probably as a result of *Helicobacter pylori* infection (Allen, 2008).

A more common cause of vitamin B<sub>12</sub> deficiency is malabsorption because of inadequate production and secretion of IF. Clinically a form of pernicious anemia, it may result from atrophy of gastric parietal cells or autoimmune incapacitation of IF. Gene polymorphisms in TCs affect plasma vitamin B<sub>12</sub> concentrations (Allen, 2008). Although cobalamin injections are commonly prescribed, oral cobalamin therapy is especially useful for food-cobalamin malabsorption (Andrés et al., 2007).

The long-term consumption of strict vegan diets without supplemental vitamin B<sub>12</sub> leads to very low circulating levels. Vitamin B<sub>12</sub> deficiency and bone fractures are common in vegetarians and so must be managed carefully (Hermann et al., 2009). In addition, bariatric surgeries may aggravate preexisting B<sub>12</sub> deficiency or cause one. The Roux-en-Y procedure is more problematic than laparoscopic sleeve gastrectomy (Gehrer et al., 2010).

Serum B<sub>12</sub> level is not a good indicator of status. Although the methods are expensive, vitamin B<sub>12</sub> is best assessed by measuring blood levels of the metabolites methylmalonic acid and homocysteine, which are B<sub>12</sub> dependent.

## Toxicity

Vitamin B<sub>12</sub> has no appreciable toxicity.

## Biotin

**Biotin** (see Table 3-12) consists of a ureido ring joined to a thiophene ring with a valeric acid side chain and is necessary for critical carboxylations in metabolism.

## Absorption, Transport, and Storage

Biotin in foods is largely protein bound. It is released by proteolytic digestion to yield free biotin, biocytin, or biotin-peptide. Biotinidase of pancreatic or intestinal origin releases free biotin from the latter two compounds. Free biotin is absorbed in the proximal small intestine by carrier-mediated diffusion or specific transporters (Zempleni, 2009 2008). Smaller amounts of biotin can also be absorbed from the colon, which facilitates the use of the vitamin produced by hindgut microflora. Biotin is transported in the plasma primarily as free biotin, but approximately 12% is also bound to protein and biotinidase. Biotin is taken into cells by a specific carrier-mediated process. Appreciable amounts of the vitamin are stored in the liver; however, these stores do not seem to be mobilized well when the body is deprived of the vitamin.

## Metabolism

Little catabolism of biotin occurs, but some of the vitamin is oxidized to biotin sulfoxides. The vitamin is rapidly excreted in the urine (95% of an oral dose is excreted within 24 hours)—half as free biotin and the balance as bisnorbiotin, biotin sulfoxides, and various side-chain metabolites.

## Functions

Biotin is a carboxyl carrier covalently bound to the carboxylase enzymes pyruvate carboxylase (which converts pyruvate to oxaloacetate in gluconeogenesis), acetyl CoA carboxylase (which synthesizes malonyl CoA for fatty acid formation), propionyl CoA carboxylase (which allows the use of odd-chain fatty acids by converting propionate to succinate), and 3-methylcrotonyl-CoA carboxylase (which catabolizes leucine). These roles of biotin link it to the metabolic roles of folic acid, pantothenic acid, and vitamin B<sub>12</sub>. In recent years noncarboxylase roles for biotin have been elucidated, including a direct effect of biotin at the transcription level on glucokinase and phosphoenol pyruvate carboxykinase, as well as other enzymes (Dakshinamurti, 2005; Zempleni et al., 2009).

## Dietary Reference Intake

The AIs for biotin have been established. However, because of uncertainty about the amount of biotin provided by intestinal flora and differences in bioavailability of biotin

from foods, the establishment of EARs and RDAs is problematic.

## Sources

Biotin is widely distributed in foods, but its content varies significantly, it has been determined for relatively few foods, and it may not be very accurate. Peanuts, almonds, soy protein, eggs, yogurt, nonfat milk, and sweet potatoes are sources. Biotin content is not usually reported in food composition tables (IOM, Food and Nutrition Board, 2000b). The bioavailability of biotin varies considerably among different foods because of differences in the digestibility of various biotin-protein complexes. Biotin is unstable in oxidizing conditions and is destroyed by heat, especially in the presence of lipid peroxidation.

In addition to foods, intestinal bacteria can also contribute appreciable amounts of biotin. Fecal and urinary excretions are considerably higher than dietary intake, reflecting the magnitude of the microfloral synthesis of biotin.

## Deficiency

Because biotin can be obtained from many foods and gut microbial metabolism, simple biotin deficiency in animals is rare. Biotin deficiency has been induced by feeding raw egg white or its active component—the heat-labile, biotin-binding protein avidin. Avidin impairs biotin absorption, causing such symptoms as seborrheic dermatitis, alopecia, and paralysis. Impaired biotin absorption can also occur in such GI tract disorders as inflammatory bowel diseases or achlorhydria. Zempleni et al., (2009) noted that decreases in the activities of biotinidase and other proteins associated with digestion, absorption, and transport of biotin can cause a deficiency.

The few cases of biotin deficiency that have been described in humans have involved patients receiving incomplete parenteral nutrition and nursing infants whose mothers' milk contained very low amounts of the vitamin. In each case the signs included dermatitis, glossitis, anorexia, nausea, depression, hepatic steatosis, and hypercholesterolemia. Inherited defects in all of the known biotin enzymes have been identified in humans, but they are rare and usually have serious neurologic consequences. Blood levels of biotin are most often used to assess biotin status.

## Toxicity

Biotin has no known toxic effects, even in very large doses.

## Ascorbic Acid

Vitamin C, or **ascorbic acid** (see Table 3-12), is synthesized from glucose and galactose by plants and most animals. However, humans, other primates, guinea pigs, some bats, and a few species of birds, lack the enzyme L-gulonolactone oxidase and thus cannot biosynthesize the factor; for them, it is a vitamin.

## Absorption, Transport, and Storage

Species that cannot biosynthesize ascorbic acid absorb it from the diet by active transport and passive diffusion. The

oxidized form of the vitamin, dehydroascorbic acid, is better absorbed than the reduced form, ascorbate, or ascorbic acid. The efficiency of enteric absorption of the vitamin is 80% to 90% at low intakes, but declines markedly at intakes greater than 1 g/day.

Vitamin C is transported in the plasma in the reduced form in free solution. It is taken up by cells via GLUT 1, GLUT 2, and GLUT 3, as well as sodium-coupled transporters (sodium-dependent vitamin C transporter 1 and 2) (Rivas et al., 2008). Each system moves dehydroascorbic acid into cells, where it is readily reduced to ascorbate. The GLUT-based system of uptake is not as fast as the specific system, but it is stimulated by insulin and inhibited by glucose. Thus diabetic patients with high glucose levels typically have high plasma levels and low cellular levels of dehydroascorbic acid. The vitamin is concentrated primarily as dehydroascorbic acid in many vital organs, particularly the adrenals, brain, and eye.

## Metabolism

Ascorbic acid is oxidized in vivo by two successive losses of single electrons forming the free radical (monodehydroascorbic acid). This intermediate can be further oxidized to dehydroascorbic acid (Figure 3-25). Subsequently the oxidized product undergoes irreversible hydrolysis to yield 2,3-diketo-l-gulonic acid, which can be decarboxylated to yield carbon dioxide and several five-carbon fragments (e.g., xylose, xylonic acid) or oxidized to yield oxalic acid and several four-carbon fragments (e.g., threonic acid). In addition, the vitamin can be converted to ascorbic acid 2-sulfate.

## Functions

Because ascorbic acid easily loses electrons and is reversibly converted to dehydroascorbic acid, it serves as a biochemical redox system involved in many electron transport reactions, including those involved in the synthesis of collagen and carnitine and other metabolic reactions. During collagen and carnitine synthesis, vitamin C acts as a reducing agent to keep iron in its ferrous state, thus enabling hydroxylase enzymes to function. For example, collagen, the major protein in fibrous tissues such as connective tissue, cartilage, bone matrix, and tendons, depends on the posttranslational

hydroxylation of proline residues in procollagen to form hydroxyproline.

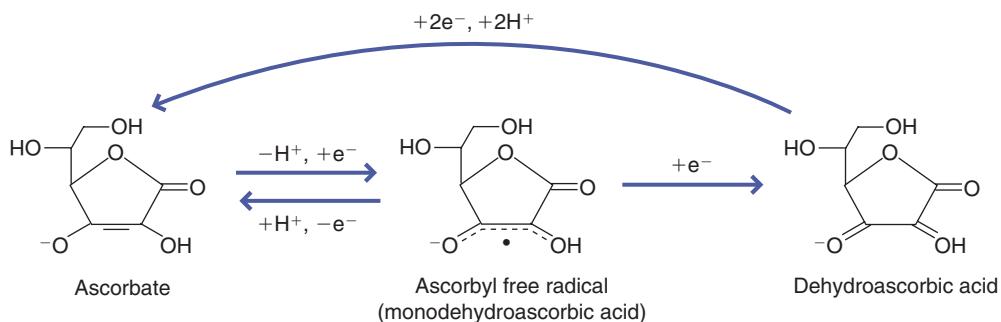

Cellular vitamin C deficiency may lead to oxidative stress in cells, contributing to an increased risk of ischemic heart disease (McNulty et al., 2007). An important role for vitamin C in atherogenesis is as a vasodilator because of its redox properties (Frikke-Schmidt and Lykkesfeldt, 2009). Vitamin C concentration decreases in periods of stress when adrenal cortical hormone activity is high. During periods of emotional, psychological, or physiologic stress, the urinary excretion of ascorbic acid increases.

Ascorbic acid also acts as an antioxidant as it undergoes single-electron oxidation to the ascorbyl radical and dehydroascorbate. By reacting with potentially toxic reactive oxygen species such as the superoxide or hydroxyl radical, the vitamin can prevent oxidative damage. Vitamin C is essential for the oxidation of phenylalanine and tyrosine, the conversion of folate to FH<sub>4</sub>, the conversion of tryptophan to 5-hydroxytryptophan and the neurotransmitter serotonin, and the formation of norepinephrine from dopamine. It also reduces ferric to ferrous iron in the intestinal tract to facilitate iron absorption and is involved in the transfer of iron from plasma transferrin to liver ferritin.

Vitamin C promotes resistance to infection through its involvement with the immunologic activity of leukocytes, the production of interferon, the process of inflammatory reaction, and the integrity of the mucous membranes. The value of large amounts of ascorbic acid to prevent and cure the common cold has been reported, but conclusions from these studies remain controversial (Heimen et al., 2009). It is generally accepted that taking high doses of vitamin C for colds reduces the severity of the symptoms, but it does not prevent them. Vitamin C maintains proper lung function, especially in asthma (Kaur et al., 2009).

## Dietary Reference Intakes

The DRIs for vitamin C are expressed quantitatively in milligrams. Although as little as 10 mg of vitamin C can prevent scurvy, this level does not provide acceptable reserves of the vitamin. Because of the lower concentrations of ascorbic acid in the serum of cigarette smokers, it has been recommended that smokers increase their intake. Whereas the average body pool of vitamin C is 1.5 g, of which 40 to

**FIGURE 3-25** Oxidation-reduction reaction of vitamin C. (From Combs GF: *The vitamins: fundamental aspects in nutrition and health*, ed. 2, Orlando, 1998, Academic Press.)

**TABLE 3-24****Vitamin C Content of Selected Foods**

Food	Amount	Content (mg)
Pepper, sweet, yellow	1 cup	283
Orange juice		
Fresh	1 cup	124
Frozen, diluted, canned	1 cup	97
Canned	1 cup	86
Broccoli		
Fresh, boiled	1 cup	116
Frozen, chopped, boiled	1 cup	74
Brussels sprouts, cooked	1 cup	97
Strawberries	1 cup	106
Grapefruit juice, from frozen concentrate, unsweetened	1 cup	83
Cantaloupe	1 cup	68
Mango	1	57
Kale, from raw, cooked	1 cup	53
Tomato juice	1 cup	45

**DRI Range**

15–120 mg/day, depending on age and gender

From U.S. Department of Agriculture, Agricultural Research Service: Nutrient Database for Standard Reference, Release 18, Data Laboratory home page: <http://www.nal.usda.gov/fnic/foodcomp/Data/SR18/nutrlst/sr18w401.pdf>; accessed 2011.

DRI, Dietary reference intake.

60 mg is used daily, smokers may need as much as 140 mg/day (Berger, 2009).

**Sources**

Vitamin C is found in plants and animal tissues as ascorbic acid and dehydroascorbic acid. The best sources are fruits, vegetables, and organ meats, but the actual ascorbic acid contents of foods can vary with the conditions of growth and degree of ripeness when harvested. Refrigeration and quick freezing help retain the vitamin. Most commercially frozen foods are processed so close to the source of supply that their ascorbic acid content is often higher than that of fresh foods that have been shipped across the country and spent time in storage and on supermarket shelves. Table 3-24 lists the vitamin C content of selected fruits and vegetables. Citrus fruits and juices are very important sources of the vitamin for many Americans, who tend not to eat many servings of other fruits and vegetables.

Ascorbic acid is easily destroyed by oxidation, and, because it is soluble in water, it is often extracted and discarded in cooking water. Sodium bicarbonate, added to preserve and improve the color of cooked vegetables, destroys vitamin C. The cumulative losses of the vitamin from prepared vegetables refrigerated for 24 hours can be

as high as 45% in fresh products and 52% in frozen products. Because consumers are eating out more frequently and more foods are being supplied to restaurants or institutions partially prepared (e.g., shredded lettuce, peeled and diced vegetables) or served from open salad bars, this vitamin loss must be considered when evaluating dietary intake.

**Deficiency**

Acute vitamin C deficiency results in **scurvy** in individuals unable to synthesize the vitamin. In human adults signs are manifest after 45 to 80 days of vitamin C deprivation. In children the syndrome is called *Moeller-Barlow disease*; it can also develop in infants fed formulas not enriched with vitamin C. In both cases lesions occur in mesenchymal tissues and result in impaired wound healing; edema; hemorrhages; and weakness in bone, cartilage, teeth, and connective tissues. Adults with scurvy may have swollen, bleeding gums with eventual tooth loss, lethargy, fatigue, rheumatic pains in the legs, muscular atrophy, skin lesions, and a variety of psychological changes.

**Toxicity**

Vitamin C is one of the most commonly used supplements in the United States. The adverse effects of high doses of vitamin C in humans include GI disturbances and diarrhea. Because the catabolism of vitamin C yields oxalate (among other metabolites), it is also reasonable to be concerned about the possibility of high doses of the vitamin increasing the risk of forming renal oxalate stones (see Chapter 36). Individuals with histories of forming renal stones should avoid consuming too much vitamin C. Excess ascorbic acid excreted in the urine can also give a false-positive urinary glucose test. The relationship of vitamin C to cancer is discussed later in the text. Table 3-12 summarizes the information on the known vitamins.

**OTHER VITAMIN-LIKE FACTORS**

Other food factors have vitamin characteristics but do not meet the criteria of vitamin status. These quasivitamins include those that can be biosynthesized but may be beneficial supplements in certain life stages or medical conditions (e.g., choline and betaine, carnitine) and those yet to be proven to be essential in the diet (e.g., myo-inositol, the ubiquinones, the bioflavonoids).

**Choline and Betaine**

Choline (2-hydroxy-*N,N,N*-trimethylenthanolamine) is a methyl-rich essential component of animal tissues, where it is a structural component of lecithin (phosphatidylcholine) in membrane phospholipids and the neurotransmitter acetylcholine. Choline is released by the hydrolysis of lecithin by pancreatic and intestinal lipases and is absorbed by a

carrier-mediated process and passive diffusion. Absorbed choline is transported via chylomicrons in the lymphatic circulation primarily in the form of lecithin; it is transferred to lipoproteins in this form for distribution to peripheral tissues. Choline can be biosynthesized from ethanolamine by sequential methylations using S-adenosylmethionine, but most humans obtain it from dietary phosphatides.

Betaine (*N,N,N*-trimethylglycine) was named for its source, sugar beets.

## Functions

Choline and betaine are important components of the one-carbon metabolism cycle, linked with the amino acid homocysteine and lipid metabolism (Bruce et al., 2010). Choline has several other functions as a methyl donor. As phosphatidylcholine it is a structural element of membranes, a precursor to the sphingolipids, and a promoter of lipid transport. As acetylcholine, it is a neurotransmitter and a component of platelet-activating factor. It functions as an emulsifier in bile, thus helping with the absorption of fat, and is also a component of pulmonary surfactant.

Betaine (Cystadane) may be prescribed to treat homocystinuria or homocystinemia; it is a “nutrient” within the drug classification system. Betaine may also be used to protect against ethanol damage in the brain and the liver. Betaine homocysteine methyltransferase catalyzes a methionine pathway. When ethanol intake is prolonged, this enzyme remethylates homocysteine and supports desirable levels of *S*-adenosylmethionine, which is the key methylating agent (Kharbanda, 2009).

## Dietary Reference Intakes

The AIs were established for choline as part of the 1998 DRIs. The UL has been set at 3.5 g/day. Mean choline intakes for older children, men, women, and pregnant women are far below the AI level established by the IOM (Zeisel and da Costa, 2009). There are no DRIs or AIs established for betaine.

## Sources

Choline is widely distributed in fat as lecithin (eggs, liver, soybeans, beef, milk, and peanuts). Eggs and meats are the richest sources of choline in the North American diet, providing up to 430 mg/100 g (Zeisel and da Costa, 2009). Whole-grain cereal products and products containing cereal bran are excellent dietary sources of free choline and betaine (Bruce et al., 2010). Free choline is also present in liver, oatmeal, soybeans, iceberg lettuce, cauliflower, kale, and cabbage.

## Deficiency

Choline deficiency is thought to have an effect on diseases such as liver disease, atherosclerosis, and neurologic

disorders (Zeisel and da Costa, 2009). Deficiency during the perinatal period results in “metabolic imprinting,” a permanent alteration in the cholinergic organization of the brain (Meck and Williams, 2003). Elevated neural tube defects are associated with lower levels of total choline, despite grain fortification with folic acid in the United States (Shaw et al., 2009).

Metabonomics may become a diagnostic tool in conditions such as ulcerative colitis (UC). In active and quiescent UC, biopsies show lower levels of lipid, glycero-phosphocholine, myo-inositol, and betaine (Bjerrum et al., 2010). Oral supplements of choline may increase endurance in athletes, but only if blood choline levels are low (Penry and Manore, 2008). Finally, no correlation has been found from low intakes of choline or betaine with cancers at this time.

## Carnitine

Carnitine ( $\beta$ -hydroxy- $\gamma$ -*N*-trimethylaminobutyrate) helps transport LCFAs into the mitochondria for oxidation as sources of energy in the carnitine palmitoyltransferase system (Rufer et al., 2009). Mammals and birds can synthesize carnitine from the amino acid lysine using a process that requires vitamin C. In some instances carnitine may be a conditionally essential nutrient. Carnitine is efficiently absorbed across the gut by active transport and simple diffusion. Approximately half of carnitine is acetylated during absorption; free and acetylated forms are found in circulation in plasma and erythrocytes. Carnitine is taken up primarily by skeletal peripheral tissues, which contain approximately 90% of the body stores. Foods of plant origin are generally low in carnitine, whereas meats and dairy products are good sources.

Tissue depletion of carnitine has been reported in adults undergoing hemodialysis, adults with liver disease, and preterm infants. Carnitine supplementation improves fatty acid oxidation, which is important in cardiovascular disease and in type 2 diabetes (Mingrone, 2004). Deficiency may also be apparent in some genetic metabolic disorders (see Chapter 44).

## Myo-inositol

**Myo-inositol** (*cis*-1,2,3,5-*trans*-4,6-cyclohexanhexol) functions in metabolism as *phosphatidylmyo-inositol* (PI). This provides structural support in membranes and serves as an anchor for membrane proteins through covalent bonding. PI is a source of arachidonic acid for the biosynthesis of eicosanoids. In addition, PI is the source of important intracellular signals and secondary cell messengers in response to hormonal stimuli. For example, hormone-sensitive phospholipase C can act on phosphorylated PI, producing free inositol triphosphate (IP<sub>3</sub>) and a diacylglycerol (DAG). IP<sub>3</sub> activates the release of calcium ions, which in turn stimulate calcium-dependent enzymes. DAG initiates a process that results in the alteration of some cellular enzyme activities

(Gropper et al., 2005). IP is concentrated in the brain and cerebrospinal fluid but also exists in other tissues. Myo-inositol may be useful in the treatment of bipolar disorder caused by abnormalities in the role of PI as a cell messenger, but has not yet been found relevant to other psychiatric disorders (Kim, 2005).

Myo-inositol is efficiently absorbed in its free form by an active transport process. It is transported in the blood primarily in its free form, with some as PI associated with lipoproteins. Free myo-inositol is converted in the tissue to PI, which is metabolized by sequential phosphorylations to the monophosphate and diphosphate forms.

Mammals synthesize myo-inositol from glucose; but it is also obtained from fruits, grains, vegetables, nuts, legumes, and organ meats such as liver and heart. Dietary sources include various inositol phospholipids in animal products and phytic acid (inositol hexaphosphate) in plant materials. Because humans and most other mammals lack an intestinal phytase, phytic acid is not a useful source of myo-inositol. Phytates are not listed in food composition tables, but they may actually have some benefits for lowering blood glucose and lipids (Schlemmer et al., 2009).

Only female gerbils and certain fish have been shown to have a clear dietary need for pre-formed myo-inositol. In these animals deprivation of the factor produced anorexia, dermatologic lesions, and intestinal lipodystrophy. Experimental pharmaceutical treatment alternatives for treatment-resistant depression are being explored; they include inositol along with  $\omega$ -3 fatty acids, S-adenosyl-L-methionine, and folic acid (Shelton et al., 2010). In addition, inositol has been studied for its role in sleep management, bipolar disorder, and other neurologic disorders. To date, a daily requirement for inositol has yet to be defined.

### Ubiquinones

The **ubiquinones** are a group of substituted 1,4-benzoquinone derivatives with varying lengths of isopentyl side chains. The principal species has 10 such side-chain units and is referred to as **coenzyme Q<sub>10</sub>** (**CoQ<sub>10</sub>**), first isolated in 1957. The ubiquinones are essential components of the mitochondrial electron transport chain, in which they undergo reversible reduction-oxidation reactions to pass electrons from flavoproteins (NAD or succinic dehydrogenases) to the cytochromes via cytochrome b5. In addition, the redox properties of CoQ<sub>10</sub> enable it to function as a fat-soluble antioxidant, much like  $\alpha$ -tocopherol. Relatively high concentrations of the ubiquinones are maintained in tissues, apparently by biosynthesis from endogenous precursors.

The use of CoQ<sub>10</sub> in clinical situations has been extensively reviewed. Low ubiquinone synthesis may play a role in the causal factors of heart disease; supplemental CoQ<sub>10</sub> may be useful in treating cardiomyopathy and congestive heart failure. CoQ<sub>10</sub> and its analogue, idebenone, have also been widely used in the treatment of Parkinson disease, Huntington disease, ALS, Friedreich ataxia, and other

mitochondrial disorders (Mancuso et al., 2010). Mitochondrial dysfunction leads to oxidative stress, deletions or damage to mitochondrial DNA, altered morphology, and ultimately neuronal demise (Beal, 2009). Loss of CoQ<sub>10</sub> after HMG-CoA reductase inhibitor (statin) treatment has been implicated in the associated myotoxicity (Mancuso et al., 2010). CoQ<sub>10</sub> is found in various foods, most notably fish oils, nuts, fish, and meats.

### Bioflavonoids

The **bioflavonoids** (phenolic derivatives of 2-phenyl-1,4-benzopyrone) have no known immediate metabolic function. They have been shown to reduce capillary fragility and potentiate the antiscorbutic activity of ascorbic acid, both of which may involve their chelation of divalent metal ions (Cu<sup>++</sup>, Fe<sup>++</sup>) and their intrinsic antioxidant properties. Epidemiologic studies have shown an association between diets high in bioflavonoids and reduced risks for cardiovascular disease and several cancers. The bioflavonoids are ubiquitous in foods of plant origin; more than 800 different bioflavonoids, such as quercetin, rutin, and hesperidin, have been isolated from plants in which they are the major sources of noncarotenoid red, blue, and yellow pigments.

## MICRONUTRIENTS: MINERALS

The mineral nutrients most are traditionally divided into **macrominerals** ( $\geq 100$  mg/day required) and **microminerals** or trace elements (<15 mg/day required). Studies of patients receiving long-term total parenteral nutrition (TPN) have helped to determine the essentiality of **ultratrace elements** that are necessary in microgram quantities each day. Mineral nutrients are recognized as essential for human function, even though specific requirements have not been established for a few of them.

### MINERAL COMPOSITION OF THE BODY

Minerals represent approximately 4% to 5% of body weight, or 2.8 to 3.5 kg in adult women and men, respectively. Approximately 50% of this weight is calcium, and another 25% is phosphorus, existing as phosphates. Almost 99% of the calcium and 70% of the phosphates are found in bones and teeth. The five other essential macrominerals (magnesium, sodium, potassium, chloride, and sulfur) and the 11 established microminerals (iron, zinc, iodide, selenium, manganese, fluoride, molybdenum, copper, chromium, cobalt, and boron) constitute the remaining 25%. The ultratrace elements such as arsenic, aluminum, tin, nickel, vanadium, and silicon, provide a negligible amount of weight.

Macrominerals exist in the body and food chiefly in the ionic state. Sodium, potassium, and calcium form positive

ions (cations), whereas other minerals exist as negative ions (anions). The latter include chlorine as chloride, sulfur as sulfate, and phosphorus as phosphates. Minerals also exist as components of organic compounds such as phosphoproteins, phospholipids, metalloenzymes, and other metalloproteins such as hemoglobin.

With the exception of heme iron, minerals are usually absorbed in the ionic state. Therefore minerals that remain bound to organic molecules (chelated) or remain as inorganic complexes after the digestion usually cannot be absorbed and are not bioavailable. However, a few minerals may be absorbed better in a chelated form when they are properly bound to an amino acid in a covalent bond (e.g., selenomethionine). Unabsorbed minerals are excreted in the feces. Once a mineral is absorbed at the brush border of the intestinal epithelial cells, each must transfer through the cytosol and be transported across the basolateral membrane into the blood, usually by an active transport mechanism. If the mineral is not transported across the basolateral membrane, it remains in the intestinal cell bound to proteins. For example, calcium ions bind to calbindins, iron to intestinal ferritin, and zinc to metallothionein; if not transported into the blood, they are excreted when the intestinal cells die and slough off into the intestinal lumen. Such mechanisms may have evolved to protect the body against the potential toxicity of excessive absorption.

**Bioavailability** also is equated with absorption of a mineral element after its digestion from food and before its use in tissue and cells. Several factors can affect bioavailability of ingested minerals. Low bioavailability may also result from the formation of soaps, from calcium and magnesium binding to free fatty acids in the lumen in fat malabsorption, or from precipitation when one of a pair of ions (e.g., calcium, which combines with phosphates) is present in the lumen in a very high concentration. Mineral-mineral interactions also can result in depressed absorption of elements or reduced bioavailability. For example, the absorption of zinc is typically reduced by nonheme iron supplementation; excessive intake of zinc reduces the absorption of copper; and excessive intake of calcium may reduce the absorption of manganese, zinc, and iron.

Many organic molecules in foods influence bioavailability, either by enhancing absorption or inhibiting absorption. Examples of inhibitors include the binding by phytates and oxalates of calcium and other divalent cations. Enhancers include ascorbate for nonheme iron or the hemoglobin protein for iron. Vegetarians tend to consume foods with higher quantities of many of the inhibiting factors, but they typically also ingest more ascorbic acid, an enhancer. In addition, the bioavailability of elements may be influenced by many physiologic factors such as gastric acidity, homeostatic adaptations, and stress. NDOs fermented by intestinal bacteria stimulate the intestinal absorption and retention of calcium, magnesium, zinc, and iron.

Certain minerals generally have a low bioavailability from foods (e.g., iron, chromium, manganese), whereas others have a high bioavailability (e.g., sodium, potassium,

chloride, iodide, fluoride). Calcium and magnesium have a medium bioavailability.

## Problem Minerals in the U.S. Diet

A few minerals, such as calcium and iron, continue to be consumed in less than optimal amounts by a large percentage of people in the United States. The intakes of magnesium, zinc, and possibly a couple of other trace minerals are also generally insufficient in the population. In the last decade fortification of foods, especially of ready-to-eat cereals, have improved intakes of iron and zinc but not calcium (Heaney and Rafferty, 2009); the mean intakes still do not meet DRI levels.

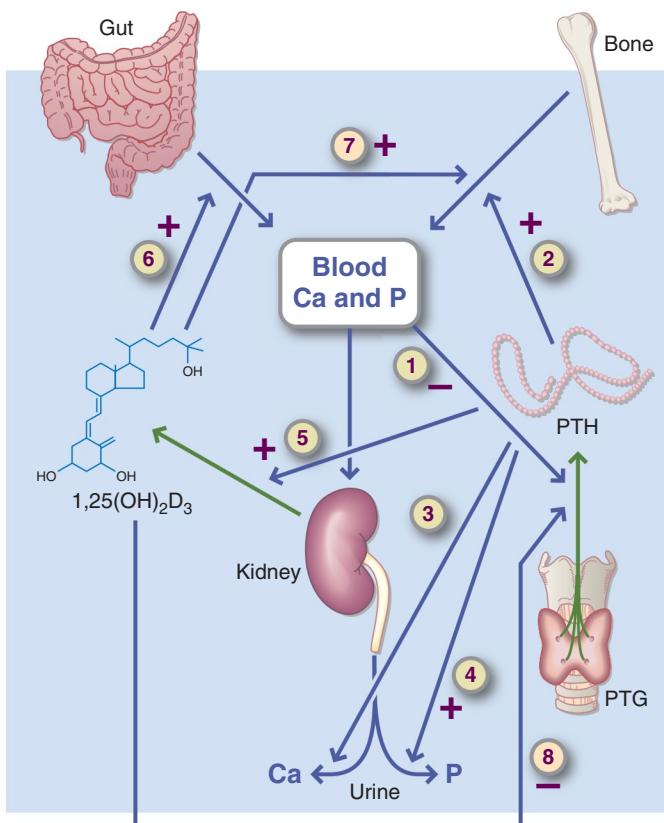

### Calcium

Calcium, the most abundant mineral in the body, makes up approximately 1.5% to 2% of the body weight and 39% of total body minerals. Approximately 99% of the calcium exists in the bones and teeth. The calcium in teeth, unlike bone, cannot be mobilized back to the blood; the minerals of erupted teeth are fixed. The remaining 1% of calcium is in the blood and extracellular fluids and within the cells of all tissues, where it regulates many important metabolic functions. Figure 3-26 illustrates the pathways of calcium metabolism. Bone is a dynamic tissue that returns calcium and other minerals to the extracellular fluids and blood on demand. Bone also takes up calcium and other minerals from the blood when they are consumed.

### Absorption, Transport, Storage, and Excretion

Calcium is absorbed by all parts of the small intestine, but the most rapid absorption after a meal occurs in the more acidic ( $\text{pH} < 7$ ) duodenum. Absorption is slower in the remainder of the small bowel because of the alkaline pH, but the amount of calcium absorbed is actually greater in the lower segments of the small intestine, including the ileum. Small amounts of calcium can also be absorbed in the colon. Only approximately 30% of ingested calcium is absorbed by adults, but a few individuals may absorb as little as 10% and some (rarely) as much as 60% of ingested calcium. Late in life, bone retention of calcium from food and supplements is limited unless sufficient vitamin D or a bone-conserving drug is available.

Calcium is absorbed by two mechanisms: active transport, which operates predominantly at low luminal concentrations of calcium ions, and passive transport or paracellular transfer, which operates at high luminal concentrations of calcium ions. The active transport mechanism, mainly in the duodenum and proximal jejunum, has limited capacity. It is controlled through the action of  $1,25(\text{OH})_2\text{D}_3$ . This vitamin-hormone increases calcium uptake at the brush border of the intestinal mucosal cell by also stimulating the production of calcium-binding proteins (**calbindins**) and other mechanisms. The role of calbindins in the intestinal absorbing cells is to store calcium ions temporarily after a meal and ferry them to the basolateral membrane for the final step of absorption. The

**FIGURE 3-26** Pathways of calcium metabolism. The regulation of calcium metabolism involves intestinal absorption (gut), blood calcium, and phosphate concentrations, bone, the kidneys—which produce the hormonal form of vitamin D ( $1,25(\text{OH})_2\text{D}_3$ )—and the parathyroid glands, which secrete parathyroid hormone (PTH). Steps 1 through 8 are specific regulation points. A low serum calcium or high serum phosphate level stimulates PTH secretion (step 1) through negative feedback.

calcium-binding proteins bind two or more calcium ions per protein molecule.

The second absorption mechanism, which is passive, nonsaturable (with no limit), and independent of vitamin D, occurs along the entire length of the small intestine. When large amounts of calcium are consumed in a single meal (e.g., from a dairy food or a supplement), much of the calcium is absorbed by this passive route. The active transport mechanism is more important when calcium intakes are well below recommended intakes and body requirements are not being met.

Numerous factors influence the bioavailability and absorption of calcium within the gut lumen. The greater the need and the smaller the dietary supply, the more efficient is absorption. Increased needs during growth, pregnancy, lactation, calcium-deficient states, or exercise resulting in high bone density enhance calcium absorption. Low vitamin D intake or inadequate exposure to sunlight reduces calcium absorption, especially among older adults. In addition, the efficiency of skin production of vitamin D by older adults is

lower than that of younger people. Aging is also characterized by achlorhydria, which results in less gastric acidity and reduced calcium absorption.

Calcium is absorbed only if it is present in an ionic form. Thus calcium is best absorbed in an acidic medium; the hydrochloric acid secreted in the stomach, such as that secreted during a meal, increases calcium absorption by lowering the pH in the proximal duodenum. This also applies to calcium supplements; therefore taking a calcium supplement with a meal improves absorption, especially in older adults. Lactose enhances calcium absorption. Even in adults with lactose intolerance, lactose probably improves calcium absorption.

Calcium is not absorbed if it is precipitated by another dietary constituent such as oxalate or if it forms soaps with free fatty acids. Oxalic acid (oxalate) in rhubarb, spinach, chard, and beet greens forms insoluble calcium oxalate in the digestive tract (see Chapter 36). For example, only 5% of the calcium in spinach is absorbed. Phytic acid (phytate) combines with calcium to form calcium phytate, which is insoluble and cannot be absorbed. These unabsorbed forms of calcium are excreted in the feces as calcium oxalates and calcium soaps.

Dietary fiber may decrease calcium absorption, but this may only be a problem for those who consume more than 30 g/day. Lower intakes of fiber have little effect on calcium availability. Medications can affect bioavailability or increase calcium excretion, both of which may contribute to bone loss. With fat malabsorption, calcium absorption is decreased because of the formation of calcium-fatty acid soaps. Calcium absorption does not seem to be affected by the amount of phosphate in the diet unless the intake of phosphate is excessively high or by the calcium/phosphorus ratio.

**Renal Excretion.** Approximately 50% of the ingested calcium is excreted in the urine each day, but an almost equivalent amount is also secreted into the intestine and joins unabsorbed calcium in the feces. Calcium resorption from the renal tubules occurs by transport mechanisms similar to those in the small intestine. Urinary calcium excretion varies throughout the life cycle, but it is typically low during periods of rapid skeletal growth. At menopause calcium excretion increases greatly, but in postmenopausal women treated with estrogen, less calcium is excreted. After approximately 65 years of age, calcium excretion decreases, most likely because of decreased intestinal absorption of calcium. In general, urinary calcium levels correlate well with calcium intake. A high sodium intake contributes to lower renal resorption of calcium and higher urinary calcium losses.

**Skin Losses.** Dermal losses of calcium occur in the form of skin exfoliation and sweat. The amount of calcium lost in sweat is approximately 15 mg/day. Strenuous physical activity with sweating increases the loss, even in persons with a low calcium intake.

**Serum Calcium.** Total serum calcium consists of three distinct fractions: free, or ionized, calcium; complexes between calcium and anions such as phosphate and citrate;

and calcium that is protein bound with albumin. Serum albumin binds between 70% and 90% of the calcium that is protein bound. Ionized calcium ( $\text{Ca}^{2+}$ ) is regulated and equilibrates rapidly with protein-bound calcium in blood. The serum ionized calcium concentration is controlled primarily by PTH, although other hormones have minor roles in its regulation. These other hormones include calcitonin, vitamin D, estrogens, and others.

Total serum calcium level is maintained within a narrow range of 8.8 to 10.8 mg/dL, of which the ionized calcium concentrations range from 4.4 to 5.2 mg/dL because hypocalcemia and hypercalcemia have significant physiologic effects. Serum levels of calcium are highest early in life, gradually decrease throughout life, and reach the lowest levels during the older years. Several factors affect the relative distribution of calcium in blood serum or plasma. One of these is pH; the ionized calcium fraction is higher in acidosis and lower in alkalosis. Total calcium changes concurrently with changes in plasma protein levels; however, the ionized fraction usually remains within normal limits. The strict regulation of ionized calcium makes it a useful diagnostic tool in assessing parathyroid gland function, monitoring kidney disease, and monitoring sick neonates for whom hypocalcemia could be life threatening.

**Regulation of Serum Calcium.** Calcium in bones is in equilibrium with calcium in the blood. PTH plays the major role in maintaining serum calcium, as noted previously. When the blood calcium concentration falls below this level, PTH stimulates the transfer of exchangeable calcium from the bone into the blood. At the same time, PTH promotes renal tubular resorption of calcium, and it indirectly stimulates increased intestinal absorption of calcium by increasing kidney production of vitamin D ( $1,25[\text{OH}]_2\text{D}_3$ ) (see Figure 3-26).

Other hormones—such as glucocorticoids, thyroid hormones, and sex hormones—also have important roles in calcium homeostasis. Glucocorticoid excess leads to bone loss, particularly of trabecular bone, as a result of impaired calcium absorption through both active and passive mechanisms. Thyroid hormones ( $T_4$  and  $T_3$ ) may stimulate bone resorption; chronic hyperthyroid conditions result in loss of compact and trabecular bone. In women normal bone balance requires serum estrogen concentrations to be within normal limits. The rapid decrease of the serum estrogen concentration during menopause is a major factor contributing to bone resorption. Treating postmenopausal women with estrogen slows the rate of bone resorption; bone reabsorption is also inhibited by testosterone.

## Functions

Adequate dietary calcium is needed to permit optimal gains in bone mass and density in the prepubertal and adolescent years. These gains are especially critical for girls because the accumulated bone may provide additional protection against osteoporosis in the years after menopause. Peak calcium retention by girls has been shown to occur in the prepubertal and early pubertal periods and is influenced by race, with

black girls having significantly higher retention rates (Wigertz et al., 2005).

Postmenopausal women need to obtain sufficient amounts of calcium to maintain bone health and suppress PTH, which increases later in life in most individuals, perhaps as a result of inadequate calcium in the diet. Additional amounts of calcium are recommended to meet the needs of pregnancy and lactation, infancy, childhood, and adolescence.

In addition to its function in building and maintaining bones and teeth, calcium also has numerous critical metabolic roles in cells in all other tissues. However, compared with the significant needs of the skeleton, only small amounts of calcium are required for all other cellular and extracellular functions.

The transport functions of cell membranes are influenced by calcium, which affects membrane stability in poorly understood ways. Calcium also influences the transmission of ions across membranes of cell organelles, the release of neurotransmitters at synaptic junctions, the function of hormones, and the release or activation of intracellular and extracellular enzymes.

Calcium is required for nerve transmission and regulation of heart muscle function. The proper balance of calcium, sodium, potassium, and magnesium ions maintains skeletal muscle tone and controls nerve irritability. A significant increase in the serum calcium level can cause cardiac or respiratory failure, whereas a decrease results in **tetany** of skeletal muscles. In addition, calcium ions play a critical role in smooth muscle contractility.

Ionized calcium initiates the formation of a blood clot by stimulating the release of thromboplastin from blood platelets. Calcium ions also serve as required cofactors for several enzymatic reactions, including the conversion of prothrombin to thrombin, which aids in the polymerization of fibrinogen to fibrin and the final step in blood clot formation.

High dietary calcium intakes are associated with decreased prevalence of overweight and obesity. The mechanism for this effect appears to be related to (1) depression of the PTH and 1,25 hydroxy vitamin D, which leads to inhibition of lipogenesis and increased lipolysis; and (2) increased excretion of fecal fat caused by soaps formation (Heaney and Rafferty, 2009) (Table 3-25).

## Dietary Reference Intakes

The IOM, Food and Nutrition Board (2010) has recently set the RDA for calcium, based on estimates of requirements of both genders throughout the life cycle. The tolerable UL has also been established for this nutrient. During several periods of the female life cycle, calcium intake is critical: prepuberty and adolescence, postmenopause, and during pregnancy and lactation (Kovacs, 2005). In a study of adolescent girls, calcium intakes of 1300 mg or more each day were necessary for maximum calcium retention by the body's skeleton. Abrams (2005) noted that calcium supplementation was helpful to children and adolescents and that catch-up mineralization was possible later in puberty if intakes were adequate.

**TABLE 3-25****Minerals in Human Nutrition**

	<b>Body Location and Selected Biologic Functions</b>	<b>DRI<sup>s</sup></b>	<b>Food Sources</b>	<b>Likelihood of Deficiency</b>
<b>Macronutrients Essential at Daily Levels of 100 mg or More</b>				
Calcium	99% is found in bones and teeth. Ionic calcium in body fluids is essential for ion transport across cell membranes. Calcium may also be bound to protein, citrate, or inorganic acids.	1300 mg ages 9 through 18. 1000 mg for adults 19–50 yr. 1200 mg for females 51+ yr and all adults over age 70.	Milk and milk products, sardines, clams, oysters, kale, turnip greens, mustard greens, tofu	Dietary surveys indicate that many people do not meet AIs for calcium. Because bone serves as a homeostatic mechanism to maintain calcium levels in the blood, many essential functions are maintained, regardless of dietary intake. Long-term dietary deficiency is probably one of the factors responsible for development of osteoporosis later in life.
Phosphorus	Approximately 80% is found in inorganic portion of bones and teeth. Phosphorus is a component of every cell, as well as of important metabolites, including DNA, RNA, ATP, and phospholipids. Phosphorus is also important for pH regulation.	700 mg for adults (RDA)	Cheese, egg yolk, milk, meat, fish, poultry, whole-grain cereals, and almost all other foods	Dietary inadequacy is not likely if protein and calcium intake are adequate.
<b>Micronutrients Essential at Daily Levels of a Few Milligrams or Less</b>				
Magnesium	Approximately 50% is in bone; the remaining 50% is almost entirely inside body cells, with only about 1% located in extracellular fluid.	400–420 mg for men, 310–320 mg for women 14–70+ yr (RDA)	Whole-grain cereals, tofu nuts, meat, milk, green vegetables, legumes, chocolate	Dietary inadequacy is considered unlikely, but conditioned deficiency often develops and is usually associated with surgery, alcoholism, malabsorption, loss of body fluids, and certain hormonal and renal diseases.
Sulfur	Bulk of dietary sulfur is present in sulfur-containing amino acids needed for synthesis of essential metabolites. Sulfur functions in oxidation-reduction reactions, as part of thiamin and biotin.	No DRI; the need for sulfur is satisfied by essential sulfur-containing amino acids.	Protein foods such as meat, fish, poultry, eggs, milk, cheese, legumes, nuts	Dietary intake is chiefly from sulfur-containing amino acids, and adequacy is related to protein intake.
Iron	Approximately 70% is found in hemoglobin; approximately 25% is stored in liver, spleen, and bone. Iron is a component of hemoglobin and myoglobin and is important in oxygen transfer. It is also present in serum transferring and certain enzymes.	8 mg for men, 18 mg for women (after menopause, 8 mg) (RDA)	Liver, meat, egg yolk, legumes, whole or enriched grains, dark green vegetables, dark molasses, shrimp, oysters	Iron deficiency anemia occurs in women of reproductive age and infants and preschool children. Deficiency may be associated with unusual blood loss, parasites, or malabsorption. Anemia is the last state of deficiency.
	Almost none exists in ionic form.			<i>Continued</i>

**TABLE 3-25****Minerals in Human Nutrition—cont'd**

	<b>Body Location and Selected Biologic Functions</b>	<b>DRI's</b>	<b>Food Sources</b>	<b>Likelihood of Deficiency</b>
Zinc	Zinc is present in most tissues, with greatest amounts in the liver, voluntary muscle, and bone. A constituent of many enzymes and of insulin, zinc is important for nucleic acid metabolism.	11 mg for men, 8 mg for women (RDA)	Oysters, shellfish, herring, liver, legumes, milk, wheat bran	The extent of dietary zinc inadequacy in the United States is not known. Conditioned deficiency may develop with systemic childhood illnesses and in patients who are nutritionally depleted or have been subjected to severe stress such as surgery. No evidence shows that specific deficiencies of copper occur in humans. Menkes disease is a genetic disorder resulting in copper deficiency.
Copper	Copper is found in all body tissues, with the bulk in the liver, brain, heart, and kidney. Copper is a constituent of enzymes and ceruloplasmin and erythrocuprein in blood. It may be an integral part of DNA or RNA. Iodine is a constituent of $T_4$ and related compounds synthesized by the thyroid gland. $T_4$ functions in the control of reactions involving cellular energy.	900 mcg for men and women (RDA)	Liver, shellfish, whole grains, cherries, legumes, kidney, poultry, oysters, chocolate, nuts	Iodization of table salt is recommended, especially in areas where food is low in iodine. Deficiency is unlikely to occur in humans.
Iodine	The highest concentration of manganese is in bone; relatively high concentrations also exist in pituitary, liver, pancreas, and gastrointestinal tissue. Manganese is a constituent of essential enzyme systems and is rich in mitochondria of liver cells.	150 mcg for men and women (RDA)	Iodized table salt, seafood, water and vegetables in regions without goiter	Beet greens, blueberries, whole grains, nuts, legumes frit, tea
Manganese	Fluoride exists in bones and teeth. In optimal amounts from water and diet, fluoride reduces dental caries and may minimize bone loss.	2.3 mg for men, 1.8 mg for women (AI)	Drinking water (1 ppm), tea, coffee, rice, soybeans, spinach, gelatin, onions, lettuce	In areas where the fluoride content of water is low, fluoridation of water (at 1 ppm) has reduced the incidence of dental caries.
Fluoride	Molybdenum is a constituent of an essential enzyme (xanthine oxidase) and flavoproteins.	4 mg for men, 3 mg for women (AI)	Legumes, cereal, grains, dark green leafy vegetables, organ meats	No available information.
Molybdenum		45 mcg for men and women (RDA)		

Cobalt	Cobalt is a constituent of cyanocobalamin (vitamin B <sub>12</sub> ), existing bound to protein in foods of animal origin. Cobalt is essential for the normal function of all cells, particularly cells of bone marrow and nervous and gastrointestinal systems.	2.4 mcg vitamin B <sub>12</sub>	Liver, kidney, oysters clams, poultry, milk	Primary dietary inadequacy is rare except in those who consume no animal products. Deficiency may be associated with lack of gastric intrinsic factor, gastrectomy, or malabsorption syndromes.
Selenium	Selenium is involved in fat metabolism, cooperates with vitamin E, and acts as an antioxidant.	55 mcg for men and women (RDA)	Grains, onions, meats, milk; varied amounts in vegetables depending on selenium content of soil	Keshan disease is a selenium-deficient state. Deficiency has occurred in patients receiving long-term TPN without selenium supplementation.
Chromium	Chromium is associated with glucose metabolism.	35 mcg for men, 25 mcg for women (AI)	Corn oil, clams, whole-grain cereals, brewer's yeast, meats, drinking water (amount varies)	Deficiency is found in those with severe malnutrition and may be a factor in diabetes in older adults and cardiovascular disease.

AI, Adequate intake; DR<sub>I</sub>, dietary reference intake; RDA, recommended dietary allowance; TPN, total parenteral nutrition.

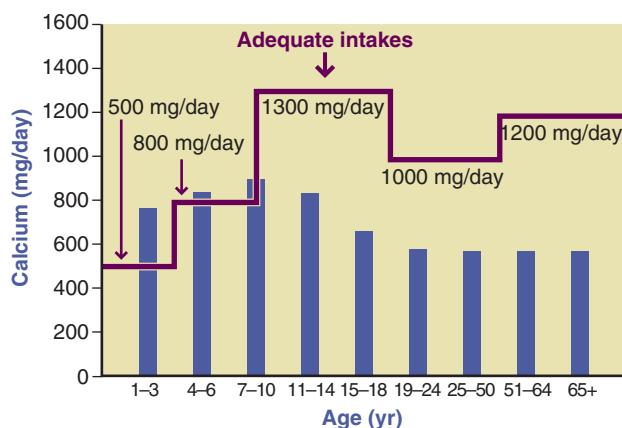

## Food Sources and Intakes

Cow's milk and dairy products are the most concentrated sources of calcium. Dark green leafy vegetables such as kale, collards, turnip greens, mustard greens, and broccoli; almonds; blackstrap molasses; the small bones of sardines and canned salmon; and clams and oysters are good sources of calcium. Soybeans also contain ample amounts. Oxalic acid limits the availability of calcium in rhubarb, spinach, chard, and beet greens. Fortified foods (orange juice, soy, nut, grain or rice milks) contain as much calcium as cow's milk. Many bottled waters and energy bars have calcium and sometimes vitamin D added. Tofu prepared by calcium precipitation is also a source of calcium. Table 3-26 shows the calcium content of selected foods.

Calcium supplements are now commonly used to increase intake. The most common form is calcium carbonate, which is relatively insoluble, particularly at a neutral pH. Although it has less calcium than calcium carbonate by weight, calcium citrate is much more soluble and would be suitable for patients with a lack of hydrochloric acid in the stomach (achlorhydria). In patients with achlorhydria, the efficiency of calcium absorption is greatly decreased because of the higher pH of the stomach contents; however, calcium absorption is increased by the consumption of a meal, which improves the solubility of calcium ions because of the increased gastric acidity. The selection of the most appropriate calcium supplement depends on several factors, including physical and chemical properties, interactions with other medications being taken concurrently, current medical conditions, and age. Beginning at the age of 11 years, median dietary calcium intakes in the United States are considerably less than the AIs (Figure 3-27). Therefore calcium intakes of Americans are insufficient for the critical ages of bone deposition in both genders, as well as being inadequate at other critical stages.

## Deficiency

The development of peak bone mass requires adequate amounts of calcium and phosphorus, vitamin D, and other

**FIGURE 3-27** Comparison of the median daily calcium intake for females in the United States and the adequate intakes established in 1998.

**TABLE 3-26**

## Calcium Content of Selected Foods

Food	Content (mg)
Milkshake, vanilla, 11 oz	457
Yogurt, low fat, with fruit, 1 cup	345
Fast-food enchilada, 1	324
Rhubarb, cooked, $\frac{1}{2}$ cup	318
Spinach, frozen, cooked, 1 cup	291
Milk, 2% milkfat, 1 cup	285
Cheese, cheddar, 1 oz	204
Waffle, frozen, 4-inch diameter, 1	191
Salmon, canned, with bones, 3½ oz	181
Tofu, regular, $\frac{1}{4}$ block	163
Cheese, cottage, 2% fat, 1 cup	155
Ice cream, vanilla, softserve, $\frac{1}{2}$ cup	113
Almonds, 1 oz	70
Baked beans, white, $\frac{1}{2}$ cup	64
Broccoli, cooked from fresh, 1 cup	62
Frankfurter, turkey, 1	58
Orange, 1 medium	52
Halibut, baked, 3 oz	51
Kale, fresh, cooked, $\frac{1}{2}$ cup	47
Bread, whole wheat, 1 slice	20
Banana, 1 medium	7
Ground beef, lean, 3 oz	4
<b>DRIs</b>	
Infants	200-260 mg/day, depending on age
Children aged 1-8 years	700-1000 mg/day, depending on age
Children over age 9 and adolescents	1300 mg/day
Adults (ages 19-50)	1000 mg/day
Adults 51 to 70	1000 mg/day males; 1200 mg/day females
Adults over age 70	1200 mg/day
Pregnant	1000 mg/day; 1300 mg/day aged 14-18 years
Lactating	Same as for pregnancy

From U.S. Department of Agriculture, Agricultural Research Service: Nutrient Database for Standard Reference, Release 18. Data Laboratory home page: <http://www.nal.usda.gov/fnic/foodcomp/Data/SR18/nutrlist/sr18w301.pdf>; accessed 2011.

AI, Adequate intake; DRI, dietary reference intake.

nutrients. Compared with adulthood, greater amounts of calcium and phosphate are required for skeletal development; therefore AIs of these minerals and others have a significant effect on peak bone mass development until the time of puberty and throughout adolescence. After adolescence, bone gains may still occur, but the amounts of calcium required decrease. Vitamin D status may or may not be a problem, depending on the intakes of calcium and phosphorus. When calcium intake is well below the recommended amount, PTH is released; a persistent elevation may contribute to low bone mass. Calcium and vitamin D intakes of many older women are inadequate.

Hogan (2005) suggested that epidemic obesity and subsequent dieting may have a detrimental effect on bone status, leading to osteoporosis. An inadequate intake of calcium, in addition to an inadequate intake of vitamin D, may contribute to osteomalacia, colon cancer, and hypertension. Dietary Approaches to Stop Hypertension studies show that adequate dietary intakes of calcium, magnesium, potassium, and other micronutrients from low-fat dairy foods, fruits, and vegetables can substantially reduce blood pressure in those with hypertension or prevent its development.

### Toxicity

A very high intake of calcium (>2000 mg/day) may lead to hypercalcemia. This can be exacerbated by high intakes of vitamin D. Such toxicity may lead to excessive calcification in soft tissues, especially the kidneys, and may be life-threatening. In addition, long-term high intakes of calcium may lead to increased bone fractures in older adults, perhaps because of high bone remodeling rates that lead to exhaustion of osteoblast (Klompmaker, 2005).

High intakes of calcium may also interfere with the absorption of other divalent cations such as iron, zinc, and manganese. Therefore supplements of certain minerals should be taken at different times. Another effect of excessive calcium intake is constipation, common among older women who take calcium supplements.

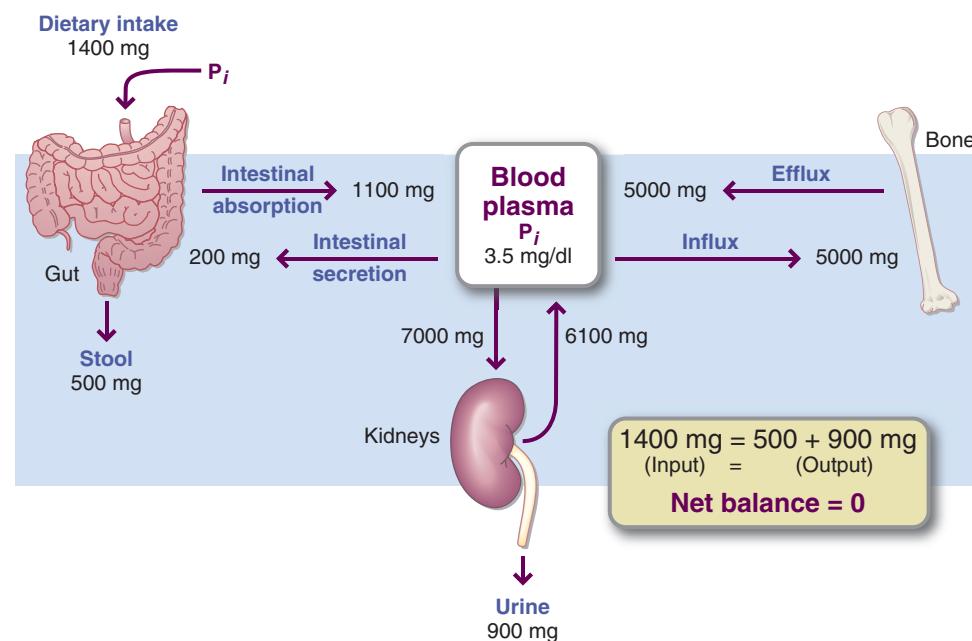

### Physical Immobility

Prolonged bed rest or periods of weightlessness during space travel promote significant calcium losses in response to a lack of tension or gravity on the bones. Older individuals who require a prolonged recovery with limited activity, such as those with hip fractures or other illnesses, also have increased calcium losses. Physical activity, especially weight-bearing exercise, promotes bone health.

### Phosphorus

Phosphorus ranks second to calcium in abundance in human tissues. Approximately 700 g of phosphorus exists in adult tissues, and approximately 85% is present in the skeleton and teeth as calcium phosphate crystals. The remaining 15% exists in the metabolically active pool in every cell in the body and in the extracellular fluid compartment. Almost 50% of the inorganic phosphate is present in serum as free ions (i.e.,  $\text{H}_2\text{PO}_4^-$  and  $\text{H}_2\text{PO}_4^{2-}$ ). Smaller percentages are bound to protein ( $\approx 10\%$ ) or complexed ( $\approx 40\%$ ).

The serum inorganic phosphorus level is closely maintained by PTH at 3 to 4 mg/100 mL in adults, but it is not as closely regulated as the serum calcium level. Normal blood concentrations in infants are higher. In older adults serum phosphate concentrations are typically lower; hypophosphatemia ( $<2.5$  mg/dL) may be common among older adults. Phosphorus balance is illustrated in Figure 3-28.

**FIGURE 3-28** Phosphorus balance is maintained primarily by the amount of phosphate absorbed versus the amount excreted by the kidneys and intestine. Bone is the major storage site for phosphate, as it is for calcium. The metabolic pathways share many similarities with the calcium pathways.

## Absorption, Transport, Storage, and Excretion

The relative amounts of inorganic and organic phosphates in the diet vary with the food or supplement consumed. Regardless of the form, most phosphates are absorbed in the inorganic state. Organically bound phosphate is hydrolyzed in the lumen of the intestine and released as inorganic phosphate, primarily through the action of pancreatic or intestinal phosphatases. Bioavailability depends on the form of the phosphate and the pH. The acidic milieu of the most proximal portion of the duodenum is important in maintaining phosphorus solubility and therefore bioavailability. In vegetarian diets the major portion of the phosphorus exists as phytate, which is poorly digested. Humans do not have the phytase enzyme; however, intestinal bacteria have the enzyme needed to hydrolyze phosphates. The yeast used in making bread contains a phytase, which releases phosphate.

In general, the efficiency of phosphate absorption is 60% to 70% in adults, twice as high as that of calcium. Phosphate absorption is also much more rapid than that of calcium. Peak absorption of phosphates occurs approximately 1 hour after ingestion of a meal; calcium enters the blood 3 to 4 hours after a meal.

The primary route of phosphorus excretion is renal, which also is the primary site of phosphate regulation. Major determinants of urinary phosphorus loss are an increased intake of phosphate, an increase in phosphate absorption, and the plasma phosphorus concentration. Other factors contributing to increased urinary phosphate loss are hyperparathyroidism, acute respiratory or metabolic acidosis, diuretic use, and the expansion of extracellular volume. If PTH levels are high, the urinary route excretes additional phosphate. Starvation or chronic undernutrition typically contributes to most of the alterations in metabolism that result in hypophosphatemia and renal losses of phosphate. According to Berndt and Kumar (2009), long-term regulation of phosphorus homeostasis may be controlled by hormones such as the vitamin D endocrine system and PTH as well as the phosphatonins (FGF-23, sFRP-4, MEPE). Endogenous fecal phosphate excretion can also contribute to phosphorus homeostasis by eliminating excessive phosphate when PTH levels are elevated and phosphate load in the blood or tissues is excessively high. Reduced phosphate excretion is associated with dietary phosphorus restriction; increased plasma insulin, thyroid hormone, growth hormone, glucagon, or glucocorticoids; metabolic or respiratory alkalosis; and extracellular volume contraction.

## Functions

As phosphates, phosphorus participates in numerous essential functions of the body. DNA and RNA are based on phosphate. The major cellular form of energy, ATP, contains high-energy phosphate bonds, as do creatinine phosphate and PEP. Cyclic adenosine monophosphate (cAMP) acts as a secondary signal within cells following peptide hormone activation of many membrane receptors. As

part of phospholipids, phosphorus is present in every cell membrane in the body. Numerous phospholipid molecules also act as secondary messengers within the cytosol. Phosphorylation-dephosphorylation reactions control various steps in the activation or deactivation of cytosolic enzymes by kinases or phosphatases. Total intracellular concentrations of phosphate (but not ionic concentrations) are much higher than extracellular concentrations because phosphorylated compounds do not cross cell membranes easily and are trapped within the cell.

The phosphate buffer system is important in intracellular fluid and the kidney tubules, where phosphate functions in the excretion of hydrogen ion. Filtered phosphate reacts with secreted hydrogen ions, releasing sodium in the process. In turn, the sodium can be resorbed under the influence of aldosterone. Finally, phosphate ions combine with calcium ions to form **hydroxyapatite**, the major inorganic molecule in teeth and bones. Bone mineral, but not tooth mineral, provides phosphate ions via homeostatic regulation of serum calcium by PTH.

## Dietary Reference Intakes

DRI<sup>s</sup> for phosphorus are somewhat lower than those for calcium for all age groups. Tolerable ULs are also established.

## Food Sources and Intakes

In general, good sources of protein are also good sources of phosphorus. Meat, poultry, fish, and eggs are excellent sources. Milk and milk products are good sources, as are nuts and legumes, cereals, and grains. Phosphorus is bound to serine, threonine, and tyrosine in proteins. In the outer coating of cereal grains, particularly wheat, phosphorus exists in the form of phytic acid, which can form a complex with some minerals to create insoluble compounds. In conventional breads phytic acid is converted to the soluble form of orthophosphate during the leavening process. However, in the unleavened breads commonly eaten in the Middle East, the availability of practically all minerals is much lower. Table 3-27 and Appendix 36 list the phosphorus content of selected foods.

The average intakes of phosphorus by adults in the United States are approximately 1300 mg/day for men and 1000 mg/day for women. More than 60% of phosphorus comes from milk, meat, poultry, fish, and eggs. Cereals and legumes provide another 20%. Less than 10% is derived from fruits and their juices; tea, coffee, vegetable oils, and spices supply only small amounts of phosphorus. The amount provided by food additives to such products as meats, cheeses, dressings, beverages, and bakery products can be significant.

## Deficiency

Phosphate deficiency is rare. It could develop in individuals who are taking phosphate binders for renal disease or in older adults because of poor intake in general. The widespread, ultimately fatal consequences of severe phosphorus depletion reflect its ubiquitous roles in body functions.

**TABLE 3-27****Phosphorus Content of Selected Foods**

Food	Content (mg)
Fast food pancakes, 2	476
Sole (fillet)	246
Fast food hamburger (1)	284
Macaroni and cheese, 1 cup	322
Milk, 2% fat, 1 cup	232
Cheddar cheese, 1 oz	146
Ham, 3 oz	210
Ice milk, soft serve, 1 cup	202
Mixed nuts, 1 oz	123
Cheese, cottage, 2% fat, 1 cup	341
Cheese, cheddar, 1 oz	146
Shrimp, boiled, 2 large	137
Baked beans, 1 cup	293
Ground beef, cooked, 3 oz	165
Tofu, regular, ½ cup	120
Potato, baked, with skin, 1	115
Egg, 1	96
Bread, whole wheat, 1 slice	65
Cola beverage, 1 can, 12 oz	46
Potato chips, 14	43
Bread, white, 1 slice	23
Cauliflower, fresh, ½ cup	23
Orange, 1	18

**DRI<sub>s</sub>**

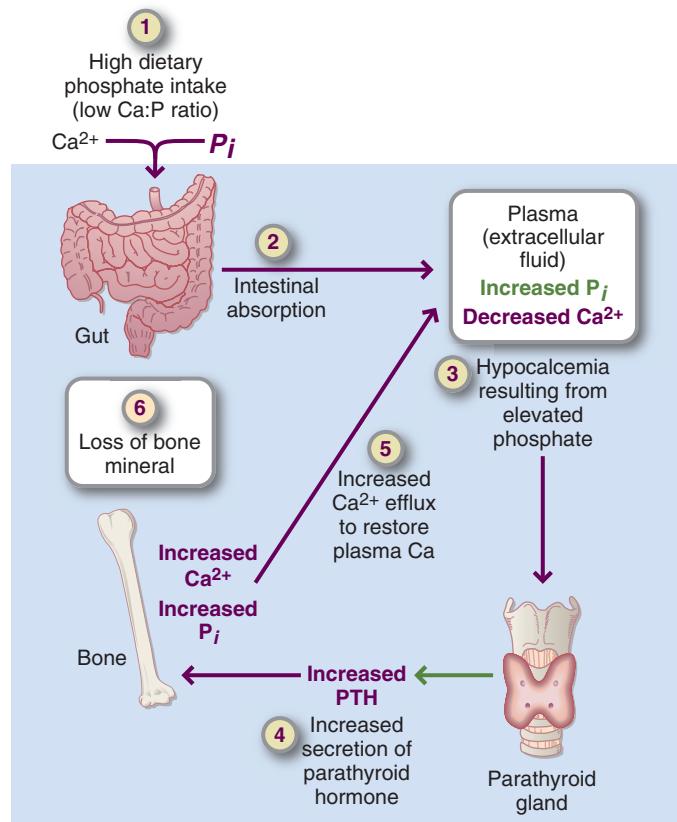

Infants and young children	100-500 mg/day, depending on age
Older children and adolescents	1250 mg/day
Adults	700 mg/day
Pregnant	700-1250 mg/day, depending on age
Lactating	700-1250 mg/day, depending on age

From U.S. Department of Agriculture, Agricultural Research Service: Nutrient Database for Standard Reference, Release 18, retrieved 2005, Data Laboratory home page: <http://www.nal.usda.gov/fnic/foodcomp/Data/SR18/nutrlst/sr18w305.pdf>; accessed 1-14-11.

DRI, Dietary reference intake.

Symptoms result from decreased synthesis of ATP and other organic phosphate molecules. Neural, muscular, skeletal, hematologic, renal, and other abnormalities occur.

Because phosphorus is so widely available from foods, including processed foods and soda types of soft drinks, a dietary inadequacy is unlikely. Clinical phosphate depletion and hypophosphatemia can result from long-term administration of glucose or TPN without sufficient phosphate, excessive use of phosphate-binding antacids, hyperparathyroidism, or treatment of diabetic acidosis. It may develop in those who have alcoholism, with or without decompensated liver disease. Premature infants who are fed unfortified human milk may also develop hypophosphatemia.

**FIGURE 3-29** Mechanism through which a low dietary calcium/phosphorus ratio contributes to the development of a persistently high parathyroid hormone concentration.

**Toxicity**

A persistently high concentration of PTH may result after chronic consumption of a low-calcium, high-phosphorus diet, called *nutritional secondary hyperparathyroidism*. PTH levels in blood that result from this diet typically remain within a high normal range (Figure 3-29). This persistently high PTH contributes to increased bone turnover, reduction of bone mass and density, and even fragility fractures because of excessive resorption and thinning of trabecular plates at bone sites throughout the skeleton. Individuals with a low calcium/phosphorus ratio benefit from increasing calcium intake from foods or supplements. Adequate calcium intake reduces the serum PTH concentration and may inhibit bone loss. The persistently high PTH level contributes to the limited bone mineralization during growth; this yields inadequate peak bone mass accumulation and the loss of bone mass.

**Magnesium**

After potassium, magnesium is the second-most abundant intracellular cation in the body. The adult human body contains approximately 20 to 28 g of magnesium, of which approximately 60% is found in bone, 26% in muscle, and the remainder in soft tissues and body fluids. Gender differences in the body content of magnesium begin before

puberty. Magnesium in bone is present in exchangeable and nonexchangeable pools. Magnesium ions in the bone fluid compartment are much more exchangeable than magnesium ions that have become part of the crystal lattice. Normal serum levels are usually in the range of 1.5 to 2.1 mEq/L (0.75 to 1.1 mmol/L). Approximately half the magnesium in plasma is free; approximately one third is bound to albumin; and the remainder is complexed with citrate, phosphate, or other anions. Magnesium homeostasis is governed by intestinal absorption and renal excretion. No hormone is known to have a major role in the control of serum magnesium.

### Absorption, Transport, Storage, and Excretion

The efficiency of absorption of magnesium varies widely from 35% to 45%. Magnesium may be absorbed along the length of the small intestine, but most absorption occurs in the jejunum. Like other divalent cation minerals, the entry of magnesium from the gut lumen occurs by two mechanisms: a carrier-facilitated process and simple diffusion. A saturable facilitated mechanism operates at low intraluminal concentrations, whereas paracellular movement across the mucosa predominates throughout the length of the small bowel when intraluminal concentrations are high. The efficiency of absorption varies with the magnesium status of the individual, the amount of magnesium in the diet, and the composition of the diet as a whole. Vitamin D has little or no effect on magnesium absorption.

Serum magnesium concentration is remarkably constant. Maintenance of these constant values depends on absorption, excretion, and transmembranous cation flux rather than on hormonal regulation. Once in the cells, magnesium is bound mainly to protein and energy-rich phosphates. The magnesium balance is illustrated in Figure 3-30.

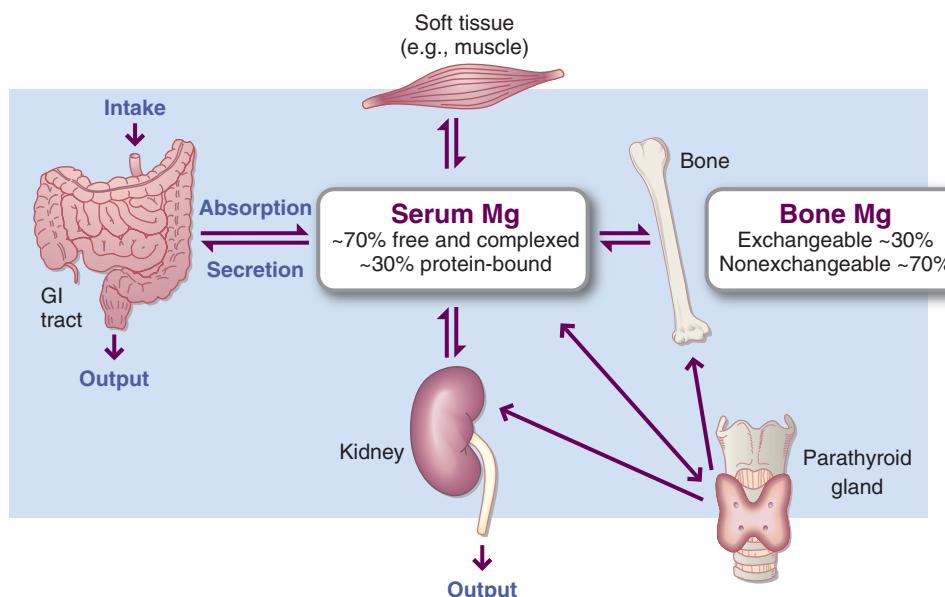

The kidneys control magnesium balance by conserving magnesium efficiently, particularly when intake is low. Supplementing a normal intake increases urinary excretion while serum levels remain stable. Low dietary intake of magnesium results in reduced urinary excretion of magnesium. To allow nursing mothers to meet the increased needs for magnesium, urinary excretion of the mineral tends to decrease during lactation. Renal resorption varies inversely with that of calcium.

### Functions

The major function of magnesium is to stabilize the structure of ATP in ATP-dependent enzyme reactions. Magnesium is a cofactor for more than 300 enzymes involved in the metabolism of food, synthesis of fatty acids and proteins, phosphorylation of glucose in the glycolytic pathway, and promoting transketolase reactions. Magnesium is important in the formation of cAMP, the first cytosolic messenger to be identified as a mechanism for transmitting messages from outside the cells in response to hormones, local hormonelike factors, or other molecules.

Magnesium plays a role in neuromuscular transmission and activity, working in concert with and against the effects of calcium, depending on the system involved. In a normal muscle contraction, calcium is a stimulator, and magnesium is a relaxant. Magnesium acts as a physiologic calcium-channel blocker. High magnesium intakes are associated with greater bone density. The reactivity of vascular and other smooth muscle cells depends on the ratio of calcium to magnesium in the blood.

Magnesium also plays a role in learning and memory. A new product, magnesium-L-threonate, leads to the enhancement of learning, working memory, and short and long-term memory in all ages of rats (Slatsky et al., 2010).

**FIGURE 3-30** Magnesium balance is maintained largely by gastrointestinal absorption and renal excretion.

Although it is too early to extrapolate to humans, this is an exciting area of research. Magnesium depletion has been detected in persons with migraine headaches, severe asthma, dysmenorrhea, leg cramps, diabetes mellitus, chronic renal failure, nephrolithiasis, osteoporosis, aplastic osteopathy, and heart and vascular disease (Guerrera et al., 2009; Musso, 2009).

Large doses of magnesium can result in central nervous system depression, anesthesia, or even paralysis, especially in patients with renal insufficiency. Thus patients with renal problems should not be given magnesium supplements.

### Dietary Reference Intakes

The RDA for magnesium was increased in 1997; different recommendations were made for boys and girls beginning at puberty. ULs were also established, as were AIs for infants.

### Food Sources and Intakes

Magnesium is abundant in many foods. Good sources are seeds, nuts, legumes, and milled cereal grains, as well as dark green vegetables, because magnesium is an essential constituent of chlorophyll. Milk is a moderately good source of magnesium, especially because milk and other dairy products are so widely consumed. Tofu prepared by magnesium precipitation (check the label) is a good source.

Fish, meat, oranges, apples, and bananas, are poor sources of magnesium. Diets high in refined foods, meat, and dairy products are usually lower in magnesium than diets rich in vegetables and unrefined grains (Table 3-28). Magnesium is lost during the processing of foods such as sugar; after refining wheat cereals, it is not generally replaced as enrichment.

The most commonly consumed food sources include milk, bread, coffee, ready-to-eat cereals, beef, potatoes, and dried beans and lentils. Americans have had median intakes of magnesium well below the RDAs, with older adults having the lowest intakes (Figure 3-31). This trend is implicated in development of diseases such as osteoporosis and diabetes (He et al., 2006). High intakes of calcium, protein, vitamin D, and alcohol all increase the requirements for magnesium; physical or psychologic stress may also increase magnesium needs.

### Deficiency

Although rare, severe magnesium deficiency symptoms include tremors, muscle spasms, personality changes, anorexia, nausea, and vomiting. Tetany, myoclonic jerks, athetoid movements, convulsions, and coma have also been reported. Hypocalcemia and hypokalemia typically occur first, combined with impairment of the individual's responsiveness to PTH and sodium retention.

The effects of severe magnesium depletion on bone metabolism include decreased PTH secretion by the parathyroid glands, very low serum PTH, impaired responsiveness of bone and kidneys to PTH, decreased serum  $1,25(\text{OH})_2\text{D}_3$ , vitamin D resistance, altered hydroxyapatite crystal formation, impaired bone growth in young patients, or the development of osteoporosis in seniors. With

**TABLE 3-28**

### Magnesium Content of Selected Foods

Food	Content (mg)
Halibut, baked, $\frac{1}{2}$ fillet	170
Spinach, canned, 1 cup	163
Cow peas, cooked, 1 cup	91
Muffin, oat bran 1	89
Rice, brown, cooked, 1 cup	84
Refried beans, 1 cup	83
Cashews, roasted, 1 oz	77
Orange juice, 6 oz	72
Mixed nuts, roasted, 1 oz	67
Baked potato with skin, 1	57
Raisins, 1 cup	46
Tofu, firm, $\frac{1}{4}$ block	30
Bread, whole wheat, 1 slice	29
Milk, 2% fat, 1 cup	27
Spinach, fresh, 1 cup	24
Ground beef, lean, cooked, 3 oz	18
Fruits	10-25

### DRI

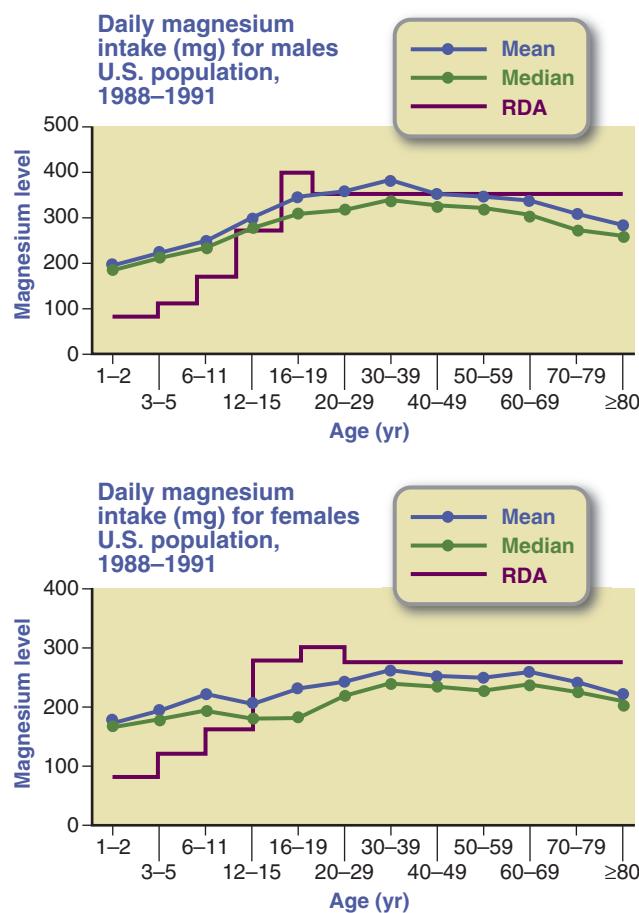

Infants, AIs	30-75 mg/day, depending on age
Young children, RDAs	80-130 mg/day, depending on age
Older children and adolescents, RDAs	240-410 mg/day, depending on age and gender
Adults	310-400 mg/day, depending on age and gender
Pregnant	350-400 mg/day, depending on age
Lactating	310-360 mg/day, depending on age

*AI*, Adequate intake; *DRI*, dietary reference intake; *RDA*, recommended dietary allowance.

continued depletion of magnesium, PTH concentrations drop even further. Intravenous administration of magnesium reverses the clinical signs and symptoms within a short time.

Moderate depletion of magnesium apparently is prevalent in older populations in Western nations (Leenhardt et al., 2005). Such deficiencies are typically precipitated by low dietary intakes, especially in individuals who avoid consuming dark green leafy vegetables, milk, and other good sources of magnesium. An increased loss of electrolytes, especially potassium, or a shift in electrolyte balance also triggers a moderate magnesium deficiency. Conditions and situations that may cause acute deficiencies

**FIGURE 3-31** Comparison of the median daily magnesium intake for Americans and the dietary reference intakes.

include renal disease, diuretic therapy, malabsorption, hyperthyroidism, pancreatitis, protein insufficiency, diabetes, parathyroid gland disorders, postsurgical stress, and vitamin D-resistant rickets. Magnesium deficiency has also been linked to insulin resistance and metabolic syndrome because magnesium is required for carbohydrate metabolism (He et al., 2006).

Magnesium status is difficult to determine from serum measurements of magnesium because the total serum magnesium level remains constant within a wide range of intake levels. Leukocyte magnesium contents are much more sensitive to nutritional status, which makes them a superior marker. Urinary excretion of magnesium (and often of potassium) is less in those with a magnesium deficiency than in those with sufficient magnesium, suggesting that those with magnesium deficiencies have greater retention of magnesium and improved tissue magnesium status throughout the body.

Attention has focused on the interrelationships of magnesium and other electrolytes, particularly potassium, and related effects. For example, a low magnesium intake contributes to hypertension along with inadequate intakes of potassium and calcium. Oral magnesium supplementation may lower systolic and diastolic blood pressure significantly. Low magnesium intakes have also been

associated with coronary heart disease, myocardial infarction, and osteoporosis.

### Toxicity

Although excess magnesium can inhibit bone calcification, excesses from dietary sources and supplements are unlikely to result in toxicity. However, the ULs for magnesium from supplements or pharmacologic agents were established in 1998. The only cases of toxicity that have been reported involve smelter workers who inhale or otherwise ingest toxic levels of magnesium dust.

### Sulfur

Although sulfur has long been studied as a mineral, it functions almost entirely as a component of organic molecules. Sulfur exists in the body as a constituent of three amino acids—cystine, cysteine, and methionine—and as part of organic molecules in all cells and extracellular compartments, such as connective tissue. The tertiary structure of proteins is attributable in part to covalent bonding between cysteine residues in which the SH groups are oxidized to form disulfide bridges. These bridges also provide the three-dimensional structural modifications necessary for the activity of some enzymes, insulin, and other proteins. Sulfhydryl groups of proteins also participate in diverse cellular reactions. For example, the poisonous effects of arsenic are caused by its ability to bind sulfhydryl groups of enzymes. The sulfur of cysteine binds to iron-sulfur clusters in electron transfer proteins involved in basic, life-sustaining processes, such as photosynthesis, nitrogen fixation, and oxidative phosphorylation.

Glutathione, a tripeptide-containing cysteine, acts as a donor of reducing equivalents for the reduction of hydrogen peroxide and organic peroxides by GSH-Px. In the broadest sense, sulfur can be considered an antioxidant. Sulfur is as a component of heparin, an anticoagulant found in liver and tissues, and as chondroitin sulfate in bone and cartilage. Sulfur is also an essential component of three vitamins—thiamin, biotin, and pantothenic acid (Brosnan and Brosnan, 2009).

Sulfur is also part of the molecule, S-adenosylmethionine. The transmethylation pathway within cells, especially in the liver, converts methionine to homocysteine while transferring the methyl group to other molecules. This pathway is linked to the metabolism of other important molecules such as cysteine, adenine (a nucleoside), and polyamines.

Sulfur-containing amino acids regulate lipid metabolism (Oda, 2006). Taurine, a sulfur-containing amino acid made by liver cells, is used to conjugate bile acids before secretion. Nonhepatic cells use sulfate bound to an organic donor for the synthesis of iron-sulfur proteins. In addition, structural molecules within cells like proteoglycans contain sulfated monosaccharide (glucose and galactose) residues.

The metabolism of sulfur-containing amino acids generates inorganic acids, especially sulfate anions, in substantial amounts. These sulfates are thought to combine with calcium ions in the glomerular ultrafiltrate, thereby reducing the renal tubular resorption of calcium. This mechanism

may explain as much as 50% of the calcium loss associated with protein-induced hypercalciuria, which develops after consumption of meals rich in animal proteins—proteins that are rich in sulfur.

Methionine and cysteine provide almost 100% of the sulfur in the human diet. Food sources of sulfur include meat, poultry, fish, eggs, dried beans, broccoli, and cauliflower. Sulfur deficiency or toxicity is highly unlikely. Excess inorganic sulfur generated as a result of hepatic or renal metabolism is excreted in the urine as sulfates. There are no DRIs for sulfur.

## MICROMINERALS/TRACE ELEMENTS

Numerous microminerals or **trace elements** are present in minute amounts in body tissues and are essential for optimum human growth, health, and development. The functions of and deficiency symptoms produced by trace elements are subtle and difficult to identify, partly because many of these effects occur at the cellular or subcellular level. For example, iron deficiency eventually results in a type of anemia that is easy to identify. The cellular effects cannot be identified as easily but may actually be more harmful to the individual.

The knowledge of the various functions of trace and ultratrace minerals continues to grow. DRIs and ULs have been established for nine essential trace elements: chromium, copper, iodine, iron, manganese, molybdenum, selenium, zinc, and fluoride. DRIs for five potentially essential trace elements—arsenic, boron, nickel, silicon, and vanadium—have not yet been published. No DRI exists for cobalt, just for cobalt-containing vitamin B<sub>12</sub> (cobalamin).

### General Characteristics

Trace elements exist in two forms: as charged ions or bound to proteins. Each element has different chemical properties that become critical in its functional role in cells or extracellular compartments. In blood and other tissue and cellular fluids, the trace elements do not exist in the free ionic state; they are typically bound to transporting or holding proteins. Fluoride ions become bound in the hydroxyapatite crystals of bones and teeth.

### Functions

Many enzymes require small amounts of one or more trace metals for full activity. Metals function in enzyme systems by participating directly in the catalyzed reaction, by combining with substrates to form complexes on which enzymes act, by forming metalloenzymes that bind substrates, by combining with reaction end products, or by maintaining quaternary structures. Minute concentrations of trace minerals affect the whole body through interactions with the enzymes or hormones that regulate masses of substrate. This ability is amplified if, in turn, the substrate has some regulatory function. Trace minerals may also interact with DNA to control the transcription of proteins important for the metabolism of that particular trace mineral.

### Food Sources

Compared with other sources, foods of animal origin are generally superior sources of trace elements because concentrations of the elements tend to be higher and the metals more available for absorption. Seafood in particular is usually rich in nearly all micronutrients except manganese, which is more readily available from plant sources. The trace element content of many plants depend on the minerals content of the soil; in addition, trace elements are not distributed evenly in wheat grains, and the germ and outer layers that contain major amounts of most minerals are removed to a large extent by the milling process. However, the small quantities of minerals that remain in white flour are more biologically available than those in whole-wheat flour, which are in complexes with or bound by molecules in the inner layer such as phytate and fiber. Unless the pH is lowered during product production, these minerals remain unavailable.

### Iron

Iron has been recognized as an essential nutrient for more than a century. Nutritional iron deficiency and iron deficiency anemia remain far too common in the twenty-first century given the wide availability of iron-rich foods (see Chapter 33). Indeed, iron-deficiency anemia is the world's most common nutritional deficiency disease. Many advances have been made in the study of iron metabolism and iron deficiency, but questions persist about mechanisms regulating absorption and iron balance. The adult human body contains iron in two major pools: (1) functional iron in hemoglobin, myoglobin, and enzymes; and (2) storage iron in ferritin, hemosiderin, and transferrin. Healthy adult men have approximately 3.6 g of total body iron, whereas women have approximately 2.4 g (Table 3-29). Adult women

**TABLE 3-29**

**Relative Proportions of Iron in Young, Healthy Adults**

Iron Type	Men: Iron Content		Women: Iron Content	
	(mg)	(%)	(mg)	(%)
<b>Functional</b>				
Hemoglobin	2300	64	1700	73
Myoglobin	320	9	180	8
Heme enzymes	80	2	60	3
Nonheme enzymes	100	3	80	3+
<b>Storage</b>				
Ferritin	540	15	200	9
Hemosiderin	230	6	100	4
Transferrin	5	<1	4	<1
Total	3575	100	2314	100

store much lower amounts of iron than do men. Iron is highly conserved; approximately 90% is recovered and reused every day and the rest is excreted, primarily in bile. If dietary iron is not available to meet this 10% gap, iron deficiency results.

Two concerns about iron nutritional status predominate: the incidence of iron-deficiency anemia and the role of excessive iron intake in coronary heart disease and cancer. Because of food fortification and the use of iron supplements by so many individuals, high iron intakes by men and postmenopausal women may be contributing to the risk of these chronic diseases. In fact, a study of older adults replete with iron in the Framingham Heart Study cohort concluded that increased iron stores are a liability (Fleming et al., 2001).

### Absorption, Transport, Storage, and Excretion

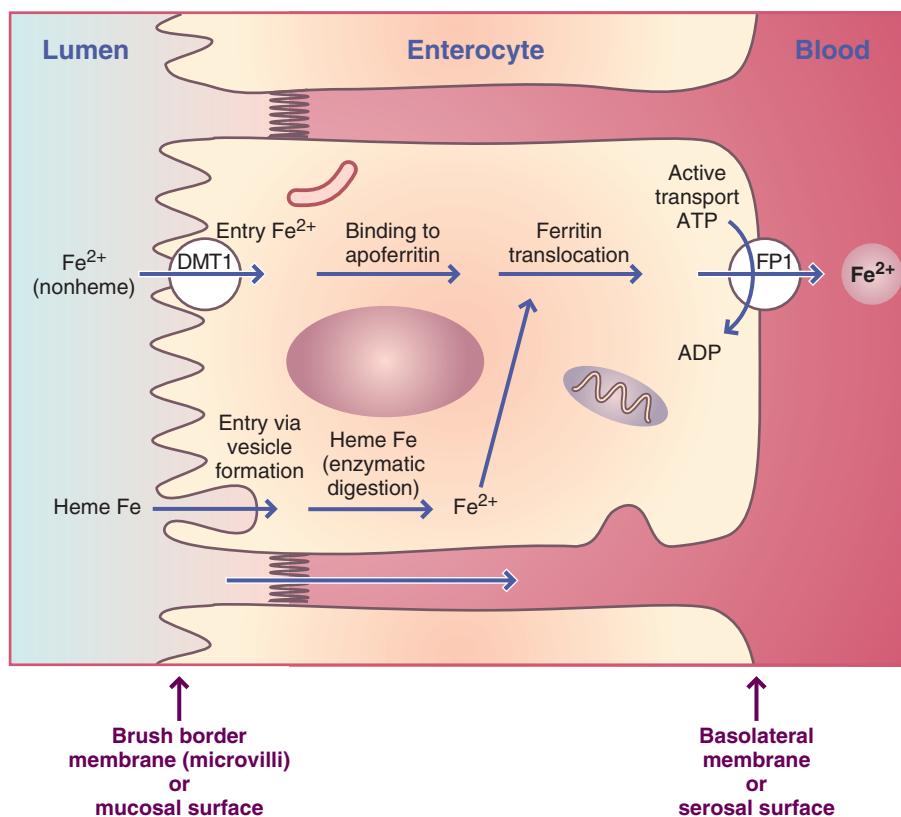

Dietary iron exists as **heme iron**, found in hemoglobin, myoglobin, and some enzymes; and as **nonheme iron**, found predominantly in plant foods, but also in some animal foods as nonheme enzymes and ferritin. Heme iron is absorbed across the brush border of intestinal absorbing cells after it is digested from animal sources. After heme enters the cytosol, the ferrous iron is enzymatically removed from the ferroporphyrin complex. The free iron ions combine immediately with apoferritin to form ferritin in the same way that free nonheme iron combines with apoferritin.

**Ferritin** is an intracellular store, a “ferry” that carries bound iron from the brush border to the basolateral membrane of the absorbing cell. The final step of absorption

by which iron ions are moved into the blood involves an active transport mechanism. At this point, it is the same for heme and nonheme iron (Figure 3-32). The absorption of heme iron is affected only minimally by the composition of meals and GI secretions. Heme iron represents only 5% to 10% of the dietary iron in a mixed diet, but absorption may be as high as 25%, compared with only 5% for nonheme iron. Because vegans consume only plant foods, sufficient amounts of nonheme iron must be ingested and absorbed to meet body requirements or supplements would be needed.

Three steps of absorption also precede the entry of nonheme iron into the circulation. Nonheme iron must be digested from plant sources and enter the duodenum and upper jejunum in a soluble, ionized form if it is to be transferred across the brush border. The acid of gastric secretions enhances the solubility and changes iron to the ionic state—either as ferric (+3 oxidation state) or ferrous (+2 oxidation state) iron—within the gut luminal contents. Iron in the reduced, ferrous state is preferred for the entry step of absorption. The brush border iron transporter, divalent metal transporter 1 (DMT1), transports ferrous iron. Ferric iron may be reduced by a brush border enzyme, ferric reductase, for absorption. As chyme moves down the duodenum, pancreatic and duodenal secretions increase the pH of the contents to 7, at which point most ferric iron is precipitated unless it has been chelated. However, ferrous iron is significantly more soluble at a pH of 7, so these ions remain available for absorption in the remainder of the small intestine.

**FIGURE 3-32** Intestinal absorption of iron from heme and nonheme sources by an intestinal absorbing cell, or enterocyte. Enterocytes contain two membranes: the brush border membrane and the basolateral membrane. The entry step of nonheme iron at the brush border membrane is different from that of heme iron. Heme iron enters by vesicle formation around the heme, whereas nonheme iron (ionic iron) enters by facilitated diffusion down a concentration gradient. Absorbed ions combine with apoferritin to form ferritin complexes that move across the cell by diffusion to the basolateral membrane for the exit step of absorption by active transport. The iron of heme iron is enzymatically removed, and these ions exit at the basolateral membrane by an unknown mechanism. ADP, Adenosine diphosphate; ATP, adenosine triphosphate.

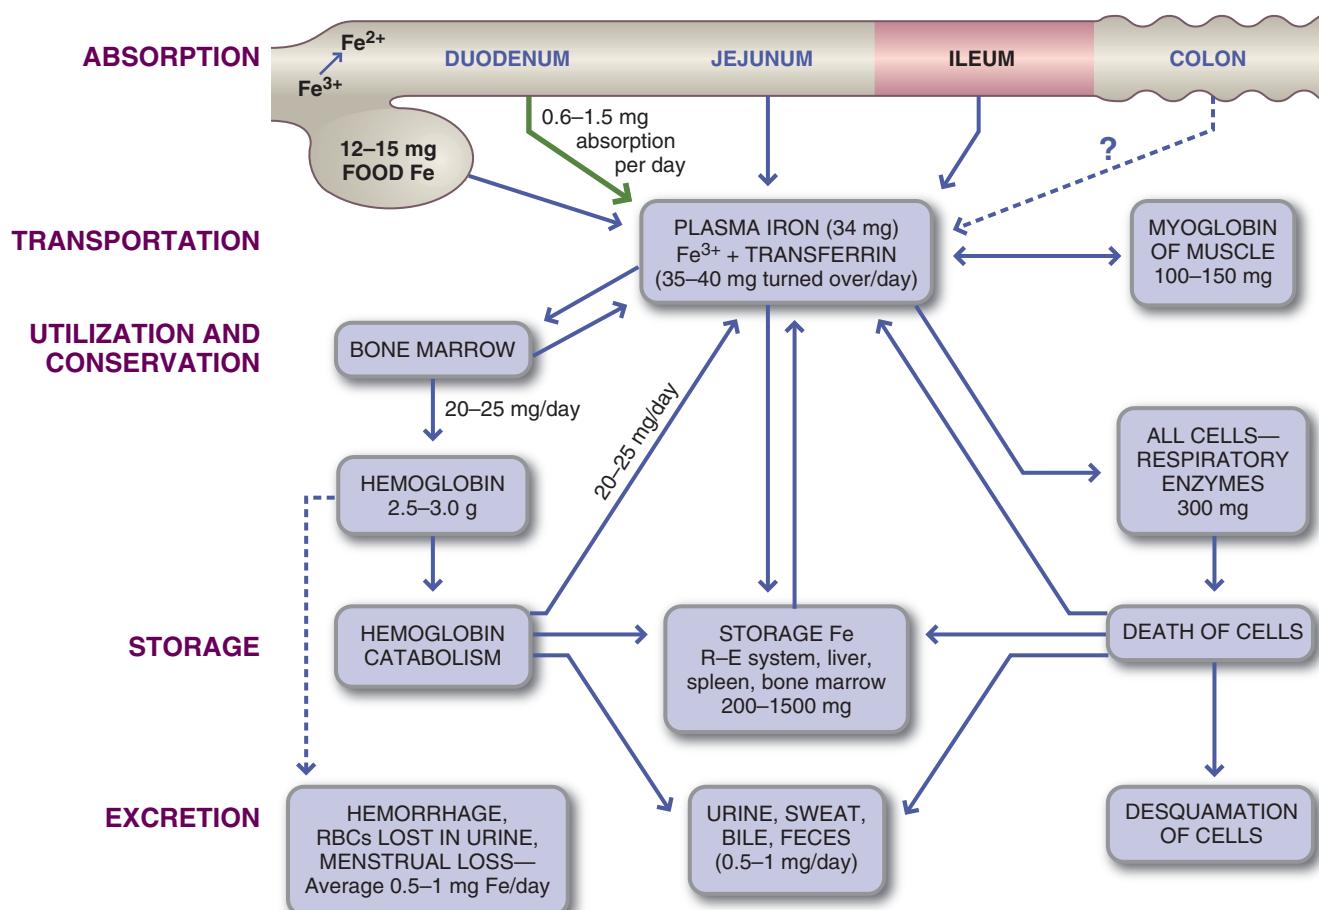

The efficiency of nonheme iron absorption seems to be controlled by the intestinal mucosa, which allows certain amounts of iron to enter the blood from the cytosolic ferritin pool according to the body's needs. A small peptide hormone known as **hepcidin** is the main iron regulatory hormone. Production in the liver is responsive to liver iron levels, inflammation, hypoxia, and anemia. Its major action is to act on the mucosa cell and inhibit iron absorption. Therefore chronic inflammation can lead to decreased iron absorption from production of hepcidin (Muñoz et al., 2009).

Other signals from the body to the absorbing cells may be transferrin saturation, or the percentage of iron bound to transferrin (Figure 3-33). Normally transferrin saturation is 30% to 35% in healthy, iron-consuming individuals. The percentage can vary greatly, depending on iron intake and bioavailability. A low percentage (e.g., 15%) of the **total iron-binding capacity (TIBC)** of transferrin would stimulate the absorbing cells to transport iron by the exit step at the basolateral membrane to the blood. Conversely, if the iron concentration in the body is excessive, absorbing cells would be downregulated, and less iron would be absorbed. The

latter situation occurs during iron overloads to protect the body against toxicity.

The life span of an intestinal absorbing cell is approximately 3 to 6 days. During this time the cell emerges from the crypt after cell division, passes up the villus to the tip, and eventually sloughs off as a dead cell. During the early life of the individual cell, signals resulting from the saturation percentage of circulating transferrin are sent to the young cells to adjust their number of receptors for transferrin (e.g., to increase iron absorption in a state of iron deficiency). Other cells formed before or after may have different numbers of receptors, depending on the nutritional supply of iron.

In individuals who persistently consume inadequate levels of iron, especially women in their childbearing years, the number of receptors may consistently be upregulated to maximize iron absorption. The efficiency of iron absorption by adults with normal hemoglobin values averages 5% to 15% of the iron, heme and nonheme, from food and supplements. Although absorption may be as high as 50% in those with iron deficiency anemia, this level is not common. Most women with an iron deficiency, but not anemia, probably

**FIGURE 3-33** Iron metabolism in adults. Most iron is absorbed from the duodenum and jejunum, after which it is transported as plasma iron or bound to transferrin. RBCs, Red blood cells; *R-E system*, reticuloendothelial system.

have absorption efficiencies of 20% to 30%. From 2% to 10% of nonheme iron in vegetables is absorbed, and from 10% to 30% of iron heme and nonheme from animal sources is typically absorbed.

Several factors affect the intestinal absorption of iron. The efficiency of iron absorption is determined to some extent by the foods from which it is derived or with which it is consumed. Ascorbic acid, the most potent enhancer of iron absorption, reduces ferric to ferrous iron and forms a chelate with iron that remains soluble at the alkaline pH of the lower small intestine. Other food molecules, such as sugars and sulfur-containing amino acids, may also enhance iron entry by forming chelates with ionic iron. In addition, animal proteins from beef, pork, veal, lamb, liver, fish, and chicken enhance absorption. The substance responsible for this improved absorption—the **meat-fish-poultry (MFP) factor**—remains unknown, but specific amino acids or dipeptide digestion products may enhance iron absorption.

Although the iron content of human milk is very low, it is highly bioavailable because of the presence of milk lactoferrin, which enhances iron absorption. Infants retain more iron from human milk than from cow's milk or infant formulas because of the presence of lactoferrin in breast milk. Whey protein (lactalbumin), which constitutes a greater percentage of the total protein in human milk than in cow's milk, may also improve iron absorption.

The degree of gastric acidity enhances solubility and therefore bioavailability of iron derived from foods. Therefore achlorhydria, hypochlorhydria, or administration of alkaline substances such as antacids can interfere with nonheme iron absorption by not permitting the solubilization of iron in gastric and duodenal fluids. Gastric secretions also seem to increase the absorption of heme iron.

Certain physiologic states such as pregnancy and growth that involve increased blood formation stimulate iron absorption. In addition, more iron is absorbed during iron deficiency states because of adaptive mechanisms that enhance nonheme iron absorption.

Foods with high phytate content have low iron bioavailability, but whether phytate is the cause is not clear. Oxalates can inhibit absorption. Tannins, which are polyphenols, in tea also reduce nonheme iron absorption. On the other hand, the presence of an adequate amount of calcium helps to remove phosphate, oxalate, and phytate that would otherwise combine with iron and inhibit its absorption.

The availability of iron from various compounds used for food enrichment or as supplements varies widely according to their chemical composition. Although iron in the ferrous form is most readily absorbed, not all ferrous compounds are equally available. Ferrous pyrophosphate is used frequently in products such as breakfast cereals because it does not add a gray color to the food; however, this compound and others such as ferrous citrate and ferrous tartrate are poorly absorbed. Iron is usually added to baby foods in an elemental form, the absorbability of which depends on the iron particle size. Increased intestinal motility decreases iron absorption by decreasing contact time and rapidly removing the chyme from the area of highest intestinal acidity. Poor

fat digestion leading to steatorrhea also decreases iron absorption and the absorption of other cations.

**Transport.** Iron (nonheme) is transported, bound to transferrin (see Figure 3-33), from the intestinal absorbing cells to various tissues to meet their needs. It rarely exists in the free ionic state in serum.

**Storage.** Between 200 and 1500 mg of iron is stored in the body as ferritin and hemosiderin; 30% is in the liver, 30% is in the bone marrow, and the rest is in the spleen and muscles. Up to 50 mg/day can be mobilized from storage iron, 20 mg of which is used in hemoglobin synthesis; see estimates in Table 3-29. The amounts of circulating ferritin in blood correlate closely with total body iron stores, which makes this measurement valuable for evaluation of iron status.

**Intestinal Excretion.** Iron is lost from the body only through bleeding and in very small amounts through defecation, sweat, and the normal exfoliation of hair and skin. Most of the iron lost in the feces could not be absorbed from food. The remainder comes from bile and the cells exfoliated from the GI epithelium. Almost no iron is excreted in the urine. Daily iron loss is approximately 1 mg for men and slightly less for nonmenstruating women. The loss of iron accompanying menstruation averages approximately 0.5 mg/day. However, wide variations exist among individuals, and menstrual losses of more than 1.4 mg of iron daily have been reported in approximately 5% of normal women.

## Functions

The functions of iron relate to its ability to participate in oxidation and reduction reactions. Chemically, iron is a highly reactive element that can interact with oxygen to form intermediates with the potential of damaging cell membranes or degrading DNA. Iron must be tightly bound to proteins to prevent these potentially destructive oxidative effects.

Iron metabolism is complex because this element is involved in so many aspects of life, including red blood cell function, myoglobin activity, and the roles of numerous heme and nonheme enzymes. Because of its oxidation-reduction (redox) properties, iron has a role in the blood and respiratory transport of oxygen and carbon dioxide, and it is an active component of the cytochromes (enzymes) involved in the processes of cellular respiration and energy (ATP) generation. Iron is also involved in immune function and cognitive performance; this underscores the importance of preventing iron deficiency anemia throughout the world.

**Hemoglobin**, which is present in red blood cells, is synthesized in immature cells in bone marrow. Hemoglobin works in two ways: the iron-containing heme combines with oxygen in the lungs; and the heme releases the oxygen in tissues, where it picks up carbon dioxide and then releases it in the lungs after its return from the tissues. **Myoglobin**, also a heme-containing protein, serves as an oxygen reservoir within muscle. Table 3-30 lists the major iron molecules in the body and their functions.

Oxidative production of ATP within the mitochondria involves many heme and nonheme iron-containing enzymes.

**TABLE 3-30****Iron Molecules in the Body**

Molecule	Function
<b>Metabolic Proteins</b>	
Heme proteins	
Hemoglobin	Oxygen transport from lungs to tissues
Myoglobin	Transport and storage of oxygen in muscle
Enzymes: Heme	
Cytochromes	Electron transport
Cytochrome P-450	Oxidative degradation of drugs
Catalase	Conversion of hydrogen peroxide to oxygen and water
Enzymes: Nonheme	
Iron-sulfur and metalloproteins	Oxidative metabolism
Enzymes: Iron dependent	
Tryptophan pyrolase	Oxidation of tryptophan
<b>Transport and Storage Proteins</b>	
Transferrin	Transport of iron and other minerals
Ferritin	Storage
Hemosiderin	Storage

The cytochromes, present in nearly all cells, function in the mitochondrial respiratory chain in the transfer of electrons and the storage of energy through the alternate oxidation and reduction (redox) of iron ( $\text{Fe}^{2+}$  to and from  $\text{Fe}^{3+}$ ). Numerous water-insoluble drugs and endogenous organic molecules are transformed by the iron-containing cytochrome P-450 system in the liver into more water-soluble molecules that can be secreted in the bile and eliminated. Ribonucleotide reductase, the rate-limiting enzyme involved in DNA synthesis, is also an iron enzyme. Although these vital enzymes represent only a small portion of the total iron in the body, a severe decrease in their concentrations can have long-term consequences. Other enzymes, including several in the brain, also require iron.

An adequate iron intake is essential for the normal function of the immune system. Iron overloads and deficiencies result in changes in the immune response. Iron is required by bacteria; therefore an iron overload (especially intravenously) may result in an increased risk of infection. Iron deficiency affects humoral and cellular immunity. Concentrations of circulating T-lymphocytes decrease in individuals with an iron deficiency, and the mitogenic response is typically impaired. Natural killer (NK) cell activity also decreases. Production of interleukin-1 is reduced in iron-deficient animals, and depressed interleukin-2 production has been reported.

Two iron-binding proteins—transferrin (in blood) and lactoferrin (in breast milk)—seem to protect the body against infection by withholding iron from microorganisms that need it for proliferation. Iron is used by brain cells for normal function in people of all ages. Iron is involved in the function and synthesis of neurotransmitters and possibly myelin. The detrimental effects of early iron deficiency anemia in children can persist for many years. For example, declines have been found between the scholastic performance, sensorimotor competence, attention, learning, and memory of children with anemia. Iron supplementation in children with iron deficiency anemia has been found to improve learning, as indicated by achievement test scores (Beard, 2001). Changes in iron metabolism occur in Alzheimer disease and other disorders.

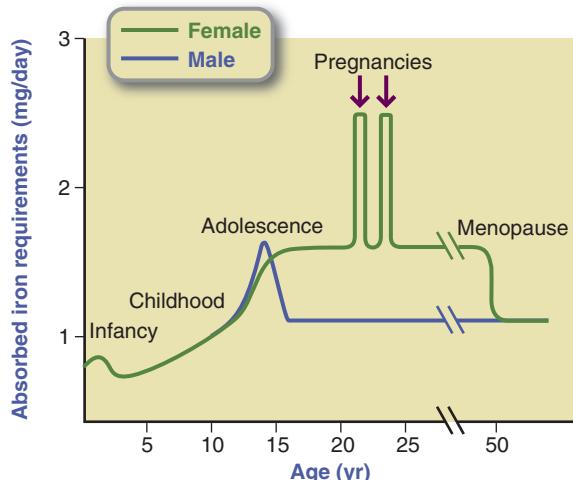

**Dietary Reference Intakes**

DRI<sup>s</sup> have been established for iron. The RDA for men and postmenopausal women is 8 mg/day. The RDA for women of childbearing age (to replace iron loss from menstruation and provide for iron stores sufficient to support a pregnancy) is 18 mg/day. For teenage boys (ages 14 to 18) the iron RDA is 11 mg/day. Full-term infants are born with a reserve supply of iron from placental transfer during gestation, but normal-term infants still require adequate iron from food sources and fortified milk products during the first year of life. Premature infants have limited iron stores because they lack most of the iron and other trace minerals that are normally transferred during the last trimester of pregnancy. The need for iron to support rapid growth in premature infants becomes apparent at approximately 2 to 3 months of age. The RDAs for ages 1 year and older are (variably) 7, 8, or 10 mg/day until adolescence begins at age 14. Figure 3-34 shows the physiologic requirements for iron in relation to age. Requirements are highest during infancy and adolescence. Iron needs among males decrease after the adolescent growth spurt, whereas the iron needs of their female counterparts continue to be high until the menopause. Iron allowances increase during pregnancy from 15 to 27 mg/day, but not during lactation, although many lactating women are told to continue taking their iron supplements.

**Food Sources and Intakes**

By far the best source of dietary iron is liver, followed by seafood, kidney, heart, lean meat, and poultry. Dried beans and vegetables are the best plant sources. Some other foods that provide iron are egg yolks, dried fruits, dark molasses, whole-grain and enriched breads, wine, and cereal. Old-fashioned iron skillets used for cooking add to the total iron intake. Table 3-31 presents the iron content of selected foods.

The availability of iron derived from food is important in the consideration of dietary sources. For example, only 50% or less of the iron in whole-grain cereals and in some green vegetables is available in a usable form. Corn is a notoriously poor source of iron; milk and milk products are practically devoid of iron. When dietary intake focuses

**FIGURE 3-34** The absorbed iron requirement for various ages. The greatest requirements for iron occur during infancy. During childhood, requirements are the same for boys and girls. During the adolescent growth spurt, iron needs increase and are greater for boys than girls. However, because of menstruation, the requirements after adolescence remain high for females but decrease for males.

primarily on these foods, anemia levels can be high. Vegetarian or vegan women can obtain enough iron from their plant-based diet, but they must consume sufficient amounts of moderately iron-rich foods, such as legumes and dried fruits. Soy products are typically good sources of both iron and zinc.

Iron fortification of cereals, flours, and bread has added significantly to the total iron intake of the U.S. population. Fortified cereals are a substantial source of iron for infants and children, as well as for adolescents and adults. Concern about potential iron overloading from fortified breakfast foods has been raised because analyzed values of iron content may be considerably greater than labeled values. The foods that supply the greatest amount of iron in the U.S. diet include ready-to-eat cereals fortified with iron; bread, cakes, cookies, doughnuts, and pasta (all fortified with iron); beef; dried beans and lentils; and poultry.

Whereas the median iron intakes of most women are lower than the RDA, the median intakes of men generally exceed the RDA. An adequate diet containing meats and other animal sources typically has high iron content, containing approximately 6 mg of iron per 1000 kcal. Therefore the average omnivorous woman of childbearing age consuming 2000 kcal takes in only 12 mg of iron, or approximately 67% of the RDA of 18 mg/day. This intake level meets the needs of almost no menstruating woman. However, iron intakes totaling much less than 12 mg/day place women at more serious risk for developing deficiency anemia. Women with high daily iron losses compensate with an increased rate of absorption. Even with this adaptation, insufficient stores of iron typically exist and the risk of anemia remains high.

**TABLE 3-31**

### Iron Content of Selected Foods

Food	Content (mg)
Cereal, ready-to-eat, fortified, 1 cup	1-22
Clams, canned, 3 oz	23.7
Rice, white, enriched, 1 cup	9.73
Baked beans, 1 cup	8.2
Braunschweiger, 2 slices	6.35
Oysters, cooked, 3 oz	5.9
Bagel, enriched, 1, 4-inch	5.38
Beef liver, fried, 3 oz	5.24
Fast food roast beef sandwich, 1	4.23
Refried beans, 1 cup	4.18
Potato skin, 1	4.08
Burrito, bean, 1	1.13
Ground beef, lean, 3 oz	1.8
Oatmeal, unfortified, 1 cup	1.6
Spinach, cooked, 1 cup	6.43
Corn dog, 1	6.18
Macaroni and cheese, 1 cup	1.86
Egg, 1	0.92
Peanuts, dry roasted, 3 oz	0.8
Blueberries, frozen, ½ cup	4.5
Chicken, breast, roasted, ½	0.64
Broccoli, fresh, cooked, ½ cup	0.64
Wine, red, ½ cup	0.5
Cheese, cheddar, 1 oz	0.2
Milk, 2% fat, 1 cup	0.07

### RDA

Infants and young children	7-11 mg/day, depending on age
Older children and adolescents	8-15 mg/day, depending on age
Adults	8-18 mg/day, depending on age and gender
Pregnant	27 mg/day
Lactating	9-10 mg/day, depending on age

From U.S. Department of Agriculture, Agricultural Research Service: Nutrient Database for Standard Reference, Release 18, Data Laboratory home page: <http://www.nal.usda.gov/fnic/foodcomp/Data/SR18/nutrlst/sr18w303.pdf>; accessed 2011.

RDA, Recommended dietary allowance.

### Deficiency

Iron deficiency, the precursor of iron deficiency anemia, is the most common of all nutritional deficiency diseases. In the United States and worldwide, iron deficiency anemia is prevalent among children and women of childbearing age. The groups considered to be at greatest risk for iron deficiency anemia are infants younger than 2 years of age, adolescent girls, pregnant women, and older adults. Pregnant

teenagers are frequently at high risk because of poor eating habits and continuing growth. Women in their childbearing years who are iron deficient benefit from either a diet rich in iron-containing foods or supplements.

The final stages of iron deficiency include hypochromic, microcytic anemia. Anemia may be corrected by providing high-dose supplements in the form of ferrous sulfate or ferrous gluconate until blood parameters return to normal. To prevent worsening of the iron deficiency, individuals should be counseled regarding a diet that is appropriately rich in iron.

Iron deficiency can be caused by injury, hemorrhage, or illness (e.g., blood loss from hookworms, GI diseases that interfere with iron absorption). Iron deficiency may also be aggravated by an unbalanced diet containing insufficient iron, protein, folate, and vitamin C. Anemia typically develops because of an inadequate amount of dietary iron or faulty iron absorption.

Female athletes, especially cross-country runners and others involved in endurance sports, often have an iron deficiency at some point in their training if they are not taking iron supplements or do not have diets high in iron. The source of the additional iron losses in those with athletic amenorrhea may be through the gut; losses may increase during the stressful conditions of training. It seems that without supplementation, the greater the intensity of training, the lower the iron levels become in women.

### Toxicity

The major cause of iron overload is hereditary hemochromatosis, whereas transfusion iron overload is rare. The latter may be seen in individuals with sickle cell disease or thalassemia major who require transfusions for their anemia. Iron overload is linked to a distinct gene that favors excessive iron absorption if the iron is available in the diet. Both are linked to decreased hepcidin levels (Nemeth and Ganz, 2009). The characteristic chemical parameters of iron overload are listed in Box 3-7.

Frequent blood transfusions or long-term ingestion of large amounts of iron can lead to abnormal accumulation of iron in the liver. Saturation of tissue apoferritin with iron is followed by the appearance of **hemosiderin**, which is similar to ferritin but contains more iron and is very insoluble. Hemosiderosis is an iron storage condition that develops in

### BOX 3-7

#### Iron Overload Symptoms (Hemochromatosis)

- Abnormal accumulation of iron in the liver
- Excessive tissue ferritin levels
- Elevated serum transferrin levels
- Oxidation of LDL cholesterol
- Cardiovascular complications
- LDL*, Low-density lipoprotein.

individuals who consume abnormally large amounts of iron or in those with a genetic defect resulting in excessive iron absorption. If the hemosiderosis is associated with tissue damage, it is called *hemochromatosis*. See Chapter 33.

Iron supplements may not be beneficial for postmenopausal women and older men because of increased risks for heart disease and cancer; iron contributes to an environment that favors oxidation of LDL cholesterol, arterial vessel damage, and other adverse effects. In addition, excessive iron may help generate free radicals that attack cellular molecules, thereby increasing the number of potentially carcinogenic molecules within cells. These potential adverse iron-disease linkages need to be confirmed.

### Zinc

Zinc is abundantly distributed throughout the human body, second only to iron among trace elements. The human body has approximately 2 to 3 g of zinc, with the highest concentrations in the liver, pancreas, kidney, bone, and muscles. Other tissues with high concentrations include parts of the eye, prostate gland, spermatozoa, skin, hair, fingernails, and toenails. Zinc is primarily an intracellular ion, functioning in association with more than 300 different enzymes of various classes. Even though zinc is abundant in the cytosol, virtually all of it is bound to proteins, but it is in equilibrium with a small ionic fraction.

The most readily available form of zinc occurs in animal flesh, particularly red meats and poultry. Meat intake is frequently low among preschoolers, usually displaced by cereal foods, milk, and milk products that children tend to prefer. This observation led to the fortification of infant and children's foods, especially cereals, with zinc. Milk is a good source of zinc, but high intakes of calcium from milk may interfere with the absorption of iron and zinc (see the bioavailability discussion). The phytates from whole grains in unleavened breads may limit zinc absorption in some populations. According to the WHO, zinc deficiency is one of the 10 major factors contributing to disease in developing countries (Shrimpton et al., 2005). Deficiencies are less likely to be a problem in Western nations, where breads, breakfast foods, and other cereal-based foods are made primarily from refined grains and are typically fortified.

### Absorption, Transport, Storage, and Excretion

Zinc absorption and excretion are controlled by poorly understood homeostatic mechanisms. The mechanism of absorption involves two pathways. A saturable carrier mechanism operates most efficiently at low zinc intakes when luminal zinc concentrations are low; a passive mechanism works when zinc intakes and luminal concentrations are high. Solubility of zinc in the gut lumen is critical. Zinc ions are generally bound to amino acids or short peptides in the lumen, released at the brush border for absorption via the carrier mechanism (hZIP family). The entry step of absorption across the brush border is followed by the binding of zinc ions to metallothionein and other proteins within the cytosol of the absorbing cell. Metallothionein carries the zinc (via transcellular movement) to the basolateral border

for the exit step from the absorbing cell to the blood. The exit step occurs by active transport because the blood concentration of zinc is significantly greater than the cytosolic ion concentration. The process of zinc absorption is illustrated in Figure 3-35.

Zinc absorption is affected not only by the level of zinc in the diet but also by the presence of interfering substances, especially phytates. After the consumption of zinc in a meal, the serum zinc level rises and then decreases in a dose-response pattern. A protein-rich diet promotes zinc absorption by forming zinc–amino acid chelates that present zinc in a more absorbable form. Zinc absorption is slightly higher during pregnancy and lactation. Absorbed zinc is taken up from the portal circulation initially by the liver, but most of the zinc is subsequently redistributed to other tissues. Impaired absorption is associated with a variety of intestinal diseases such as Crohn disease or pancreatic insufficiency.

Several dietary factors affect zinc absorption. Phytate decreases zinc absorption, but other complexing agents (e.g., tannins) do not. Copper and cadmium compete for the same carrier protein; thus they reduce zinc absorption. High calcium or iron intakes reduce zinc absorption and balance. Folic acid may also reduce zinc absorption when zinc intake is low. On the other hand, high doses of zinc can impair absorption of iron from ferrous sulfate, the form in vitamin and mineral supplements. Dietary fiber may also interfere with zinc absorption, but the significance is unclear. Zinc absorption may be enhanced by glucose or lactose and by soy protein consumed alone or mixed with beef. Red table wine also increases zinc absorption, probably because of its congeners. Like iron, zinc is better absorbed from human milk than from cow's milk.

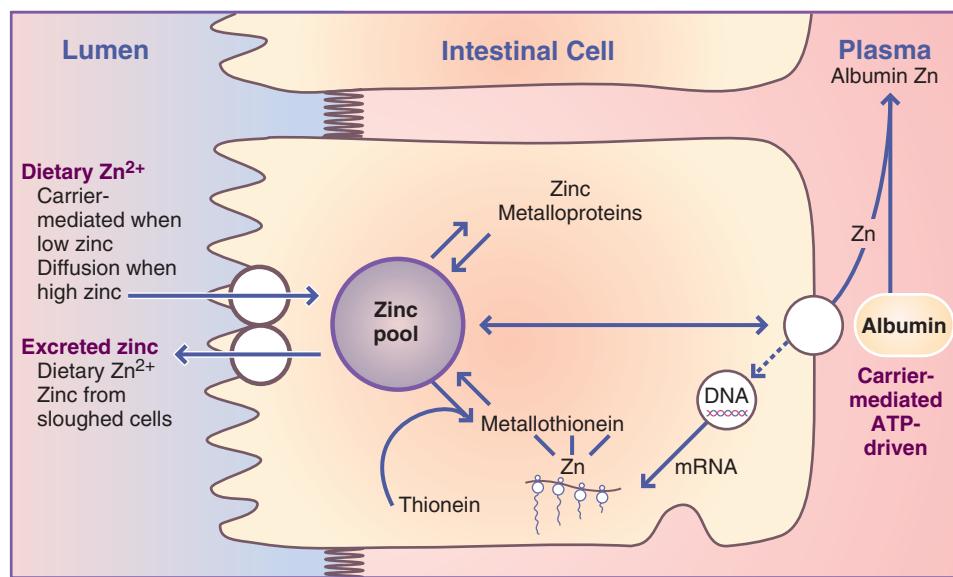

**Transport in Blood.** Albumin is the major plasma carrier of zinc. The amount of zinc transported in the blood

depends not on zinc but also on the availability of albumin. Some zinc is transported by transferrin and by  $\alpha_2$ -macroglobulin. Most zinc in the blood is localized in erythrocytes and leukocytes. Plasma zinc is metabolically active and fluctuates in response to dietary intake and physiologic factors such as injury or inflammation. Levels drop by 50% in the acute phase of a response to an injury, probably because of the sequestering of zinc by the liver.

**Intestinal Excretion.** Excretion of zinc in normal individuals is via the feces. When zinc is administered intravenously, approximately 10% of the dose appears in the intestine within 30 minutes. However, increased urinary excretion has been reported in starvation, nephrosis, diabetes, alcoholism, hepatic cirrhosis, and porphyria. Plasma and urine concentrations of zinc-binding cysteine and histidine, and other urinary metabolites, may have a role in increasing zinc losses in these patients.

## Functions

Zinc has structural, catalytic, and regulatory functions in the cell, primarily as an intracellular ion (Tuerk and Fazel, 2009). Zinc plays important structural roles as components of several proteins. It also functions in association with more than 300 different enzymes, in reactions involving either synthesis or degradation of carbohydrates, lipids, proteins, and nucleic acids. It also functions as an intracellular signal in brain cells where it is stored in specific synaptic vesicles and is fundamental to normal central nervous system function (Bitanahirwe and Cunningham, 2009). In addition, zinc is involved in the stabilization of protein and nucleic acid structure and the integrity of subcellular organelles, as well as in transport processes, immune function, and expression of genetic information.

**FIGURE 3-35** Model for zinc absorption showing the relationship between metallothionein and cysteine-rich intestinal protein. *ATP*, Adenosine triphosphate; *DNA*, deoxyribonucleic acid; *mRNA*, messenger ribonucleic acid.

**Metallothionein** is the most abundant, nonenzymatic zinc-containing protein. This low-molecular-weight protein is rich in cysteine and exceptionally high in metals, among which are zinc and lesser amounts of copper, iron, cadmium, and mercury. The biologic role of metallothionein is not clear, but it does have a function in zinc absorption. Metallothionein may function as an intracellular reservoir that can donate zinc ions to other proteins, or it may have a redox role that reduces oxidative stress, especially in cells with high stress. Thus metallothionein may have a role in the detoxification of metals as well as in their absorption.

Zinc is abundant in the nucleus, where it stabilizes RNA and DNA structure, and is required for the activity of RNA polymerases important in cell division. Zinc also functions in chromatin proteins involved in transcription and replication, and it protects against age-related macular degenerative disease. Although widely touted to cure or prevent common colds, zinc gluconate lozenges or nasal sprays are not very effective.

Dietary zinc causes an increase in bone mass. Zinc appears in the crystalline structure of bone, in bone enzymes, and at the zone of demarcation. It is needed for adequate osteoblastic activity, formation of bone enzymes such as alkaline phosphatase, and calcification (see Table 3-25). Beta-alanyl-histidine (carnosine) is a zinc compound that stimulates bone formation intensively and restores bone loss from aging, skeletal unloading, aluminum bone toxicity, calcium and vitamin D deficiency, adjuvant arthritis, estrogen deficiency, diabetes, and fracture healing (Yamaguchi, 2010). Such new zinc compounds may become adjuvant therapy for osteoporosis and other disorders.

### Dietary Reference Intakes

The zinc DRI for adolescent and adult males is 11 mg/day. Because of the lower body weight of adolescent and adult women, their DRI is 8 to 9 mg/day. The DRI for preadolescents is estimated to be 8 mg/day. The DRIs for infants are 2 mg/day for the first 6 months and 3 mg/day for the second 6 months of life.

### Food Sources and Intakes

For most Americans, most daily intake of zinc is provided by meat, fish, poultry, ready-to-eat breakfast cereals fortified with zinc, and milk and milk products. Oysters are especially high in zinc, and other shellfish, liver, whole-grain cereals, dry beans, and nuts are all good sources (Table 3-32). Soy products may also be fairly good sources of zinc. In general, zinc intake correlates well with protein intake.

The zinc content of typical diets of adults in Western countries ranges between 10 and 15 mg/day; women consume less than men because of lower energy intakes. The zinc density of the American adult's diet is approximately 5.6 mg/1000 kcal.

### Deficiency

The clinical signs of zinc deficiency were first described as short stature, hypogonadism, mild anemia, and low plasma zinc level. This deficiency was caused by a diet high in

**TABLE 3-32**

**Zinc Content of Selected Foods**

Food	Content (mg)
Oysters, 6 medium	76.7
Beef shanks, cooked, 3 ounces	8.9
Crab, Alaska king, cooked, 3 ounces	6.5
Pork shoulder, cooked, 3 ounces	4.2
Breakfast cereal fortified with 25% of the DV for zinc, $\frac{3}{4}$ cup serving	3.8
Chicken leg, roasted, 1 leg	2.7
Pork tenderloin, cooked, 3 ounces	2.5
Lobster, cooked, 3 ounces	2.5
Baked beans, canned, $\frac{1}{2}$ cup	1.7
Cashews, dry roasted, 1 ounce	1.6
Yogurt, fruit, low fat, 1 cup	1.6
Raisin bran, $\frac{3}{4}$ cup	1.3
Chickpeas, $\frac{1}{2}$ cup	1.3
Cheese, Swiss, 1 ounce	1.1
Almonds, dry roasted, 1 ounce	1.0
Milk, 1 cup	0.9
Chicken breast, roasted, $\frac{1}{2}$ breast with skin removed	0.9
Cheese, cheddar or mozzarella, 1 ounce	0.9
Kidney beans, cooked, $\frac{1}{2}$ cup	0.8
Peas, boiled, $\frac{1}{2}$ cup	0.8
Oatmeal, instant, 1 packet	0.8
Flounder or sole, cooked, 3 ounces	0.5
<b>DRIs</b>	
Infants and young children	2-5 mg/day, depending on age
Older children and adolescents	8-11 mg/day, depending on age and gender
Adults	8-11 mg/day, depending on gender
Pregnant	11-13 mg/day, depending on age
Lactating	12-14 mg/day, depending on age

From U.S. Department of Agriculture, Agricultural Research Service: Nutrient Database for Standard Reference, Release 18, Data Laboratory home page: <http://www.nal.usda.gov/fnic/foodcomp/Data/SR18/nutrlst/sr18w309.pdf>; accessed 1-14-11.

DRI, Dietary reference intake.

unrefined cereals and unleavened breads, which contain high levels of fiber and phytate, which chelate with zinc in the intestine and prevent absorption. Additional symptoms of zinc deficiency include hypogeusia (decreased taste acuity), delayed wound healing, alopecia, and diverse forms of skin lesions. Acquired zinc deficiency may occur as the

**FIGURE 3-36** Cutaneous manifestations of zinc deficiency. (From Callen WBS et al: *Color atlas of dermatology*, Philadelphia, 1993, Saunders.)

result of malabsorption, starvation, or increased losses via urinary, pancreatic, or other exocrine secretions. Patients with alcoholism may have altered zinc metabolism. Pregnant women and older adults are also at increased risk for deficiency. Low-dose zinc supplementation may improve measures of poor zinc status.

Acrodermatitis enteropathica, an autosomal-recessive disease characterized by zinc malabsorption, results in eczematoid skin lesions (Figure 3-36), alopecia, diarrhea, bacterial and yeast infections, and even death if left untreated. Symptoms generally first develop during weaning from human milk to cow's milk. Researchers are working to identify the genetic basis of inherited nutritional deficiencies such as acrodermatitis enteropathica; the hZIP4 gene is involved. Zinc, biotin, protein, or essential fatty acid deficiency should be considered when there are systemic signs of failure to thrive (Gehrig and Dinulos, 2010).

Zinc deficiency results in various immunologic defects. Severe deficiency is accompanied by thymic atrophy, lymphopenia, reduced lymphocyte proliferative response to mitogens, a selective decrease in T-helper cells, decreased NK cell activity, anergy, and deficient thymic hormone activity. Even mild zinc deficiency can reduce immune function, such as impaired interleukin-2 production. Supplementation with zinc may improve immune status, but more studies are needed. Moderate zinc deficiency is associated with anergy and diminished NK cell activity but not with thymic atrophy or lymphopenia. Box 3-8 summarizes the clinical manifestations of human zinc deficiency. Similarities between patients with sickle cell anemia and zinc deficiency suggest the possibility of a secondary zinc deficiency in those with the anemia.

Problems caused by low zinc intakes seem to be increasing, partly because of the low bioavailability of zinc. Athletes may also have an increased risk for developing zinc deficiency. Physical activity may increase mobilization of zinc from bone stores for cellular needs (e.g., for the synthesis of zinc-metalloenzymes). Finally, patients on long-term parenteral nutrition who do not receive zinc will show signs of deficiency; requirements have been estimated to be

### BOX 3-8

#### Zinc Deficiency Symptoms

- Growth retardation
- Delayed sexual maturation
- Hypogonadism and hypospermia
- Alopecia
- Delayed wound healing
- Skin lesions
- Impaired appetite
- Immune deficiencies
- Behavioral disturbances
- Eye lesions, including photophobia and night blindness
- Impaired taste (hypogeusia)

3 mg/day in patients without GI losses and a mean of 12 mg/day in patients with diarrhea and fistula losses (Jeejeebhoy, 2009).

#### Toxicity

Oral ingestion of toxic amounts of zinc (100 to 300 mg/day) is rare, but the UL for zinc in adults is 40 mg/day. Excessive zinc supplementation has long been known to interfere with copper absorption. A major form of zinc toxicity develops in patients receiving hemodialysis for renal failure, with contamination of dialysis fluids from the adhesive plastic used on the dialysis coils or from galvanized pipes. The toxic syndrome in these patients is characterized by anemia, fever, and central nervous system disturbances. Zinc sulfate in amounts of 2 g/day or more may cause GI irritation and vomiting. Inhalation of zinc fumes during welding may be toxic, but exposure to fumes can be prevented with proper precautions.

#### Fluoride

Fluoride is a natural element found in nearly all drinking water and soil, although the fluoride content varies greatly

throughout the world. For example, some well water has much more fluoride than other water, so families who use well water need to monitor fluoride levels periodically to make sure that levels are not in the toxic range. Although fluoride is not considered an essential element, this anion is known to be important for the health of bones and teeth. The average skeleton contains 2.5 mg of fluoride.

## Functions

Fluoride is considered important, if not essential, because of its benefits for tooth enamel. Its incorporation into enamel produces more stable apatite crystals (Robinson et al., 2004). Fluoride also acts as an antibacterial agent in the oral cavity, serving as an enzyme inhibitor. Fluoride has no known requirement in human metabolic pathways.

The prevalence of dental caries has decreased by 50% in recent decades because of fluoridation of drinking water and the use of topical fluorides. The prevalence of dental caries has also decreased in communities without fluoridated water. This decrease probably results from the use of fluoridated toothpaste, topical fluoride applications, and use of fluoridated water used in food processing, all of which provide fluoride for incorporation into teeth. Soft drinks typically are prepared with fluoridated waters at bottling plants in urban areas.

Fluoride substitutes for the hydroxyl group on the lattice structure of calcium phosphate salts (i.e., hydroxyapatites) of the bones and teeth to form fluoroapatite, which is harder and less readily resorbed than hydroxyapatite (Chachra et al., 2008). After fluoridation, bone tissue formed at high fluoride blood levels is not healthy; it is subject to fractures from too tight binding of the fluoroapatite crystals compared with the hydroxyapatite in unfluoridated bone.

## Dietary Reference Intakes

The AIs for fluoride were established for the first time in 1997. AIs for adult men and women are 4 and 3 mg/day, respectively. Depending on age, the AIs range from 2 to 3 mg/day for children and adolescents and from 0.7 to 1 mg/day for young children between the ages of 1 and 8 years. For comparison, an 8-oz glass of fluoridated water (1 ppm or 1 mg/L) provides approximately 0.2 mg of fluoride. ULs have also been established for fluoride.

## Food Sources and Intakes

The major dietary sources of fluoride are drinking water and processed foods that have been prepared or reconstituted with fluoridated water. Seafood also is high in fluoride, but the content in freshwater fish is lower than that of saltwater fish. Soups and stews made with fish and meat bones also provide substantial fluoride, as do beef liver and mechanically deboned meat and fowl. Although fluorides exist in fruits and vegetables, the amounts in most foods are not significant.

The amount in tea leaves can be substantial, depending on the brewing strength. One cup of tea may contain as much as 1 mg of fluoride. Fluoridated toothpastes are also a source of fluoride; calcium carbonate-based fluoride

toothpastes are effective in reducing caries and provide oral calcium as well (Lynch and Cate, 2005). The standard recommendation is 1 ppm for fluoridated community water supplies. Children who drink fluoridated water typically consume more total fluoride than those who do not. Intakes higher than 2 mg raise concerns about mild fluorosis, which has been reported in a few U.S. communities.

## Deficiency

Because no known metabolic function exists for fluoride, fluoride cannot have a true deficiency that results in disease. Fortuitous binding in hydroxyapatite crystals, especially from fluoridated water supplies, reduces dental caries, but it does not seem to have any effect on reducing osteoporotic fractures.

## Toxicity

A mild fluorosis can develop from daily doses of 0.1 mg/kg (i.e., greater than approximately 2 to 3 ppm of fluoride in the drinking water). The resulting discoloration of the teeth, or mottling, has no adverse effect except cosmetically. However, higher intakes lead to tooth flaking and more serious dental effects. Some evidence suggests that fluoride intakes are increasing among toddlers and young children because of the proliferating sources of fluoride. When drinking water contained less fluoride, the average intake was lower. Even the highest values did not exceed the recommendation of 0.08 mg/kg daily. Intakes of fluoride by young children may vary greatly from the use of dentifrices, fluoridated water, bottled drinks, and other sources. Some children may ingest total amounts of fluoride that exceed the optimum intake level (0.05 to 0.07 mg/kg daily), possibly causing dental fluorosis.

## Copper

Copper, a normal constituent of blood, is another established essential micronutrient. Recent interest in copper has increased because of the many tissue-related functions. Concentrations of copper are highest in the liver, brain, heart, and kidney. Muscle contains a low level of copper, but, because of its large mass, skeletal muscle contains almost 40% of all the copper in the body. Recent investigations have increased the understanding of the physiologic roles of copper, copper homeostasis, and copper needs throughout the life cycle.

## Absorption, Transport, Storage, and Excretion

Copper absorption, transport, storage and excretion are highly controlled (Kaplan and Lutsenko, 2009; Lalioti et al., 2009). Copper absorption occurs in the small intestine. Entry at the mucosal surface is by facilitated diffusion, and exit across the basolateral membrane is primarily by active transport; facilitated transfer may also occur. Competition between copper ions and other divalent cations exists at each step. Within the intestinal absorbing cells, copper ions are bound to metallothionein with greater affinity than zinc or other ions; the amount of copper absorbed may be regulated by the amount of

metallothionein in the mucosal cells. Net absorption of copper varies from 25% to 60%. Low absorption efficiencies help to regulate the retention of copper in the body; therefore the percentage of absorption decreases with increased intake. Fiber and phytate intakes may slightly inhibit copper absorption.

Copper does not exist as a free ion in the body. Approximately 90% of the copper in serum is incorporated into **ceruloplasmin**, a functional enzyme at the erythrocyte-forming cells of the bone marrow. The remaining 10% is bound loosely to albumin, transcuprein, and other proteins; free amino acids; and possibly histidine. Serum copper and immunoreactive ceruloplasmin levels tend to be higher in women than in men. Serum copper concentration is greatest in the neonate, decreasing gradually during the first year of life.

Copper is transported bound to albumin, which serves as a temporary storage site for copper. In the liver copper binds to metallothionein. It serves as a storage form of copper and is incorporated into ceruloplasmin and secreted into the plasma for the transport of copper to cells. Copper is also secreted from the liver as a component of bile, its major route of excretion. Once in the GI tract, copper becomes part of the pool that may be resorbed or excreted, depending on bodily needs. Biliary excretion increases in response to excessive intakes of copper but may not be able to keep up with intake, sometimes allowing it to reach toxic levels.

Small amounts of copper are found in urine, sweat, and menstrual blood. Copper can be conserved by the kidney if necessary when substantial amounts are filtered through the glomeruli and resorbed in the tubules.

The interaction of copper with other nutrients negates the fallacy that taking vitamin and mineral supplements in amounts in excess of the recommended levels of consumption is good. In amounts of 150 mg/day, zinc induces copper deficiency by overwhelming the capacity of metallothionein in intestinal absorbing cells. High ascorbic acid intake (1500 mg/day) also reduces blood concentrations of copper, which may decrease the role of ceruloplasmin in red cell formation.

## Functions

Copper is a component of many enzymes, and symptoms of copper deficiency are attributable to enzyme failures. Copper in ceruloplasmin has a well-documented role in oxidizing iron before it is transported in the plasma. Lysyl oxidase, a copper-containing enzyme, is essential in the lysine-derived cross-linking of collagen and elastin, connective tissue proteins with great tensile strength. Through the involvement of copper-containing electron transport proteins, copper also has roles in mitochondrial energy production. As part of copper-containing enzymes such as SOD, copper protects against oxidants and free radicals and promotes the synthesis of melanin and catecholamines. Other functions of copper-containing enzymes have not yet been completely defined.

## Dietary Reference Intakes

An RDA of 900 mcg/day (0.9 mg/day) for adults of both genders has been established for copper (IOM, Food and Nutrition Board, 2001). Adolescents need 890 mcg. Copper intakes should range between 200 and 220 mcg/day for infants and between 340 and 440 mcg for young children. Premature infants are born with low copper reserves and may require additional dietary copper during their first few months of life.

## Food Sources and Intakes

Copper is distributed widely in foods, including animal products (except for milk), and most diets provide between 0.6 and 2 mg/day. Foods high in copper are shellfish (oysters), organ meats (liver, kidney), muscle meats, chocolate, nuts, cereal grains, dried legumes, and dried fruits (Table 3-33).

In general, fruits and vegetables contain little copper. Cow's milk, a poor source of copper, contains 0.015 to 0.18 mg/L, whereas the copper in human milk is well absorbed and ranges from 0.15 to 1.05 mg/L. Infants fed cow's milk may be at risk for copper deficiency because of its low copper content.

Copper intakes of individuals in several age categories in the United States have been consistently below recommended amounts, with adolescent girls consuming only approximately 50% of the recommended intakes. Typically

**TABLE 3-33**

### Copper Content of Selected Foods

Food	Content (mg)
Beef liver, fried, 3 oz	12.4
Oysters, 3 oz	3.63
Orange juice, 1 cup	0.11
Cashews, dry roasted, $\frac{1}{4}$ cup	0.61
Sunflower seeds, $\frac{1}{4}$ cup	0.59
Baking chocolate, 1 square	0.92
Mushrooms, cooked, 1 cup	0.79
Tropical trail mix, 1 cup	0.74
Beans, white, canned, 1 cup	0.61
Yogurt, 8 oz	0.03
Broccoli, raw, 1 cup	0.04
Peaches, canned, 1 cup	0.05
Milk chocolate, 1 oz	0.16
Milk, 2% fat, 1 cup	0.03

### DRI Range

0.2-1.3 mg/day, depending on age and gender

From U.S. Department of Agriculture, Agricultural Research Service: Nutrient Database for Standard Reference, Release 18, Data Laboratory home page: <http://www.nal.usda.gov/fnic/foodcomp/Data/SR18/nutrlst/sr18w312.pdf>; accessed 1-14-11.

DRI, Dietary reference intake.

the copper content of drinking water is not considered in diet surveys. The amount of copper in water from copper pipes is considered insignificant. Copper intakes may be low in U.S. diets because until recently, ready-to-eat cereals typically were not fortified with copper as they were for iron and zinc. Another reason for the potential existence of low copper intakes is the inaccuracy associated with short-term assessments of dietary copper.

### Deficiency

Serum copper and ceruloplasmin levels are useful biomarkers to assess copper status in populations. More sensitive indicators of copper status such as copper-containing enzymes in blood cells are needed (Harvey et al., 2009). Copper deficiency is characterized by anemia, neutropenia, and skeletal abnormalities, especially demineralization. Other changes may also develop, including subperiosteal hemorrhages, hair and skin depigmentation, and defective elastin formation. The failure of erythropoiesis, as well as cerebral and cerebellar degeneration, may lead to death. Neutropenia and leukopenia are the best early indications of copper deficiency in children.

Classic cases of copper deficiency were reported among infants who were poorly nourished, had diarrhea, and were fed diluted cow's milk. Other cases of deficiency have been reported. Premature infants are likely to have copper deficiency unless given a supplement because most of the copper is normally transferred across the placenta during the last few months of a full-term pregnancy. Because diets in developing countries continue to be low in copper, pregnancy outcomes need to be monitored (Pathak and Kapil, 2004).

Copper is stored in the liver; deficiency develops slowly as stores become depleted. Deficiencies have not been reported in otherwise healthy humans consuming a varied diet. Low serum copper, ceruloplasmin, and SOD levels provide supportive evidence of copper deficiency, but these markers are not sensitive to marginal copper status. Bone changes, osteoporosis, metaphyseal spur formation, and soft tissue calcification in infants receiving prolonged TPN may resolve with copper supplementation. The only signs of copper deficiency found in adults are neutropenia and microcytic anemia; deficiency is very rare because copper accumulates in the liver throughout life in most individuals.

Wilson disease is an autosomal-recessive disorder of copper metabolism and liver dysfunction (Schilsky, 2009). Menkes syndrome, also known as *kinky-hair syndrome*, is a sex-linked recessive defect caused by at least 160 identified gene mutations (Møller et al., 2009). The syndrome results in copper malabsorption, increased urinary copper loss, and abnormal intracellular copper transport, all of which cause an abnormal distribution of copper among organs and within cells. Affected infants have retarded growth, defective keratinization and pigmentation of the hair, hypothermia, degenerative changes in aortic elastin, abnormalities of the metaphyses of long bones, and progressive mental deterioration. These infants typically do not survive the first few

months of life. Many of the features of this disorder result from interference with the cross-linking of collagen and elastin, steps that require one or more copper enzymes. Brain tissue is practically devoid of cytochrome C oxidase, and a marked accumulation of copper occurs in the intestinal mucosa, although serum copper and ceruloplasmin levels remain very low. Many connective tissue defects occur in patients with Menkes syndrome.

Decreased plasma copper levels develop in patients with malabsorption diseases such as celiac disease, tropical sprue, protein-losing enteropathies, and nephrotic syndrome. Like zinc, low copper intakes may also contribute to reduced immune responses in otherwise healthy individuals.

### Toxicity

Copper toxicity from food consumption is considered impossible. Excessive supplementation or copper salts used in agriculture may lead to liver cirrhosis and abnormalities in red blood cell formation.

Ceruloplasmin concentrations increase during pregnancy and with the use of oral contraceptives. Serum copper concentrations in pregnant women are approximately twice those in women who are not pregnant. Serum and biliary copper concentrations can be elevated in acute or chronic infections, liver disease, and pellagra. The physiologic significance of these elevations is not known.

Any chronic liver disease that interferes with the excretion of bile may contribute to the retention of copper. Primary biliary cirrhosis, as well as mechanical obstruction of the bile ducts, contributes to a progressive rise in liver copper content.

## ULTRATRACE MINERALS

**Ultratrace minerals** such as iodine, selenium, manganese, molybdenum, chromium, and a few other nonessential minerals are found in the body in small quantities; their amounts are typically measured in micrograms. Each of these elements has one or more essential roles. Because of their small quantities in human tissues, special analytic instrumentation and ultraclean laboratories are necessary for the routine analysis or experimental work relating to the ultratrace minerals.

### Iodine

Iodine deficiency in the United States and many Western nations has practically been eliminated with the iodization of salt. However, people living in many mountainous areas of the world and a few low-lying delta regions still have low iodine intakes because of the low content in soil used for cultivating crops. Others living in lowlands may have high goitrogen consumption that reduces iodine use by the thyroid gland. The body normally contains 20 to 30 mg of iodine, with more than 75% in the thyroid gland and the rest distributed throughout the body, particularly in the lactating mammary gland, gastric mucosa, and blood.

## Absorption, Transport, Storage, and Excretion

Iodine is absorbed easily as iodide. In the circulation iodine exists freely and protein bound, but the bound iodide predominates. Excretion is primarily via urine, but small amounts are found in the feces as a result of biliary secretion.

## Functions

Dietary iodine is needed for the synthesis of thyroid hormones. Iodine is stored in the thyroid gland, where it is used in the synthesis of **triiodothyronine (T<sub>3</sub>)** and **thyroxine (T<sub>4</sub>)**. Uptake of iodide ions by the thyroid cells may be inhibited by goitrogens (substances that exist naturally in foods). Thyroid hormone is degraded in target cells and the liver, and the iodine is highly conserved under normal conditions. Selenium is important in iodine metabolism because of its presence in one enzyme responsible for forming active T<sub>3</sub> from thyroglobulin stored in the thyroid gland.

## Dietary Reference Intakes

An iodine intake of 150 mcg/day has been suggested as sufficient for all adults and adolescents. The RDA for pregnant and lactating women increases to 220 mcg and 290 mcg, respectively. The AI is 110 mcg for infants up to 6 months of age and 130 mcg for older infants. The RDA for children is between 90 and 120 mcg and increases with age or body size. Urinary iodine, serum thyroxine, or thyroid-stimulating hormone levels are useful biomarkers of iodine status (Ristic-Medic et al., 2009). See Chapter 32.

## Food Sources and Intakes

Iodine exists in variable amounts in food and drinking water. Seafood, such as clams, lobsters, oysters, sardines, and other saltwater fish, is the richest source. Saltwater fish contain 300 to 3000 mcg/kg of flesh; freshwater fish contain 20 to 40 mcg/kg, but they are still good sources. The iodine content of cow's milk and eggs is determined by the iodides available in the diet of the animal; the iodide content of vegetables varies according to the iodine content of the soil in which they grow. Iodine also enters the food chain through iodophors, which are used as disinfectants in dairy processing, coloring agents, and dough conditioners. These sources add significant amounts of iodine to the food supply. Table 3-34 lists the iodine content of various foods.

The best way to obtain an AI of iodine is to use iodized salt (approximately 60 mcg of iodine per gram of salt) in food preparation. Sea salt naturally contains variable amounts of iodine and only approximately one-tenth the level of iodized salt. More than 50% of the table salt sold in the United States is iodized; however, iodized salt is not used in processed foods. Mandatory iodization has been adopted by many nations, including Canada, but is not legally required in the United States, where iodine deficiency is now very rare. The use of iodized salt should still be advocated in certain areas to prevent goiter.

**TABLE 3-34**

### Iodine Content of Selected Foods

Food	Content (mcg)
Ocean fish, 6 oz	650
Salt, iodized, $\frac{1}{4}$ teaspoon	95
Bread, made with iodate dough conditioner and continuous mix process, 1 slice	142
Yogurt, low fat, 8 oz	87
Bread, made with regular process, 1 slice	35
Cheese, cottage, 2% fat, 4 oz	26-71
Shrimp, 3 oz	21-37
Egg, 1	24
Cheese, cheddar, 1 oz	5-23
Ground beef, 3 oz	8

### DRIs

Infants	110-130 mcg/day, depending on age
Children ages 1-8 years	90 mcg/day
Children 9-13 years	120 mcg/day
Adolescents and Adults	150 mcg/day
Pregnant	220 mcg/day
Lactating	290 mcg/day

(2) Medline Plus. Website <http://www.nlm.nih.gov/medlineplus/ency/article/002421.htm>, accessed 1-14-11.

DRI, Dietary reference intake.

The Total Diet Study of the FDA showed that median adult iodine intakes from 1982 to 1991 ranged from 130 to 140 mcg/day for women and 182 to 204 mcg/day for men. The median iodine intake for male and female teenagers was even higher. Intakes of iodine in the United States seem adequate for most people because of iodination of salt and the use of iodofors. Vegans consume iodine in seaweed or kelp tablets; some individuals may have excessive iodine intakes.

## Deficiency

An estimated two billion people worldwide remain at risk for iodine deficiency. Most are in developing countries, especially those who do not have seafood as part of their diets. These individuals may have a moderate iodine deficiency, even when obvious goiter, a severe condition, is not evident. In children, iodine deficiency is associated with poor cognition. Use of iodized salt or the oral administration of a single dose of iodized oil and weekly iodine supplements are effective. Use of iodized salt should be encouraged during pregnancy, especially through the end of the second trimester.

Very low iodine intakes are associated with the development of endemic or simple **goiter**, which is an enlargement of the thyroid gland (Figure 3-37). Deficiency may be nearly total, especially in mountainous areas and regions of high goitrogen intakes, or relative, subsequent to an increased need for thyroid hormones (e.g., by females during adolescence, pregnancy, and lactation).

Although many countries have worked to eliminate iodine deficiency, goiter may affect as many as 200 to 300 million people worldwide (Kusic and Jukic, 2005). In some countries goiter is so common that it is regarded as a normal physical feature. In the United States the prevalence rate of goiter for all ages is 1.9/1000 persons. The rate is higher in women than in men and in older individuals than in younger ones.

**Goitrogens**, which exist naturally in foods, can also cause goiter by blocking uptake of iodine from the blood by thyroid cells. Foods containing goitrogens include cabbage, turnips, rapeseeds (from rape plants), peanuts, cassava, sweet potatoes, kelp, and soybeans. Goitrogens are inactivated by heating or cooking.

Severe iodine deficiency during gestation and early postnatal growth results in **cretinism** in infants, characterized by mental deficiency, spastic diplegia or quadriplegia, deaf mutism, dysarthria, a characteristic shuffling gait, shortened stature, and hypothyroidism. Less severe variations of this syndrome also exist, manifesting as moderate retardation in intellectual or neuromotor maturation. In some areas, use of iodine supplementation has been found to improve cognitive function in school-aged children who are mildly deficient (Gordon et al., 2009). The WHO has increased the recommended iodine intake during pregnancy from 200 to 250 mcg/day; in regions where less than 90% of households are using iodized salt, iodine supplementation should be used in pregnancy and infancy (Zimmerman, 2009).

**FIGURE 3-37** Goiter caused by iodine deficiency. (From Swartz MH: *Textbook of physical diagnosis history and examination*, ed 3, Philadelphia, 1998, Saunders.)

## Toxicity

Even though iodine intakes have a wide margin of safety, tolerable ULs have been established (IOM, Food and Nutrition Board, 2001). Adults have a UL of 1100 mcg/day, and young children have a UL of 200 to 300 mcg/day. In some cases goiter develops slowly as a consequence of long-term iodine intakes that are much higher than physiologic requirements. The role of excessive iodine in thyroid disease or disorder is not clear. Today the level of iodine in foods is not considered a significant public health problem in the United States or Canada. The level of iodine in most American diets is appropriate for good health. For small groups of people with underlying thyroid pathologic conditions, excessive iodine in the diet may result in hypothyroidism, goiter formation, or hyperthyroidism (Mussig et al., 2006).

## Selenium

A narrow dietary intake range exists for selenium, below which deficiency occurs and above which toxicity develops. Only in China have these extremes been shown to relate to the selenium content of the soil. A dietary intake of approximately 40 mcg of selenium per day seems to be necessary to maintain **glutathione peroxidase (GSH-Px)**, an enzyme containing selenium (Schrauzer and Surai, 2009). GSH-Px, discovered to be a selenoenzyme in the early 1970s, is considered the major active form of selenium in tissues, although other selenium proteins have since been discovered. Tissue levels are influenced by dietary intake and reflect the geochemical environment. Regions of North America identified as low in selenium content are the Northeast, Pacific, Southwest, and coastal plains of the southeastern region of the United States, as well as north central and eastern Canada. The lowest selenium content of soil exists in a few regions of China, especially Keshan, where severe selenium deficiency was first reported in a human population in 1979. Other areas with low selenium content include parts of Finland and New Zealand.

## Absorption, Transport, Storage, and Excretion

Absorption of selenium, which occurs in the upper segment of the small intestine, is more efficient under conditions of deficiency. Increased intake frequently results in increased excretion of selenium in the urine. Selenium status is assessed by measuring selenium or GSH-Px in serum, platelets, and erythrocytes or in whole blood. Erythrocyte selenium measurement is an indicator of long-term intake. Selenium is transported bound to albumin initially and subsequently to  $\alpha_2$ -globulin.

## Functions

Selenium, as selenomethionine or selenocysteine, exists in several proteins that are widely distributed in the body. Cellular GSH-Px has been found in almost all cells and extracellularly in serum and milk. GSH-Px acts with other antioxidants to reduce cellular peroxides and free radicals in general into water and other harmless molecules. This family of enzymes may help provide a reserve of selenium

in proteins that can be drawn on when needed. Many but not all of the pathologic changes caused by selenium deficiency reflect inadequate levels of GSH-Px enzymes.

Phospholipid hydroperoxide GSH-Px is found in lipid-soluble fractions of the cell and has roles in lipid and eicosanoid metabolism. Type 1 iodothyronine 5'-deiodinase, an enzyme capable of converting T<sub>4</sub> to T<sub>3</sub>, is a selenoprotein. Moderate selenium intakes (40 mcg/day) seem adequate to maintain activities of these deiodinases. However, high intakes (350 mcg/day) are associated with depressed T<sub>3</sub> levels. GSH-Px enzymes have also been shown to be critical in several endocrine systems (Beckett and Arthur, 2005).

Selenoprotein P may act as a free radical scavenger or a transporter of selenium. Selenium is used in the synthesis of these molecules in the anionic form. In the molecules, selenium is covalently bound, as is sulfur, which it typically replaces in some of these molecules. The antioxidant effects of selenium and vitamin E may reinforce each other by the overlap of their protective actions against oxidative damage. These two antioxidant nutrients may participate in other cooperative activities that help maintain healthy cells. GSH-Px acts in the cytosol and the mitochondrial matrix, whereas vitamin E exerts its antioxidative actions within cell membranes.

The GSH-Px reaction step is illustrated in Figure 3-38. Other selenium-dependent enzymes exist in mammalian systems, but less is known about their requirements for selenium. The selenium-containing enzymes may have an antioxidative role in preventing cancer. Many other selenoproteins have been identified, but their functions have not yet been elucidated.

### Dietary Reference Intakes

The RDAs for selenium are 55 mcg/day for women, men, and adolescents (ages 14 to 18), whereas the RDAs for children range from 20 to 30 mcg/day. The AIs for infants is 15 to 20 mcg/day. The RDA during pregnancy is 60 mcg, and the RDA during lactation is 70 mcg/day. Requirements for selenium may increase with a high consumption of unsaturated fatty acids because of the need for higher antioxidant activity. However, low-dose chronic exposure to selenium

may be widespread in some populations; the upper safe limit may actually be set too high (Vinceti et al., 2009).

### Food Sources and Intakes

No comprehensive table of the selenium content of foods has been published. The selenium concentration in foods depends on the selenium content of the soil and water where the food was grown. Improvements in analytic techniques have resulted in changes being made to many previously published data of the selenium content of foods during the last few decades (Table 3-35).

Major food sources of selenium are Brazil nuts, seafood, kidney, liver, meat, and poultry. Highest intake in the United States is from animal flesh foods. Grains vary in selenium content, depending on where they are grown. Fruits and vegetables are low in selenium content.

Selenium content and GSH-Px activity in human breast milk are influenced directly by maternal intake and by the

**TABLE 3-35**

### Selenium Content of Selected Foods

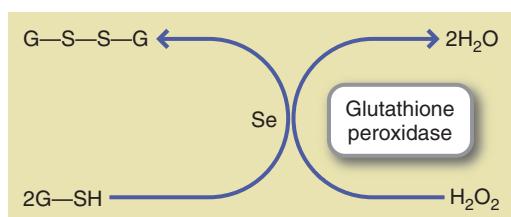

Food	Content (mcg)
Brazil nuts, 1 oz	543
Fast food fish sandwich, 1	89
Halibut, baked, $\frac{1}{2}$ fillet	74
Tuna, canned, 3oz	68
Oysters, raw, 3 oz	56
Rice, white, long grain, 1 cup	44
Chicken, breast, baked, 3 oz	39
Pie crust, 1	38
Egg noodles, cooked, 1 cup	38
Lobster, 3 oz	36
Wheat germ, toasted, $\frac{1}{4}$ cup	28
Bagel, 1, 4-inch	27
Sunflower seeds, $\frac{1}{4}$ cup	25
Egg, 1	16
Bread, whole wheat, 1 slice	10
Asparagus, cooked, 1 cup	7
Milk, 2% fat, 1 cup	6

### DRIs

Infants	15-20 mcg/day, depending on age
Young children	20-30 mcg/day, depending on age
Older children and adolescents	40-55 mcg/day, depending on age
Adults	55 mcg/day
Pregnant	60 mcg/day
Lactating	70 mcg/day

From U.S. Department of Agriculture, Agricultural Research Service: Nutrient Database for Standard Reference, Release 18, Data Laboratory home page: <http://www.nal.usda.gov/fnic/foodcomp/Data/SR18/nutrlist/sr18w317.pdf>; accessed 2011.

DRI, Dietary reference intake.

**FIGURE 3-38** Enzymatic reaction catalyzed by the selenium-containing enzyme, glutathione peroxidase. Selenium is a prosthetic form of the enzyme that removes highly reactive hydrogen peroxide from within cells by converting it to water while simultaneously converting two molecules of reduced glutathione to oxidized glutathione.

form of selenium consumed. Plasma selenium concentrations of infants fed unsupplemented formula are lower than those of infants fed supplemented formula or human milk. Selenium fortification of infant formulas has been shown to improve the status of infants.

### Deficiency

Despite a wide range of selenium intakes from food, selenium deficiency is rare in populations throughout the world. Selenium deficiency takes years to develop when food intake is adequate. Severe selenium deficiency in a population has only been reported in China. Keshan disease, a cardiomyopathy that mainly affects children and women, was first observed in the Keshan province of China. Since its discovery, supplementation programs in Keshan have totally eradicated the disease. However, in individuals with established disease, the response to supplementation is poor, probably because of other factors contributing to myopathy; a viral infection combined with selenium deficiency has been suggested (Beck et al., 1995).

The second selenium deficiency disease, discovered in Mongolia, is known as *Kashan-Beck disease* and is common in preadolescent and adolescent children. These two diseases occur in areas where the soil content of selenium is very low. This disease may also have a viral component combined with the selenium deficiency. Illness initially involves symmetric stiffness, swelling, and often pain in the interphalangeal joints of the fingers, followed by generalized osteoarthritis. Here iodine deficiency may be another risk factor.

Patients with some cancers have been shown to have low serum selenium levels, although the underlying mechanisms for this correlation have not been established. One possible explanation lies in the possible failure of GSH-Px to scavenge free radicals efficiently in dividing cells. In addition, patients with cirrhosis have low plasma selenium concentrations, which may predispose them to cancer (Latavayova et al., 2006).

Selenium deficiency has been reported in malnourished patients receiving long-term TPN. Supplementation results in improved serum selenium levels, platelet GSH-Px activity, and reduced clinical symptoms. Selenium deficiency should no longer be a problem in patients receiving long-term TPN or enteral nutrition because these solutions now include a trace element supplement.

### Toxicity

Indicators of selenium toxicity have been reported in China and Australia. Signs of toxicity (*selenosis*) include skin and nail changes, tooth decay, and nonspecific GI and neurologic abnormalities. Research also suggests that excessive intakes may be mutagenic or genotoxic, a point that is important to note for pregnant women. In addition, the long-term effects of selenium supplementation on the thyroid hormones have not been clearly identified (Combs et al., 2009). In countries such as New Zealand, where both selenium and iodine levels tend to be low, supplementation with selenium alone will not improve

thyroid function; iodine is also required (Thomson et al., 2009).

### Manganese

Manganese deficiency in humans was first reported in 1972, and its essentiality in humans is well established. Chronic exposure to excessive manganese levels can result in psychiatric and motor disturbances, referred to as *manganism* (Yin et al., 2010). A healthy balance is required.

### Absorption, Transport, Storage, and Excretion

Manganese is absorbed throughout the small intestine. Iron and cobalt compete for common binding sites for absorption. Men absorb less manganese than women, a difference noted by iron status and plasma ferritin levels. Heme iron has no influence on manganese status, but diets high in nonheme iron can be associated with lower serum manganese values, higher urinary manganese losses, and lower activity of manganese-containing enzymes.

Manganese is transported bound to a macroglobulin, transferrin, and transmanganin. Excretion occurs mainly in the feces after secretion into the intestine via the bile. The cytoplasmic iron exporter ferroportin (Fpn) functions as a manganese exporter; manganese exposure promotes Fpn protein expression, which reduces manganese accumulation and its related cytotoxicity (Yin et al., 2010). Antioxidants may also play a role in the excretion of toxic levels of manganese.

### Functions

Manganese is associated with the formation of connective and skeletal tissues, growth, and reproduction. The 10 to 20 mg of manganese contained in the adult human body tends to be concentrated predominantly in mitochondria. Manganese activates many enzymes, especially in conjunction with magnesium. Manganese is essential for proper metabolism of amino acids, proteins and lipids.

Manganese is a component of many enzymes, including glutamine synthetase, pyruvate carboxylase, and mitochondrial SOD (MnSOD). It catalyzes detoxification of free radicals and may protect against some types of cancer. MnSOD converts superoxide anion into hydrogen peroxide but this must be detoxified by GSH-Px. If that does not occur, hydrogen peroxide forms a hydroxyl radical with iron, which is detrimental for patients with cirrhosis who have an altered SOD gene (Nahon et al., 2009).

### Dietary Reference Intakes

The AIs for manganese are 2.3 mg/day for men and 1.8 mg/day for women. For children 9 years of age and older the AIs are 1.9 to 2.2 mg/day for boys and 1.6 mg/day for girls. For children younger than 9 the AIs are 1.2 to 1.5 mg/day, depending on their age.

### Food Sources and Intakes

The manganese content of foods varies greatly. The richest sources are whole grains, legumes, nuts, and tea. Fruits and

vegetables are moderately good sources. Relatively high amounts exist in instant coffee and tea.

Animal tissues, seafood, and dairy products are poor sources. Human milk is relatively low in manganese. Intakes are often low for adolescent girls.

## Deficiency

Manganese deficiency, although rare, affects reproductive capacity, pancreatic function, and aspects of carbohydrate metabolism. Symptoms of deficiency are weight loss, transient dermatitis, occasionally nausea and vomiting, a change in hair color, and slow hair growth. In addition, there is a correlation between low blood manganese and convulsions (Gonzalez-Reyes et al., 2007).

Animal studies have established that manganese is necessary for reproduction. Sterility develops in both sexes; striking skeletal abnormalities and ataxia characterize the offspring of mothers who are manganese deficient. Lower blood manganese levels may be associated with fetal intrauterine growth retardation and lower birth weight in humans (Wood, 2009).

## Toxicity

Manganese toxicity has developed in miners as a result of absorption of manganese through the respiratory tract. The excess, which accumulates in the liver and central nervous system, produces Parkinson-like symptoms. Manganese intake in excess leads to neurotoxicity, impairing energy metabolism and causing cell death (Puli et al., 2006). This is especially true for dopaminergic neurons.

Toxicity has also been reported in patients receiving TPN with added manganese. Symptoms include headaches, dizziness, and abnormal magnetic resonance imaging results and hepatic dysfunction (Masumoto et al., 2001).

The ULs of manganese from diet have been difficult to establish. Red wine may be a source of relatively high levels of metal ions, leading to a very high target hazard quotient for those individuals consuming at least 250 mL per day for many years (Hague et al., 2008). The implications for manganese require further study.

## Chromium

A biologic role for chromium was proposed in 1954 but not accepted until 1977. Patients receiving parenteral nutrition exhibited abnormalities of glucose metabolism that were reversed with chromium supplementation. The low concentrations of chromium in food, body tissues, and body fluids require careful, appropriate analytic techniques, and new standard reference materials for accurate measurements.

## Absorption, Transport, Storage, and Excretion

As with other minerals, organic and inorganic forms of chromium are absorbed differently. Organic chromium is readily absorbed but quickly passes out of the body. Less than 2% of the trivalent chromium consumed is absorbed. Chromium absorption is increased by oxalate and is higher in iron-deficient animals than in animals with adequate iron, suggesting that it shares some similarities with the iron

absorption pathway. With dietary intakes of 40 mcg or more per day, chromium absorption reaches and remains at a plateau; at such high intakes, urinary excretion increases to maintain balance.

The type of dietary carbohydrate consumed modifies absorption from chromium chloride. Starch rather than sugar increases absorption. Absorption is also greater from chromium picolinate than from chromium chloride, where absorption is 2% or less.

Chromium and iron are carried by transferrin; however, albumin is also capable of assuming this role if iron transfer saturation is high. In addition,  $\alpha$ - and  $\beta$ -globulins and lipoproteins can also bind chromium.

Primarily the kidney excretes inorganic chromium, with small amounts being excreted through hair, sweat, and bile. Organic chromium is excreted through bile. Strenuous exercise, physical trauma, or an increased intake of simple sugar results in increased chromium excretion.

## Functions

Chromium potentiates insulin action and influences carbohydrate, lipid, and protein metabolism. It may have a beneficial effect on serum triglyceride levels. Although the chemical nature of the relationship between chromium and insulin activity has not been clearly identified, a possible chromium-NA (chromium polynicotinate) complex has been identified. Chromium may regulate the synthesis of a molecule that potentiates insulin action; this **glucose tolerance factor (GTF)** is controversial. However, chromium supplementation alone or combined with vitamins C and E minimizes oxidative stress; it also improves glucose metabolism in type 2 diabetes mellitus patients (Lai, 2008). Another possible role for chromium, similar to that of zinc, is in the regulation of gene expression.

## Dietary Reference Intakes

The AIs recommended for chromium range from 25 to 35 mcg/day for males 9 years of age and older and 21 to 25 mcg/day for females of the same age. Depending on the age of the child, 11 to 15 mcg/day has been established for children 1 to 8 years of age.

## Food Sources and Intakes

Precise assessment of chromium in foods is difficult; biologically available chromium and inorganic chromium cannot be distinguished from each other. Analyses done before 1980 must be considered with caution because determinations were flawed by contamination and analytic problems.

Brewer's yeast, oysters, liver, and potatoes have high chromium concentrations; seafood, whole grains, cheeses, chicken, meats, and bran have medium chromium concentrations. The refining of wheat removes chromium with the wheat germ and the bran; refining sugar fractionates the chromium into the molasses portion. Dairy products, fruits, and vegetables are low in chromium. Table 3-36 and Appendix 52 present the chromium content of selected foods.

**TABLE 3-36****Chromium Content of Selected Foods**

Food	Content (mcg)
Broccoli, 1/2 cup	11
Grape juice, 1 cup	8
English muffin, whole wheat, 1	4
Potatoes, mashed, 1 cup	3
Garlic, dried, 1 teaspoon	3
Basil, dried, 1 tablespoon	2
Beef cubes, 3 ounces	2
Orange juice, 1 cup	2
Turkey breast, 3 ounces	2
Whole wheat bread, 2 slices	2
Red wine, 5 ounces	1-13
Apple, unpeeled, 1 medium	1
Banana, 1 medium	1
Green beans, ½ cup	1

**DRI<sub>s</sub> = AI<sub>s</sub>**

Infants	0.2-5.5 mcg/day, depending on age
Young children	11-15 mcg/day, depending on age
Older children and adolescents	21-35 mcg/day, depending on age and gender
Adults	20-35 mcg/day, depending on age and gender
Pregnant	29-30 mcg/day, depending on age
Lactating	44-45 mg/day, depending on age

From:

- (1) Anderson RA, Bryden NA, Polansky MM: Dietary chromium intake, *Biol Trace Elem Res* 32:117, 1992.  
 (2) Chromium Fact Sheet. <http://ods.od.nih.gov/factsheets/chromium/>; accessed 1-14-11.

AI, Adequate intake; DRI, dietary reference intake.

Usual chromium intakes range between 25 and 35 mcg/day for women and men, respectively. Chromium intakes are not assessed in the USDA, National Health and Nutrition Examination Survey, or Total Diet Study surveys because of inadequate methodology. Human breast milk contains 3 to 8 nmol/L of chromium, which is lower than the recommended intake for infants.

**Deficiency**

Chromium deficiency results in insulin resistance and a few lipid abnormalities, which can be ameliorated by chromium supplementation. Insufficient chromium may be consumed by some Americans; true deficiency is more likely to occur in populations with very low intakes. Some epidemiologic

studies suggest low tissue levels of chromium in patients with diabetes. However, they recommend long-term clinical trials to assess safety of chronic chromium supplementation before it is used in these patients. Claims that the ingestion of high doses of chromium consumed as chromium picolinate improves strength, body composition, endurance, or other characteristics of physical fitness are controversial, with some studies supporting these claims and others not.

**Toxicity**

Chromium toxicity from food has not been reported. Chromium picolinate taken as a supplement in high doses by athletes and power lifters has resulted in some adverse effects, primarily skin lesions. An increase risk of cancer has been identified in China in a population that was exposed to high chromium levels in drinking water (Smith and Steinmaus, 2009).

**Molybdenum**

Molybdenum has been established as an essential micronutrient, particularly because of its requirement in the enzyme xanthine oxidase (see Table 3-25). Interrelationships among molybdenum, copper, and sulfate absorption in livestock and between molybdenum intake and copper excretion in humans and animals have been demonstrated. Individuals receiving long-term TPN have displayed symptoms of molybdenum deficiency, including mental changes and abnormalities of sulfur and purine metabolism.

**Absorption, Transport, Storage, and Excretion**

Molybdenum, which is found in minute amounts in the body, is readily absorbed from the stomach and small intestine, with the rate of absorption being higher in the proximal small intestine than in the distal small intestine. As with other minerals, molybdenum is absorbed by two mechanisms: carrier-mediated and passive diffusion. Molybdenum is excreted primarily in the urine. Excretion rather than absorption is the homeostatic mechanism. Some molybdenum is also excreted in the bile.

**Functions**

Xanthine oxidase, aldehyde oxidase, and sulfite oxidase, all enzymes that catalyze oxidation-reduction reactions, require a prosthetic group containing molybdenum (Schwarz et al., 2009). Sulfite oxidase is important to the degradation of cysteine and methionine and catalyzes the formation of sulfate from sulfite. Whether molybdenum is involved in the response of some asthmatics to sulfites is not known. Genetic sulfite oxidase deficiency is a fatal disorder of cysteine metabolism. Clinical symptoms include severe brain damage with mental retardation, dislocation of the lens, and increased urinary output of sulfate.

**Dietary Reference Intakes**

The RDAs for molybdenum throughout the life cycle range from 43 to 45 mcg/day for adolescents and adults. Depending on the child's age, RDAs range from 17 to 34 mcg/day for children.

## Food Sources and Intakes

Molybdenum is distributed widely in commonly consumed foods such as legumes, whole-grain cereals, milk and milk products, and dark green leafy vegetables. Estimated intakes, as determined by the Total Diet Study of the FDA, ranged from 50 mcg/day in infants to 80 and 126 mcg/day for 14- to 16-year-old girls and boys, respectively. These intakes were found to decrease slowly over the lifetime.

## Deficiency

Molybdenum deficiency has not been established in humans other than patients treated with TPN. Symptoms of molybdenum deficiency include mental changes and abnormalities of sulfur and purine metabolism.

## Toxicity

An excessive molybdenum intake of 10 to 15 mg/day is associated with a goutlike syndrome (Nielsen, 2009). However, no good biomarkers are available to assess the presence of molybdenum excess accurately. Nonetheless, plasma molybdenum does seem to reflect molybdenum intake.

## Boron

The essentiality of boron for humans has not yet been established, but its essentiality for plants and animals is widely accepted. Boron, an ultratrace element, is obtained from foods such as sodium borate, and it is rapidly and almost completely (90%) absorbed. The highest concentrations of boron are found in bone, spleen, and thyroid, although it is present in all other tissues of the body.

## Functions

Boron is associated with cell membranes and in plants is involved with the functional efficiency of cell membranes. Response to boron deprivation is enhanced when other nutrients that alter membrane functions are also deficient. Boron apparently binds to the active site of some enzymes, reducing their ability to function. Boron is also thought to compete with some enzymes for the coenzyme NAD.

Boron influences the activity of many metabolic enzymes and the metabolism of such nutrients as calcium, magnesium, and vitamin D (Devirian and Volpe, 2003). Evidence from animal studies shows that boron deprivation affects two major organs: the brain and bone. Boron deficiency alters brain composition and function and reduces bone composition, structure, and strength. Because of the role of boron in bone, studies in humans have focused on its potential role in the development of osteoporosis. Boron may have actions similar to estrogens on bone (Nielsen, 2009). Boron is also required for normal reproduction and healthy immune response. Other roles of boron in humans have not been well studied.

## Dietary Reference Intakes

No DRIs have been established for boron.

## Food Sources and Intakes

Foods that are good sources of boron include plant foods, especially noncitrus fruits, vegetables, nuts, and legumes. Wine, cider, and beer are other good sources of boron.

## Deficiency and Toxicity

Symptoms of severe boron deficiency have not been established (Nielsen, 2009). No toxicity level has been identified.

## Cobalt

Most of the cobalt in the body exists with vitamin B<sub>12</sub> stores in the liver. Only one enzyme has an established specific requirement for cobalt. Blood plasma contains approximately 1 mcg of cobalt per 100 mL.

## Absorption, Transport, Storage, and Excretion

Cobalt may share part of the same intestinal transport mechanism as iron. Absorption is higher in patients with deficient iron intake, portal cirrhosis with iron overload, and idiopathic hemochromatosis. The major route of cobalt excretion is the urine; small amounts are excreted via feces, sweat, and hair.

## Functions

The well-known essential role of cobalt is as a component of vitamin B<sub>12</sub> (cobalamin). This vitamin is essential for the maturation of red blood cells and the normal function of all cells. Methionine aminopeptidase, an enzyme involved in the regulation of translation (i.e., of DNA to RNA), is the only enzyme in humans known to have an established requirement of this trace element.

## Dietary Reference Intakes

The dietary requirement for cobalt is expressed in terms of vitamin B<sub>12</sub>. Approximately 2 to 3 mcg of vitamin B<sub>12</sub> is needed daily.

## Food Sources and Intakes

Cobalt exists in foods; however, only microorganisms are able to synthesize vitamin B<sub>12</sub>. Ruminant animals obtain cobalamin as the result of a symbiotic relationship with the microorganisms of their GI tract. The microorganisms of monogastric species such as humans have an extremely limited capacity for synthesis; therefore humans must obtain vitamin B<sub>12</sub>—and thus cobalt—from animal foods such as organ and muscle meats. In some circumstances ordinary bacterial contamination of foods of vegetable origin may supply the minute required amounts of this vitamin. Strict vegetarians who avoid all animal products may develop vitamin B<sub>12</sub> deficiency, either after 3 to 6 years or not at all.

## Deficiency

A cobalt deficiency develops only in relation to a vitamin B<sub>12</sub> deficiency. Insufficient vitamin B<sub>12</sub> causes a macrocytic anemia. A genetic defect limiting vitamin B<sub>12</sub> absorption

results in pernicious anemia, which is treated appropriately with massive doses of the vitamin.

### Toxicity

A high intake of inorganic cobalt (existing freely from cobalamin) in animal diets produces polycythemia (an overproduction of red blood cells), hyperplasia of bone marrow, reticulocytosis, and increased blood volume.

The information on the microminerals known to be required by humans is summarized in Table 3-36.

## OTHER TRACE ELEMENTS

Several other trace elements of uncertain essentiality exist, including aluminum, lithium, nickel, silicon, tin, and vanadium. A few other ultratrace elements, including arsenic, may be added to this list in the future. They are classified as ultratrace elements because of their very low quantities in human tissues. Requirements remain undefined for all of these elements because of their uncertain essentiality. The ultratrace elements continue to be enigmas because of their uncertain roles in human function. It has long been established that these elements exist in human tissues, especially in the skeleton, because of their abundance on the earth's surface, but the essentiality of any of these in humans remains questionable (Nielsen, 2009).

## CHAPTER 4

Kathleen A. Hammond, MS, RN, BSN,  
BSHE, RD, LD

# Intake: Analysis of the Diet

### KEY TERMS

24-hour recall  
ageusia  
anosmia  
diet history  
dietary intake data  
dysgeusia  
food diary  
food frequency questionnaire

### Geriatric Nutritional Risk Index (GNRI)

Mini Nutritional Assessment (MNA)  
Malnutrition Universal Screening Tool (MUST)  
nutrient intake analysis (NIA)  
nutrition assessment  
nutrition status  
overnutrition  
Subjective Global Assessment (SGA)  
undernutrition

**Nutrition status** mirrors the degree to which physiologic nutrient needs are met for an individual. The balance between nutrient intake and nutrient requirements equals that nutrition status. When adequate nutrients are consumed to support the body's daily needs, including any increased metabolic demands, the person moves into optimal nutrition status (Figure 4-1). Adequate intake promotes growth and development, maintains general health, supports activities of daily living, and helps protect the body from disease and illness.

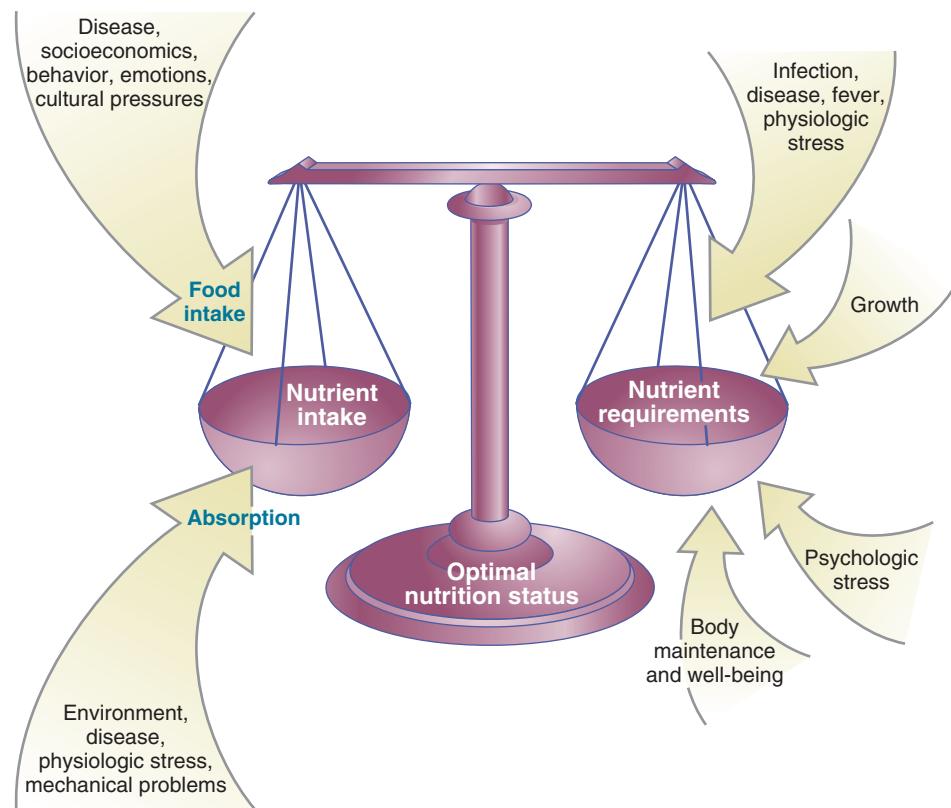

Accurate assessment of dietary intake is essential for researchers and public health practitioners to make advancements in public health, especially for population groups that display high disease prevalence rates (Fialkowski et al., 2010). Appropriate assessment techniques can detect a nutritional deficiency in the early stages of development, allowing dietary intake to be improved through nutrition support and counseling before a more severe condition develops. Personal intake is influenced by factors such as economic situation, eating behavior, emotional climate, cultural influences, effects of disease states on appetite, and the ability to acquire and absorb nutrients. Nutrient

requirements are influenced by genetics, physiologic stressors such as infection, acute or chronic disease processes, fever, trauma; anabolic states such as pregnancy, childhood, or rehabilitation; overall body maintenance; and psychological stress.

Although a nutrition assessment can be performed routinely for any individual, ideal tools will differ for healthy versus critically ill individuals. Persons at nutritional risk can be identified on the basis of screening information that is routinely obtained at the time of admission to a hospital or nursing home, in a clinic setting, or after returning to home-based care. This information is then used to design an individualized nutrition care plan. A thorough assessment increases the likelihood that effective interventions will be applied to resolve the identified nutritional diagnoses.

### NUTRITION IMBALANCE

Nutrition is an important factor in the cause and management of several major causes of death and disability in contemporary society (Table 4-1) (Centers for Disease Control and Prevention [CDC], 2009b; Xu et al., 2009).

**FIGURE 4-1** Optimal nutrition status: a balance between nutrient intake and nutrient requirements.**TABLE 4-1****Ranking of the Leading Causes of Death in the United States, 2005**

All Causes	Rank for All Races, Both Sexes, All Ages	Rank for White Race, Both Sexes, All Ages	Rank for Hispanic, Both Sexes, All Ages	Rank for Black, Both Sexes, All Ages	Rank for Native American, Both Sexes, All Ages
Heart diseases	1	1	1	1	1
Malignant neoplasms	2	2	2	2	2
Cerebrovascular diseases	3	3	4	3	5
Chronic lower respiratory	4	4	8	7	7
Accidents, unintentional injuries	5	5	3	4	3
Diabetes mellitus	6	7	5	5	4
Alzheimer disease	7	6	—	—	—
Influenza and pneumonia	8	8	9	—	9
Nephritis, nephritic syndrome, nephrosis	9	9	—	8	10
Septicemia	10	—	—	10	—
Suicide	—	10	—	—	8
Chronic liver disease or cirrhosis	—	—	6	—	6
Assault or homicide	—	—	7	6	—
Conditions originating in prenatal period	—	—	10	—	—
AIDS or HIV infection	—	—	—	9	—

From Heron M, Tejada-Vera B: Deaths: leading causes for 2005: national vital statistics reports, vol 58, no. 8, Hyattsville, Md, 2009, National Center for Health Statistics.

—, a ranking was not in the top 10 causes for the category; AIDS, Acquired immunodeficiency syndrome; HIV, human immunodeficiency virus.

Heart disease, strokes, diabetes, and most cancers are influenced by the type and amount of food consumed. Nutrition is also significant in major diseases such as obesity, anemia, and osteoporosis. In addition, cirrhosis of the liver and some accidents may be associated with excessive alcohol intake. Modifications in diet can assist in the prevention of disease, particularly for overweight and obese individuals. In addition, nutrition intake affects gene expression and vice versa, with implications for many disorders.

States of nutritional deficiency or excess occur when nutrient intake does not match an individual's requirements for optimal health. Within the safe range of intake, homeostatic mechanisms allow the body to use nutrients equally effectively, with no detectable advantage gained by a specific intake. As deficiencies or excesses develop, adaptations are made to achieve a new steady state without any significant loss in physiologic function. As the intake departs further from the desirable range, the organism accommodates to the changing supply of nutrients by reducing the function, size, or status of the affected body compartments. The nutrition status of an individual is identified by the success or failure of these adaptations. For example, before iron deficiency anemia is diagnosed from measures of hematocrit, hemoglobin, and clinical signs, a gradual diminution in iron stores can be diagnosed on the basis of increased iron absorption, decreased serum ferritin levels, or bone marrow evaluation.

When nutritional reserves are depleted or intake is inadequate to meet daily metabolic needs, a state of **undernutrition** develops. Undernutrition may stem from inadequate ingestion, impaired digestion or absorption, dysfunctional metabolic processing, or increased excretion of essential nutrients. Infants, children, pregnant women, individuals with low incomes, hospitalized persons, and older adults are at the greatest risk for becoming undernourished. Impaired growth and development, lowered resistance to infection, delayed wound healing, poor clinical outcome from disease or trauma, development of chronic disease and increased morbidity and mortality may result.

Critically ill patients who have severe injury and stress can rapidly break down their body protein and energy stores; in such cases, malnutrition and protein wasting can negatively affect patient outcome (Btaiche et al., 2010). Hospital malnutrition was identified more than 30 years ago in a landmark article by Butterworth (1974), yet the problem continues today (DeLegge and Drake, 2007). It is estimated that in academic hospitals in the United States, 25% to 50% of patients show some type of malnutrition, generalized wasting, or protein depletion; this is most detrimental in a lengthy hospital stay.

**Overnutrition** also presents problems manifesting as obesity, diabetes, atherosclerotic heart disease, hypertension, and the metabolic syndrome. These conditions may also result in poor clinical outcomes. Obesity is associated with low-grade inflammation, high levels of inflammatory markers such as C-reactive protein, and proinflammatory cytokines. Obesity has reached epidemic proportions in the

United States and in other parts of the world. One third of all adults are classified as obese and 300,000 deaths per year in the US are related to obesity (CDC, 2009a; USDHHS, 2007; 2009). Assessing the obese injured patient presents an even greater challenge. Screening tools that identify one to be at risk only when undernourished may label the injured obese patient as low risk and less likely to be identified as having the potential for increased morbidity. More appropriate tools are needed to accurately assess this population.

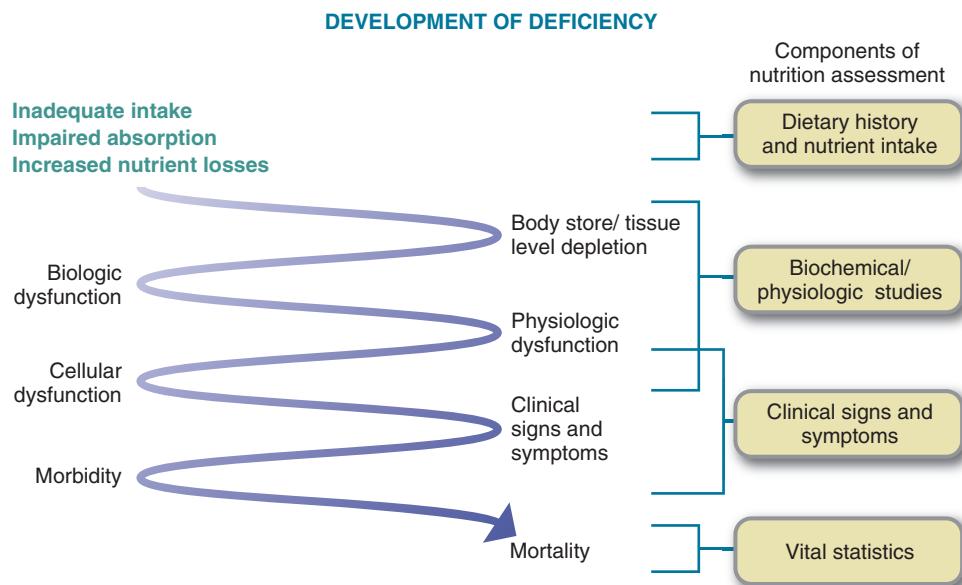

Nutritional well-being and the continuum of nutritional health are essential concepts to understand. Indeed, the best nutrition-based strategy for promoting optimal health and reducing the risk of chronic disease is to choose a wide variety of nutrient-rich foods and to use supplements when necessary (American Dietetic Association [ADA], 2009). Figure 4-2 illustrates the general sequence of steps leading to nutritional decline and the development of a nutritional deficiency, as well as areas in which an assessment can identify problems.

Many factors help measure whether a person is at nutritional risk. Factors to consider include food and nutrient intake patterns, psychosocial factors, medical and health histories, physical conditions associated with particular disease states and disorders, body weight and fatness, physical examination, biochemical abnormalities, medication regimens and use of herbs or botanical products (Table 4-2).

Screening and assessment are integral parts of nutrition care. The accepted nutrition care process (NCP) has four steps: (1) assessment of nutrition status; (2) identification of nutritional diagnoses; (3) interventions such as goal setting, food and nutrient delivery, education, counseling, coordination of care; and (4) monitoring and evaluation of the effectiveness of the interventions (ADA, 2010).

## NUTRITION SCREENING

Ideally everyone should undergo periodic nutrition screening throughout life. Just as a medical provider conducts an annual health examination, a trained nutrition provider conducts regular nutritional evaluations. To provide cost-effective nutrition services in today's health care environment, it is important first to screen patients to find those who are at nutritional risk. Screening precedes the NCP provided by a registered dietitian (RD). The purpose of a nutrition screen is to quickly identify individuals who are malnourished or at nutritional risk and determine whether a more detailed assessment is warranted (ASPEN, 2009; Charney, 2005). In most settings the nutrition screen is completed by a dietetic technician, nurse, physician, or other qualified health care professional. Once completed, patients who are at nutritional risk are referred to an RD to perform a more in-depth assessment. Evaluation of intake is truly the specialized role of the dietetics profession, as it requires depth and skills related to nutrition and food sciences, social and behavioral sciences, physiology, and biochemistry.

**FIGURE 4-2** Development of clinical nutritional deficiency with corresponding dietary, biochemical, and clinical evaluations.

Although the components of nutrition screening may vary slightly from one setting to another, the tool should be simple and easy to complete, inclusive of readily available data, cost-effective, and effective in identifying nutrition problems. The tools must be both *reliable* (consistent between measures of the same factor, such as weight) and *valid* to measure what it is supposed to measure. In a survey of clinical nutrition managers, most common screenings include history of weight loss, current need for nutrition support, skin breakdown, poor intake, and chronic use of modified diets (Chima, 2006). Further information collected during a nutrition screen depends on (1) the setting in which the information is obtained (e.g., home, clinic, hospital), (2) the life stage or disease type, (3) available data, (4) a definition of risk priorities, and (5) the goal for the screening process. Regardless of the information gathered, the goal of screening is to identify individuals who are at nutritional risk, those likely to become at nutritional risk, and those who need further assessment. For example, being 85 years or older, having low nutrient intake, losing the ability to eat independently, having swallowing and chewing difficulties, becoming bedridden, having pressure ulcers or a hip fracture or dementia, and suffering from two or more chronic illnesses are factors of concern in a nutritional screen (Salva et al., 2009).

One useful screening tool is the **Malnutrition Universal Screening Tool (MUST)** developed by Stratton and colleagues (2004) to assess malnutrition rapidly, easily, accurately, and completely (Figure 4-3). MUST is designed to be used by multiple disciplines of professionals. Three independent criteria are used: current weight and height with determination of body mass index (BMI), unintentional weight loss using specific cutoff points, and acute disease effect on nutrition intake for greater than 5 days. These three components work better together to predict outcome rather than the individual components. Once the

scores are added, the overall risk of malnutrition can be determined using three categories: 0 = low risk, 1 = medium risk, and 2 and above = high risk. Management guidelines can then be followed (Stratton et al., 2004). The MUST tool is more effective than some other available tools (Henderson et al., 2008).

The **Mini Nutritional Assessment (MNA)** is a rapid and reliable method for evaluating nutritional status in older patients (i.e., 65 years and older). This tool includes both a screening section and assessment section. The screening portion contains questions related to food intake, weight loss, mobility, stress, neuropsychological condition, and BMI. Recently, a shorter version was validated using 6 versus 18 questions; this version can be completed in 15 minutes (Kaiser et al., 2009) (Figure 4-4).

Another tool is the **Geriatric Nutritional Risk Index (GNRI)**, which relies on serum albumin and differences between current and previous body weights. With the GNRI, ideal body weight (calculated using the Lorentz formula) is used in place of usual weight because usual or normal weight is often difficult to assess in the older population (Box 4-1). The GNRI can be used to predict the risk of malnutrition from weight loss and low BMI associated with illness and functional decline (Bouillanne et al., 2005).

Regardless of the tool used, the management of under-nutrition requires a multidisciplinary approach. Dietary and environmental improvements, managing multiple comorbidities, avoiding polypharmacy, and the need for supplementation or tube feeding should be considered.

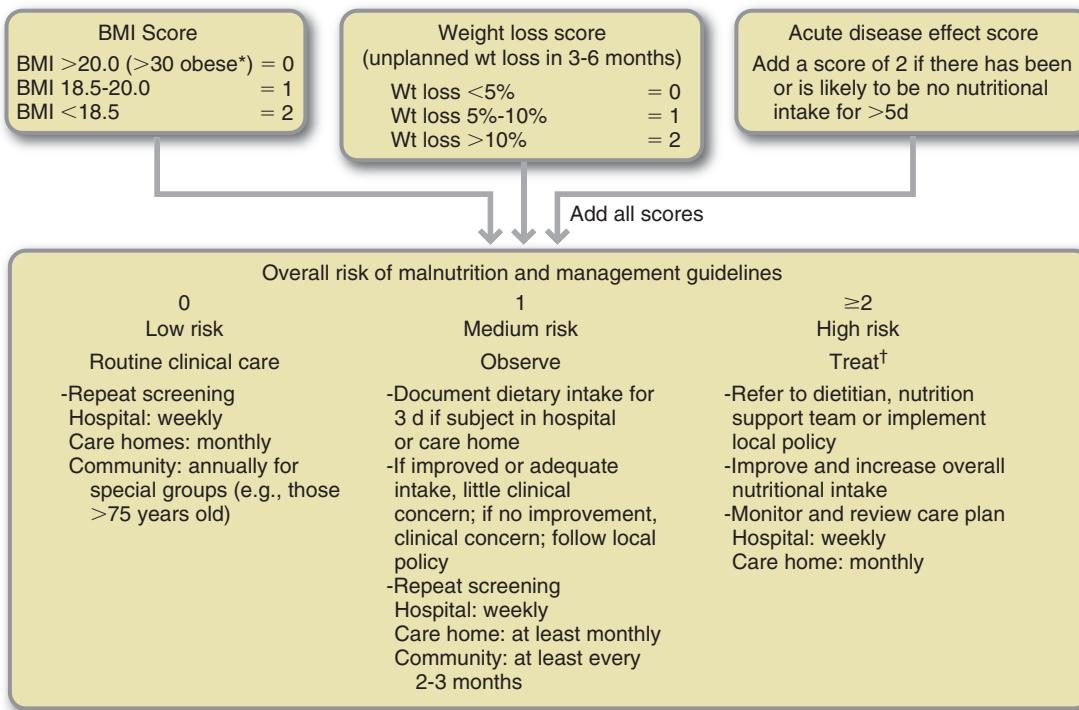

## NUTRITION ASSESSMENT

**Nutrition assessment** is a comprehensive evaluation carried out by an RD using medical, and health, social, nutritional, and medication histories; physical examination; anthropometric measurements; and laboratory data. Nutrition

**TABLE 4-2****Nutritional Risk Factors**

<b>Category</b>	<b>Factors</b>
Food and nutrient intake patterns	<ul style="list-style-type: none"> <li>• Calorie and protein intake greater or less than that required for age and activity level</li> <li>• Vitamin and mineral intake greater or less than that required for age</li> <li>• Swallowing difficulties</li> <li>• Gastrointestinal disturbances</li> <li>• Unusual food habits (e.g., pica)</li> <li>• Impaired cognitive function or depression</li> <li>• Nothing by mouth for more than 3 days</li> <li>• Inability or unwillingness to consume food</li> <li>• Increase or decrease in activities of daily living</li> <li>• Misuse of supplements</li> <li>• Inadequate transitional feeding, tube feeding or parenteral nutrition, or both</li> <li>• Bowel irregularity (e.g., constipation, diarrhea)</li> <li>• Restricted diet</li> <li>• Feeding limitations</li> </ul>
Psychological and social factors	<ul style="list-style-type: none"> <li>• Low literacy</li> <li>• Language barriers</li> <li>• Cultural or religious factors</li> <li>• Emotional disturbances associated with feeding difficulties (e.g., depression)</li> <li>• Limited resources for food preparation or obtaining food and supplies</li> <li>• Alcohol or drug addiction</li> <li>• Limited or low income</li> <li>• Lack of or inability to communicate needs</li> <li>• Limited use or understanding of community resources</li> </ul>
Physical conditions	<ul style="list-style-type: none"> <li>• Extreme age: adults older than 80 years, premature infants, very young children</li> <li>• Pregnancy: adolescent, closely spaced, or three or more pregnancies</li> <li>• Alterations in anthropometric measurements: marked overweight or underweight for height, age, or both; head circumference less than normal; depressed somatic fat and muscle stores; amputation</li> <li>• Fat or muscle wasting</li> <li>• Obesity or overweight</li> <li>• Chronic renal or cardiac disease and related complications</li> <li>• Diabetes and related complications</li> <li>• Pressure ulcers or altered skin integrity</li> <li>• Cancer and related treatments</li> <li>• Acquired immune deficiency syndrome</li> <li>• Gastrointestinal complications (e.g., malabsorption, diarrhea, digestive or bowel changes)</li> <li>• Catabolic or hypermetabolic stress (e.g., trauma, sepsis, burns, stress)</li> <li>• Immobility</li> <li>• Osteoporosis, osteomalacia</li> <li>• Neurologic impairments, including impairment in sensory function</li> <li>• Visual impairments</li> </ul>
Abnormal laboratory values	<ul style="list-style-type: none"> <li>• Visceral proteins (e.g., albumin, transferrin, prealbumin)</li> <li>• Lipid profile (cholesterol, high-density lipoproteins, low-density lipoproteins, triglycerides)</li> <li>• Hemoglobin, hematocrit, and other hematologic tests</li> <li>• Blood urea nitrogen, creatinine, and electrolyte levels</li> <li>• Fasting serum blood glucose level</li> <li>• Other laboratory indexes as indicated</li> </ul>
Medications	<ul style="list-style-type: none"> <li>• Chronic use</li> <li>• Multiple and concurrent administration (polypharmacy)</li> <li>• Drug-nutrient interactions and side effects</li> </ul>

Adapted from the Council on Practice, Quality Management Committee: ADA's definitions for nutrition screening and nutrition assessment, J Am Diet Assoc 94:838, 1994.

**FIGURE 4-3** The Malnutrition Universal Screening Tool (“MUST”) for adults. Record malnutrition risk category, presence of obesity and/or need for special diets and follow local policy for those identified at risk.

If unable to obtain height and weight, alternative measurements and subjective criteria are provided (Elia, 2003).

\*In the obese, underlying acute conditions are generally controlled before treatment of obesity.

<sup>†</sup>Unless detrimental or no benefit is expected from nutritional support (e.g., imminent death).

### BOX 4-1

#### Geriatric Nutritional Risk Index

$$\text{GNRI} = [1.489 \times \text{albumin (g/L)}] + [41.7 \times (\text{weight}/\text{IBW}^*)]$$

Interpretation: Four grades of nutrition-related risk

Major: (GNRI: <82)

Moderate: (GNRI: 82 to <92)

Low: (GNRI: 92 to  $\leq 98$ )

None: (GNRI: >98)

\*The Lorentz formula to calculate IBW is based on gender and height (Tarnus and Bourdon: Anthropometric evaluations of body composition of undergraduate students at the University of La Réunion, *Adv Physiol Educ* 30:248, 2006):

Female: IBW (kg) = height (cm) - 100 - {[height (cm) - 150]/2}

Male: IBW (kg) = height (cm) - 100 - {[height (cm) - 150]/4}

Derived from Bouillanne O et al: Geriatric nutrition risk index: a new index for evaluating at-risk elderly medical patients, *Am J Clin Nutr* 82:777, 2005.

GNRI, Geriatric Nutritional Risk Index; IBW, ideal body weight.

The information gathered depends on the particular setting, the present health status of the individual or group, how data are related to particular outcomes, whether it is an initial or follow-up assessment, and recommended practices (ADA, 2009). Once the nutrition assessment process is complete and a nutrition diagnosis made, the plan of care can be developed. Once interventions are chosen, they can be tailored for the appropriate setting (hospital, clinic, long-term care facility, rehabilitation center, or home). In an intensive care unit, assessment is best administered within 24 hours of admission to the unit. Malnourished patients experience increased morbidity and mortality and prolonged hospital stays; nutrition support measures should begin early (Agency for Healthcare Research and Quality, 2010).

The goals of nutrition assessment are to (1) identify individuals who require aggressive nutrition support, (2) restore or maintain an individual's nutrition wellness, and (3) identify appropriate medical nutrition therapy (MNT). Patients with acute or chronic illnesses who have the potential for malnutrition should be evaluated further. Malnutrition is common in those who are obese, cachexic, or older; who have undergone trauma; and in whom nutritional intervention is neglected. Furthermore, the nutrition status of patients who are hospitalized for longer than 2 weeks deteriorates. With only minimum training in nutrition in many

assessment interprets data from the nutrition screen and incorporates additional information. The purpose of assessment is to gather adequate information in which to make a professional judgment about nutrition status (ASPEN, 2009). Assessment is the first step in the nutrition care process Table 4-3.

## Mini Nutritional Assessment MNA®

Last name:

First name:

Sex:

Age:

Weight, kg:

Height, cm:

Date:

Complete the screen by filling in the boxes with the appropriate numbers. Total the numbers for the final screening score.

### Screening

**A Has food intake declined over the past 3 months due to loss of appetite, digestive problems, chewing or swallowing difficulties?**

- 0 = severe decrease in food intake  
 1 = moderate decrease in food intake  
 2 = no decrease in food intake

**B Weight loss during the last 3 months**

- 0 = weight loss greater than 3 kg (6.6 lbs)  
 1 = does not know  
 2 = weight loss between 1 and 3 kg (2.2 and 6.6 lbs)  
 3 = no weight loss

**C Mobility**

- 0 = bed or chair bound  
 1 = able to get out of bed / chair but does not go out  
 2 = goes out

**D Has suffered psychological stress or acute disease in the past 3 months?**

- 0 = yes      2 = no

**E Neuropsychological problems**

- 0 = severe dementia or depression  
 1 = mild dementia  
 2 = no psychological problems

**F1 Body Mass Index (BMI) (weight in kg) / (height in m<sup>2</sup>)**

- 0 = BMI less than 19  
 1 = BMI 19 to less than 21  
 2 = BMI 21 to less than 23  
 3 = BMI 23 or greater

IF BMI IS NOT AVAILABLE, REPLACE QUESTION F1 WITH QUESTION F2.  
 DO NOT ANSWER QUESTION F2 IF QUESTION F1 IS ALREADY COMPLETED.

**F2 Calf circumference (CC) in cm**

- 0 = CC less than 31  
 3 = CC 31 or greater

**Screening score**

(max. 14 points)

**12-14 points:**      Normal nutritional status

**8-11 points:**      At risk of malnutrition

**0-7 points:**      Malnourished

**TABLE 4-3****Nutrition Care Process: Step 1: Nutrition Assessment**

Basic definition and purpose	First step of the nutrition care process. Its purpose is to obtain adequate information to identify nutrition-related problems. It is initiated by referral or screening of individuals or groups for nutritional risk factors.  Nutrition assessment is a systematic process of verifying and interpreting data to make decisions about the nature and cause of nutrition-related problems. The specific types of data gathered in the assessment vary, depending on (1) practice settings, (2) individual's or group's present health status, (3) how data are related to outcomes to be measured, (4) recommended practices such as the American Dietetic Association's Evidence-Based Guides for Practice, and (5) whether it is an initial assessment or a reassessment.
Requirements	Requires making comparisons between the information obtained and reliable standards (ideal goals). An ongoing, dynamic process that involves not only initial data collection but also continual reassessment and analysis of patient, client, or group needs.
Data sources/tools for assessment	Provides the foundation for the nutrition diagnosis at the next step of the nutrition care process.  Referral information and interdisciplinary records Patient or client interview (across the life span) Community-based surveys and focus groups Statistical reports; administrative data Epidemiologic studies
Types of data collected	Nutritional adequacy (dietary history; detailed nutrient intake) Health status (anthropometric and biochemical measurements, physical and clinical conditions, physiologic and disease status) Functional and behavioral status (social and cognitive function, psychological and emotional factors, quality-of-life measures, change readiness)
Nutrition assessment components	Review dietary intake for factors that affect health conditions and nutrition risk. Evaluate health and disease condition for nutrition-related consequences. Evaluate psychological, functional, and behavioral factors related to food access, selection, preparation, physical activity, and understanding of health condition. Evaluate patient's, client's, or group's knowledge, readiness to learn, and potential for changing behaviors. Identify standards by which data will be compared. Identify possible problem areas for making nutrition diagnoses.
Critical thinking	The following types of critical thinking skills are especially needed in the assessment steps: Observing for nonverbal and verbal cues that can guide and prompt effective interviewing methods. Determining appropriate data to collect. Selecting assessment tools and procedures (matching the assessment methods to the situation). Applying assessment tools in valid and reliable ways. Distinguishing relevant from irrelevant data. Distinguishing important from unimportant data. Validating the data. Organizing and categorizing the data in a meaningful framework that relates to nutrition problems. Determining when a problem requires consultation with or referral to another provider.
Documentation of assessment	Documentation is an ongoing process that supports all of the steps in the nutrition care process. Quality documentation of the assessment step should be relevant, accurate, and timely; inclusion of the following information would further describe quality assessment documentation: Date and time of assessment Pertinent data collected and comparison with standards Patient's/client's/group's perceptions, values, and motivation related to presenting problems Changes in patient's/client's/group's level of understanding, food-related behaviors, and other clinical outcomes for appropriate follow-up Reason for discharge/discontinuation if appropriate
Determination for continuation of care	If on completion of an initial or reassessment it is determined that the problem cannot be modified by further nutrition care, discharge or discontinuation from this episode of nutrition care may be appropriate.

Adapted from Lacey K, Pritchett E: Nutrition care process and model: ADA adopts road map to quality care and outcomes management, J Am Diet Assoc 103(8):1064, 2003.

medical schools physicians often graduate with little practical knowledge about nutrition and the features of malnutrition. To maintain a high level of awareness, physician education programs in nutritional topics should be conducted regularly.

## Tools for Assessment of Nutritional Status

Several tools are available for the assessment of nutritional status. The **Subjective Global Assessment (SGA)** is a nutritional assessment tool that has been validated and correlates well with nutrition risk indices and other assessment data in hospitalized patients (DeLegge and Drake, 2007; Kyle et al., 2006) (see Table 6-5). The MNA tool mentioned earlier evaluates independence, medication therapy, pressure sores, number of full meals consumed per day, protein intake, consumption of fruits and vegetables, fluid intake, mode of feeding, self-view of nutritional status, comparison with peers, and mid-arm and calf circumferences (Figure 4-5) (Bauer et al., 2008; Guigoz, 2006).

## Histories

The information collected about individuals or populations is used as part of the nutrition status assessment. Frequently the information is in the form of histories—health and medical, social, medication, and dietary.

### Medical or Health History

The medical or health history usually includes the following information: chief complaint, present and past illness, current health, allergies, past or recent surgeries, family history of disease, psychosocial data, and a review of problems—by body system—from the patient's perspective (Hammond, 2006). These histories usually provide much insight into nutrition-related problems. Alcohol and drug use, increased metabolic needs, increased nutritional losses, chronic disease, recent major surgery or illness, disease or surgery of the gastrointestinal tract, and recent significant weight loss all may contribute to malnutrition. In older patients, additional review is recommended to detect mental deterioration, constipation or incontinence, poor eyesight or hearing, slowed reactions, major organ diseases, effects of prescription and over-the-counter drugs, and physical disabilities.

### Medication History

Food and drugs interact in many ways that affect nutrition status and drug therapy effectiveness; thus a medication history is an important part of any nutrition assessment. Those who are older, are chronically ill, have a history of marginal or inadequate nutritional intake, or are receiving multiple drugs for a long time are susceptible to drug-induced nutritional deficiencies. The effects of drug therapy can be altered by specific foods, the timing of food and meal consumption, and use of herbal products; see Chapter 9.

### Social History

Social aspects of the medical or health history may also affect nutrition intake. Socioeconomic status, the ability

to purchase food independently, whether the person is living alone, physical or mental handicaps, smoking, drug or alcohol addiction, confusion caused by environmental changes, unsuitable housing conditions, lack of socialization at meals, psychological problems, or poverty may add to the risks for inadequate nutrition intake. Knowledge of various cultures is also important to meet the needs of diverse groups of clients. Factors that affect a person's cultural values include religious beliefs; rituals; symbols; language; dietary practices; education; communication style; views on health, wellness, and illness; and racial identity. Establishing a bond with clients of different cultures is important for positive outcomes (Stein, 2010). See Chapter 12 for more guidance on nutrition and cultural competency.

## Nutrition or Diet History

Inadequate nutrient intake and nutritional inadequacy can result from anorexia, **ageusia** (loss of the sense of taste), **dysgeusia** (diminished or distorted taste), **anosmia** (loss of smell), excessive alcohol intake, poor-fitting dentures, fad dieting, chewing or swallowing problems, frequent meals away from home, adverse food and drug interactions, cultural or religious restrictions of diet, an inability to eat for more than 7 to 10 days, intravenous fluid therapy for more than 5 days, or feeding dependence. For many older adults, denture problems, changes in taste and smell, long-established poor food habits, food fads, and inadequate knowledge of nutrition are problems. Alternative nutrition therapies, including use of megadoses of vitamins and minerals, various herbs, macrobiotic diets, probiotics, and amino acid supplements, must be addressed because they have an effect on the person's nutritional and overall health care.

A **diet history** is perhaps the best means of obtaining dietary intake information and refers to a review of an individual's usual patterns of food intake and the food selection variables that dictate the food intake. See Box 4-2 for the kind of information collected from a dietary history. **Dietary intake data** may be assessed either by collecting retrospective intake data as with a 24-hour recall or food frequency questionnaire or summarizing prospective intake data, as with a food record kept for a number of days by an individual or the caretaker. Each method has specific purposes, strengths, and weaknesses. Any self-reported method of obtaining data can be challenging because it is difficult for people to remember what they ate, the content, or even an accurate statement of portion size (Thompson et al., 2010). The choice of data collection depends on the purpose and setting in which the assessment is completed. The goal is to determine the nutrient content of the food and the appropriateness of the intake for a particular individual. The prospective method involves recording data at the time the food is consumed or shortly thereafter.

A daily food record, or **food diary**, involves documenting dietary intake as it occurs and is often used in outpatient clinic settings. The food diary is usually completed by the individual client (Figure 4-6). A food diary or record is usually most accurate if the food and amounts eaten are

## Mini Nutritional Assessment MNA®

recorded at the time of consumption, minimizing error from incomplete memory or attention (Thompson et al., 2010). The individual's nutrient intake is then calculated and averaged at the end of the desired period, usually 3 to 7 days, and compared with dietary reference intakes or guidelines in the MyPlate guide.

The **food frequency questionnaire** is a retrospective review of intake frequency (i.e., food consumed per day, per week, or per month). For ease of evaluation, the food frequency chart organizes foods into groups that have common nutrients. Because the focus of the food frequency questionnaire is the frequency of consumption of food groups rather

**BOX 4-2****Diet History Information**

<b>Category</b>	
Allergies, Intolerances, or Food Avoidances	Foods avoided and reason for avoidance Length of avoidance Description of problems caused by foods
Appetite	Good, poor, any changes Factors that affect appetite Changes in taste or smell perception Disinterest in food
Attitude Toward Food and Eating	Irrational ideas about food, eating, or body weight Parental interest in child's eating
Chronic Disease	Treatment Length of treatment time Dietary modification: self-imposed or physician prescribed, date of modification Past nutrition and diet education, compliance with diet
Culture and Background	Influence of culture on eating habits Religious practices, holiday rituals Educational background Health beliefs
Dental and Oral Health	Problems with chewing Foods that cannot be eaten
Economics	Problems with swallowing, salivation, choking, food sticking Income: frequency and steadiness of employment Amount of money for food each week or month Individual's perception of financial adequacy for meeting food needs Eligibility for food stamps and cost of stamps Public aid assistance status
Gastrointestinal Factors	Problems with heartburn, bloating, gas Problems with diarrhea, vomiting, constipation, distention Frequency of problems Home remedies Antacid, laxative, or other drug use
Home Life and Meal Patterns	Number in household (eat together?) Person who does shopping Person who does cooking Food storage and cooking facilities (e.g., stove, refrigerator) Type of housing (e.g., home, apartment, room) Ability to shop and prepare foods, disabilities
Medications, Supplements, Herbal Remedies	Vitamin and mineral supplements: frequency of administration, type, amount Medications: type, amount, frequency of administration, length of time on medication Herbal remedies: type, amount, purpose
Nutritional Problems	Concerns as perceived by patient and family Referrals from physician, nurse, other therapist, agency
Physical Activity	Occupation: type, hours/week, shift, energy expenditure Exercise: type, amount, frequency (seasonal?) Sleep: hours/day (uninterrupted?) Handicaps
Weight Pattern and History	Loss or gain: how many pounds and over what length of time? Intentional or nonvolitional % Usual weight; healthy weight; desirable weight

**FIGURE 4-6** Food diary format.

Food Diary: DAY _____

Food Supplements Cans/Day: _____ Name: _____ Vitamins/Mineral Supplement: _____				

than of specific nutrients, the information obtained is general, not specific, for certain nutrients. During illness, food consumption patterns can change, depending on the stage of illness. Therefore it is helpful to complete food frequency questionnaires for the period immediately before hospitalization and before illness to obtain a complete and accurate history. Box 4-3 shows a food frequency questionnaire. Another more specific, quantified questionnaire is online at [http://www.fhcrc.org/science/shared\\_resources/nutrition/ffq/gsel.pdf](http://www.fhcrc.org/science/shared_resources/nutrition/ffq/gsel.pdf).

The **24-hour recall** method of data collection requires individuals to remember the specific foods and amounts of foods they consumed in the past 24 hours. The information is then analyzed by the person or professional gathering the information. Problems commonly associated with this method of data collection include (1) an inability to recall accurately the kinds and amounts of food eaten, (2) difficulty in determining whether the day being recalled represents an individual's typical intake, and (3) the tendency for persons to exaggerate low intakes and underreport high intakes of foods. Concurrent use of food frequency and 24-hour recall questionnaires (i.e., doing a cross-check) improves the accuracy of intake estimates.

Reliability and validity of dietary recall methods are important issues. When attention is directed toward the diet, people may consciously or unconsciously alter their intake either to simplify recording or impress the interviewer, thus decreasing the information's validity. The validity of dietary recall information from obese individuals is often questionable because they tend to underreport their intakes. The same can be true for children, patients with eating disorders, those who are critically ill, those who abuse drugs or alcohol, individuals who are confused, and those

whose intake is unpredictable. Table 4-4 describes the advantages and disadvantages of the various methods used to obtain accurate dietary intake data.

Technology is currently being adapted and incorporated into dietary assessment through a variety of means that are found to be very helpful and reduce associated cost. Electronic diaries can be more accurate and useful compared with handwritten entries. There are also recording electronic devices that can link a kitchen scale directly to a computer, and other devices use a bar code reader to transmit data by telephone (Thompson et al., 2010). Sun and associates (2010) describe an electronic system for dietary reporting by a person wearing a device to record food intake. The device contains a camera, a microphone, and other sensors that can be worn around the neck and can collect pictures of the actual meal to identify food items.

### Nutrient Intake Analysis

A **nutrient intake analysis (NIA)** may also be referred to as a *nutrient intake record* or *calorie count*, depending on the information collected and the analysis done. The NIA is a tool used in various inpatient settings to identify nutritional inadequacies by monitoring intakes before deficiencies develop. Information about actual intake is collected through direct observation or an inventory of foods eaten based on observation of what remains on the individual's tray or plate after a meal. Intake from tube feeding and intravenous products (enteral and parenteral nutrition) is also recorded.

An NIA should be recorded for at least 72 hours to reflect variations in intake that may occur from day to day. Complete records for this period usually accurately reflect an average intake for most individuals. If the record is incomplete, it may be necessary to extend the duration of the

**BOX 4-3****General Food Frequency\***

1. Do you drink milk? If so, how much? What kind? Whole Skim Low-fat
2. Do you use fat? If so, what kind? How much?
3. How often do you eat meat? Eggs? Cheese? Beans?
4. Do you eat snack foods? If so, which ones? How often? How much?
5. Which vegetables (in each group) do you eat? How often?
  - a. Broccoli Green peppers Cooked greens Carrots Sweet potatoes
  - b. Tomatoes Raw cabbage
  - c. Asparagus Beets Cauliflower Corn Cooked cabbage Celery Peas Lettuce
6. Which fruits do you eat? How often?
  - a. Apples or applesauce Apricots Bananas Berries Cherries Grapes or grape juice
  - Peaches Pears Pineapple Plums Prunes Raisins
  - b. Oranges, orange juice Grapefruit Grapefruit juice
7. Bread and cereal products
  - a. How much bread do you usually eat with each meal? How much between meals?
  - b. Do you eat cereal? (daily? weekly?) What type? Cooked Dry
  - c. How often do you eat foods such as macaroni, spaghetti, and noodles?
  - d. Do you eat whole-grain breads and cereals? How often?
8. Do you use salt? Do you salt your food before tasting it? Do you cook with salt? Do you crave salt or salty foods?
9. How many teaspoons of sugar do you use daily? Include sugar on cereal, fruit, toast, and in beverages such as coffee and tea.
10. Do you eat desserts? How often?
11. Do you drink sugar-containing beverages such as soda pop or sweetened juice drinks? How often? How much?
12. How often do you eat candy or cookies?
13. Do you drink water? How often during the day? How much each time? How much water do you drink each day?
14. Do you use sugar substitutes in packet form or in drinks? What type do you use? How often?
15. Do you drink alcohol? Which type: beer, wine, liquor? How often? How much?
16. Do you drink caffeinated beverages? How often? How much per day?

\*To determine the frequency of food consumption, the following pattern of questions may be useful. However, questions may need to be modified based on information from the 24-hour recall. For instance, if a woman states that she drank a glass of milk the day before, do not ask, "Do you drink milk?" Rather, ask, "How much milk do you drink?" Record answers with the appropriate time frame designated (e.g., 1/day, 1/wk, 3/mo) or as accurately as possible. The frequency may need to be recorded as "occasionally" or "rarely" if the patient cannot be more specific.

**TABLE 4-4****Methods of Obtaining Dietary Intake Data**

<b>Method</b>	<b>Advantages</b>	<b>Disadvantages</b>
Nutrient intake analysis	Allows actual observation of food in clinical setting	Does not account for possible variation in portion size. Does not reflect intake of free-living individual
Daily food record or diary	Provides daily record of food consumption. Can provide information on quantity of food, how food is prepared, and timing of meals and snacks.	Depends on variable literacy skills of participants. Requires ability to measure or judge portion size. Actual food intake possibly influenced by the recording process.
Food frequency	Easily standardized. Can be beneficial when considered in combination with usual intake. Provides overall picture of intake.	Reliability of records is questionable. Requires literacy skills. Does not provide meal pattern data. Requires knowledge of portion sizes.
24-h recall	Is quick and easy.	Relies on memory. Requires knowledge of portion sizes. May not represent usual intake. Requires interviewing skills.

Data from Diet manual and nutrition practice guidelines: a manual of the Georgia Dietetic Association, Section 5.5-5.3, 2004.

intake until a full 72-hour record can be completed. It should be kept in mind that eating habits or meals consumed during the weekend and during the week may differ.

The record of total intake can then be analyzed for its nutrient content, using one of several available computerized methods. The diet can be analyzed for macronutrient and micronutrient intake. Macronutrients are analyzed to assess total calorie intake along with the carbohydrate, fiber, fat, and protein content of the diet. Micronutrients, vitamins and minerals, can also be analyzed to assess intake to ensure proper body functioning. In addition, it may be advantageous to assess the phytonutrient and prebiotic content of the diet. Determining the oxygen radical absorbance capacity (ORAC) of certain types of fruits, nuts, and vegetables in the diet gives a measure of the anti-inflammatory effect of the diet because inflammation and its downstream effect of oxidative stress is linked to many chronic and degenerative diseases, including cancer, heart disease, Alzheimer disease, Parkinson disease, and also the aging process. A diet rich in fruit, nuts, and vegetables with high ORAC scores is considered to contain good sources of antioxidants. It is possible to search selected foods to obtain the ORAC value of each (U.S. Department of Agriculture, 2007).

Technological advances have been made for processing dietary intake data. Computerized processing of dietary intake data is a common practice in most settings. Several database choices are available for estimation of intake and can vary by the nutrient composition database used to process the data (Thompson et al., 2010).

## CLINICAL SCENARIO

Laverne, a 66-year-old black woman, has contacted you to set up an outpatient nutrition screening appointment. She has a 20-year history of diabetes mellitus, a 10-year history of colon cancer, and hypertension. She is 5 ft, 8 in tall and weighs 203 lb. Her current medications are glyburide and a diuretic. (She does not know its name.) She tells you that she eats throughout the day and sometimes at night after going to bed.

### Nutrition Diagnostic Statement

Overweight/obesity related to poor food choices as evidenced by a BMI of 31.

### Nutrition Care Questions

1. What would you include in a nutrition screening for Laverne?
2. What would you include in a nutrition assessment for Laverne?
3. How could you identify her medications?
4. What additional information is needed for assessment of her dietary and nutrient intake?
5. If you need more details, what questions would you ask her physician?

BMI, Body mass index.

Ruth DeBusk, PhD, RD

# Clinical: Nutritional Genomics

### KEY TERMS

- allele
- autosomal dominant
- autosomal recessive
- autosome
- bioactive food components
- bioinformatics
- coding region
- codon
- CpG island
- deletion
- deoxyribonucleic acid (DNA)
- DNA methylation
- dominant
- epigenetics and epigenomics
- exon
- gene x environment (GxE)
- genetic code
- genetic engineering
- Genetic Information Nondiscrimination Act (GINA)
- genetic variation
- genome
- genomic imprinting
- genomics
- genotype
- heterozygous
- histone
- homozygous
- inborn errors of metabolism (IEM)
- intervening sequences
- intron
- karyotype
- ligand
- meiosis
- Mendelian inheritance
- messenger RNA (mRNA)
- metabolomics
- microarray technology (DNA “chips”)
- mitochondrial (maternal) inheritance
- mitosis
- model system
- mutation
- nucleosome
- nucleotide
- nutrigenetics
- nutrigenomics
- nutritional genomics
- pedigree
- penetrance
- peroxisome proliferator-activated receptor (PPAR)
- pharmacogenomics
- phenotype
- polymerase chain reaction (PCR)
- polymorphism
- posttranscriptional processing
- posttranslational processing
- promoter region
- proteomics
- recessive
- recombinant DNA
- regulatory region
- response element
- restriction endonuclease (restriction enzyme)
- RNA interference (RNAi)
- sex chromosome
- sex-linked
- signal transduction
- silent mutation
- single nucleotide polymorphism (SNP)
- transcription

**transcription factor**  
**translation**  
**whole exome capture**  
**xenobiotics**  
**X-linked dominant**  
**X-linked recessive**  
**Y-linked inheritance**

Nutrition professionals have long been intrigued and puzzled by the fact that one person can be lean, yet that person's identical twin can be overweight; that the Pima Indians living in northern Mexico are lean, but their genetic counterparts in the American southwest struggle with a high prevalence of obesity and type 2 diabetes mellitus (T2DM); and that a low-fat diet can improve blood lipid levels in many people, but not in everyone. Although our genetic makeup sets the stage, environmental factors such as nutrition and other lifestyle choices determine who among the susceptible actually develops a disease. The interactions among genes, diet, lifestyle factors, and their influence on health and disease are the focus of **nutritional genomics**.

Genetic research is rapidly clarifying how variations are correlated with dysfunction and disease. This appreciation for the central role of genes is having a significant effect on the way health is viewed. As the details of the connections among genes, their protein products, and disease unfold, the focus of the health care system is shifting. During the past 50 years the focus has been on treating overt disease, and physicians have had increasingly sophisticated drugs and technologies available to meet this challenge. However, with the understanding that disease is genetically based but environmentally influenced, the focus is now on targeted intervention and prevention. Although the first applications of this changed focus in health care involved the medical and pharmaceutical aspects of acute care, nutrition therapy is expected to figure prominently as a cornerstone of preventive care and in the management of the chronic, diet- and lifestyle-related diseases.

Genetic research is helping to clarify the pathogenesis of disease with the influence of bioactive components in food. From these advances will come diagnostic tests and assessments of disease susceptibility that, coupled with genetic testing and family history analysis, will allow health care professionals to predict those at risk for particular disorders. Nutrition can mitigate the harmful effects of many genetic changes that predispose to disease, from supplying missing metabolites to altering gene expression.

Nutritional genomics can also offer effective approaches for preventing disease. By analyzing individual genotypes prenatally or at birth, disease susceptibilities will be known from an early age and can be factored into the nutrition and lifestyle choices made throughout life. Armed with extensive knowledge of one's genetic makeup (**genotype**) and how to

make lifestyle choices that support that genotype, humans will have the option to live to their full genetic potential throughout a healthy, active life.

The nutrition profession is pivotal in this new era of health promotion and disease prevention. The role includes assessing disease susceptibilities, then recommending preventive therapy and lifestyle approaches. Increasingly, genotyping must be incorporated into the nutrition assessment and recommendations customized to the genetic uniqueness of individuals.

## THE HUMAN GENOME PROJECT

The Human Genome Project has been the impetus for this fundamental shift to integrating genetic principles into health care. This project, completed in 2003, was a multi-national effort to identify each of the nucleotides in the deoxyribonucleic acid (DNA) that makes up the genetic material (genome) of human beings. Currently the focus is on (1) cataloging the number of genes present in human DNA; (2) identifying the protein encoded within each gene and understanding its function (**proteomics**); (3) associating variations in genes with specific diseases; (4) understanding the way genes, proteins, and environmental factors interact to cause the functional changes that result in disease; (5) identifying metabolites that are useful in monitoring health status (**metabolomics**); and (6) understanding **epigenetics** (changes in single genes caused by environmental factors in utero, from chemicals or diet or aging) and **epigenomics** (population-specific gene changes) and their implications for human development and health. These efforts will lead to an understanding of effective approaches for restoring health and preventing disease.

Additional goals include sequencing the genomes of other organisms that are used as **model systems** in the laboratory to explore the molecular basis of disease, addressing the ethical, legal, and social implications of genetic research, developing genetic technologies useful for clinical applications, educating genetic scientists and clinicians, and integrating the results of genetic research into clinical practice. Sophisticated computer technology that can handle the vast amount of data is the backbone of the field of **bioinformatics**.

## Clinical Applications

Much of the knowledge and many of the technologic advances gained from the Human Genome Project have clinical applications. Knowing the gene associated with a particular disease and the gene's DNA sequence, its protein product, and the function of the protein in promoting health or illness provides the basis for diagnostic assays and effective interventions. For example, tumors that appear identical physically can be distinguished by their genetic profiles. This distinction is important for effective therapy because different types of tumors respond to different therapeutic approaches. Not only can such assays be used to definitively reach a diagnosis, they also can be used to detect dysfunction in those without symptoms, which allows interventions to

be initiated before the symptoms of a disease become apparent.

Similarly, the information gained has been pivotal in developing diagnostic assays to determine **genetic variations** in drug-metabolizing enzymes (**pharmacogenomics**). Each human being has the same basic set of drug-metabolizing enzymes, but the genes and the resulting enzyme functions can vary. One drug may have the intended effects on one person, be ineffective for another, and actually be harmful to a third. The ability to assess an individual's major drug-metabolizing gene variants helps the physician select the right drug and dosage. Like drugs, food requires enzymatic processes to be digested, absorbed, and used by the body's cells. The ability to tailor food to the genetic makeup of individuals—the science of nutritional genomics—is expected to be an important application of genetic research, similar in concept to pharmacogenomics.

## GENOTYPE AND NUTRITION ASSESSMENT

The application expected to have the most dramatic effect on clinical nutrition professionals is the ability to associate a unique genotype with that person's susceptibility to particular diseases. This advance is an important enhancement in the nutrition assessment, diagnosis, and intervention phases of the nutrition care process. As understanding of how genotype influences the ability to function within a particular environment and how environmental factors influence gene expression, nutrition protocols will be developed. Specific counseling and nutrient recommendations will be guided by the client's genetic profile.

Nutrition professionals must be able to translate client genotypes to develop appropriate interventions. If nutrition professionals are going to be prepared for the era of genomic-directed health care, they must build a foundation in genetics, biochemistry, molecular biology, metabolism, and other foundational sciences of 21st century nutrition (Milner, 2008; Panagiotou and Nielsen, 2009; Stover and Caudill, 2008).

## GENETIC FUNDAMENTALS

The reader must have a basic understanding of DNA as the genetic material for chromosomal and molecular genetics. Among the key concepts at the chromosomal level are the packaging of DNA into chromosomes within the nucleus, the processes of meiosis and mitosis, autosomal and **sex-linked** inheritance, linkage and the mapping of genes, and chromosomal mutation and its consequences. At the molecular level, key concepts include (1) information stored within DNA must be decoded and converted into proteins through the processes of transcription, posttranscriptional processing, translation, and **posttranslational processing**; (2) genes have a regulatory region with response elements, transcription factors, promoters, and a coding region with exons and introns; and (3) genetic variations

within the human genome affect an individual's phenotype, including disease susceptibility.

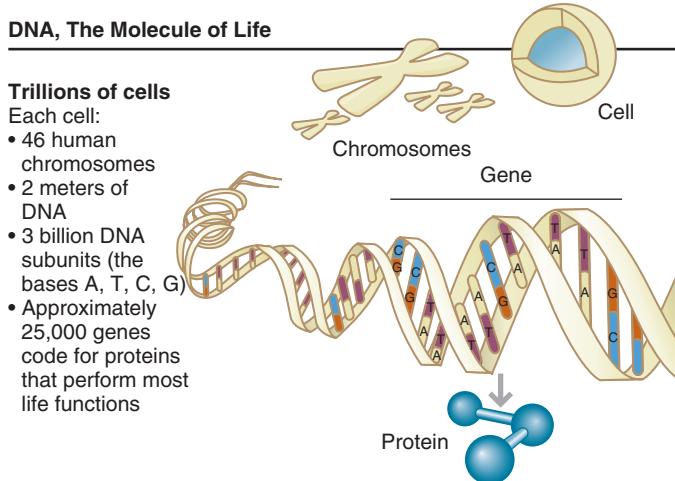

In addition to the information contained in the nucleotide sequence of DNA (the “DNA code”), there are two other sources of information: the epigenetic code and the environmental factors to which cells are exposed. Epigenetics is nature's “pen-and-pencil set” (Gosden and Feinberg, 2007). Acetyl or methyl groups covalently attached to histone proteins associated with DNA or to the DNA itself, respectively, affect whether DNA is accessible for decoding. These groups can be added and removed as needed, and are influenced by diet. Nutrition counselors will have a great opportunity to affect this. (Kauwell, 2008.)

Molecules in the environment such as traditional nutrients, phytochemicals, toxins, hormones, and drugs communicate information as to the state of the environment and ultimately influence when and whether particular genes are expressed. The science of nutritional genomics encompasses all of these types of interactions between diet and lifestyle factors and DNA and their influence on health outcomes. Figures 5-1 through 5-5 review these fundamental genetic principles.

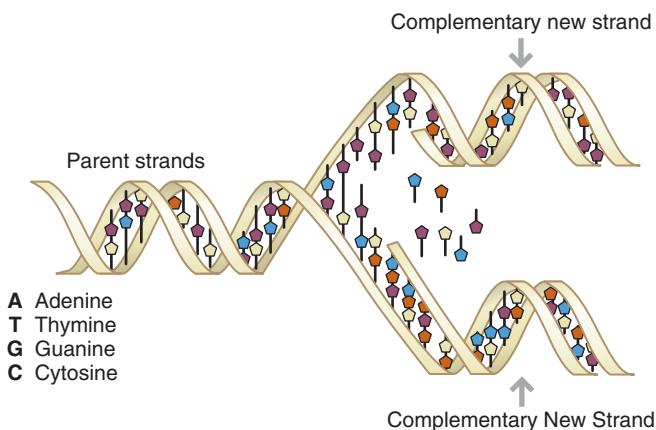

### Genetics and Genomics: Nutritional Genomics, Nutrigenetics, and Nutrigenomics

**Genetics** is the science of inheritance. Historically genetics focused on identifying the mechanisms by which traits were passed from parent to child, such as eye or hair color, and certain rare diseases that were inherited from generation to generation. Originally, genetic diseases were in a separate category of disease. Today scientists realize that, directly or indirectly, all disease is connected to the information in the genes.

The science of genetics has significantly expanded in scope and includes the whole set of genetic information in

**FIGURE 5-1** Cells are the fundamental working units of every living system. All the instructions needed to direct their activities are contained within the chemical deoxyribonucleic acid. (From U.S. Department of Energy, Human Genome Program: [www.ornl.gov/hgmis](http://www.ornl.gov/hgmis).)

**DNA Replication Prior to Cell Division**

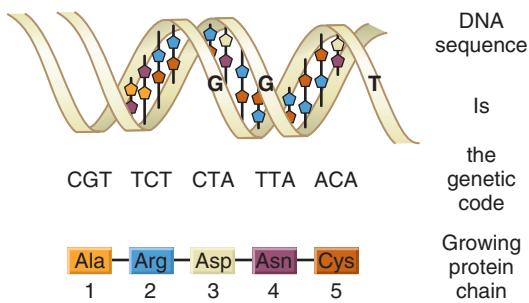

**FIGURE 5-2** Each time a cell divides into two daughter cells, its full genome is duplicated; for humans and other complex organisms, this duplication occurs in the nucleus. During cell division the deoxyribonucleic acid (DNA) molecule unwinds, and the weak bonds between the base pairs break, allowing the strands to separate. Each strand directs the synthesis of a complementary new strand, with free nucleotides matching up with their complementary bases on each of the separated strands. Strict base-pairing rules are adhered to (i.e., adenine pairs only with thymine [an A-T pair] and cytosine with guanine [a C-G pair]). Each daughter cell receives one old and one new DNA strand. The cells' adherence to these base-pairing rules ensures that the new strand is an exact copy of the old one. This minimizes the incidence of errors (mutations) that may greatly affect the resulting organism or its offspring. (From U.S. Department of Energy, Human Genome Program: [www.ornl.gov/hgmis](http://www.ornl.gov/hgmis).)

*Department of Energy, Human Genome Program: [www.ornl.gov/hgmis](http://www.ornl.gov/hgmis).*

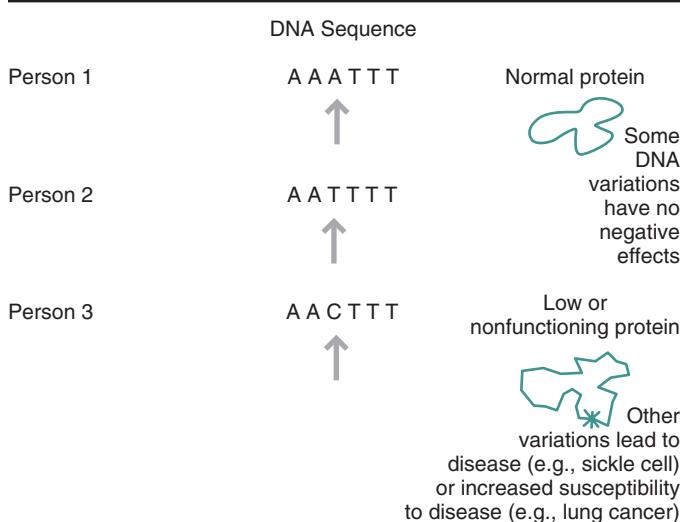

**DNA Sequence Variation in a Gene Can Change the Protein Produced by the Genetic Code**

Gene A from person 1	CGT	TCT	CTA	TTA	ACA	Protein products
	Ala	Arg	Asp	Asn	Cys	
	1	2	3	4	5	
Gene A from person 2	CGC	TCT	GAT	TTA	ACA	
(Codon made no difference in amino acid sequence)	Ala	Arg	Asp	Asn	Cys	
	1	2	3	4	5	
Gene A from person 3	CGT	TTT	GAT	TTA	ACA	
(Codon resulted in a different amino acid at position 2)	Ala	Lys	Asp	Asn	Cys	 Or
	1	2	3	4	5	

**FIGURE 5-4** Some variations in a person's genetic code will have no effect on the protein that is produced; others can lead to disease or an increased susceptibility to a disease. (From U.S. Department of Energy, Human Genome Program: [www.ornl.gov/hgmis](http://www.ornl.gov/hgmis).)

**DNA Genetic Code Dictates Amino Acid Identity and Order**

**FIGURE 5-3** All living organisms are composed largely of proteins. Proteins are large, complex molecules made up of long chains of subunits called *amino acids*. Twenty different kinds of amino acids are usually found in proteins. Within the gene, each specific sequence of three deoxyribonucleic acid bases (codons) directs the cells protein-synthesizing machinery to add specific amino acids. For example, the base sequence ATG codes for the amino acid methionine. Because three bases code for one amino acid, the protein coded by an average-sized gene (3000 bp) will contain 1000 amino acids. The genetic code is thus a series of codons that specify which amino acids are required to make up specific proteins. *A*, Adenine; *bp*, base pairs; *G*, guanine; *T*, thymine. (From U.S. Department of Energy, Human Genome Program: [www.ornl.gov/hgmis](http://www.ornl.gov/hgmis).)

**Health or Disease?**

**FIGURE 5-5** It is estimated that human beings differ from each other in only 0.1% of the total sequence of nucleotides that compose deoxyribonucleic acid. These variations in genetic information are thought to be the basis for the physical and functional differences between individuals. (From U.S. Department of Energy, Human Genome Program: [www.ornl.gov/hgmis](http://www.ornl.gov/hgmis).)

an organism—its **genome**—and the interactions of the various genes and their protein products with each other and the environment. **Genomics** more accurately describes this complex, interactive situation. Whereas genetics was initially concerned with diseases that arose from a change in a single gene, genomics is more concerned with today's chronic diseases that result from the interaction between gene variants and factors in the environment. Nutritional genomics focuses on diet- and lifestyle-related disorders that result from these interactions. Nutritional genomics is the field itself, and includes *nutrigenetics*, *nutrigenomics*, and *epigenetics* or *epigenomics*.

**Nutrigenetics** concerns how an individual's particular genetic variations affect function. For example, an individual with a particular variant in the 5,10-methylenetetrahydrofolate reductase (*MTHFR*) gene is likely to require a more bioavailable form of folate for optimal health. **Nutrigenomics** is the study of the influence of specific environmental factors on changes in the expression of particular genes. Epigenetics and epigenomics provide another influence on outcomes by controlling whether genes can be expressed, which in turn determines whether nutrigenetic or nutrigenomic influences can occur. Diet and other lifestyle choices should be geared toward the particular variants of each individual.

## Genetic Basics

**Deoxyribonucleic acid (DNA)** is the genetic material of all living organisms. The molecule is a double helix consisting of two strands of **nucleotide** subunits held together by hydrogen bonds. Each subunit contains the sugar deoxyribose, the mineral phosphorus, and one of four nitrogenous bases: adenine (A), thymine (T), guanine (G), or cytosine (C). The nucleotides are arranged side by side, and it is this linear arrangement that determines the particular information encoded in a stretch of DNA.

Approximately 3 billion nucleotides make up the human genome, which is housed in the nucleus of cells. A gene is a sequence of nucleotides that encodes the information for synthesizing a protein. The human genome contains approximately 20,000 to 25,000 genes, which is only 2% of the total genome (Human Genome Project, 2010). Long stretches of nucleotides are often found between one gene and the next along the chromosome. Such sequences are called **intervening sequences** and compose the majority of the DNA in humans. These sequences do not code for proteins, but they are not “junk DNA.” Instead, they perform structural and regulatory functions, such as controlling when, where, and how much of a protein is produced.

To be useful to the cells, information in the DNA must first be decoded and translated into proteins, which perform the work of the organism at the cellular level. Information decoding occurs in two steps: (1) the process of **transcription**, during which the enzyme ribonucleic acid polymerase (RNA polymerase) converts DNA into an intermediate molecule (**messenger RNA [mRNA]**) and (2) a subsequent **translation** step in which the information

encoded within the mRNA directs the assembly of amino acids into the protein molecule according to a universal **genetic code**. Genes have a common structure, with a **promoter region** where the binding of the RNA polymerase is controlled, which in turn controls transcription; and a **coding (informational) region** where the RNA polymerase transcribes the DNA into mRNA. Within the coding region are sequences of nucleotides (**exons**) that correspond to the order of the amino acids in the gene's protein product. The coding region also contains **introns** (sequences that are interspersed between exons and do not code for amino acids).

Following transcription, the mRNA must be processed (**posttranscriptional processing**) so that the introns are removed before the protein is synthesized. At this point, each set of three nucleotides in the transcribed and processed exon makes up a **codon**, which in turn specifies a particular amino acid and its position within the protein. Some proteins need further posttranslational processing before they are active, such as occurs with glycoproteins, proenzymes, and prohormones that must be cleaved or enzymatically processed before becoming active.

Prior to (“upstream from”) the promoter region is the **regulatory region**, where control of transcription takes place. Within this region are **response elements**, DNA sequences that serve as binding sites for regulatory proteins such as **transcription factors** and their bound **ligands**. The binding of transcription factors triggers the recruitment of additional proteins to form a protein complex that in turn changes the expression of that gene by changing the conformation of the promoter region, increasing or decreasing the ability of RNA polymerase to attach and transcribe (express) the gene. The array of response elements within the promoter region can be quite complex, allowing for the binding of multiple transcription factors that in turn fine-tune the control of gene expression. It is through the binding of transcription factors to response elements that environmental factors such as the bioactive components in food essentially “talk” to a gene, conveying information that more or less of its protein product is needed.

The proteins coded for by the genes provide the metabolic machinery for the cells, such as enzymes, receptors, transporters, antibodies, hormones, and communicators. Changes within a gene can alter the amino acid sequence of the DNA protein. Such changes are called **mutations**, which historically have been associated with the concept of severely impairing the function of that protein and creating dysfunction within the cells and, ultimately, the organism. A single nucleotide change may be all that is needed to cause a debilitating disease. For example, in those with sickle cell disease a single nucleotide change causes a single amino acid change in the hemoglobin molecule, resulting in severe anemia (see Chapter 33).

Changes in the DNA are the basis for evolution; thus clearly not all mutations are harmful. Some changes actually improve function, and many **silent mutations** have no effect. The effect of the mutation on the functioning of the encoded protein is what determines the outcome, from debilitating

disease to no effect at all. All changes to the DNA are technically mutations. However, at this point in the development of genomics, the term mutation tends to be applied to those changes that sufficiently influence function such that a measurable outcome results. In contrast, the term *genetic variation* (or *gene variant*) is reserved for those mutations with an effect on function that is not strong enough to lead to a disease or other measurable outcome by itself. Nutritional genomics is primarily concerned with those variations that interact with environmental factors.

Thus a gene can exist in slightly different forms as a result of a seemingly minor change, such as a substitution of a single nucleotide with another (e.g., guanine can replace cytosine). The term for the different forms of a gene is an **allele** or **polymorphism**. As a result, genes have protein products with differing amino acid sequences (isoforms) and often different functions. Polymorphism (allelism) is an important concept because it explains why human beings, although 99.9% alike genetically, are distinctively different. The 0.1% difference is sufficient to explain the obvious physical variations among humans. It is also the basis for more subtle differences that may not be readily observable, such as in the functional ability of a key metabolic enzyme to catalyze its characteristic reaction. Such variations are thought to underlie many of the inconsistencies that are observed in therapeutic outcomes and in nutritional intervention research.

The **single nucleotide polymorphism (SNP)** is the structural variant best studied to date. However, ongoing analysis of the human genome suggests that other structural variations may also play an important role in the genotypic and phenotypic variation among humans (Feuk et al., 2006). Loss or gain of nucleotides, duplication of nucleotide sequences, and copy number variants also have important consequences.

Understanding the prevalence and significance of genetic variation is a primary focus of 21st-century nutrition, which represents a major departure from nutrition research and therapy to date. Each person is susceptible to a different set of diseases, handles environmental toxins differently, metabolizes molecules somewhat differently, and has slightly unique nutritional requirements. These exciting discoveries are revolutionizing the way people think about the clinical aspects of medicine, pharmacology, and nutrition. Personalized therapy using individualized dietary requirements will be the practice of future dietitians.

## Modes of Inheritance

Traits are transmitted from one generation to the next in three ways: Mendelian inheritance, mitochondrial inheritance, and epigenetic inheritance.

### Mendelian Inheritance

Each cell's nucleus contains a complete set of genetic material (genome), divided among 22 pairs of chromosomes (called **autosomes**) and 2 **sex chromosomes** for a total of 46 chromosomes. During cell division (**mitosis**) all 46 chromosomes are duplicated and distributed to each new cell.

During **meiosis**, one member of each of the autosome and sex chromosome pairs is distributed to each egg or sperm; the full set of 46 chromosomes is then restored upon fertilization.

Because genes are carried on chromosomes, the rules governing the distribution of chromosomes during mitosis and meiosis govern the distribution of genes and any changes (mutations, variations) they contain. These rules describe the **Mendelian inheritance** of a gene, named after Gregor Mendel, who first deduced that the inheritance of traits was governed by a predictable set of rules. It is possible to track a mutation through multiple generations by knowing these rules of inheritance. This transmission is typically depicted as a **pedigree** and can be used to predict the probability of a genetic change being inherited by a particular family member. When the change causes a disease, a pedigree can be helpful in predicting the probability that another family member will inherit the disease. The Family History Initiative, implemented by the U.S. Surgeon General, helps people construct their family pedigree.

Mendelian transmission can be autosomal or sex-linked, dominant or recessive. There are five classic modes of Mendelian inheritance: autosomal dominant, autosomal recessive, X-linked dominant, X-linked recessive, and Y-linked. An individual's genotype obeys the laws of inheritance, but the **phenotype** (the measurable expression of the genotype) may not. Each gene in an individual is present in two copies (alleles), one on each chromosome. When the alleles are the same (either both are the common or usual version or both are the mutant or variant form), the individual is said to be **homozygous**. If the alleles are different, the individual is **heterozygous** (also called a *carrier*).

**Dominance** and **recessiveness** refer to whether a trait is expressed in a heterozygous individual that has one common allele and one variant allele. If a trait is expressed when only a single copy of a variant allele is present, the allele is said to be **dominant** (i.e., the phenotype of the variant allele is the predominant one). Alleles that do not dominate the genotype when only a single copy is present are called **recessive**. The variant allele is present in the genome but the trait is not expressed unless two copies of the variant allele are present.

Further confounding the nomenclature is the concept of **penetrance**. Even when a pedigree suggests that a gene is present that should lead to the individual displaying a certain phenotype, the disease may not be evident. Such a gene is said to have *reduced penetrance*, meaning that not everyone who has the gene expresses it in a measurable form. An interesting side note is that “measurable form” very much depends on what is able to be measured. Many alleles that were thought to be recessive 50 years ago can be detected today as the result of new and more sensitive technologies. Penetrance is of interest to nutrition professionals because it reflects the inability of a genetic variation to impair function and cause disease unless the individual is exposed to specific environmental triggers, such as diet and lifestyle factors. Modifying these factors can potentially improve outcomes for those with

such variants. Terminology may change as understanding advances in the field.

### Mitochondrial Inheritance

In addition to genetic material in the nucleus, the mitochondria in each cell also contain DNA that codes for a limited number of proteins. The majority of these genes are involved in maintenance of the mitochondrion and its energy-producing activities. As with nuclear DNA, changes in mitochondrial DNA (mtDNA) can lead to disease. Traits resulting from mitochondrial genes have a characteristic inheritance pattern; they are non-Mendelian because mitochondria and their genetic material typically pass from mother to child, called **mitochondrial** or **maternal inheritance**. This biologic principle has become the basis for anthropologic studies that trace lineage and population migration patterns through the centuries. It also has provided a way to trace familial diseases caused by changes in mtDNA. However, as with other biologic processes, occasional mistakes occur; reports exist of some mtDNA being passed from father to child.

### Epigenetic Inheritance, Genomic Imprinting

Epigenetic inheritance illustrates another mechanism by which genetic information is passed between generations. Epigenetics provides an additional set of instructions beyond that contained in the DNA nucleotide sequence. It affects gene expression but does not change the nucleotide sequence itself (van der Maarel, 2008; Villagra et al., 2010). At least three mechanisms are involved: histone modification, DNA modification, and RNA interference (RNAi).

**Histones** are proteins associated with DNA. Units of histones form a scaffolding around which DNA is wrapped to create the **nucleosome**, similar to thread wrapped around a spool. Similar in concept to condensing data on a hard drive, this mechanism helps to fit the large amount of DNA into the small space of the nucleus. When DNA is condensed, it is not available for transcribing into mRNA. The attachment and removal of acetyl groups is an important mechanism for controlling whether DNA is relaxed and available for transcription to proceed or condensed and closed to transcription, respectively.

Similarly, DNA itself can be modified by the covalent attachment and removal of functional groups, such as methyl groups. Methylation takes place at cytosine residues that occur within CpG islands found near a gene's promoter region. **CpG islands** (the *p* refers to the phosphodiester bond between (C) cytosine and (G) guanine nucleotides) are DNA sequences enriched in cytosine and guanine that, when methylated, interfere with transcription and therefore gene expression. In general, methylation silences gene expression and demethylation promotes gene expression.

DNA methylation and histone modification can contribute to genomic imprinting and affect gene expression. **Genomic imprinting** is an unusual phenomenon in which only one of the two alleles of a gene is expressed, either the allele contributed by the mother or by the father. If each allele contains a different mutation that leads to

a measurable phenotype, the individual's phenotype will differ depending on whether the mother's or the father's allele is the one expressed. Prader-Willi syndrome and Angelman syndrome provide examples of genomic imprinting; they involve DNA on chromosome 15. When the father's allele is expressed, the child develops Prader-Willi syndrome. When the mother's allele is expressed, the child develops Angelman syndrome. Both syndromes are characterized by intellectual disabilities, but Prader-Willi individuals also experience a lack of perception of satiety, which leads to overeating and morbid obesity. The suspected underlying basis for the phenotypic differences is the different pattern of epigenetic markings (either histone acetylation or **DNA methylation**) between the two parents rather than differences in the DNA sequence itself. Genomic imprinting has important clinical implications (Butler, 2009; Das et al., 2009).

The third mechanism, **RNA interference (RNAi)**, is a posttranscriptional mechanism whereby short pieces of single-stranded RNA (21–23 nucleotides) attach to DNA or mRNA. Attaching to mRNA interferes with gene expression by preventing translation of the gene into its encoded protein. Attaching to DNA leads to silencing of whole regions of chromosomes, a phenomenon called *epigenetic gene silencing*, which is the basis for X-inactivation in mammalian females in which one of the two X-chromosomes is silenced. In this way the amount of information contributed by the X-chromosome is equalized between females and males, the latter having only a single X-chromosome (Kloc and Martienssen, 2008; Suzuki and Kelleher, 2009).

Epigenetics is of interest to nutrition professionals because diet has been found to influence at least one epigenetic mechanism, DNA methylation, and the effects can be inherited. The mouse has been used as a mammalian model system for dissecting this complex process. In a landmark study by Waterland and Jirtle (2003), a strain of mice with a mutation in the *agouti* gene was used. The wild-type (normal) *agouti* allele causes the mouse's coat color to be brown. The Avy mutation (*agouti viable yellow* allele) causes the coat color to be yellow and, because this allele is dominant, all mice with at least one copy of Avy have the potential to develop the yellow coat color. The researchers bred genetically identical female mice with brown coats (two copies of the normal *agouti* allele) with genetically identical males that had two copies of the Avy mutation and had yellow coats. On a standard mouse chow diet, the coat color of the mothers would be brown, that of the fathers would be yellow, and the coat color of the offspring, who have one *agouti* allele and one Avy allele, would be yellow because the Avy allele is dominant. In this study, half of the females were fed the usual diet and half were fed a methyl-rich diet in which methyl donors such as folate, vitamin B<sub>12</sub>, choline, and betaine were added to the diet. Most of the un-supplemented mothers had offspring with yellow coats. Most of the offspring from the mothers on the methyl-rich diet, however, had a mottled coat with a mix of brown and yellow (called *pseudo-agouti*). Clearly, the mother's diet affected the coat color of the offspring and this effect

persisted into adulthood. There was a correlation between mottled coat and degree of methylation of the *agouti* gene, suggesting that the methyl-rich diet led to epigenetic silencing of the Avy allele.

Furthermore, this effect of diet could be inherited. Cropley and associates (2006) found that feeding the females of the “grandmother” generation a methyl-rich diet but not enriching the daughter offspring’s diet with methyl donors still produced a number of offspring with mottled brown coats, suggesting that the effect the diet had on coat color could be transmitted between generations. Diet and possibly other environmental factors may have a transgenerational effect through their influence on epigenetic “markings” that affect gene expression without altering the DNA sequence. This type of gene-diet epigenetic mechanism could explain why identical twins, although having the exact same genotype, typically do not have identical phenotypes.

## Inheritance and Disease

Changes to the genetic material, whether to the chromosomal DNA, mtDNA, or even a single nucleotide, have the potential to alter one or more proteins that may be critical to the operation of the cells, tissues, and organs of the body. There are important consequences from changes to the genetic material at each of these levels.

### Disease at the Chromosomal Level

Change in the number of chromosomes, or the arrangement of the DNA within a chromosome, is almost always detrimental or fatal to the individual. Chromosomal disorders are detected by means of a **karyotype**, a visualization of all the chromosomes in picture form. An example of a nonfatal chromosomal abnormality is trisomy 21 (Down syndrome), which results from an addition to chromosome 21.

Some syndromes are caused by the loss of a portion of a chromosome (a partial **deletion**). In Beckwith-Wiedemann syndrome (a chromosome 11 deletion), changes are characterized by organ overgrowth, including an oversized tongue, which leads to feeding difficulties and hypoglycemia. Nutrition professionals play an important role in the therapy of those with chromosomal disorders because these individuals often have oral-motor problems that affect their nutritional status and cause growth problems in early life. Later in development, obesity may become an issue, and nutrition therapy is helpful in controlling weight, diabetes, and cardiovascular complications. In people with such abnormalities, varying degrees of mental retardation often complicate therapy. A knowledgeable nutrition professional can mitigate the detrimental effects of these disorders on nutritional status (see Chapter 45).

### Disease at the Mitochondrial Level

Mitochondria are subcellular organelles that are thought to have originated from bacterium; they function primarily to produce adenosine triphosphate. Human mtDNA codes for 13 proteins, 2 ribosomal RNAs, and 22 transfer RNAs to synthesize these proteins; the remainder of the

proteins are coded for by nuclear DNA. In contrast to nuclear DNA, mtDNA is small (16,569 base pairs), circular, and exists in hundreds to thousands of copies in each mitochondrion. As noted earlier, mtDNA is passed from the mother to her offspring.

Not surprisingly, alterations in mtDNA are typically degenerative and primarily affect tissues with a high demand for oxidative phosphorylation. They also have varied clinical manifestations because of the multiple copies of mtDNA, not all of which may contain the genetic change. Mutations in mtDNA can manifest at any age and include neurologic diseases, cardiomyopathies, and skeletal myopathies (MITOMAP, 2009). For example, Wolfram syndrome, a form of diabetes with associated deafness, was one of the earliest disorders to be traced to mtDNA. More than 60 diseases that result from changes in mtDNA have been identified thus far (Tuppen et al., 2009.)

### Disease at the Molecular Level

The majority of disease conditions associated with nutritional genomics involve changes at the molecular level. Changes to the DNA typically involve a single nucleotide change or several nucleotides within a single gene through substitutions, additions or deletions. In addition, larger-scale changes involving the deletion or addition of multiple nucleotides can also occur in the regulatory or protein coding regions of a gene. Alterations in the regulatory region may increase or decrease the quantity of protein produced or alter the ability of the gene to respond to environmental signals. Alterations in the coding region may affect the amino acid sequence of the protein, which in turn can affect the conformation and function of the protein and thereby the functioning of the organism. Because the vast majority of human genes reside on nuclear chromosomes, gene variations are transmitted according to Mendelian inheritance and are subject to modification from epigenetic markings.

**Autosomal dominant** single-gene disorders that have nutritional implications include several that may result in oral-motor problems, growth problems, susceptibility to weight gain, and difficulties with constipation. Examples include Albright hereditary osteodystrophy, which commonly results in dental problems, obesity, hypocalcemia, and hyperphosphatemia; chondrodysplasias, which often result in oral-motor problems and obesity; and Marfan syndrome, which promotes cardiac disease, excessive growth, and increased nutritional needs. Familial hypercholesterolemia results in a defective low-density lipoprotein (LDL) receptor, elevated levels of cholesterol, and susceptibility to atherosclerosis.

**Autosomal recessive** disorders are much more common and include metabolic disorders of amino acid, carbohydrate, and lipid metabolism. Traditionally these disorders were detected because the mutation had a detrimental effect on the newborn infant that led to serious developmental consequences or death. These disorders were heritable, ultimately associated with a particular mutation, and designated **inborn errors of metabolism (IEM)**.

IEM disorders are the earliest known examples of nutritional genomics, and dietary modification is the primary treatment modality (see Chapter 44). A brief overview of IEM from a genetic perspective is included here to emphasize the important role of the nutrition professional in restoring health to these individuals and to contrast the IEM with chronic disorders that result from the same type of genetic change but that affect function less severely.

A classic example of an IEM of amino acid metabolism is phenylketonuria (PKU). PKU results from a mutation in the gene coding for the enzyme phenylalanine hydroxylase, leading to an inability to convert phenylalanine to tyrosine. Lifelong dietary restriction of phenylalanine enables individuals with PKU to live into adulthood and enjoy a quality life. In maple syrup urine disease, the metabolic defect is branched-chain alpha-keto acid decarboxylase, an enzyme complex encoded by six genes. A mutation in any one of these genes can result in accumulation of alpha-keto acids in the urine, which produces an odor similar to maple syrup. Failure to limit branched-chain amino acid intake can lead to mental retardation, seizures, and death.

Heredity fructose intolerance is an example of an autosomal recessive IEM of carbohydrate metabolism. A mutation in the gene encoding aldolase B (fructose-1, 6-biphosphate aldolase) impairs the catalytic activity of the enzyme and prevents fructose from being converted to glucose. Breast-fed infants are typically asymptomatic until fruit is added to the diet. Nutrition therapy involves the elimination of fructose and the fructose-containing disaccharide sucrose.

Autosomal recessive disorders of lipid metabolism include the deficiency of medium-chain acyl-coenzyme A (acyl-CoA) dehydrogenase, which prevents medium-chain fatty acids from being oxidized to provide energy during periods of fasting. Nutrition therapy focuses on preventing the accumulation of toxic fatty acid intermediates that, when not controlled, can lead to death (Isaacs and Zand, 2007). Recent guidelines for expanded newborn screening for IEM in the United States use tandem mass spectrometry and provide information on approximately 40 diseases (Dietzen et al., 2009).

The **X-linked dominant** fragile X syndrome also affects nutritional status. Fragile X syndrome is characterized by developmental delays, mental impairment, and behavioral problems. The lesion occurs within the *FMR1* gene on the X chromosome in which a CGG segment is repeated more times than normal. The multiple repeats of this trinucleotide make the X chromosome susceptible to breakage.

**X-linked recessive** conditions include nephrogenic diabetes insipidus, adrenoleukodystrophy, and Duchenne muscular dystrophy (DMD) disorders. Individuals with X-linked recessive nephrogenic diabetes insipidus are unable to concentrate urine and exhibit polyuria and polydipsia. This disorder is usually detected in infancy and can manifest as dehydration, poor feeding, vomiting, and failure to thrive. X-linked recessive adrenoleukodystrophy results from a defect in the enzyme that degrades long-chain fatty acids. These fats accumulate and lead to brain and adrenal

dysfunction and ultimately motor dysfunction. X-linked recessive DMD is characterized by fatty infiltration of muscles and extreme muscle wasting. Children are typically confined to a wheelchair by the time they reach their teens and need assistance with feeding.

**Y-linked inheritance** disorders involve male sex determination and physiologic “housekeeping functions.” To date no nutrition-related disorders have been conclusively assigned to the Y chromosome.

In summary, any gene can potentially undergo mutation, which can affect the function of its protein and the health of the individual. Its location within the nuclear or mtDNA determines the mode of inheritance.

## Genetic Technologies

Progressing beyond knowing the chromosomal location of a disease trait to associating the disease with a particular mutation and understanding its functional consequences has required the development of sophisticated molecular genetic technologies. One of the most critical technologic advances occurred in the early 1970s with the introduction of **recombinant DNA** technology, which allowed major progress in terms of studying genes, their functions, and the regulation of their expression. Using bacteria-derived **restriction endonucleases (restriction enzymes)**, researchers could cut the DNA in precise, reproducible locations along the nucleotide chain, isolate the fragments and, using **polymerase chain reaction (PCR)** technology, make unlimited copies of the DNA for various applications. This basic approach has been the cornerstone of many routine techniques, such as **genetic engineering** and the production of therapeutic proteins such as insulin and growth hormone as well as new genetic strains of crops and food for animals.

Recombinant DNA technology paved the way for DNA sequencing, which is used to identify the sequence of nucleotides within a gene, pinpoint the exact location of any change, and identify each of the nucleotides in an individual's genome. A recent improvement to DNA sequencing, **whole exome capture**, promises to be an efficient way to identify the DNA sequences that constitute genes (Choi et al., 2009). Recombinant DNA is also the basis for detecting variations in DNA sequences that can be used to identify individuals for forensic and paternity purposes and to predict disease susceptibilities. Another important application is gene therapy, by which a corrected gene sequence can be introduced into the cells of an individual with a disease-causing mutation.

One of the outgrowths of these earlier technologies is **microarray technology**. Microarrays, also called **DNA “chips,”** are used to determine which genes are expressed at a particular time under particular conditions, such as during the different developmental stages. They can also be used to determine which genes are turned on (or off) in response to environmental factors, such as nutrients. A useful clinical application is the comparison of gene expression between normal and diseased cells, with important implications in cancer.

Another type of genetic technology involves interfering with a gene's expression to determine the function of that gene and its encoded protein. The concept was originally exploited in model systems involving transgenic animals, particularly the laboratory mouse ("knockout mouse"). Because the mouse and human share many of the same genes, the ability to manipulate the genetic material of the mouse and examine the effect on metabolism and physiologic function has been valuable for understanding humans.

In the knockout mouse, a gene is altered ("knocked out") so that the normal protein is no longer made. Alternatively, a gene can be altered so that it expresses too much or too little of its product. Regulatory sequences can be altered so that a gene no longer responds appropriately to environmental signals. In these ways the normal function of a gene can be determined, the effects of over-expressing or under-expressing a gene can be studied, and details of the communication process between signals outside the organism and the genetic material inside the organism can be determined. Transgenic mice are particularly valuable for studying gene-diet interactions. A recent application of this concept involves RNAi. Short sequences of RNA bind to mRNA and interfere with translation of the mRNA into protein ("knock down"). By measuring the outcome of a decrease in a particular protein, researchers can gain insight into the role of the protein and its contribution to the organism's function.

## GENETICS AND NUTRITION THERAPY

Chromosomal or single-gene mutations alter nutrition status and illustrate the importance of nutrition therapy. The rapid development of molecular nutrition and nutritional genomics expands the role of the nutrition professional beyond rare disorders and into more prevalent chronic diseases such as cardiovascular disease (CVD), cancer, diabetes, inflammatory disorders, osteoporosis, and even obesity.

Progress in identifying gene variants associated with particular chronic disorders and understanding the interaction of **bioactive food components** with these variants requires that nutrition professionals be able to interpret genetic screening information and integrate the findings into their services. Nutrition professionals will be needed at an advanced practice level to assist individuals in making gene-directed diet and lifestyle choices (DeBusk, 2009; DeBusk and Joffe, 2006; Jones et al., 2010).

Nutritional genomics is unique in its focus on how the interactions between genetic variations and environmental factors influence the genetic potential of individuals and populations, the "**gene x environment**" (**GxE**) premise (Ordovas and Tai, 2008). Here, *environment* broadly encompasses the typical toxins to which humans are exposed, as well as diet and lifestyle choices that also influence genetic potential. Nutrigenetics is concerned with how an

individual's unique set of genetic variations affects the ability to function optimally in a particular environment. Nutrigenomics identifies how the environment affects gene expression.

### Nutrigenetic Influences on Health and Disease

The interplay between nutrition and genetics varies from being straightforward to being highly complex. The most straightforward is the direct correlation between a faulty gene, a defective protein, a deficient level of a metabolite, and a resultant disease state that is passed on through Mendelian inheritance and is responsive to nutrition therapy. The IEM are good examples of such interactions and have been referred to as *genetic diseases*. As our understanding of disease at the molecular level has become more sophisticated, this terminology is no longer appropriate. The IEM are characterized as rare mutations that result in protein dysfunction that leads to metabolic disorders. The distinguishing characteristic is the rare occurrence of these particular mutations.

All humans have mutations that result in protein dysfunction that leads to metabolic disease. The human species requires certain amino acids, fatty acids, vitamins, and mineral, and there are mutations that limit the ability to synthesize these important nutrients. The diet must supply them to prevent dysfunction and disease. For example, humans lack the gene for the enzyme gulonolactone oxidase and cannot synthesize vitamin C. If dietary vitamin C intake is below needed levels, individuals are at risk for developing scurvy, which can be fatal.

New is the understanding of the genetic basis for nutrient requirements, the realization that nutrition therapy can circumvent genetic limitations by supplying the missing nutrients, and that each individual may require a different level of nutrient because of his or her particular set of genetic variations. More than 50 metabolic reactions that involve enzymes with decreased affinities for their cofactors and that require high levels of a nutrient to restore function have been identified. Many of the supplementation levels are well in excess of the usual recommended nutrient levels, which highlights the importance of remembering that each individual is genetically unique and has distinct metabolic needs.

Although generalized guidelines for recommended nutrient levels are helpful, individuals may have genetic variations that require them to consume significantly more or less of certain nutrients than the general recommendation. Nutritional genomics has changed the thinking about global dietary recommended intakes, from an age- and sex-related orientation to incorporating nutrigenetic makeup and its influence on protein function (Stover, 2006). Nutrition therapy, then, is a critical tool for compensating for changes in the DNA that can lead to increased risk of disease.

The inborn error of amino acid metabolism, classic homocystinuria, is of interest because it led to the realization that an elevated blood level of homocysteine is an independent risk factor for CVD. A defect in the vitamin B<sub>6</sub>-requiring enzyme cystathione beta-synthase prevents

the conversion of homocysteine to cystathione. Homocysteine accumulates, promotes atherosclerosis, and forms the dipeptide homocystine, which leads to abnormal collagen crosslinking and osteoporosis. Nutrition therapy is multipronged, depending on the specific genetic defect. Some individuals have an enzyme defect that requires a high concentration of the vitamin B<sub>6</sub> cofactor for activity. Others are not responsive to B<sub>6</sub> and need a combination of folate, vitamin B<sub>12</sub>, choline, and betaine to convert homocysteine to methionine. Others must limit their methionine intake. At least three forms of homocystinuria exist, each requiring a different nutritional approach. The ability to use genetic analysis to distinguish these similar disorders has been a useful technologic advance (see Chapters 6 and 33).

Genetic variation in the *MTHFR* gene provides an excellent example of nutrigenetics as well as how genetic variation can influence nutrient requirements. This gene codes for the enzyme 5,10-methyltetrahydrofolate reductase that produces the biologically active form of folate (5-methyltetrahydrofolate). Folate is essential for the conversion of homocysteine to S-adenosylmethionine, a critical methyl donor to numerous metabolic reactions, including those involved in synthesizing nucleic acids (see Chapter 33). A common variation in the *MTHFR* gene is the 677C>T gene variant, which involves substitution of thymine (T) for cytosine (C) at nucleotide position 677 within the coding region of the *MTHFR* gene. The resultant enzyme has reduced activity, which leads to decreased production of active folate and accumulation of homocysteine. In addition to the increased risk of CVD, elevated serum homocysteine increases the risk of neural tube defects in developing fetuses. As a result of these risks, in the United States cereal grains are now fortified with folic acid to ensure adequate levels in women of childbearing age (see Chapter 16).

Studies indicate that homocysteine levels can be lowered through supplementation with one or more of the B vitamins folate, B<sub>2</sub>, B<sub>6</sub>, and B<sub>12</sub> (Albert et al., 2008; Ebbing et al., 2008; Shidfar et al., 2009; Varela-Moreiras et al., 2009). The genotype of the individual is an important factor in this response, supporting the need for tailoring nutrient recommendations accordingly.

Disease-causing changes can also occur in genes coding for other types of proteins such as transport proteins, structural proteins, membrane receptors, hormones, and transcription factors. Mutations that increase the transport of iron (hereditary hemochromatosis) or copper (Wilson disease) to higher-than-normal levels have nutritional implications (see Chapter 30). Mutations in vitamin D receptors are not only associated with deleterious effects on bone health, but throughout the body because vitamin D is a hormone involved in hundreds of metabolic and regulatory processes. Changes in the gene coding for insulin can result in structural changes in the insulin hormone and lead to dysglycemia, as can mutations in the insulin receptor. Many proteins such as kinases, cytokines, and transcription factors that are involved in critical signaling

processes are subject to mutational changes, altered activities, and health consequences.

## Nutrigenomic Influences on Health and Disease

In addition to compensating for metabolic limitations, nutrients and other bioactive components in food can influence gene expression. This ability has long been known from studies with lower organisms, such as is seen with the *lac* and *trp* operons of bacteria. In these situations the organism “senses” the presence of a nutrient in its external environment and alters its gene expression accordingly. In the case of lactose, the proteins required to use lactose as an energy source are induced by transcriptional regulation of the genes that code for the lactose transport system and for the enzyme that initially metabolizes lactose. The opposite occurs when tryptophan is present in the environment: the organism inhibits the endogenous biosynthesis of tryptophan by inhibiting transcription of the genes that encode tryptophan biosynthetic proteins. GxE interactions, such as monitoring and responding to environmental signals by changing gene expression, are fundamental processes of living systems, allowing them to use resources efficiently.

Higher organisms such as humans have similar mechanisms by which they monitor the environment that bathes their cells and alter cellular or molecular activities as needed. An example is the response of cells to the presence of glucose. Insulin is secreted and binds to its receptor on the surface of skeletal muscle cells and initiates a stepwise biochemical signaling cascade (**signal transduction**). Signaling results in the translocation of glucose transporter type 4 (GLUT4), a receptor involved in glucose entry into cells, from the interior of the cell to the cell surface. Exercise also promotes the translocation of GLUT4, which is helpful in controlling blood sugar levels. A drop in blood sugar levels triggers the release of epinephrine and glucagon that, in turn, bind to cell surface receptors in the liver and skeletal muscle and, through signal transduction, stimulate glycogen breakdown to glucose to restore blood sugar levels.

Nutrients and other bioactive food components can also serve as ligands, molecules that bind to specific nucleotide sequences (response elements) within a gene's regulatory region. Binding results in a change in gene expression through the regulation of transcription. Examples of such food components are the polyunsaturated ω-3 fatty acids. These fats decrease inflammation. They serve as precursors for the synthesis of antiinflammatory eicosanoids and decrease the expression of genes that lead to the production of inflammatory cytokines, such as tumor necrosis factor-alpha and the interleukin-1 genes (Calder, 2009).

The ω-3 and ω-6 fatty acids have also been found to serve as ligands for the **peroxisome proliferator-activated receptor (PPAR)** family of transcription factors. The PPARs function as lipid sensors and regulate lipid and lipoprotein metabolism, glucose homeostasis, adipocyte proliferation and differentiation, and the formation of foam cells from monocytes

during atherogenic plaque formation. They are important components in the sequence of events by which a high-fat diet promotes insulin resistance and obesity (Christodoulides and Vidal-Puig, 2009).

To influence the expression of the genes under its control, a PPAR transcription factor must complex with a second transcription factor, the retinoic X receptor (RXR). Each has its ligand attached—polyunsaturated fatty acid and retinoic acid (vitamin A derivative), respectively. The PPAR-RXR complex can then bind to the appropriate response element within the regulatory region of a gene under its control. Binding results in a conformational change in the structure of the DNA molecule that allows RNA polymerase to bind and transcribe the PPAR-regulated genes, leading to a host of lipogenic and proinflammatory activities. A large number of transcription factors have been identified and the mechanisms of action are under investigation.

The bioactive components that serve as ligands for these transcription factors are either provided by the diet or made endogenously, such as  $\omega$ -3 and  $\omega$ -6 fatty acids, cholesterol, steroid hormones, bile acids, **xenobiotics** (foreign chemicals, or “new-to-nature” molecules), the active form of vitamin D, and numerous phytonutrients, to name just a few (Wise, 2008). In all cases these bioactives must communicate their presence to the DNA sequestered within the nucleus. Depending on their size and lipid solubility, some bioactives can penetrate the various membrane barriers and interact directly with the DNA, as in the fatty acid example discussed previously. Others, including phytochemicals found in the cruciferous vegetables, may not be able to cross the cell membrane and will instead interact with a receptor on the cell surface and set into motion the cascade of signal transduction events that results in a transcription factor being translocated to the nucleus. See *Focus On: Phytochemical and Bioactive Food Components*.

Identification of the genetic and biochemical mechanisms underlying health and disease provides the basis for developing individualized intervention and prevention strategies. In the case of the  $\omega$ -3 fatty acids, researchers are actively seeking conditions under which dietary  $\omega$ -3s can be used to decrease inflammation and increase insulin sensitivity. An understanding of the mechanisms by which gene expression is controlled is also helpful in developing drugs that can target various aspects, including gene expression. For example, the thiazolidinedione class of antidiabetic drugs targets the PPAR mechanism described previously to improve insulin sensitivity.

Identifying bioactive components in fruits, vegetables, and whole grains that are responsible for positive health effects and the mechanisms by which they influence gene expression is of considerable interest. Small-molecular-weight lipophilic molecules can penetrate the cellular and nuclear membranes and serve as ligands for transcription factors that control gene expression. Depending on the gene and the particular bioactive, expression may be turned on or off or increased or decreased in magnitude in keeping with the information received. Examples include resveratrol from purple grape skins; along with a large number of

## ◎ FOCUS ON

### Phytochemical and Bioactive Food Components

Bioactive food components are molecules in food that influence biological responses in living tissues, including gene expression. Bioactives may be an integral part of a food or they may be contaminants that have entered the food supply. They serve as molecular sensors, communicating valuable information to cells about the surrounding environment and influencing health outcomes.

Phytochemicals are a major source of bioactives that occur naturally in plants; many have been found to positively affect health. They may be traditional nutrients such as vitamins that have been documented to be essential for health or they may be more recently discovered compounds with health effects under investigation, such as resveratrol in red wine for its heart and longevity benefits and lutein in spinach for protection against macular degeneration in the eye. Although numerous studies have positively associated various phytochemicals with health, how they work remains to be defined. Various roles that are emerging include protection against oxidative stress (antioxidant properties), promotion of cancer cell death (apoptosis), alteration of hormone metabolism, enhancement of the immune response or cell-cell communication, protection against the effects of environmental toxins, and promotion of a healthy mix of microorganisms in the digestive tract.

Phytochemicals are classified by their chemical structure into alkaloids (e.g., caffeine), carotenoids (alpha- or beta-carotene, lutein, zeaxanthin, and lycopene), nitrogen-containing compounds (some alkaloids and organosulfur compounds), organosulfur compounds (e.g., glucosinolates), and phenolics. Phenolics include numerous flavonoids and stilbenes and are abundant in plant foods, especially fruits and vegetables and are of particular interest for their possible protection against heart disease and cancer.

flavonoids such as the catechins found in tea, dark chocolate, and onions and the isoflavones genistein and daidzein from soy.

For bioactive phytochemicals that are too large or too hydrophilic to penetrate the cell's membrane barriers, communication occurs by means of signal transduction. The bioactive interacts with a receptor protein at the cell surface and initiates a cascade of biochemical reactions that ultimately results in one or more transcription factors interacting with DNA and modulating gene expression. Examples of this type of indirect communication are seen with the organosulfur compounds such as sulforaphane and other glucosinolates from the cabbage family vegetables. As a result of the signaling pathway, transcription factors (e.g., *nrf*) are activated and increase transcription of the

glutathione-S-transferases needed for phase II detoxification, which helps to protect against cancer. Flavonoids such as naringenin found in citrus fruits and quercetin from onions and apples activate signaling pathways, leading to increased apoptosis of cancer cells.

It can be challenging to communicate the specifics of phytochemicals to consumers because they do not think about the bioactive substances in the food they eat. Attempts have been made to simplify the message, such as focusing on thinking of food in terms of its dominant color and understanding that each color contributes different valuable phytochemicals. For example, eating one to two servings from a wide variety of fruits, vegetables, legumes, grains, nuts, and seeds within the red, orange, green, purple, and white color categories daily will supply a variety of healthy phytochemicals. Individuals with particular disease susceptibilities or environmental challenges should increase the number of servings within a particular category to meet their specific health needs. Practitioners can provide a valuable service by translating these research findings into practical food solutions for consumers (Keijr et al., 2010; Kim et al., 2009).

## Epigenetic Influences on Health and Disease

Epigenetics, including gene silencing and genomic imprinting, is under active investigation presently (Butler, 2009; Mathers, 2008; Waterland, 2009). Inappropriate gene expression can have serious consequences. During development, for example, specific genes are turned on or off with precise timing. Alterations in that timing can impair fetal development and may cause death. Cancer is another example. Certain genes (oncogenes) promote uncontrolled cell growth; others (tumor suppressor genes) help to put the brakes on such growth. Inappropriate methylation of these genes can result in oncogenes being expressed when they should be silent and tumor suppressor genes being silenced when they would normally be expressed. Either situation can promote uncontrolled cell growth and the development of cancer.

As the significance of epigenetics and the critical nature of epigenetic reprogramming during germ cell development and early embryogenesis is increasingly appreciated, researchers have begun to ask how reproductive technologies such as in vitro fertilization might affect fetal development (Dupont et al., 2009; Grace et al., 2009; Swanson et al., 2009).

## Nutritional Genomics and Chronic Disease

Chronic disorders (e.g., CVD, cancer, diabetes, osteoporosis, inflammatory disorders) are typically more complex than single-gene disorders in which the change in the DNA is known, the abnormal protein can be identified and analyzed, and the resulting phenotype is clearly defined. Multiple genes, each with multiple variations, contribute in small ways to the overall chronic condition rather than a single

variant having a dramatic effect. The genes involved with chronic disease are influenced by environmental factors in addition to the genetic variation. An individual might have gene variants that predispose to a particular chronic disorder, but the disorder may or may not develop.

## Genetic Variability

Given the genetic variability among individuals in a population, the high degree of variability in client response to nutrition therapy should not be surprising. Although a change in a gene—including diet- and lifestyle-related genes—can affect function severely enough to cause disease outright, the majority of these genes appear to affect the magnitude of response and do not pose a life-threatening situation. They confer an increased susceptibility. Many of these variants are responsive to diet and other lifestyle parameters, providing the opportunity to minimize their effect through informed lifestyle choices.

The major focus of nutritional genomics research is on identifying (1) gene-disease associations, (2) the dietary components that influence these associations, (3) the mechanisms by which dietary components exert their effects, and (4) the genotypes that benefit most from particular diet and lifestyle choices. The practical applications of this research include a new set of tools that nutrition professionals can use. The growing body of knowledge will support strategies for disease prevention and intervention that are specifically targeted to the underlying mechanisms.

The following section takes a brief look at some of the key diet-related genes, their known variants, and how these variants affect a person's response to diet. Chronic disease involves complex interactions among genes and bioactive food components, and unraveling the details will require population and intervention studies large enough to have the statistical power needed to draw meaningful conclusions.

## Cardiovascular Disease

CVD remains the number one disease plaguing developed countries. Not surprisingly, a major focus of nutritional genomics has been to identify gene-diet associations for CVD and to study the influence of diet and exercise parameters in managing and preventing this chronic disease. Nutrition professionals who work with clients with dyslipidemia know firsthand the high degree of individual variability of responses to standard dietary interventions. These therapies are used primarily to lower elevated blood levels of LDL cholesterol (LDL-C), raise high-density lipoprotein cholesterol (HDL-C), and lower triglycerides (TGs). The standard approach is a diet low in saturated fat, with increased content of polyunsaturated fats (PUFAs). Response across a population varies, ranging from reduced LDL-C levels and TGs in some to decreased HDL-C levels or elevated TGs in others. Furthermore, some have had their LDL-C levels respond dramatically to dietary oat bran and other soluble fibers, whereas others have had more modest responses. In some a low-fat diet has caused a shift

to a lipid pattern that is more atherogenic than the original. Genotype is an important factor; dietary interventions must be matched to genotypes to accomplish the intended lipid-lowering response.

A number of contributing genes have already been identified and include those involved with postprandial lipoprotein and TG response, homocysteine metabolism, hypertension, blood-clotting, and inflammation (Lovegrove and Gitau, 2008; Minihane, 2009). Gene-diet interactions are noted for those that code for apolipoprotein E (*APOE*), apolipoprotein A-1 (*APOA1*), cholesterol ester transport protein (*CETP*), hepatic lipase (*LIPC*), lipoxygenase-5 (*ALOX5*), *MTHFR*, angiotensinogen (*AGT*), angiotensin-converting enzyme (*ACE*), the interleukin-1 family (*IL1*), interleukin-6 (*IL6*), and tumor necrosis factor-alpha (*TNF*). Five new SNPs that appear to be common among multiple populations have been identified from the Atherosclerosis Risk in Communities Study by using the genome-wide association study technique (Bressler et al., 2010).

Data from the Framingham Study provided an early example of how knowing the client's genetic variants could be helpful in developing effective nutritional interventions. The *APOA1* gene codes for apolipoprotein A-1, the primary protein in HDL (see Chapters 15 and 34). One variant that is diet-related is  $-75G>A$ , in which guanine has been replaced with an adenine at position 75 within the regulatory region of the *APOA1* gene (the “-” sign indicates the site for the variation comes prior to the first nucleotide—position “0”—of the gene's coding region). In women with two copies of the more common G allele, increasing dietary PUFA was accompanied by declining HDL levels. However, in women with at least one copy of the A allele, increasing PUFA concentrations increased HDL levels. Manipulating PUFA levels will have different effects on HDL levels, depending on which variant an individual has and how many copies.

A sampling of other diet- and lifestyle-responsive gene variants that have implications for nutrition therapy related to preventing and treating CVD include *APOE* gene variants and the responses to dietary fat, soluble fiber, and alcohol (Corella and Ordovas, 2005); *CETP* variants and effects on HDL levels, lipid-modifying response to statin drugs, and response of lipid parameters to physical activity (Ayyobi et al., 2005); *APOE*, *CETP*, and *APOA-IV* gene variants and low HDL levels (Miltiadous et al., 2005); effect of *LIPC* gene variants on HDL levels and modification by saturated fat (Zhang et al., 2005); *APOA2*, dietary fat, and body mass index (Corella et al., 2009); and *APOA5* and TGs (Lai et al., 2006; Tai and Ordovas, 2008). The possibilities for nutritional intervention are endless (Afman and Müller, 2006).

CVD is also an inflammatory disorder (Rocha and Libby, 2009), and variants of *TNF*, *IL1*, and *IL6* are being investigated for their effect on CVD susceptibility. Knowing the genotype of clients provides additional important information as to how they are likely to respond to particular dietary interventions (Ordovas, 2007).

## Inflammatory Disorders

Inflammation is now recognized as an underlying factor in chronic disorders, from heart disease to cancer to diabetes to obesity to more traditional inflammatory disorders such as arthritis and the inflammatory bowel disorders. Inflammation is a normal and desirable response to insult by the body. Typically, inflammation is an acute phase response; once the threat has passed, inflammation subsides and healing ensues. Certain genetic variations predispose individuals to be proinflammatory, making them more reactive to inflammatory triggers and extending the inflammation phase so that inflammation becomes a chronic state. The regular assault of proinflammatory mediators such as the cytokines and eicosanoids on tissues leads to oxidative stress and cellular degeneration rather than the healing that is characteristic of the acute phase.

Among the genes known to be of particular importance to the inflammatory response are *IL1*, which encodes the interleukin-1 $\beta$  cytokine (also known as IL-1F2), *IL6* (encoding the interleukin-6 cytokine), and *TNF*. Variants in each of these genes have been discovered that increase the susceptibility of humans to be in a proinflammatory state, which in turn increases the risk of developing one or more chronic disorders. Certain diet and lifestyle approaches can minimize susceptibility and dampen existing inflammation (Massaro et al., 2008). Examples include the inclusion of fish and foods that contain  $\omega$ -3 fatty acids and plant foods rich in various polyphenols.

## Immune Health and Cancer

The relationship of gene variants and gene-diet interactions to immune health and cancer is of considerable interest to researchers around the world (Milner, 2008; Trottier et al., 2010; Villagra et al., 2010). One of the key mechanisms by which the body protects against cancer is detoxification, the process of neutralizing potentially harmful molecules. Among the better-characterized genes involved in various aspects of detoxification are the cytochrome P450 isozymes (*CYPs*), glutathione S-transferases (*GSTs*), and superoxide dismutases (*SOD1*, *SOD2*, *SOD3*). The *CYP* and *GST* genes are part of the phase I and phase II detoxification system, respectively, found in the liver and the gut. The *SOD* genes code for proteins that dismantle the reactive oxygen species superoxide. Each of these genes has nutritional implications, and variants have been identified that result in decreased detoxification. Nutritional genomics provides the basis for directing nutrition therapy to protect against cancer by augmenting endogenous detoxification activity.

Epidemiologic studies have suggested that consuming plant foods is cancer-protective. Numerous dietary factors play a role in protecting against cancer. Examples include curcumin from the spice turmeric (Aggarwal and Shishodia, 2006; Surh and Chun, 2007; Trottier et al., 2009), resveratrol from purple grape skins (Athar et al., 2009; Udenigwe et al., 2008), glucosinolates in cruciferous

vegetables (Ambrosone and Tang, 2009), epigallocatechin gallate catechins from green tea (Na and Surh, 2008), isoflavones from soybeans (Steiner et al., 2008), folic acid (Ebbing et al., 2009; Fife et al., 2009; Oaks et al., 2009), and vitamin D (van der Rhee et al., 2009). Numerous labs are investigating the underlying mechanisms by which these phytochemicals exert their protective effects (Surh et al., 2008; Tan and Spivack, 2009).

### Blood Sugar Regulation

Glucose is the preferred source of energy for the body's cells. Accordingly, blood glucose levels are carefully controlled through an intricate system of checks and balances. When glucose levels are higher than normal (hyperglycemia), the hormone insulin is secreted from the beta-cells of the pancreas, glucose is taken up by the cells, and a normal blood sugar level (euglycemia) is restored. When blood glucose levels fall (hypoglycemia), the hormone glucagon is secreted by the liver, glycogen is hydrolyzed to glucose, and euglycemia is again restored. When this process goes awry, the stage is set for the chronic conditions of insulin resistance, metabolic syndrome, and, ultimately, T2DM.

Identification of gene variants that lead to T2DM would allow individuals with this susceptibility to be identified early in the lifespan so that intervention could be initiated. A few rare mutations have been associated with the development of T2DM, but they do not explain the high prevalence of the disease. It is likely that multiple gene variants contribute to the development of this condition. One promising variant is the transcription factor 7-like 2 (*TCF7L2*) identified by Grant and colleagues (2006). The variant occurs frequently within multiple populations. Evidence suggests the gene is involved in insulin secretion from pancreatic beta-cells (Villareal et al., 2010).

### Bone Mineralization and Maintenance

Healthy bone tissue depends on a balance between the action of the osteoblasts that synthesize new bone tissue and resorption by osteoclasts. Important components in this dynamic balance are vitamin D, calcium, other nutrients, and hormones such as parathyroid hormone and estrogen. When resorption predominates, bones become fragile, are subject to fracture, and osteoporosis results. Osteoporosis can occur in men and women as they age; it is prevalent among older postmenopausal women.

Numerous genes and their protein products are involved in the overall process. Variants are being investigated, including the *VDR* gene, which codes for the vitamin D receptor present on the surface of many cell types. Vitamin D has multiple roles in metabolism, but its control of the absorption of dietary calcium from the digestive tract truly affects bone health. Four *VDR* variants have been studied over several years (ApaI, BsmI, FokI, and TaqI), but no clear association has emerged (Gennari et al., 2009). Two of the more promising variants at this time are *COL1A1*, which encodes the major protein in bone ( $\alpha 1$  peptide of Type 1 collagen) and *LRP5*, which encodes a protein that forms a

cell surface receptor and activates the signaling pathway. Further research is imperative.

### Weight Management

The ability to maintain a healthy weight is another challenge of modern society. As with the other chronic disorders, the regulation of body weight is a complex process and offers multiple points at which a gene variant can give rise to an impaired protein that, when combined with the appropriate environmental trigger, promotes body fat storage. Similar to T2DM, variations in single genes have been associated with excess weight, but these genetic changes are not likely the basis for the rapid rise in prevalence of excess body weight during the past several generations (Hetherington and Cecil, 2010).

A variant in the *FTO* gene has been identified and found to occur frequently among multiple populations (Chu et al., 2008; Dina et al., 2007). An SNP in the *FTO* gene is associated with increased risk of obesity, and the effect was directly correlated with the number of copies of the SNP. That is, those with one copy of the risk allele weighed more than those with no copies, and those with two copies weighed the most of the three groups (Frayling et al., 2007). In 2009, two large genome-wide association studies found the *FTO* variant to be associated with BMI (Thorleifsson et al., 2009; Willer et al., 2009). The mechanism of action of the *FTO* gene is not yet known. A number of other gene variants have been implicated in weight management, including *ADRB3*, *FABP2*, *POMC*, and *PPARG*, but none so dramatically as *FTO*. The *FTO* variant may also increase risk for T2DM and CVD through its effect on susceptibility to increased body fat.

Adipose tissue is dynamic tissue that is highly vascularized and produces hormones, inflammatory peptides (cytokines), and new adipocytes in addition to storing excess calories as TGs and hydrolyzing them as energy is needed. The multistep process of transporting free fatty acids into the adipocyte, esterifying them into TGs, and mobilizing the TGs potentially provides many proteins that could be affected by genetic variation such that fat is stored more readily or mobilized more slowly than normal. Adipocytes have cell surface receptors that respond to various environmental factors, such as catecholamines produced during exercise, to mobilize stored fat. An example is the receptor encoded by the *ADRB2* gene, which has a greater propensity to store dietary fat as body fat. Individuals with either of these variants will find it more challenging to maintain a healthy weight and may need to restrict their dietary fat intake or engage in regular, vigorous exercise to achieve and maintain a healthy weight.

### Other Chronic Diseases

Candidate genes, gene variants, and diet-gene interactions are being investigated for many chronic disorders. Populations differ in the types and frequencies of the gene variants; dietary approaches that are most appropriate will vary accordingly. As gene variants and their health implications are identified, attention is also being paid to

examining the frequency of particular variants among populations.

## ETHICAL, LEGAL, AND SOCIAL IMPLICATIONS

If nutritional genomics is to realize its potential as a valuable tool, genetic testing is an essential component of identifying the variations in each individual. Such testing is not, however, without controversy. Consumers worry that genetic testing for any purpose could be used against them, primarily to deny insurance coverage or employment; they are particularly uncomfortable with insurers and employers having access to their personal genetic information (Genetics & Public Policy Center, 2010.)

Although theoretically possible, according to existing case law such discrimination has rarely occurred. Furthermore, identifying gene variants that increase susceptibility to diet- and lifestyle-related diseases that can be addressed through readily available diet and lifestyle measures may also lead to legal debate. Many legislators and legal experts believe the Americans with Disabilities Act sufficiently protects against discrimination, but, as an added measure of protection, the **Genetic Information Nondiscrimination Act (GINA)** was passed by Congress and went into effect on November 21, 2009. GINA defines genetic testing and genetic information, bans discrimination based on genetic information, and penalizes those who violate the provisions of this law. Consumers and health care professionals can feel comfortable in adopting this new service.

Consumers and health care professionals should ask critical questions prior to consent for genetic testing. The laboratory itself should have the appropriate credentials and state licensing, if required (at a minimum, Clinical Laboratory Improvement Amendment (CLIA) certification according to the CLIA of 1988) and should have an appropriately credentialed health professional available for assistance in interpreting the test results. The laboratory should have written, readily available policies concerning how it will protect the privacy of the individual being tested and whether the DNA sample will be retained by the lab or destroyed following testing. Transparency in each of these areas will increase consumer comfort.

A second concern on the part of consumers and health care professionals is that nutritional genomics is elitist by nature, in that only the wealthy will be able to benefit. At this early stage in its development, the cost of nutritional genomics testing precludes its use as a public health measure and effectively restricts access to those with sufficient disposable income. However, like any other new technology, as the sales volume increases, the cost will decrease.

Numerous additional issues need to be thoroughly discussed in the course of integrating genetic technologies into health care. **Box 5-1** lists key questions to be answered in the development of nutritional genomics practices. These and other ethical, legal, and social issues relating to nutritional genomics in particular have been explored. Authors

address ethical treatment of research participants (Bergman et al., 2008), consumer versus health care professional testing (Foster and Sharp, 2008; Royal et al, 2010); the capacity gap in terms of health care professionals trained in nutritional genomics (Farrell, 2009); and various other aspects of the ethical, legal, and social implications of nutritional genomics (Reilly and DeBusk, 2008; Ries and Castle, 2008).

### CLINICAL SCENARIO

Jared and Matthew are identical twins who grew up together but have lived apart since college. Jared lives in New York City and is a certified public accountant in a high-profile accounting firm, working long hours in a stressful environment. Matthew attended college in California, where he studied nutrition and exercise physiology and now manages the wellness program at a large fitness center. At age 30 the two brothers are noticeably different in weight and body shape. Jared has a body mass index of 29 compared with Matthew's 23. Jared has developed central obesity, hypertension, and problems with blood sugar regulation, all signs of a tendency toward developing type 2 diabetes. In contrast, Matthew is lean and has normal blood pressure and normal blood sugar levels.

#### Nutrition Diagnostic Statement

Overweight related to possible genetic susceptibility, limited physical activity, overeating with snacks and consumption of large meals as evidenced by diet history, central obesity, and body mass index

#### Nutrition Care Questions

1. Because they are identical twins, would you have expected the two brothers to have similar health profiles?
2. How would you expect their diets to be different?
3. What is going on? Does Matthew not have the same genetic susceptibilities that Jared has? If not, why not? If so, why doesn't Matthew exhibit the same phenotype as Jared? This question is complex: think about the twins' deoxyribonucleic acid, but also their environmental influences and their epigenetic markings.
4. How could you confirm your suspicion that Jared is genetically predisposed to type 2 diabetes?
5. What would you advise Jared to do to decrease his genetic susceptibility to diabetes?
6. As part of the nutrition assessment, Jared is found to be homozygous for IL1 -511C>T and heterozygous for IL6 -174G>C. These genes code for the proinflammatory cytokines interleukin-1 and interleukin-6 and these particular single nucleotide polymorphisms have been strongly associated with chronic inflammation. What would you discuss with Jared about the implications of these genotype findings and his susceptibility to chronic disease?

**BOX 5-1****Important and Ethical Questions Related to Genetics Testing**

- Which laboratory will analyze the deoxyribonucleic acid?
- What measures are in place in that laboratory to protect privacy?
- What is the total cost of the test?
- Which gene variants are tested?
- Is there a lifestyle action that can be taken for each variant?
- Has the test been scientifically validated for accuracy and reliability?
- When will the test results be received?
- How and to whom will the test results be presented?
- Who should be tested?
- Should individuals be tested for a disease for which there is no cure?
- Do parents have the right to have their minor children tested for a genetic susceptibility?
- Do parents have the right to withhold the results from the children?
- Should gene therapy be allowed on reproductive cells so that any corrected genes can be inherited by subsequent generations?
- Should human cloning be allowed?
- What is the best way to educate those who are already in practice as health care professionals?
- What changes are needed so that future health care practitioners can be properly educated?

# Clinical: Inflammation, Physical, and Functional Assessments

### KEY TERMS

air displacement plethysmogram (ADP)  
anthropometry  
bioelectrical impedance analysis (BIA)  
body composition  
body mass index (BMI)  
functional laboratory testing  
functional medicine  
Functional Nutrition Assessment (FNA)  
head circumference  
height-for-age curve  
length-for-age curve

ideal body weight  
inflammation  
malabsorption  
midarm circumference (MAC)  
stadiometer  
Subjective Global Assessment (SGA)  
usual body weight (UBW)  
waist circumference  
waist-to-hip circumference ratio (WHR)  
weight-for-age curve  
weight-for-length curve

### NUTRITION AND INFLAMMATION

Nutrition assessment would be incomplete if the effects of inflammation on health status were not noted. **Inflammation** is a protective response by the immune system to infection, acute illness, trauma, toxins, many chronic diseases, and physical stress. Acute inflammatory reactions are short term because of the involvement of negative feedback mechanisms (Calder et al., 2009). These acute inflammatory mediators have short half-lives and are quickly degraded.

Chronic inflammation begins as a short-term process, but is not extinguished. The body continues to synthesize inflammatory mediators, which alter normal physiological processes and affect innate immunity (Germolec, 2010). Loss of barrier function, responsiveness to a normally benign stimulus, infiltration of large numbers of inflammatory cells, overproduction of oxidants, cytokines, chemokines, eicosanoids, and matrix metalloproteinases all contribute to disease onset and progression (Calder et al.,

2009). For example, insulin resistance in the setting of obesity results from a combination of altered functions of insulin target cells and the accumulation of macrophages that secrete proinflammatory mediators, which can promote the metabolic syndrome (Olefsky and Glass, 2010). The chronic inflammatory process also contributes to allergy, asthma, cancer, diabetes, autoimmune disease and some neurodegenerative disorders and infectious diseases.

Inflammatory conditions trigger the immune response to release eicosanoids and cytokines, which mobilize nutrients required to synthesize positive acute-phase proteins and white blood cells. Cytokines (interleukin 1 $\beta$  [IL-1 $\beta$ ], tumor necrosis factor alpha [TNF- $\alpha$ ], interleukin-6 [IL-6]) and eicosanoids (prostaglandin E2 [PGE2]) influence whole-body metabolism, body composition, and nutritional status. Cytokines reorient hepatic synthesis of plasma proteins and increase the breakdown of muscle protein to meet the demand for protein and energy during the inflammatory response. Moreover, there is a redistribution of albumin to

the interstitial compartment, resulting in edema. Declining values of negative acute-phase proteins, serum albumin, prealbumin, and transferrin reflect inflammatory processes and severity of tissue injury. These laboratory values do not reflect current dietary intake or protein status (Dennis, 2008; Devakonda, 2008; Ramel, 2008). Improvements in albumin, prealbumin, and transferrin most likely reflect a change in hydration status rather than increased protein and energy intake. Table 6-1 lists acute phase reactants related to the inflammatory process.

Cytokines impair the production of erythrocytes and reorient iron stores from hemoglobin and serum iron to ferritin. During infection IL-1 $\beta$  inhibits the production and release of transferrin while stimulating the synthesis of ferritin. Therefore laboratory test results used to predict the risk of nutritional anemias are not useful in assessing the patient with an inflammatory response. The effects of cytokines on organ systems are noted in Table 6-2.

**TABLE 6-1****Acute Phase Reactants**

<b>Positive Acute-Phase Reactants</b>	<b>Negative Acute-Phase Proteins</b>
C-reactive protein	Albumin
$\alpha_1$ -antichymotrypsin	Transferrin
$\alpha_1$ -antitrypsin	Prealbumin (transthyretin)
Haptoglobins	Retinol-binding protein
Ceruloplasmin	
Serum amyloid A	
Fibrinogen	
Ferritin	
Complement and components C3 and C4	
Orosomucoid	

As the body responds to acute inflammation, TNF- $\alpha$ , IL-1 $\beta$ , IL-6, and PGE2 increase to a set threshold, then IL-6 and PGE2 inhibit TNF- $\alpha$  synthesis and IL-1 $\beta$  secretion, creating a negative feedback cycle. Hepatic synthesis of positive acute-phase proteins diminishes and synthesis of negative acute-phase proteins increases. Albumin shifts from interstitial compartment to the extravascular space. Iron stores shift from ferritin to transferrin and hemoglobin (Northrop-Clewes, 2008).

Inappropriate synthesis of inflammatory mediators can be triggered by an injury, reactive oxygen species, or abnormal levels of a body component such as glucose or visceral adipose tissue. Treatment with  $\omega$ -3 fatty acids is associated with reductions in TNF- $\alpha$  and IL-1 $\beta$  in healthy subjects and reduction in TNF- $\alpha$  in subjects with diabetes (Riediger et al., 2009). Yet overall reduction in inflammatory biomarkers through increased consumption of fruits, vegetables, or nutrient supplements has generated mixed results (Bazzano et al., 2006; Ridker, 2008). More research is needed to identify how various dietary components modulate the predisposition to chronic inflammatory conditions (Calder et al., 2009).

Chronic inflammation is present in Crohn disease, rheumatoid arthritis, cardiovascular disease, diabetes, and obesity (Hye, 2005). Factors that have an important role in disease management decrease inflammatory mediator production through effects on cell signaling and gene expression ( $\omega$ -3 fatty acids, vitamin E, plant flavonoids), reduce the production of damaging oxidants (vitamin E and other antioxidants), and promote gut barrier function and anti-inflammatory responses (prebiotics and probiotics) (Calder et al., 2009).

**Inflammation and Immune Regulation**

B cells help to regulate cellular immune responses and inflammation. There are phenotypically diverse B-cell subsets with regulatory functions related to inflammation and autoimmunity (Dilillo et al., 2010). Total lymphocyte count (TLC) is an indicator of immune function reflective

**TABLE 6-2****Cytokine Actions and Nutritional Consequences**

<b>Organ System</b>	<b>Cytokine-Modulated Behavior</b>	<b>Nutritional Consequences</b>
Brain	Sickness syndrome, including fatigue, apathy, cognitive dysfunction, anorexia, sleepiness	↓ food intake weight loss
Endocrine	Euthyroid sick syndrome, anorexia, ↑ in metabolic rate	↓ food intake muscle wasting
Liver	↑ synthesis of positive acute phase proteins, ↓ synthesis of negative acute phase proteins, ↑ fatty acid synthesis, ↑ lipolysis, ↓ LPL	↑ edema hypertriglyceridemia
Muscles	↑ insulin resistance	Hyperglycemia
Blood	↓ product RBC, redistribution of albumin, prealbumin, and iron	anemia ↑ edema
GI Tract	↓ gastric secretion, ↓ GI motility, ↓emptying time, ↑ protein degradation	↓ food intake weight loss ↓ protein reserves

GI, Gastrointestinal; LPL, lipoprotein lipase; RBC, red blood cell.

Litchford MD: Inflammatory biomarkers and metabolic meltdown, Greensboro, NC, 2009, Case Software and Books.

of B and T cells (see Chapter 27). Skin testing, or delayed cutaneous hypersensitivity (DH) reactivity, measures cell-mediated immunity. DH and TLC are affected by inflammatory metabolism, chemotherapy, and steroids, and thus are most useful in cases of uncomplicated nutrition depletion.

DH involves the intradermal injection of small amounts of antigen (tuberculin, *Candida* organisms, mumps, or trichophytin) just under the skin to determine the person's reaction. A healthy person reacts with induration, indicating that exposure has probably taken place and that immunocompetence is intact. Because electrolyte imbalance, infection, cancer and its treatments, liver disease, renal failure, trauma, and immunosuppression can alter results, DH is not always used for the nutrition assessment of hospitalized patients (Russell and Mueller, 2007). Therapeutic approaches that alter the innate immune system response to inflammatory and microbial insults are exciting areas of study in both nutrition science and medical practice. See Chapter 8 for more details on biochemical assessment.

## PHYSICAL AND FUNCTIONAL ASSESSMENTS

### Anthropometry

**Anthropometry** involves obtaining physical measurements of an individual, then relating them to standards that reflect the growth and development of that individual. These physical measurements are another component of the nutrition assessment that are useful for evaluating overnutrition or undernutrition. They can also be used to monitor the effects of nutrition interventions. Individuals conducting these measurements should be trained in the proper technique; if more than one professional is conducting these measurements, measures of accuracy between them should be established. Measurements of accuracy can be established by several clinicians taking the same measurement and comparing results. Anthropometric data are most valuable when they reflect accurate measurements recorded over time. Valuable measurements are height, weight, skinfold thicknesses, and girth measurements. Head circumference and length are used in pediatric populations. Birth weight and ethnic, familial, and environmental factors affect these parameters and should be considered when anthropometric measures are evaluated.

### Interpretation of Height and Weight

Currently, reference standards are based on a statistical sample of the U.S. population. Therefore an individual measurement shows how a person's measurement compares with that of the total population. Height and weight measurements of children are evaluated against various norms. They are recorded as percentiles, which reflect the percentage of the total population of children of the same sex who are at or below the same height or weight at a certain age. Children's growth at every age can be monitored by mapping data on growth curves, known as

**height-for-age, length-for-age, weight-for-age, and weight-for-length curves.** Appendixes 9 through 16 provide pediatric growth charts and percentile interpretations. Height and weight are also useful for evaluating nutrition status in adults. Both should be measured because the tendency is to overestimate height and underestimate weight, resulting in an underestimation of the relative weight or body mass index (BMI). In addition, many adults are shrinking as a result of osteoporosis, joint deterioration, and poor posture, and this should be noted (Box 6-1).

### Length and Height

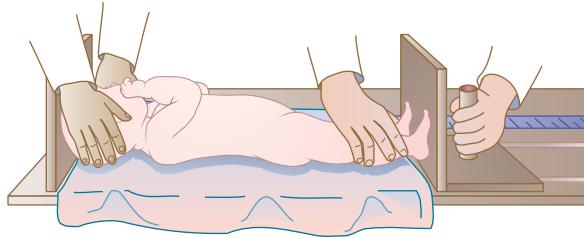

Height measurements are valuable when used in conjunction with other assessment measurements. Various methods may be used to measure length and height. Measurements of height can be obtained using a direct or an indirect approach. The direct method involves a measuring rod, or **stadiometer**, and the person must be able to stand or recline flat. Indirect methods, including knee-height measurements, arm span, or recumbent length using a tape measure, may be options for those who cannot stand or stand straight such as individuals with scoliosis, kyphosis (curvature of the spine), cerebral palsy, muscular dystrophy, contractures, paralysis, or who are bedridden (see Appendix 20). Recumbent height measurements made with a tape measure while the person is in bed may be appropriate for individuals in institutions who are comatose, critically ill, or unable to be moved. However, this method can only be used with patients who do not have musculoskeletal deformities or contractures.

Sitting heights are used for children who cannot stand (see Chapter 45). Recumbent length measurements are used for infants and children younger than 2 or 3 years of age. Ideally these young children should be measured using a length board as shown in Figure 6-1. Recumbent lengths in children ages 2 and younger should be recorded on the birth to 24-month growth grids, whereas standing heights of children ages 2 to 3 years should be recorded on the 2- to 20-year growth grids, as in Appendixes 9 through 16. Recording on the proper growth grids provides a record of a child's gain in height over time and compares the child's height with that of other children of the same age. The rate of length or height gain reflects long-term nutritional adequacy.

### BOX 6-1

#### Using Height and Weight to Assess a Hospitalized Patient's Nutritional Status

- Measure. Do not just ask a person's height.
- Measure weight (at admission, current, and usual).
- Determine percentage of weight change over time (weight pattern).
- Determine percentage above or below usual or ideal body weight.

**FIGURE 6-1** Measurement of the length of an infant.

Crown-to-heel length of children 3 years and younger should be measured as follows: (1) Lay the child on a ruled board that has an attached piece of wood at one end and a movable piece at the other. (2) Stretch the child out on the board for the most accurate measurement. (3) Place the movable end flat against the bottom of the child's foot and read the length from the side of the board.

## Weight

Weight is another measure that is important to obtain. In children it is a more sensitive measure of nutritional adequacy than height because it reflects recent nutritional intake. Weight also provides a rough estimate of overall fat and muscle stores. For those who are obese or have edema, weight alone makes it difficult to assess overall nutritional status. Body weight is obtained and interpreted using various methods, including BMI, usual weight, and actual weight. Ideal weight for height reference standards such as the Metropolitan Life Insurance Tables from 1959 and 1983 or the National Health and Nutrition Examination Survey percentiles are no longer used. A commonly used method of determining ideal body weight is the Hamwi Equation (Hamwi, 1964). It does not adjust for age, race, or frame size and its validity is questionable. Nonetheless, it is in widespread use by clinicians as a quick method of estimation:

Men: 106 lbs for first 5 feet of height and 5 lbs per inch over 5 feet; or 6 lbs subtracted for each inch under 5 feet.

Women: 100 lbs for first 5 feet of height and 5 lbs per inch over 5 feet; or 5 lbs subtracted for each inch under 5 feet.

Actual body weight is the weight measurement obtained at the time of examination. This measurement may be influenced by changes in the individual's fluid status. Weight loss can reflect dehydration but can also reflect an immediate inability to meet nutrition requirements; this may indicate nutritional risk. The percentage of weight loss is highly indicative of the extent and severity of an individual's illness. The [Blackburn formula](#) (1977) is useful for determining the percentage of recent weight loss:

Significant weight loss: 5% loss in 1 month,  
7.5% loss in 3 months, 10% loss in 6 months

Severe weight loss: >5% weight loss in 1 month, >7.5% weight loss in 3 months, >10% weight loss in 6 months

Another method for evaluating the percentage of weight loss is to calculate an individual's current weight as a percentage of usual weight. [Usual body weight \(UBW\)](#) is a more useful parameter than [ideal body weight](#) for those who are ill. Comparing present weight to the UBW allows weight changes to be assessed. However, one problem with using UBW is that it may depend on the patient's memory.

## Body Mass Index

Another method to determine whether an adult's weight is appropriate for height is the Quetelet index ( $W/H^2$ ) or the [body mass index \(BMI\)](#) (Lee and Nieman, 2003). The BMI calculation requires weight and height measurements and can indicate overnutrition or undernutrition. BMI accounts for differences in body composition by defining the level of adiposity and relating it to height, thus eliminating dependence on frame size (Stensland and Margolis, 1990). The BMI has the least correlation with body height and the highest correlation with independent measures of body fat for adults. The BMI does not measure body fat directly, but correlates with the direct body fat measures such as underwater weighing and dual x-ray absorptiometry (Keys et al., 1972; Mei et al., 2002). BMI is calculated as follows:

$$\text{Metric: } \text{BMI} = \text{Weight (kg)} \div \text{Height (m)}^2$$

$$\text{English: } \text{BMI} = \text{Weight (lb)} \div \text{Height [in]}^2 \times 703$$

Nomograms are also available to calculate BMI, as are various charts (see [Appendix 23](#)). *Clinical Insight: Calculating BMI and Determining Appropriate Body Weight* gives an example of the BMI calculation for a woman.

Standards classify a BMI for an adult at less than 18.5 as underweight, a BMI between 25 and 29 as overweight, and a BMI greater than 30 as obese. A healthy BMI for adults is considered between 18.5 and 24.9 (CDC, 2009). Although a strong correlation exists between total body fat and BMI, individual variations need to be recognized before making conclusions (Russell and Mueller, 2007).

Differences in race, sex, and age must be considered when evaluating the BMI (Yajnik and Yudkin, 2004). BMI values tend to increase with age (Vaccarino and Krumholz, 2001). Although studies report an association between really high and low BMIs and mortality, the data suggest that a higher BMI range is protective in older adults (see [Chapter 21](#)). The standards for ideal weight (BMI of 18.5 to 25) may be too restrictive in the elderly. Therefore careful interpretation of risk factors must be part of the total assessment.

The method of calculation of BMI in children and teens is the same as that for adults, but the interpretation is different. [Appendices 11 and 15](#) allow for the plotting of the BMI on a growth grid used with children ages 2 to 20 years. [Appendices 12 and 16](#) provide sample grids for recording BMI measurements and changes for children and

## CLINICAL INSIGHT

### Calculating BMI and Determining Appropriate Body Weight

Example: Woman who is 5'8" (68 in) tall and weighs 185 pounds (lb)

Step 1: Calculate current BMI:

$$\begin{array}{ll} \text{Formula:} & \text{Weight (kg)} 84 \text{ kg} \div \text{Height (m}^2\text{)} \\ (\text{Metric}) & (1.72 \text{ m}) \times (1.72 \text{ m}) = 84 \div 2.96 \text{ m}^2 = \\ & \text{BMI} = 28.4 = \text{overweight} \end{array}$$

Step 2: Appropriate weight range to have a BMI that falls between 18.5 and 24.9

$$\begin{array}{ll} 18.5 & (18.5) \times (2.96) = 54.8 \text{ kg} = 121 \text{ pounds} \\ 24.9 & (24.9) \times (2.96) = 73.8 \text{ kg} = 162 \text{ pounds} \\ \text{Appropriate weight range} & = 121 - 162 \text{ lb or } 54.8 \\ & - 73.8 \text{ kg} \end{array}$$

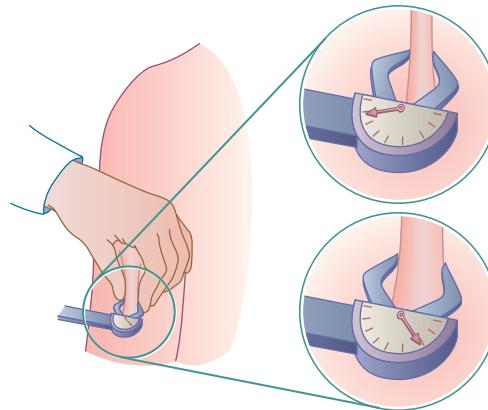

Formula (English) Weight (lb)  $\div$  (Height [in]  $\times$  Height [in])  $\times$  703 = BMI  
BMI, Body mass index.

adolescents over time. For example, a BMI of only 17 is very appropriate for a 10-year-old girl (see Appendix 19), but would be a concern in an older adult.

### Body Composition

**Body composition** is used along with other assessment factors to provide an accurate description of one's overall health. Differences in skeletal size and the proportion of lean body mass can contribute to body weight variations among individuals of similar height. For example, muscular athletes may be classified as overweight because their excess muscle mass, not their adipose mass, increases their weight. Older adults tend to have lower bone density and reduced lean body mass and therefore may weigh less than younger adults of the same height. Variation in body composition exists among different population groups as well as within the same group (Deurenberg and Deurenberg-Yap, 2003). The majority of body composition studies that were performed on whites may not be valid for other ethnic groups. There are differences and similarities between blacks and whites relative to fat-free body mass, fat patterning, and body dimensions and proportions; blacks have greater bone mineral density and body protein as compared with whites (Wagner and Heyward, 2000). In addition, BMIs for Asian populations need to be in the lower ranges for optimal health to reflect their higher cardiovascular risks (Zheng et al., 2009). These factors must be considered to avoid inaccurate estimation of body fat and interpretation of risk.

Indirect methods for measuring body composition include triceps skin fold, midarm muscle circumference, and

**FIGURE 6-2** Skinfold calipers measuring the thickness of subcutaneous fat (in millimeters), giving a rough measurement of adiposity. Measurements are read counterclockwise. (*Courtesy Dorice Czajka-Narins, PhD.*)

midarm circumference (MAC) (Russell and Mueller, 2007). The health professional must realize that these measures are useful in the assessment of individuals over time but not in critical- and acute-care settings; changes in body fluid and composition may skew the results. When conducting body composition measurements, strict adherence to established protocols must be followed to yield accurate results. For example, most North American investigators use the right side of the body to take skinfold measurements, and the standards are based on this. The methods used to gather meaningful data should be considered carefully.

### Subcutaneous Fat in Skinfold Thickness

The fat-fold or skinfold thickness measurement is a means of assessing the amount of body fat in an individual. It is practical in clinical settings, although its validity depends on the accuracy of the measuring technique (see Box 6-2) and repetition of measurements over time. If changes are going to occur, they take 3 to 4 weeks to develop. Skinfold measurement assumes that 50% of body fat is subcutaneous (Figure 6-2).

Accuracy decreases with increasing obesity. The skinfold sites identified as most reflective of body fatness are over the triceps and the biceps, below the scapula, above the iliac crest (suprailiac), and on the upper thigh. The triceps skinfold (TSF) and subscapular measurements are the most useful because the most complete standards and methods of evaluation are available for these sites (Figures 6-3 and 6-4; see Appendices 24-26). Figure 6-5 shows the measurement of the suprailiac crest skinfold.

### Circumference Measurements

If more complete information on actual body composition is needed, additional measurements can be obtained. For

**BOX 6-2****Skinfold Measurement Techniques**

1. Take measurement on the right side of the body.
2. Mark the site to be measured and use a flexible, nonstretchable tape.
3. The tape measure can be used to locate the midpoints on the body.
4. Firmly grasp the skinfold with the thumb and index finger of the left hand approximately 1 cm or  $\frac{1}{2}$  inch proximal to the skinfold site, pulling it away from the body.
5. Hold the caliper in the right hand, perpendicular to the long axis of the skin fold and with the caliper's dial face up. Place the caliper tip on the site and approximately 1 cm or  $\frac{1}{2}$  inch distal to the fingers holding the skinfold. (Pressure from the fingers does not affect the measurement.)
6. Do not place the caliper too deeply into the skinfold or too close to the tip of the skinfold.
7. Read the caliper approximately 4 seconds after pressure from the measurer's hand has been released from the

lever. Exerting force longer than 4 seconds results in smaller readings because fluids are forced from the compressed tissue. Measurements should be recorded to the nearest 1 mm.

8. Take a minimum of two measurements at each site to verify results. Wait 15 seconds between measurements to allow the skinfold site to return to normal. Maintain pressure with thumb and index finger during measurements.
9. Do not take measurements immediately after the person has exercised or if the person is overheated because the shift in body fluid makes the result larger.
10. When measuring obese clients, it may be necessary to use both hands to pull the skin away while a second person makes the measurement. If the calipers do not fit, another technique may be required.

Data from Lee RD, Nieman DC: Nutritional assessment, ed 3, New York, 2003, McGraw-Hill.

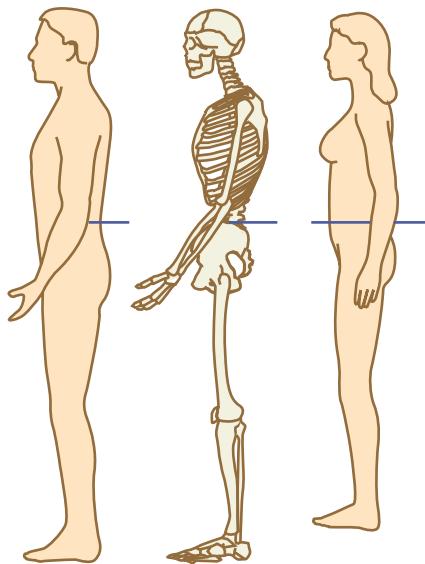

**FIGURE 6-3** Measurement of the subscapular skinfold thickness.

**FIGURE 6-5** Measurement of the suprailiac crest skinfold (in mm) above the bony prominence of the iliac crest and across from the navel.

**FIGURE 6-4** **A**, Measurement and marking of the midpoint between the acromion process at the shoulder and the olecranon process at the elbow. **B**, Measurement of the triceps skinfold (in mm) at the marked midpoint, and **C**, measurement of the biceps skinfold (in mm) at the marked midpoint.

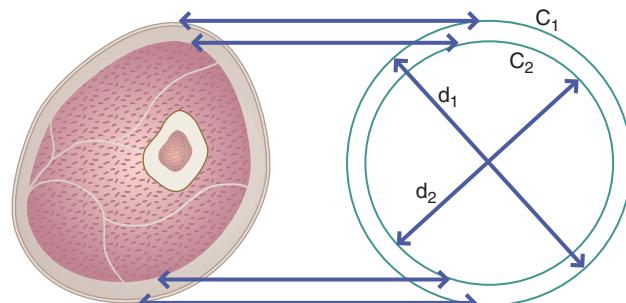

**FIGURE 6-6** Measuring tape position for waist (abdominal) circumference measurement. (From [www.nhlbi.nih.gov/guidelines/obesity/e\\_txthbk/txgd/4142.htm](http://www.nhlbi.nih.gov/guidelines/obesity/e_txthbk/txgd/4142.htm).)

example, in the acute-care setting where the patient experiences more acute pathophysiologic changes such as daily fluid shifts, measures of arm circumference and TSF measurements are not usually performed. But in the long-term care setting, sports clinic, or home environment, these measurements can be tracked over time (e.g., monthly or quarterly) to provide valuable information on overall nutrition status.

Because fat distribution is an indicator of risk, circumferential or girth measurements may be used. The presence of excess body fat around the abdomen out of proportion to total body fat is a risk factor for chronic diseases associated with obesity and the metabolic syndrome. **Waist-to-hip circumference ratio (WHR)** is used to detect possible signs of excess fat deposition (lipodystrophy) in those infected with HIV. It also detects cardiovascular risk somewhat better than BMI (Elsayed et al., 2008). A ratio of 0.8 or above indicates risk in a woman, and 1 or more indicates risk in a man.

**Waist circumference** is obtained by measuring the distance around the smallest area below the rib cage and above the umbilicus with the use of a nonstretchable tape measure. A measurement of greater than 40 inches (102 cm) for men and greater than 35 inches (88 cm) for women is an independent risk factor for disease (CDC, 2009). These measurements may not be as useful for those less than 60 inches tall or with a BMI of 35 or above (CDC, 2009). Figure 6-6 shows the proper location to measure waist (abdominal) circumference.

**Midarm circumference (MAC)** is measured in centimeters halfway between the acromion process of the scapula and the olecranon process at the tip of the elbow (see Figure 6-4, A). Combining MAC with TSF measurements allows indirect determination of the arm muscle area (AMA) and

$$\text{AA (mm}^2\text{)} = \frac{\pi}{4} \times d_1^2 \text{ where } d_1 = C_1/\pi$$

$$\text{AMA (mm}^2\text{)} = (C_1 - \pi T)^2/4\pi = (C_1 = \pi T)/12.56$$

$$\text{AFA (mm}^2\text{)} = \text{AA} - \text{AMA}$$

$$\text{Bone-free AMA} = \text{AMA} - 10 \text{ for males}$$

$$\text{Bone-free AMA} = \text{AMA} - 6.5 \text{ for females}$$

**FIGURE 6-7** Upper arm area (AA), upper arm muscle area (AMA), and upper arm fat area (AFA) are derived from measurements of upper arm circumference in centimeters (C1) and triceps skinfold (T) in millimeters.

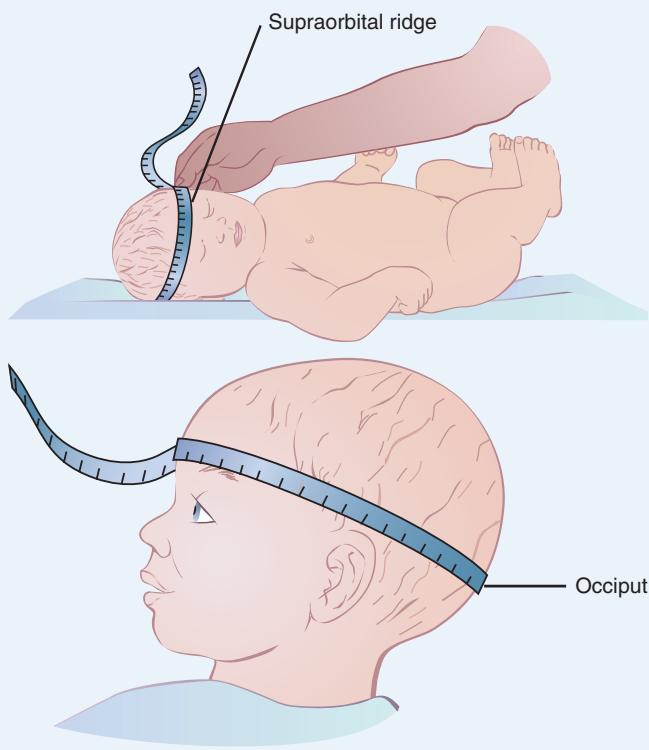

arm fat area (see [Appendices 25 and 26](#)). Bone-free AMA is calculated by using the formula shown in Figure 6-7. For men, a factor of 10 is subtracted from the AMA, whereas for women a factor of 6.5 is subtracted (Frisancho, 1984). The bone-free muscle area (AMA) is a good indication of lean body mass and skeletal protein reserves. The AMA is important in growing children and in evaluating possible protein-energy malnutrition as a result of chronic illness, stress, eating disorders, multiple surgeries, or an inadequate diet.

**Head circumference** measurements are useful in children younger than 3 years of age, primarily as an indicator of nonnutritional abnormalities. Undernutrition must be very severe to affect head circumference; see [Box 6-3, Measuring Head Circumference](#).

### Other Methods of Measuring Body Composition

**Air Displacement Plethysmogram.** **Air displacement plethysmogram (ADP)** relies on measurements of body density to estimate body fat and fat-free masses. Performing an ADP with the BOD-POD device is a densitometry technique found to be an accurate method to measure body composition. ADP appears to be a reliable instrument in body composition assessment; it is of particular interest in the pediatric and obese individual. ADP does not rely on body water content to determine body density and body composition, which makes it potentially useful in those adults with end-stage renal disease (Flakoll et al., 2004). However, further research is needed in understanding possible sources of measurement error (Fields et al., 2005). The use of a BOD-POD is usually based on budget, the patient population, and the experience of the clinician (Figure 6-8).

**Bioelectrical Impedance Analysis.** **Bioelectrical impedance analysis (BIA)** is a body composition analysis technique based on the principle that, relative to water, lean

**BOX 6-3****Measuring Head Circumference****Indications**

Head circumference is a standard measurement for serial assessment of growth in children from birth to 36 months and in any child whose head size is in question.

**Equipment**

Paper or metal tape measure (cloth can stretch) marked in tenths of a centimeter because growth charts are listed in 0.5-cm increments

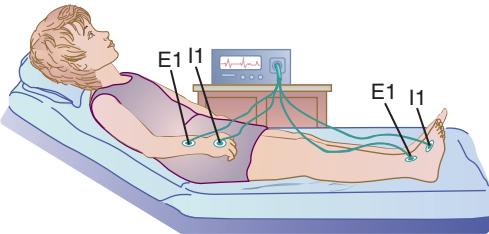

**Technique**

1. The head is measured at its greatest circumference.
2. The greatest circumference is usually above the eyebrows and pinna of the ears and around the occipital prominence at the back of the skull.
3. More than one measurement may be necessary because the shape of the head can affect the location of the maximum circumference.
4. Compare the measurement with the National Center for Health Statistics standard curves for head circumference (see [Appendices 10 and 14](#)).

Data from Hockenberry MJ, Wilson D: Wong's nursing care of infants and children, ed 8, St Louis, 2007, Mosby.

**FIGURE 6-8** The BOD-POD measures body fat and fat-free mass. (*Courtesy COSMED USA, Inc., Concord, CA.*)

**FIGURE 6-9** Bioelectrical impedance analysis.

tissue has a higher electrical conductivity and lower impedance than fatty tissue because of its electrolyte content. BIA has been found to be a reliable measurement of body composition (fat-free mass and fat mass) when compared with BMI or skinfold measurements or even height and weight measurements. BIA involves attaching electrodes to the right hand, wrist, ankle, and foot of a patient and passing a small electrical current through the body (Figure 6-9). The BIA method is popular because it is safe, noninvasive, portable, and rapid. For accurate results the patient should be well hydrated; have not exercised in the previous 4 to 6 hours; and have not consumed alcohol, caffeine, or diuretics in the previous 24 hours. If the person is dehydrated, a higher percentage of body fat than really exists is measured. Fever, electrolyte imbalance, and extreme obesity may also affect the reliability of measurements.

**Dual-Energy X-Ray Absorptiometry.** Dual-energy x-ray absorptiometry (DEXA) assesses bone mineral density and can be used for measuring fat and boneless lean tissue. The energy source in DEXA is an x-ray tube that contains an energy beam. The amount of energy loss depends on

**FIGURE 6-10** A patient undergoing a dual-energy x-ray absorptiometry scan. (*Courtesy of the Division of Nutrition, University of Utah.*)

the type of tissue through which the beam passes; the result can be used to measure mineral, fat, and lean tissue compartments (Russell and Mueller, 2007). DEXA is easy to use, emits low levels of radiation, and is relatively available in the hospital setting, making it a useful tool. However, the patient must remain still for more than a few minutes, which may be difficult for older adults and those in chronic pain. Differences in hydration status and the presence of bone or calcified soft tissue can result in inaccurate measurements (Lee and Nieman, 2003). Figure 6-10 illustrates a DEXA scan.

**Neutron Activation Analysis.** Neutron activation analysis allows measurement of lean body mass. This analysis also distinguishes between intracellular and extracellular components of the body by creating unstable isotopes of calcium, nitrogen, and sodium, and then measuring gamma radiation from the same isotopes (Russell and Mueller, 2007). This type of measurement is expensive and impractical in a daily clinical setting.

**Total Body Potassium.** Total body potassium can be used to study body composition because more than 90% of the body's potassium is found in fat-free tissues. Measurements are made with a special counter that is fitted with multiple gamma-ray detectors interfaced with a computer that is expensive and not always readily available. Not all researchers agree on the exact concentration of potassium in fat-free tissue and the differences between sexes, during the aging process, and in obese individuals.

**Underwater Weighing.** Underwater weighing is a direct measure of determining whole-body density. Densitometry includes underwater (hydrostatic) weighing based on Archimedes' principle: the volume of an object submerged in water equals the volume of water the object displaces. Once the volume and mass are known, the density can be calculated. Although this method is considered the gold standard it is not always practical, involves significant training to perform, and requires considerable cooperation on the

part of those being measured. Subjects must be submerged under water and remain motionless long enough for the measurements to be made (Lee and Nieman, 2003).

**Ultrasound and Magnetic Resonance Imaging.** Magnetic resonance imaging (MRI) can be used to measure the size of visceral organs, the size of the skeleton, and the amount and distribution of intraabdominal fat. MRI has several advantages, two of which are that it is noninvasive and involves no ionizing radiation, which makes it safe for children, females of childbearing age, and multiple studies on the same individual. The disadvantages of MRI include expense and limited availability (Russell and Mueller, 2007).

## THE NUTRITION-FOCUSED PHYSICAL EXAMINATION

The nutrition-focused physical examination is an important component of overall assessment because some nutritional deficiencies may not be identified by other approaches. Some signs of nutritional deficiency are not specific and must be distinguished from those with nonnutritional causal factors.

### Approach

A systems approach is used when performing the examination, which should be conducted in an organized, logical way that progresses from head to toe to ensure efficiency and thoroughness. The examination moves from a global to a more defined or focused examination based on the results of the medical and nutrition histories. The nutrition-focused physical examination is tailored for each patient. In short, every body system may not have to be assessed; clinical judgment guides this decision according to the problems, history, and current complaints of the individual (Hammond, 2006).

### Equipment

The extent of the nutrition-focused physical examination dictates the necessary equipment. Any or all of the following may be used: a stethoscope, a penlight or flashlight, a tongue depressor, scales, a reflex hammer, calipers, a tape measure, a blood pressure cuff, and an ophthalmoscope.

### Examination Techniques and Findings

Four basic physical examination techniques are used during the nutrition-focused physical examination. These techniques include inspection, palpation, percussion, and auscultation (Table 6-3). Appendix 29 discusses the nutrition-focused physical examination in more detail.

Some nutritional findings from the physical examination that should alert the clinician to the need for further assessment and intervention include temporal wasting, proximal muscle weakness, depleted muscle bulk, dehydration, overhydration, poor wound healing, and chewing or swallowing difficulties. The appearance of the skin should be evaluated for any pallor, scaly dermatitis, wounds, quality of wound healing, bruising, and hydration status.

Membranes such as in the conjunctiva or pharynx should be examined for integrity, hydration, pallor, and bleeding. Special attention should be given to the areas where signs of nutritional deficiencies appear most often, such as the skin, hair, teeth, gums, lips, tongue, and eyes. The hair, skin, and mouth are susceptible because of the rapid cell turnover of epithelial tissue. Symptoms of nutrient deficiencies may or may not be apparent during the physical examination, or

**TABLE 6-3****Physical Examination Techniques**

Technique	Description
Inspection	General observation that progresses to a more focused observation using the senses of sight, smell, and hearing; most frequently used technique
Palpation	Tactile examination to feel pulsations and vibrations; assessment of body structures, including texture, size, temperature, tenderness, and mobility
Percussion	Assessment of sounds to determine body organ borders, shape, and position; not always used in a nutrition-focused physical examination
Auscultation	Use of the naked ear or a stethoscope to listen to body sounds (e.g., heart and lung sounds, bowel sounds, blood vessels)

From Hammond K: Nutrition focused physical assessment, Support Line 18(4):4, 1996.

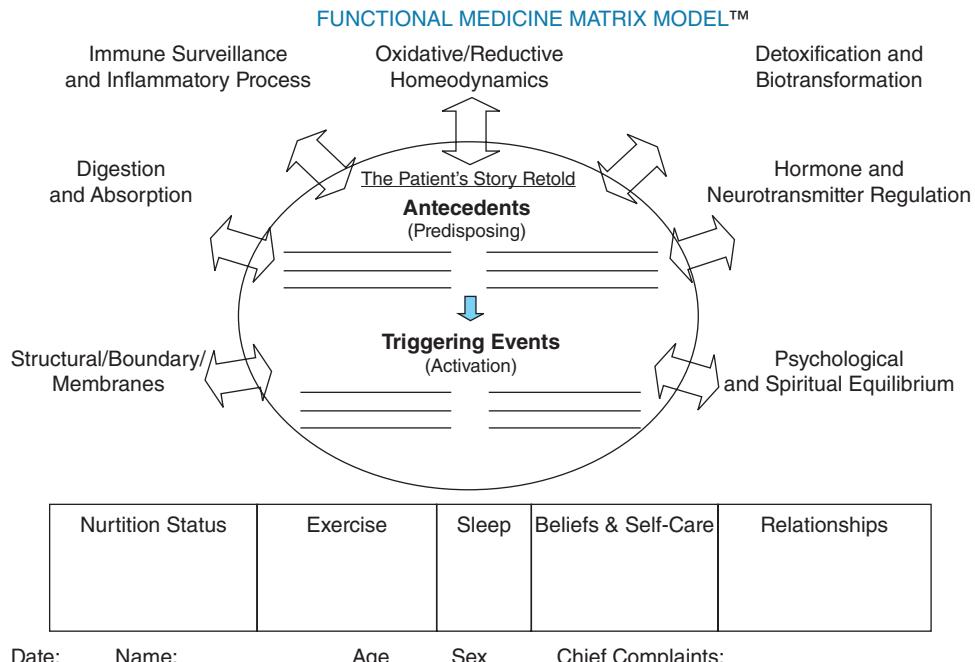

may result from a lack of several nutrients or from nonnutritional causes.

**Other Assessment Measures and Tools****Biochemical Analysis**

Biochemical tests are the most objective and sensitive measures of nutrition status. Not all of them are purely related to nutrition. Caution must be used when interpreting results because they can be affected by disease state and therapies; see Chapter 8.

**FUNCTIONAL NUTRITION ASSESSMENT**

**Functional medicine** is an evolving, evidence-based discipline that treats the body with its mutually interactive systems as a whole, rather than as a set of isolated signs and symptoms. The Institute of Functional Medicine (IFM) promotes an evaluation process that recognizes the biochemical, genetic, and environmental individuality of each person. The focus is patient-centered, not just disease-centered. Lifestyle and health-promoting factors include nutrition, exercise, adequate sleep, healthy relationships, and a positive mind-body-belief system. Assessment in the functional medicine mode identifies the following factors: pattern recognition, under- and overnutrition, reduction of toxin exposures, and antecedents or events in a person's history that may act as triggers for a response beginning a disease process. IFM has established an interdisciplinary Functional Medicine Matrix Model to guide this holistic assessment process (Figure 6-11).

**FIGURE 6-11** The Functional Medicine Matrix for assessment. (Courtesy Institute of Functional Medicine, 2010.)

For dietitians, the **Functional Nutrition Assessment (FNA)** expands traditional assessment by adding cellular, molecular, and genomic data to the process. This expanded determination of nutrition status quantifies the tissue nutrient reserves, cellular function, and genetic potential influenced by the interaction of diet, environment and lifestyle. See *New Directions: Functional Nutrition Assessment*.

## Gastrointestinal Function

Assessment of the capacity for digestion, absorption, and transport as well as the hormonal status provides critical background information as to why a patient may be

malnourished. **Malabsorption** syndrome, in which several nutrients are abnormally absorbed, is the most dramatic. Constipation, diarrhea, excessive vomiting, or flatulence also warrant further analysis. Mucosal changes in the gastrointestinal (GI) tract are indicated by problems such as diarrhea and anorexia. Tests may be done on a stool sample and can reveal excessive amounts of fat, an indication of malabsorption, the status of the GI flora and the amounts and types of bacteria present in the gut. The acidity of the stomach, important for maintaining an optimal milieu for digestion and absorption, can be assessed using manual intragastric titration, which gives an indication of gastric hydrochloric acid secretion.

## ↗ NEW DIRECTIONS

### Functional Nutrition Assessment

by Diana M. Noland, MPH, RD, CCN

The expense of dealing with the global epidemic of chronic disease is forcing national health care systems to refocus on early diagnosis and treatment of these conditions. It is becoming critical for practitioners to understand the prominent role played by diet and lifestyle factors, as well as the interaction between genes and environmental factors. Following the recent recognition of the role of long-latency nutritional insufficiencies, there is also a growing appreciation for the understanding of the molecular mechanisms that underlie chronic disease. These considerations are an important part of the Functional Nutrition Assessment (FNA) approach.

This assessment technique is uniquely suited to the identification of the root causes of chronic disease by integrating traditional dietetic practice with nutritional genomics, the restoration of gastrointestinal function, the quelling of chronic inflammation, and the interpretation of nutritional biomarkers of cellular and molecular dysfunction. The Functional Nutrition Practitioner organizes the data collected from ingestion, digestion and utilization (IDU) factors, leading to identification of the root causes for each individual. Some factors related to chronic disease risk that are examined in the FNA include:

#### Ingestion

Food, fiber, water, supplements, medication  
Intake patterns affected by emotional or disordered eating  
Toxins entering the body via food, skin, inhalants, water, environment (including pesticides and chemicals)

#### Digestion

Adequate microflora  
Allergies  
Genetic enzyme deficits  
Hydration

Infection

Lifestyle—sleep, exercise, stressors

#### Utilization—Cellular and Molecular Functional Relationships

Antioxidants—water-soluble vitamin C, phytonutrients

Methylation and acetylation—dependence on adequate B complex and minerals

Oils and fatty acids—prostaglandin balance, cell membrane function, vitamin E function

Protein metabolism—connective tissue, enzymes, immune function, etc.

Vitamin D—in concert with functional metabolic partner nutrients vitamins A and K

The ability to assess a person's nutrition status has benefited from recent, rapid advances in the science of nutrition, genomics and measurement technologies. A more thorough evaluation of cellular function is possible today. The identification of the human genome and the understanding of epigenetic effects of environment on gene expression have been especially informative. Nutrition assessment has been facilitated by additions to the nutritionist's tool kit, including bioelectric impedance analysis, **functional laboratory testing**, and a more comprehensive health history with triggering events and genetic predisposition.

Thus the FNA method is rapidly gaining acceptance for guidance in the relief of many chronic diseases and conditions with nutritional implications (Jones et al., 2009). By using an IDU approach, dietitians can develop more personalized intervention plans, support the body's natural mechanisms, and restore balance and health (Noland, 2010). In the future, the clinical encounter will require a collaborative, healing partnership. Phytonutrients, personalized dietary advice, exercise and energy requirements, meditation, and yoga may all one day be part of that therapeutic dialogue.

## Handgrip Dynamometry

Handgrip dynamometry can provide a baseline nutritional assessment of muscle function by measuring grip strength and endurance, and is useful in serial measurements. Measurements of handgrip dynamometry are expressed as a percentage of a standard. The assumption is that strong hands reflect strength elsewhere. Decreased grip strength is an important sign of frailty, especially in older adults. The Groningen Fitness Test for the Elderly was developed by Koen and colleagues (2001) for a longitudinal study in the Netherlands of age-related fitness and it continues to be useful. Low grip strength is consistently associated with a greater likelihood of premature mortality, the development of disability, and an increased risk of complications or prolonged length of stay after hospitalization or surgery in middle-aged and older adults (Bohannon, 2008).

## Hydration

It is important to recognize the fluid volume status of an individual during the nutrition-focused physical examination. Fluid disturbances can be associated with other imbalances such as electrolyte imbalance.

## Dehydration

Note excessive loss of water and electrolytes from vomiting, diarrhea, excessive laxative abuse, fistulas, GI suction, polyuria, fever, excessive sweating, edema (third-space fluid shifts), or decreased intake caused by anorexia, nausea,

depression, or inadequate access to fluids. Characteristics include weight loss that occurs over a short period, decreased skin and tongue turgor, dry mucous membranes, postural hypotension, a weak and rapid pulse, slow-filling peripheral veins, a decrease in body temperature (95°–98° F), decreased urine output, elevated hematocrit, cold extremities, disorientation, or a blood urea nitrogen (BUN) level elevated out of proportion to serum creatinine.

## Overhydration

Note any history of renal failure, congestive heart failure, cirrhosis of the liver, or Cushing syndrome, excess use of sodium-containing intravenous fluids, and excessive intake of sodium-containing food or medication products. Characteristics of fluid volume excess include weight gain that occurs over a short period, peripheral edema, distended neck veins, slow emptying of peripheral veins, rales in the lungs, polyuria, ascites, pleural effusion, a bounding and full pulse, decreased BUN, and low hematocrit. Pulmonary edema may occur in severe cases.

## Physical Activity Assessment

Because diet and physical activity are lifestyle and behavioral factors that play a role in the cause and prevention of chronic diseases, inclusion of a physical activity assessment is part of a full nutrition assessment. Many instruments used to measure activity are difficult to use, and are prone to reporting errors. However, dietetic professionals can ask a few questions to gain insight into the activity levels of their clients. Box 6-4 provides a series of questions that can be

### BOX 6-4

#### Physical Activity Assessment Questionnaire

To be considered physically active, **you must get at least:**

- 30 minutes of moderate physical activity on 5 or more days a week, **OR**
- 20 minutes of vigorous physical activity on 3 or more days a week

How physically active do you plan to be over the next 6 months? (*Choose the best answer:*)

- I am not currently active and do not plan to become physically active in the next 6 months.
- I am thinking about becoming more physically active.
- I intend to become more physically active in the next 6 months.
- I have been trying to get more physical activity.
- I am currently physically active and have been for the last 1–5 months.
- I have been regularly physically active for the past 6 months or more.

Compared to how physically active you have been over the last 3 months, how would you describe the last 7 days:

(Check one)

- More active
- Less active
- About the same

Recall your participation in activities or in sedentary behaviors, over the past 24 hours:

- Reading, watching TV, or computer time \_\_\_\_\_ minutes/day
- Fast walking \_\_\_\_\_ minutes/day
- Physical activity (swimming, tennis, racquetball, similar) \_\_\_\_\_ minutes/day
- Other physical activity (describe \_\_\_\_\_) \_\_\_\_\_ minutes/day

**BOX 6-4****Physical Activity Assessment Questionnaire—cont'd**

What are the 3 most important reasons why you would consider increasing your physical activity?

- Improve my health     Control my weight     Lower my stress  
 Look better     Improve my fitness     Feel better  
 Lower my risk     Other: \_\_\_\_\_ of disease

How confident are you that you could increase your physical activity if you decided to do so? (Check one)

- Very confident     Fairly confident  
 Somewhat confident     Not at all confident

Would you consider using a pedometer to count your steps per day? Yes \_\_\_\_ No \_\_\_\_

Record all of your activity—what you did and amount of time spent, for the next two days and review with counselor.

asked to identify the current levels and interest in future activity levels for ambulatory patients and clients.

**Subjective Global Assessment**

The **Subjective Global Assessment (SGA)** is a tool based on history, dietary data, GI symptoms, functional capacity, effects of disease on nutritional requirements, and physical appearance. This tool has been validated and more recently has been shown to correlate well with the nutrition risk index and other assessment data in hospitalized patients (DeLegge and Drake, 2007). Documentation of assessment data using the SGA allows other providers to identify the same factors as problematic, and provides a baseline for comparison in that individual over time (Box 6-5).

Once the nutrition assessment process is complete, the extent of nutritional adequacy, deficiency, or excess should be apparent. Severity of malnutrition can then be classified based on body weight, body fat, somatic and visceral protein stores, and laboratory values. When nutrition problems are noted, the appropriate nutrition diagnoses can be selected and the other steps in the nutrition care process may be implemented accordingly (see Chapter 11). Refer to the most current *International Dietetics and Nutrition Terminology Reference Manual* for updates and guidelines (American Dietetic Association, 2009).

**CLINICAL SCENARIO**

Carl is a 32-year-old man who is 5 ft, 9 in tall. He was diagnosed as having acquired immune deficiency syndrome 1 year ago. In the past year his weight has gradually decreased from a usual weight of 175 lb to the current low of 130 lb. His visceral proteins are depleted, and a triceps skinfold measurement reveals a body fat value that is 55% of standard. Carl's oral intake ability has gradually decreased; he can only take sips of an enteral supplement and occasional bites of food.

**Nutrition Diagnostic Statement**

Inadequate oral food/beverage intake related to poor appetite and inability to eat as evidenced by loss of 45 lb in 12 months and intake much less than requirements.

**Nutrition Care Questions**

1. Is Carl exhibiting a degree of undernutrition? If so, how severe is his malnutrition?
2. Carl's current weight is what percentage of his usual body weight?
3. What is Carl's body mass index?
4. Develop a nutrition assessment questionnaire for Carl.

**BOX 6-5****The Subjective Global Assessment**

Directions: Select appropriate category with a checkmark, or enter numerical values where indicated by #.

**A. History****1. Weight change:**

Overall loss in past 6 months: amount = # \_\_\_\_\_ kg, %loss = # \_\_\_\_\_

Change in past 2 weeks: \_\_\_\_\_ increase, \_\_\_\_\_ no change, \_\_\_\_\_ decrease.

**2. Dietary intake change (relative to normal)**

\_\_\_\_\_ No change

\_\_\_\_\_ Change Duration = # \_\_\_\_\_ weeks.

Type: \_\_\_\_\_ suboptimal solid diet \_\_\_\_\_ full liquid diet \_\_\_\_\_ hypocaloric liquids \_\_\_\_\_ starvation.

**3. Gastrointestinal symptoms (that persisted for >2 weeks)**

\_\_\_\_\_ none, \_\_\_\_\_ nausea, \_\_\_\_\_ vomiting, \_\_\_\_\_ diarrhea, \_\_\_\_\_ anorexia

*Continued*

**BOX 6-5****The Subjective Global Assessment—cont'd**

4. Functional capacity  
 No dysfunction (e.g., full capacity),  
 Dysfunction \_\_\_\_\_ duration = # weeks \_\_\_\_\_  
 type: \_\_\_\_\_ working suboptimally, \_\_\_\_\_ ambulatory, \_\_\_\_\_ bedridden.
5. Disease and its relation to nutritional requirements  
 Primary diagnosis (specify) \_\_\_\_\_  
 Metabolic demand (stress): \_\_\_\_\_ no stress, \_\_\_\_\_ low stress, \_\_\_\_\_ moderate stress, \_\_\_\_\_ high stress.

**B. Physical (for each trait specify: 0 = normal, 1+ = mild, 2+ = moderate, 3+ = severe)**

- # \_\_\_\_\_ loss of subcutaneous fat (triceps, chest)  
# \_\_\_\_\_ muscle wasting (quadriceps, deltoids)  
# \_\_\_\_\_ ankle edema  
# \_\_\_\_\_ sacral edema  
# \_\_\_\_\_ ascites  
SGA rating (select one): \_\_\_\_\_ A = Well nourished  
\_\_\_\_\_ B = Moderately for suspected of being malnourished  
\_\_\_\_\_ C = Severely malnourished

## CHAPTER 7

Pamela Charney, PhD, RD

# Clinical: Water, Electrolytes, and Acid-Base Balance

### KEY TERMS

acid-base balance  
acidemia  
alkalemia  
anion gap  
buffer  
colloidal osmotic pressure  
compensation  
contraction alkalosis  
corrected calcium  
dehydration  
edema  
electrolytes  
extracellular fluid  
extracellular water  
insensible water loss  
interstitial fluid  
intracellular fluid  
intracellular water (ICW)

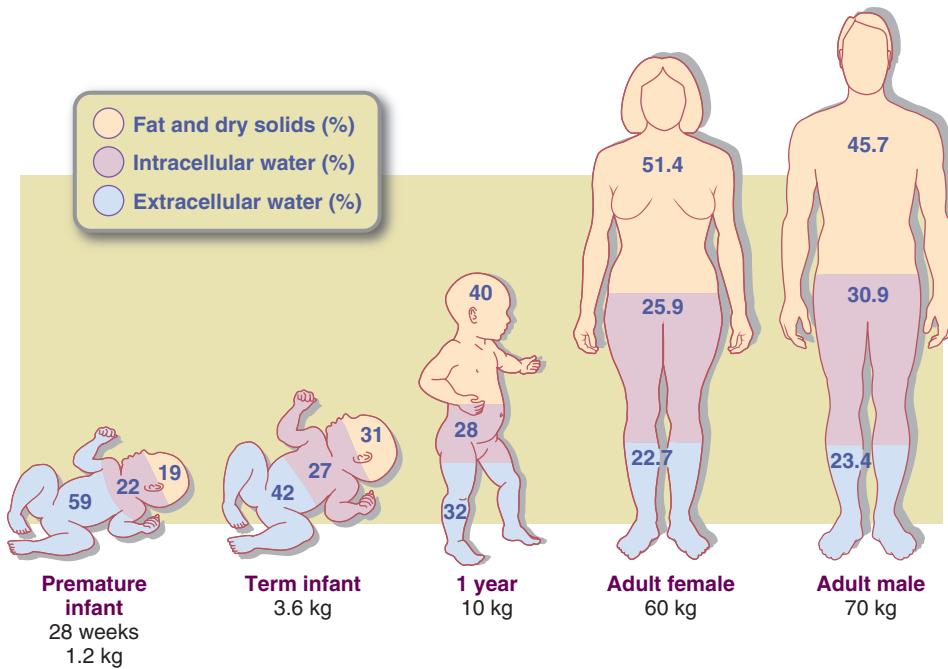

metabolic acidosis  
metabolic alkalosis  
metabolic water  
oncotic pressure  
osmolality  
osmolarity  
osmotic pressure  
renin-angiotensin system  
respiratory acidosis  
respiratory alkalosis  
sensible water loss  
sodium-potassium adenosine triphosphatase (Na/K ATPase) pump  
syndrome of inappropriate antidiuretic hormone secretion (SIADH)  
“third space” fluid  
vasopressin  
water intoxication

The volume, composition, and distribution of body fluids have profound effects on cell function. A stable internal environment is maintained through a sophisticated network of homeostatic mechanisms that are focused on ensuring that water intake and water loss are balanced. Protein-energy malnutrition, disease, trauma, and surgery can disrupt fluid, electrolyte, and acid-base balance and alter the composition, distribution, or amount of body fluids. Even small changes in pH, electrolyte concentrations, and fluid status can adversely affect cell function. If these

derangements are not corrected, severe consequences or death can ensue (Bartelmo and Terry, 2008.)

### BODY WATER

Water is the largest single component of the body. At birth, water accounts for approximately 75% to 85% of total body weight; this proportion decreases with age and adiposity. Water accounts for 60% to 70% of total body weight in the lean adult but only 45% to 55% in the obese adult.

**FIGURE 7-1** Distribution of body water as a percentage of body weight.

Metabolically active cells of the muscle and viscera have the highest concentration of water; calcified tissue cells have the lowest. Total body water is higher in athletes than in non-athletes and decreases with age and diminished muscle mass (Figure 7-1). Although the proportion of body weight accounted for by water varies with age and body fat, there is little day-to-day variation in the percentage of body water in the individual.

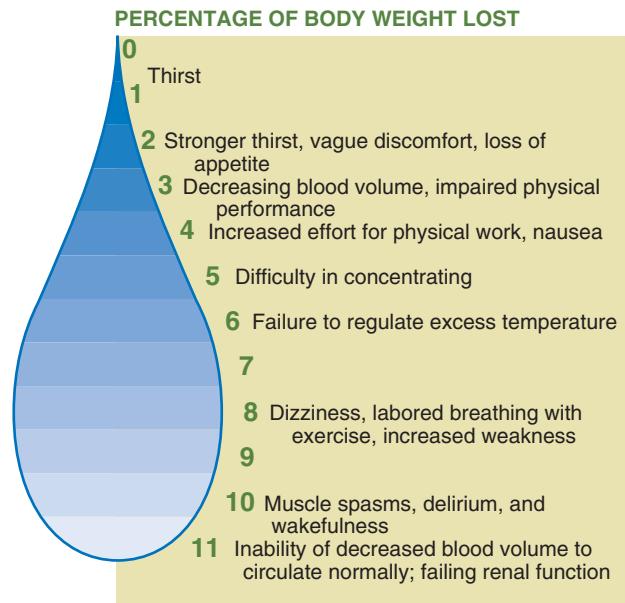

## Functions

Water makes solutes available for cellular reactions. It is a substrate in metabolic reactions and a structural component, providing form to cells. Water is essential for the processes of digestion, absorption, and excretion. It also plays a key role in the structure and function of the circulatory system and acts as a transport medium for nutrients and all body substances.

Water maintains the physical and chemical constancy of intracellular and extracellular fluids and has a direct role in maintaining body temperature. Evaporation of perspiration cools the body during warm weather, preventing or delaying hyperthermia. Loss of 20% of body water (**dehydration**) may cause death; loss of only 10% may lead to damage to essential body systems (Figure 7-2). Healthy adults can live up to 10 days without water, and children can live up to 5 days, whereas one can survive for several weeks without food.

## Distribution

**Intracellular water (ICW)** is contained within cells and accounts for two thirds of total body water. **Extracellular water** in plasma, lymph, secretions, and spinal fluid equals one third of total body water or 20% of body weight. **Extracellular fluid** is the water and dissolved substances in the

**FIGURE 7-2** Adverse effects of dehydration.

plasma, lymph, spinal fluid, and secretions; this includes the **interstitial fluid**, which is the fluid between and around the cells in tissues. While the distribution of body water varies under different circumstances, the total amount in the body remains relatively constant. Water consumed during the day through intake of foods and beverages is balanced by water lost through urination, perspiration, feces, and respiration. **Edema** is the abnormal accumulation of fluid in the intercellular tissue spaces or body cavities.

**TABLE 7-1****Water Balance**

Water Intake and Output (mL)*	Water Source
<b>Water Intake</b>

**Water Balance**

Shifts in water balance can have adverse consequences. Therefore homeostatic regulation by the gastrointestinal (GI) tract, kidneys, and brain keeps body water content fairly constant. The amount of water taken in daily is approximately equivalent to the amount lost (Table 7-1).

**Hormonal Regulation**

Changes in cellular water content are sensed by baroreceptors in the central nervous system that provide feedback to the hypothalamus, close to the centers that regulate the antidiuretic hormone, **vasopressin**. Increased serum osmolality or decreased blood volume lead to its release, signaling

the kidneys to conserve water. When vascular baroreceptors are stimulated by decreased extracellular fluid volume, the kidneys release renin to produce angiotensin II (the **renin-angiotensin system**). Angiotensin II has several functions, including stimulation of vasoconstriction and the thirst centers.

**Water Intake**

The sensation of thirst is a powerful signal to consume fluids. In fact, it controls water intake in healthy individuals. Both cellular dehydration and decreased extracellular fluid volume play a role in stimulating thirst. Sensitivity to thirst is decreased in older individuals, leading to higher risk for water deficits and ensuing dehydration.

Water is ingested as fluid and as part of food (Table 7-2). The oxidation of foods in the body also produces **metabolic water** as an end product. The oxidation of 100 g of fat, carbohydrate, or protein yields 107, 55, or 41 g of water,

respectively, for a total of approximately 200 to 300 mL/day from consumption of the usual diet. When water cannot be ingested via the GI system it must be administered intravenously in the form of salt (saline) solutions, which closely resemble the electrolyte content of body fluids; dextrose solutions; parenteral nutrition; or in blood or plasma as transfusions. Water is absorbed rapidly because it moves freely through membranes by diffusion. This movement is controlled mainly by osmotic forces generated by inorganic ions in solution in the body (see *Clinical Insight: Osmotic Forces*).

### Water Intoxication

**Water intoxication** occurs as a result of water intake in excess of the body's ability to excrete water. The increased **intracellular fluid** volume is accompanied by osmolar dilution. The increased volume of intracellular fluid causes the cells, particularly the brain cells, to swell, leading to headache, nausea, vomiting, muscle twitching, blindness, and convulsions with impending stupor. If left untreated, water intoxication can be fatal. Water intoxication is not commonly seen in normal,

healthy individuals. It may be seen in endurance athletes who consume large amounts of electrolyte-free beverages during events, individuals with psychiatric illness, or as a result of water drinking contests (Goldman, 2009; Rogers and Hew-Butler, 2009).

### Water Elimination

Water loss normally occurs through the kidneys as urine and through the GI tract in the feces (measurable, **sensible water loss**), as well as through air expired from the lungs and water vapor lost through the skin (nonmeasurable, **insensible water loss**) (see Table 7-1). The kidney is the primary regulator of sensible water loss. Under normal conditions the kidneys have the ability to adjust to changes in body water composition by either decreasing or increasing water loss in the urine. Natural diuretics are substances in the diet that increase urinary excretion, such as alcohol, caffeine and some herbs.

Insensible water loss is continuous and usually unconscious. High altitude, low humidity, and high temperatures can increase insensible fluid loss through the lungs and

### CLINICAL INSIGHT

## Osmotic Forces

**Osmotic pressure** is directly proportional to the number of particles in solution and usually refers to the pressure at the cell membrane. It is convenient (although not entirely accurate) to consider the osmotic pressure of intracellular fluid as a function of its potassium content because potassium is the predominant cation there. In contrast, the osmotic pressure of extracellular fluid may be considered relative to its sodium content because sodium is the major cation present in extracellular fluid. Although variations in the distribution of sodium and potassium ions are the principal causes of water shifts between the various fluid compartments, chloride and phosphate also influence water balance. Proteins cannot diffuse because of their size and thus also play a key role in maintaining osmotic equilibrium.

**Oncotic pressure**, or **colloidal osmotic pressure**, is the pressure at the capillary membrane. It is maintained by dissolved proteins in the plasma and interstitial fluids. Oncotic pressure helps to retain water within blood vessels, preventing its leakage from plasma into the interstitial spaces. In patients with an exceptionally low plasma protein content, such as those who are under physiologic stress or have certain diseases, water leaks into the interstitial spaces, causing edema or third spacing; and the fluid is called "**third space**" fluid.

### Osmoles and Milliosmoles

Concentrations of individual ionic constituents of extracellular or intracellular fluids are expressed in terms of milliosmoles per liter (mOsm/L). One mole equals the gram

molecular weight of a substance; when dissolved in 1 L of water, it becomes 1 osmole (osm). One milliosmole (mOsm) equals 1/1000th of an osmole. The number of milliosmoles per liter equals the number of millimoles per liter multiplied by the number of particles into which the dissolved substance dissociates. Thus 1 mmol of a nonelectrolyte (e.g., glucose) equals 1 mOsm; similarly, 1 mmol of an electrolyte containing only monovalent ions (e.g., sodium chloride) equals 2 mOsm. One mOsm dissolved in 1 L of water has an osmotic pressure of 17 mm Hg.

**Osmolality** is a measure of the osmotically active particles per kilogram of the solvent in which the particles are dispersed. It is expressed as milliosmoles of solute per kilogram of solvent (mOsm/kg). **Osmolarity** is the term formerly used to describe concentration—milliosmoles per liter of the entire solution; but osmolality is now the measurement for most clinical work. However, in reference to certain conditions such as hyperlipidemia, it makes a difference whether osmolality is stated as milliosmoles per kilogram of solvent or per liter of solution.

The average sum of the concentration of all the cations in serum is approximately 150 mEq/L. The cation concentration is balanced by 150 mEq/L of anions, yielding a total serum osmolality of approximately 300 mOsm/L. An osmolar imbalance is caused by a gain or loss of water relative to a solute. A key point is that an osmolality of less than 285 mOsm/L generally indicates a water excess; an osmolality of greater than 300 mOsm/L indicates a water deficit.

through sweat. Athletes can lose 3 to 4 lb from fluid loss when exercising in a temperature of 80° F and low humidity or even more at higher temperatures.

The GI tract can be a major source of water loss. Under normal conditions the water contained in the 7 to 9 L of digestive juices and other extracellular fluids secreted daily into the GI tract is almost entirely reabsorbed in the ileum and colon, except for approximately 100 mL that is excreted in the feces. Because this volume of reabsorbed fluid is approximately twice that of the blood plasma, excessive GI fluid losses through diarrhea may have serious consequences, particularly for very young and very old individuals.

Fluid loss through diarrhea is responsible for thousands of children's deaths in developing countries. Oral rehydration therapy with a simple mixture of water, sugar, and salt is highly effective in reducing the number of deaths if instituted early. Other abnormal fluid losses may occur as a result of emesis, hemorrhage, fistula drainage, burn and wound exudates, gastric and surgical tube drainage, and the use of diuretics.

When water intake is insufficient or water loss is excessive, healthy kidneys compensate by conserving water and excreting more concentrated urine. The renal tubules increase water reabsorption in response to the hormonal action of vasopressin. However, the concentration of the urine made by the kidneys has a limit: approximately 1400 mOsm/L. Once this limit has been reached, the body loses its ability to excrete solutes. The ability of the kidneys to concentrate urine may be compromised in older individuals or in young infants, resulting in increased risk of developing dehydration or hypernatremia, especially during illness.

Signs of dehydration include headache, fatigue, decreased appetite, light-headedness, poor skin turgor (although this may be present in well-hydrated older persons), skin tenting on the forehead, concentrated urine, decreased urine output, sunken eyes, dry mucous membranes of the mouth and nose, orthostatic blood pressure changes, and tachycardia (Armstrong, 2005). In a dehydrated person the specific gravity, a measure of the dissolved solutes in urine, increases above the normal levels of 1.010 where the urine becomes remarkably darker (Cheuvront et al, 2010.) High ambient temperature and dehydration adversely affect exercise performance; changes may be mediated by serotonergic and dopaminergic alterations in the central nervous system (Maughan et al., 2007). Fluids of appropriate composition in appropriate amounts are essential. See *Clinical Insight: Water Requirements—When Eight Cups Is Not Enough*.

## ELECTROLYTES

**Electrolytes** are substances that dissociate into positively and negatively charged ions (cations and anions) when dissolved in water. Electrolytes can be simple inorganic salts of sodium, potassium, or magnesium or complex organic molecules; they play a key role in a host of normal metabolic functions (Table 7-3). One milliequivalent (mEq) of any substance has the capacity to combine chemically with 1 mEq of a substance with an opposite charge. For univalent ions (e.g.,  $\text{Na}^+$ ) 1 millimole (mmol) equals 1 mEq; for divalent ions (e.g.,  $\text{Ca}^{++}$ ) 1 mmol equals 2 mEq (see Appendix 3 for conversion guidelines).

The major extracellular electrolytes are sodium, calcium, chloride, and bicarbonate ( $\text{HCO}_3^-$ ). Potassium, magnesium,

### CLINICAL INSIGHT

#### Water Requirements—When Eight Cups Is Not Enough

The body has no provision for water storage; therefore the amount of water lost every 24 hours must be replaced to maintain health and equilibrium. Under ordinary circumstances, a reasonable allowance based on recommended caloric intake is 1 ml/kcal for adults and 1.5 ml/kcal for infants. This translates into approximately 35 ml/kg of usual body weight in adults, 50 to 60 ml/kg in children, and 150 ml/kg in infants.

In most cases a suitable daily allowance for water from all sources, including foods, is approximately 3.7 L (15.5 cups) for men and 2.7 L (11+ cups) for women, depending on body size (Institute of Medicine, 2004). Because solid food provides 19% of total daily fluid intake, this equals 750 ml of water or approximately 3 cups daily. When this is added to the 200–300 mL (approximately 1 cup) of water contributed by oxidative metabolism, men should consume approximately 11.5 cups of fluid daily and women need 7 cups of fluids daily. Total fluid intake comes from drinking water, other liquids, and

food; the AI values for water are for total daily water intake and include all dietary water sources.

Infants need more water because of the limited capacity of their kidneys to handle a large renal solute load, their higher percentage of body water, and their large surface area per unit of body weight. A lactating woman's need for water also increases to approximately 600–700 mL (2.5–3 cups) per day for milk production.

Thirst is a less effective signal to consume water in infants, heavily exercising athletes, sick individuals, and older adults who may have a diminished thirst sensation. Anyone sick enough to be hospitalized, regardless of the diagnosis, is at risk for water and electrolyte imbalance. Older adults are particularly susceptible because of factors such as impaired renal concentrating ability, fever, diarrhea, vomiting, and a decreased ability to care for themselves. In situations involving extreme heat or excessive sweating, thirst may not keep pace with the actual water requirements of the body.

**TABLE 7-3****Normal Electrolyte Concentration of Serum**

Electrolyte	Normal Range
<b>Cations</b>	
Sodium	136-145 mEq/L
Potassium	3.5-5 mEq/L
Calcium	4.5-5.5 mEq/L (9-11 mg/dL)
Magnesium	1.5-2.5 mEq/L (1.8-3 mg/dL)
<b>Anions</b>	
Chloride	96-106 mEq/L
CO <sub>2</sub> (content)	24-28.8 mEq/L
Phosphorus (inorganic)	3-4.5 mg/dL (1.9-2.85 mEq/L as HPO <sub>4</sub> <sup>2-</sup> )
Sulfate (as S)	0.8-1.2 mg/dl (0.5-0.75 mEq/L as SO <sub>4</sub> <sup>2-</sup> )
Lactate	1.8 mEq/L (6-16 mg/dL)
Protein	6 g/dl (14-18 mEq/L); depends on albumin level

CO<sub>2</sub>, Carbon dioxide; HPO<sub>4</sub><sup>2-</sup>, monohydrogen phosphate; SO<sub>4</sub><sup>2-</sup>, sulfate.

and phosphate are the major intracellular electrolytes. These elements, which exist as ions in body fluids, are distributed throughout all body fluids. They maintain physiologic body functions, including osmotic equilibrium, acid-base balance, and intracellular and extracellular concentration differentials. Changes in either intracellular or extracellular electrolyte concentrations can have a major effect on bodily functions. The **sodium-potassium adenosine triphosphatase (Na/K ATPase) pump** closely regulates cellular electrolyte contents by actively pumping sodium out of cells in exchange for potassium. Other electrolytes follow ion gradients.

## Calcium

Although approximately 99% of the body's calcium (Ca<sup>++</sup>) is stored in the bone, the remaining 1% has important physiologic functions. Ionized calcium within the vascular compartment is a cation with a positive charge. Approximately half of the calcium found in the intravascular compartment is bound to the serum protein albumin. Thus when serum albumin levels are low, total calcium levels decrease because of hypoalbuminemia. The **corrected calcium** formula, often used in renal disease is

$$\text{serum calcium} + 0.8 (4 - \text{serum albumin}).$$

The binding ability of calcium and its ionized content in blood have implications for normal homeostatic mechanisms. Blood tests for calcium levels often measure both total and ionized calcium levels. This is because ionized (or free, unbound) calcium is the active form of calcium and is not affected by hypoalbuminemia. In healthy adults, normal levels for serum total calcium are approximately 8.5 to 10.5 mg/dL, whereas normal levels for ionized calcium are 4.5 to 5.5 mEq/L.

Ionized calcium levels are inversely altered by changes in acid-base balance; as serum pH rises, calcium binds with protein, leading to decreased ionized calcium levels. As pH is lowered, the opposite occurs. Because calcium has an important role in cardiac, nervous system, and skeletal muscle function, both hypocalcemia and hypercalcemia can become life-threatening.

## Functions

Calcium is found in bones as part of the compound hydroxyapatite. Outside of the bone, calcium is a second messenger in responding to changes in intracellular calcium content following binding of hormones or proteins to the cell surface (the first messenger). Calcium is also an important factor in regulating cell electroconductivity and in blood clotting.

Calcium content is carefully regulated by the actions of parathyroid hormone (PTH), calcitonin, vitamin D, and phosphorus. When serum calcium levels are low, PTH causes release of calcium from the bones and stimulates increased absorption from the GI tract. Calcitonin works in the opposite direction, shutting off bone calcium release and decreasing GI absorption. Vitamin D stimulates while phosphorus inhibits calcium absorption in the GI tract.

## Absorption and Excretion

Approximately 20% to 60% of dietary calcium is absorbed and is tightly regulated because of the need to maintain steady serum calcium levels in the face of fluctuating intake. The ileum is the most important site of calcium absorption. Calcium is absorbed via passive transport and through a vitamin D-regulated transport system. See Chapter 3.

The kidney is the main site of calcium excretion. The majority of serum calcium is bound to proteins and not filtered by the kidneys; only approximately 100 to 200 mg is excreted in the urine in normal adults.

## Sources

Dairy products are the main source of calcium in the American diet, with some green vegetables, nuts, canned fish including bones, and calcium-extracted tofu having moderate amounts of calcium. Food manufacturers fortify many foods with additional calcium.

## Recommended Intakes

Recommended intakes of calcium range from 1000 to 1300 mg/day, depending on age and gender. An upper limit for daily calcium intake has been estimated to be approximately 2500 mg (see inside cover).

## Sodium

Sodium (Na<sup>+</sup>) is the major cation of extracellular fluid. Normal serum concentration is 136 to 145 mEq/L. Secretions such as bile and pancreatic juice contain substantial amounts of sodium. Approximately 35% to 40% of the total body sodium is in the skeleton; however, most of it is only slowly exchangeable with that in body fluids. Contrary to common belief, sweat is hypotonic and contains a relatively small amount of sodium.

**TABLE 7-4****Dietary Reference Intakes for Sodium, Potassium, and Chloride Daily Intake**

Age	Sodium	Potassium	chloride	Salt (sodium chloride)
Adult 19-49	1.5 g (65 mmol)	4.7 g (120 mmol)	2.3 g (65 mmol)	3.8 g (65 mmol)
Adult 50-70	1.3 g (55 mmol)	4.7 g (120 mmol)	2.0 g (55 mmol)	3.2 g (55 mmol)
Adult 71	1.2 g (50 mmol)	4.7 g (120 mmol)	1.8 g (50 mmol)	2.9 g (50 mmol)
UL	2.3 g (100 mmol)			

Institute of Medicine, Food and Nutrition Board: Dietary reference intakes for water, potassium, sodium, chloride, and sulfate, Washington, DC, 2004, National Academies Press.

UL, Tolerable upper intake level.

## Functions

As the predominant ion of the extracellular fluid, sodium thus regulates both extracellular and plasma volume. Sodium is also important in neuromuscular function and maintenance of acid-base balance. Maintenance of serum sodium levels is vital, because severe hyponatremia can lead to seizures, coma and death.

Extracellular sodium concentrations are much higher than intracellular levels (normal serum sodium is approximately 135 mEq/L whereas intracellular levels are approximately 10 mEq/L). The Na/K ATPase pump is an active transport system that works to keep sodium outside the cell through exchange with potassium. The Na/K ATPase pump requires carriers for both sodium and potassium along with energy for proper function. Exportation of sodium from the cell is the driving force for facilitated transporters that import glucose, amino acids, and other nutrients into the cells.

## Absorption and Excretion

Sodium is readily absorbed from the intestine and carried to the kidneys, where it is filtered and returned to the blood to maintain appropriate levels. The amount absorbed is proportional to the intake in healthy adults.

Approximately 90% to 95% of normal body sodium loss is through the urine; the rest is lost in feces and sweat. Normally the quantity of sodium excreted daily is equal to the amount ingested. Sodium excretion is maintained by a mechanism involving the glomerular filtration rate, the cells of the juxtaglomerular apparatus of the kidneys, the renin-angiotensin-aldosterone system, the sympathetic nervous system, circulating catecholamines, and blood pressure.

Sodium balance is regulated in part by aldosterone, a mineralocorticoid secreted by the adrenal cortex. When blood sodium levels rise, the thirst receptors in the hypothalamus stimulate the thirst sensation. Ingestion of fluids returns sodium levels to normal. Under certain circumstances, sodium and fluid regulation can be disrupted, resulting in abnormal blood sodium levels. The **syndrome of inappropriate antidiuretic hormone secretion (SIADH)** is characterized by concentrated, low-volume urine and dilutional hyponatremia as water is retained. SIADH can result

from central nervous system disorders, pulmonary disorders, tumors, and certain medications. See [Chapter 36](#).

Estrogen, which is slightly similar to aldosterone, also causes sodium and water retention. Changes in water and sodium balance during the menstrual cycle, during pregnancy, and while taking oral contraceptives are partially attributable to changes in progesterone and estrogen levels.

## Dietary Reference Intakes

Actual minimum requirements for sodium are not known but have been estimated to be as low as 200 mg/day. Estimated adequate intakes (AIs) for sodium were published in the 2004 Dietary Reference Intakes ([Institute of Medicine, 2004](#)). The mean daily salt intake in Western societies is approximately 10 to 12 g (4 to 5 g of sodium) per capita, far in excess of the estimated minimum requirements and even in excess of the AIs for sodium of 1.2 to 1.5 g per day, depending on age, with lower amounts recommended for the elderly ([Table 7-4](#)).

Approximately 3 g of the daily salt intake exists naturally in foods, 3 g is added during processing, and 4 g is added by the individual. Increased reliance on restaurants, fast food, and commercially prepared convenience foods has contributed to this high per capita salt and thus sodium intake.

Healthy kidneys are usually able to excrete excess sodium intake; however, there is concern about persistent excessive sodium intake, which has been implicated in development of hypertension. See [Chapter 34](#). In addition to its role in hypertension, excessive salt intake has been associated with increased urinary calcium excretion ([Teucher and Fairweather-Tait, 2003](#)) (see [Chapter 36](#)) and some cases of osteoporosis ([He and MacGregor, 2010](#)). The dietary reference intakes (DRI) give an upper limit of 2.3 g of sodium per day (or 5.8 g sodium chloride per day), given the potential role of sodium in hypertension ([Joint National Committee, 2003](#)).

## Sources

The major source of sodium is sodium chloride, or common table salt, of which sodium constitutes 40% by weight. Protein foods generally contain more naturally existing sodium than do vegetables and grains, whereas fruits contain

little or none. The addition of table salt, flavored salts, flavor enhancers, and preservatives during food processing accounts for the high sodium content of most convenience and fast-food products. For instance,  $\frac{1}{2}$  cup of frozen vegetables prepared without salt contains 10 mg of sodium, whereas  $\frac{1}{2}$  cup of canned vegetables contains approximately 260 mg of sodium. Similarly, 1 ounce of plain meat contains 30 mg of sodium, whereas 1 ounce of luncheon meat contains approximately 400 mg of sodium. The larger-portion sizes that are being offered by dining establishments to consumers are increasing the sodium intake even more.

## Magnesium

The adult human body contains approximately 24 g of magnesium, which is the second most prevalent intracellular cation. Approximately half of the body's magnesium is located in bone, whereas another 45% resides in soft tissue; only 1% of the body's magnesium content is in the extracellular fluids (Rude, 2000). Normal serum magnesium levels are approximately 1.7 to 2.5 mEq/L; however, approximately 70% of serum magnesium is free or ionized. The remainder is bound to proteins and is not active.

### Function

Magnesium ( $Mg^{++}$ ) is an important cofactor in many enzymatic reactions in the body and is also important in bone metabolism as well as central nervous system and cardiovascular function. Many of the enzyme systems regulated by magnesium are involved in nutrient metabolism and nucleic acid synthesis, leading to the body's need to carefully regulate magnesium status. As with calcium, severe hypomagnesemia or hypermagnesemia can have life-threatening sequelae.

Intakes of  $Mg^{++}$ , potassium, fruits, and vegetables have been associated with higher alkaline status and a subsequent beneficial effect on bone health; enhanced mineral-water consumption may be an easy, inexpensive way to reduce the onset of osteoporosis (Wynn et al., 2010). See *Clinical Insight: Urinary pH—How Does Diet Affect It?* in Chapter 36.

### Absorption and Excretion

Approximately one third of ingested magnesium is absorbed. Although magnesium absorption occurs throughout the GI tract, absorption is optimized in the ileum and distal jejunum through both passive and active mechanisms. Magnesium absorption is regulated to maintain serum levels; if levels drop, more is absorbed and if levels increase, less is absorbed. The kidney is the major regulator of magnesium excretion.

### Sources

Magnesium is found in a wide variety of foods, making an isolated magnesium deficiency unlikely in otherwise healthy individuals. Highly processed foods tend to have lower magnesium content, whereas green leafy vegetables, legumes, and whole grains are good sources. The high magnesium content of vegetables helps to alleviate some concerns about the potential for phytate binding.

### Dietary Reference Intakes

The recommended intake of magnesium ranges from 310 to 420 mg/day, depending on age and gender (see tables on inside front cover).

## Phosphorus

Phosphorus is an important constituent of the intracellular fluid and in its role in ATP is vital in energy metabolism. In addition, phosphorus is important in bone metabolism. Approximately 80% of the body's phosphorus is found in bones. Phosphorus is found in the body as phosphate—the terms are often used interchangeably. Normal levels for serum phosphorus are between 2.4 and 4.6 mg/dL.

### Functions

Large amounts of free energy are released when the phosphate bonds in ATP are split. In addition to this role, phosphorus is vital for cellular function in phosphorylation and dephosphorylation reactions, as a buffer in acid-base balance, and in cellular structure as part of the phospholipids membrane. Because of the vital role that phosphorus plays in energy production, severe hypophosphatemia can be a life-threatening event.

### Absorption and Excretion

Phosphorus absorption is fairly efficient and is related to intake at most intake levels. The kidney is the major site of phosphorus excretion.

### Sources

Phosphorus is mainly found in animal products, including meats and milk; some dried beans are also good sources.

### Dietary Reference Intakes

The recommended intake of phosphorus is approximately 700 mg/day, depending on age and gender, with an upper limit of 3500 to 4000 mg. See tables on inside front cover.

## Potassium

Potassium ( $K^+$ ), the major cation of intracellular fluid, is present in small amounts in extracellular fluid. The normal serum potassium concentration is 3.5 to 5 mEq/L.

### Functions

With sodium, potassium is involved in maintaining a normal water balance, osmotic equilibrium, and acid-base balance. In addition to calcium, it is important in the regulation of neuromuscular activity. Concentrations of sodium and potassium determine membrane potentials in nerves and muscle. Potassium also promotes cellular growth. The potassium content of muscle is related to muscle mass and glycogen storage; therefore, if muscle is being formed, an adequate supply of potassium is essential. Potassium has an integral role in the Na/K ATPase pump. Both hypokalemia and hyperkalemia can have devastating cardiac implications.

## Absorption and Excretion

Potassium is readily absorbed from the small intestine. Approximately 80% to 90% of ingested potassium is excreted in the urine; the remainder is lost in the feces. The kidneys maintain normal serum levels through their ability to filter, resorb, and excrete potassium under the influence of aldosterone. Ionized potassium is excreted in place of ionized sodium through the renal tubule exchange mechanism.

## Sources

As a rule, fruits, vegetables, fresh meat, and dairy products are good sources of potassium. Box 7-1 categorizes select foods according to their potassium content.

## Dietary Reference Intakes

The AI level for potassium for adults is 4700 mg/day. No upper limit has been set. Potassium intake is inadequate in as many as 50% of adult Americans. The reason for the poor potassium intakes is simply inadequate consumption of fruits and vegetables. Insufficient potassium intakes have been linked to hypertension and cardiac arrhythmia.

## ACID-BASE BALANCE

An acid is any substance that tends to release hydrogen ions in solution, whereas a base is any substance that tends to accept hydrogen ions in solution. The hydrogen ion concentration  $[H^+]$  determines acidity. Because the magnitude of hydrogen ion concentration is small compared with that of other serum electrolytes, acidity is more readily expressed in terms of pH units. A low blood pH indicates a higher hydrogen ion concentration and greater acidity, whereas a high pH value indicates a lower hydrogen ion concentration and greater alkalinity.

**Acid-base balance** is the dynamic equilibrium state of hydrogen ion concentration. Maintaining the arterial blood pH level within the normal range of 7.35 to 7.45 is crucial for many physiologic functions and biochemical reactions. Regulatory mechanisms of the kidneys, lungs, and buffering systems enable the body to maintain the blood pH level despite the enormous acid load from food consumption and tissue metabolism. A disruption of the acid-base balance occurs when acid or base losses or gains exceed the body's regulatory capabilities, or when normal regulatory mechanisms become ineffective. These regulatory disturbances may develop in association with certain diseases, toxin ingestion, shifts in fluid status, and certain medical and surgical treatments (Table 7-5). If a disrupted acid-base balance is left untreated, multiple detrimental effects ranging from electrolyte abnormalities to death can ensue.

## Acid Generation

Acids are introduced exogenously through the ingestion of food, acid precursors, and toxins. They are also generated endogenously through normal tissue metabolism. Fixed acids such as phosphoric and sulfuric acids are produced from the metabolism of phosphate-containing substrates and sulfur-containing amino acids, respectively. Organic

acids such as lactic and keto acids typically accumulate only during exercise, acute illness, or fasting. Carbon dioxide ( $CO_2$ ), a volatile acid, is generated from the oxidation of carbohydrates, amino acids, and fat. Under normal conditions, the body is able to maintain normal acid-base status through a wide range of acid intake from foods. See *Clinical Insight: Urinary pH—How Does Diet Affect It?* in Chapter 36 for the acid and alkaline effects of foods.

## Regulation

Various regulatory mechanisms maintain the pH level within very narrow physiologic limits. At the cellular level, **buffer** systems composed of weak acids or bases and their corresponding salts minimize the effect on pH of the addition of a strong acid or base. The buffering effect involves formation of a weaker acid or base in an amount equivalent to the strong acid or base that has been added to the system (Figure 7-3).

Proteins and phosphates are the primary intracellular buffers, whereas the  $HCO_3^-$  and carbonic acid ( $H_2CO_3$ ) system is the primary extracellular buffer. The acid-base balance is also maintained by the kidneys and lungs. The kidneys regulate hydrogen ion ( $H^+$ ) secretion and  $HCO_3^-$  resorption. The lungs control alveolar ventilation by altering either the depth or rate of breathing. In turn, changes in breathing alter the amount of carbon dioxide expired.

## ACID-BASE DISORDERS

Acid-base disorders can be differentiated based on whether they have metabolic or respiratory causes. The evaluation of acid-base status requires analysis of serum electrolytes and arterial blood gas (ABG) values (Table 7-6). Metabolic acid-base imbalances result in changes in  $HCO_3^-$  (i.e., base) levels, which are reflected in the total carbon dioxide ( $TCO_2$ ) portion of the electrolyte profile.  $TCO_2$  includes  $HCO_3^-$ ,  $H_2CO_3$ , and dissolved carbon dioxide; however, all but 1 to 3 mEq/L is in the form of  $HCO_3^-$ . Thus, for ease of interpretation,  $TCO_2$  should be equated with  $HCO_3^-$ . Respiratory acid-base imbalances result in changes in the partial pressure of dissolved carbon dioxide ( $Pco_2$ ). This is reported in the ABG values in addition to the pH, which reflects the overall acid-base status.

## Metabolic Acidosis

**Metabolic acidosis** results from increased generation or accumulation of acids or loss of base (i.e.,  $HCO_3^-$ ) in the extracellular fluids. Simple, acute metabolic acidosis results in a low blood pH, or **acidemia**. Examples of metabolic acidosis include diabetic ketoacidosis, lactic acidosis, toxin ingestion, uremia, and excessive  $HCO_3^-$  loss via the kidneys or intestinal tract. Multiple deaths have previously been attributed to lactic acidosis caused by administration of parenteral nutrition devoid of thiamin. In patients with metabolic acidosis, the anion gap is calculated to help determine cause and appropriate treatment. The **anion gap** is a measurement of the interval between the sum of "routinely measured" cations minus the sum of the "routinely measured" anions in the blood.

**BOX 7-1****Classification of Select Foods by Potassium Content**

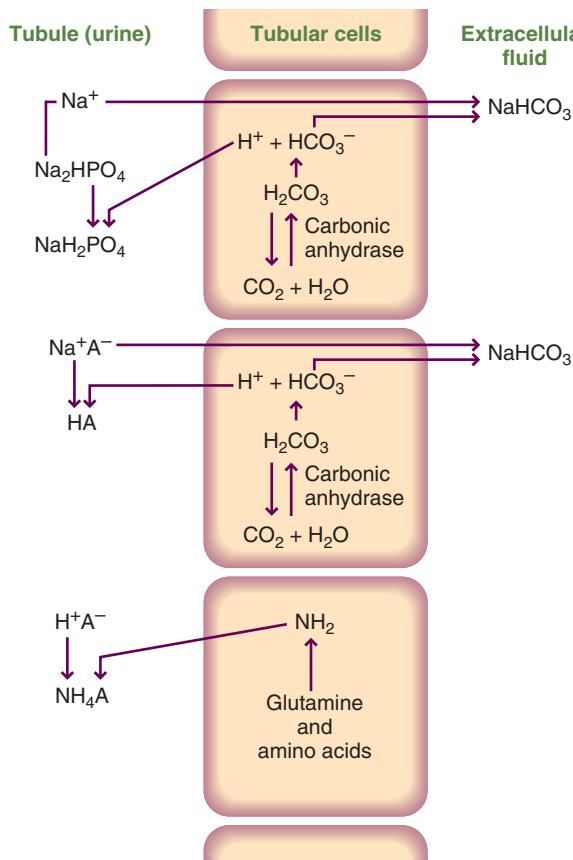

<b>Low (0-100 mg/serving)*</b>	<b>Medium (100-200 mg/serving)*</b>	<b>High (200-300 mg/serving)*</b>	<b>Very High (&gt;300 mg/serving)*</b>
<b>Fruits</b>	<b>Fruits</b>	<b>Fruits</b>	<b>Fruits</b>
Applesauce	Apple, 1 small	Apricots, canned	Avocados, $\frac{1}{4}$ small
Blueberries	Apple juice	Grapefruit juice	Banana, 1 small
Cranberries	Apricot nectar	Kiwi, $\frac{1}{2}$ medium	Cantaloupe, $\frac{1}{4}$ small
Lemon, $\frac{1}{2}$ medium	Blackberries	Nectarine, 1 small	Dried fruit, $\frac{1}{4}$ cup
Lime, $\frac{1}{2}$ medium	Cherries, 12 small	Orange, 1 small	Honeydew melon, $\frac{1}{8}$ small
Pears, canned	Fruit cocktail	Orange juice	Mango, 1 medium
Pear nectar	Grape juice	Peach, fresh, 1 medium	Papaya, $\frac{1}{2}$ medium
Peach nectar	Grapefruit, $\frac{1}{2}$ small	Pear, fresh, 1 medium	Prune juice
	Grapes, 12 small		
	Mandarin oranges		
	Peaches, canned		
	Pineapple, canned		
	Plum, 1 small		
	Raspberries		
	Rhubarb		
	Strawberries		
	Tangerine, 1 small		
	Watermelon, 1 cup		
<b>Vegetables</b>	<b>Vegetables</b>	<b>Vegetables</b>	<b>Vegetables</b>
Cabbage, raw	Asparagus, frozen	Asparagus, fresh, cooked, 4 spears	Artichoke, 1 medium
Cucumber slices	Beets, canned	Beets, fresh, cooked	Bamboo shoots, fresh
Green beans, frozen	Broccoli, frozen	Brussels sprouts	Beet greens, $\frac{1}{4}$ cup
Leeks	Cabbage, cooked	Kohlrabi	Corn on the cob, 1 ear
Lettuce, iceberg, 1 cup	Carrots	Mushrooms, cooked	Chinese cabbage, cooked
Water chestnuts, canned	Cauliflower, frozen	Okra	Dried beans
Bamboo shoots canned	Celery, 1 stalk	Parsnips	Potatoes, baked, $\frac{1}{2}$ medium
	Corn, frozen	Potatoes, boiled or mashed	Potatoes, French fries, 1 oz
	Eggplant	Pumpkin	Spinach
	Green beans, fresh raw	Rutabagas	Sweet potatoes, yams
	Mushrooms, fresh raw		Swiss chard, $\frac{1}{4}$ cup
	Onions		Tomato, fresh, sauce, or juice;
	Peas		tomato paste, 2 tbsp
	Radishes		Winter squash
	Turnips		
	Zucchini, summer squash		
<b>Miscellaneous</b>	<b>Miscellaneous</b>	<b>Miscellaneous</b>	<b>Miscellaneous</b>
	Granola	Bouillon, low sodium, 1 cup	
	Nuts and seeds, 1 oz	Cappuccino, 1 cup	
	Peanut butter, 2 tbsp	Chili, 4 oz	
	Chocolate, $1\frac{1}{2}$ -oz bar	Coconut, 1 cup	
		Lasagna, 8 oz	
		Milk, chocolate milk, 1 cup	
		Milkshakes, 1 cup	
		Molasses, 1 tbsp	
		Pizza, 2 slices	
		Salt substitutes, $\frac{1}{4}$ tsp	
		Soy milk, 1 cup	
		Spaghetti, 1 cup	
		Yogurt, 6 oz	

\*One serving equals  $\frac{1}{2}$  cup unless otherwise specified.

**TABLE 7-5****Four Major Acid-Base Imbalances**

Acid-base Imbalance	Plasma pH	Primary Disturbance	Compensation	Possible Causes
<b>Respiratory</b>				
Respiratory acidosis	Low	Increased $\text{Pco}_2$	Increased renal net acid excretion with resulting increase in serum bicarbonate	Emphysema, COPD, neuromuscular disease in which respiratory function is impaired, excessive retention of $\text{CO}_2$
Respiratory alkalosis	High	Decreased $\text{Pco}_2$	Decreased renal net acid excretion with resulting decrease in serum bicarbonate	Aftermath of intense exercise, anxiety, early sepsis, excessive expiration of $\text{CO}_2$ and $\text{H}_2\text{O}$
<b>Metabolic</b>				
Metabolic acidosis	Low	Decreased $\text{HCO}_3^-$	Hyperventilation with resulting low $\text{Pco}_2$	Diarrhea; uremia; ketoacidosis from uncontrolled diabetes mellitus; starvation; high-fat, low-carbohydrate diet; drugs
Metabolic alkalosis	High	Increased $\text{HCO}_3^-$	Hypoventilation with resulting increase in $\text{Pco}_2$	Diuretics use, increased ingestion of alkali, loss of chloride, vomiting

$\text{CO}_2$ , Carbon dioxide; COPD, chronic obstructive pulmonary disease;  $\text{H}_2\text{O}$ , water;  $\text{HCO}_3^-$ , bicarbonate;  $\text{Pco}_2$ , carbon dioxide pressure.

**FIGURE 7-3** Generation of sodium bicarbonate and clearance of hydrogen ion concentration by the three buffer systems that function in the kidney. HA, Any acid in the body.

**TABLE 7-6****Normal Arterial Blood Gas Values**

Clinical Test	ABG Value
pH	7.35-7.45
$\text{Pco}_2$	35-45 mm Hg
$\text{Po}_2$	80-100 mm Hg
$\text{HCO}_3^-$	22-26 mEq/L
$\text{O}_2$ saturation	>95%

ABG, Arterial blood gas;  $\text{HCO}_3^-$ , bicarbonate;  $\text{O}_2$ , oxygen;  $\text{Pco}_2$ , carbon dioxide pressure;  $\text{Po}_2$ , oxygen pressure.

$$\text{Anion gap} = (\text{Na}^+ + \text{K}^+) - (\text{Cl}^- + \text{HCO}_3^-)$$

in which  $\text{Na}^+$  is sodium,  $\text{K}^+$  is potassium,  $\text{Cl}^-$  is chloride, and  $\text{HCO}_3^-$  is bicarbonate. Normal is 12 to 14 mEq/L.

Anion gap metabolic acidosis occurs when a decrease in  $\text{HCO}_3^-$  concentration is balanced by increased acid anions other than chloride. This causes the calculated anion gap to exceed the normal range of 12 to 14 mEq/L. This normochloremic metabolic acidosis may develop in association with the following conditions, represented by the acronym MUD PILES (Wilson, 2003):

Methanol ingestion	Paraldehyde ingestion
Uremia	Iatrogenic
Diabetic ketoacidosis	Lactic acidosis
	Ethylene glycol or ethanol ingestion
	Salicylate intoxication

Nongap metabolic acidosis occurs when a decrease in  $\text{HCO}_3^-$  concentration is balanced by an increase in chloride concentration, resulting in a normal anion gap. This hyperchloremic metabolic acidosis, may develop in association with the following, represented by the acronym USED CARP) (Wilson, 2003):

Urterosigmoidostomy	Carbonic anhydrase inhibitor
Small bowel fistula	Adrenal insufficiency
Extra chloride ingestion	Renal tubular acidosis
Diarrhea	Pancreatic fistula

## Metabolic Alkalosis

**Metabolic alkalosis** results from the administration or accumulation of  $\text{HCO}_3^-$  (i.e., base) or its precursors, excessive loss of acid (e.g., during gastric suctioning), or loss of extracellular fluid containing more chloride than  $\text{HCO}_3^-$  (e.g., from villous adenoma or diuretic use). Simple, acute metabolic alkalosis results in a high blood pH, or **alkalemia**. Metabolic alkalosis may also result from volume depletion; decreased blood flow to the kidneys stimulates reabsorption of sodium and water, increasing  $\text{HCO}_3^-$  reabsorption. This condition is known as **contraction alkalosis**. Alkalosis can also result from severe hypokalemia (serum potassium concentration  $<2$  mEq/L). As potassium moves from the intracellular to the extracellular fluid, hydrogen ions move from the extracellular to the intracellular fluid to maintain electroneutrality. This process produces intracellular acidosis, which increases hydrogen ion excretion and  $\text{HCO}_3^-$  reabsorption by the kidneys.

## Respiratory Acidosis

**Respiratory acidosis** is caused by decreased ventilation and consequent carbon dioxide retention. Simple, acute respiratory acidosis results in a low pH, or acidemia. Acute respiratory acidosis can occur as a result of sleep apnea; asthma; aspiration of a foreign object; or acute respiratory distress syndrome, also known as *adult respiratory distress syndrome*. Chronic respiratory acidosis is associated with obesity hypoventilation syndrome, chronic obstructive pulmonary disease or emphysema, certain neuromuscular diseases, and starvation cachexia.

## Respiratory Alkalosis

**Respiratory alkalosis** results from increased ventilation and elimination of carbon dioxide. The condition may be mediated centrally (e.g., from head injury, pain, anxiety, cerebrovascular accident, or tumors) or by peripheral stimulation (e.g., from pneumonia, hypoxemia, high altitudes, pulmonary embolism, congestive heart failure, or interstitial lung disease). Simple, acute respiratory alkalosis results in a high pH, or alkalemia.

## Compensation

When an acid-base imbalance occurs, the body attempts to restore the normal pH by developing an opposite acid-base

## CLINICAL SCENARIO

Mary has been admitted to your hospital through the Emergency Room. She was running in the local marathon and collapsed. Her labs are, as follows: plasma sodium 120 mEq/L, other electrolytes are normal. Mary states that she drank a liter of water during her run. The doctor indicates that Mary is suffering from exercise-induced hyponatremia.

### Nutrition Diagnostic Statement

Altered nutritional labs related to excessive fluid intake as evidenced by low plasma sodium (120 mEq/L) and collapse during a marathon.

### Nutrition Care Questions

1. Would you offer Mary a sports drink? Why or why not?
2. What happens to the body when the kidneys cannot excrete excess fluid?
3. What tips would you suggest to Mary for her next marathon?

imbalance to offset the effects of the primary disorder, a response known as **compensation**. For example, the kidneys of a patient with a primary respiratory acidosis (decreased pH) compensate by increasing  $\text{HCO}_3^-$  reabsorption, thereby creating a metabolic alkalosis. This response helps to increase the pH. Similarly, in response to a primary metabolic acidosis (decreased pH), the lungs compensate by increasing ventilation and carbon dioxide elimination, thereby creating a respiratory alkalosis. This compensatory respiratory alkalosis helps to increase pH.

Respiratory compensation for metabolic acid-base disturbances occurs quickly—within minutes. In contrast, renal compensation for respiratory acid-base imbalances may take 3 to 5 days to be maximally effective. Compensation does not always occur; and when it does, it is not completely successful (i.e., does not result in a pH of 7.4). The pH level still reflects the underlying primary disorder. It is imperative to distinguish between primary disturbances and compensatory responses because treatment is always directed toward the primary acid-base disturbance and its underlying cause. As the primary disturbance is treated, the compensatory response corrects itself. Predictive values for compensatory responses are available to differentiate between primary acid-base imbalances and compensatory responses (Whitmire, 2002). Clinicians may also use tools such as clinical algorithms.

## CHAPTER 8

Mary Demarest Litchford, PhD, RD, LDN

# Clinical: Biochemical Assessment

### KEY TERMS

25-hydroxy vitamin D (25-[OH]D<sub>3</sub>)  
albumin  
analyte  
anemia of chronic and inflammatory diseases (ACD)  
apolipoprotein E (apoE) phenotype  
basic metabolic panel (BMP)  
complete blood count (CBC)  
comprehensive metabolic panel (CMP)  
C-reactive protein (CRP)  
creatinine  
differential count  
ferritin  
functional assay  
hematocrit (Hct)  
hemoglobin (Hgb)  
hemoglobin A1C (Hgb A1C)  
high-sensitivity CRP (hs-CRP)

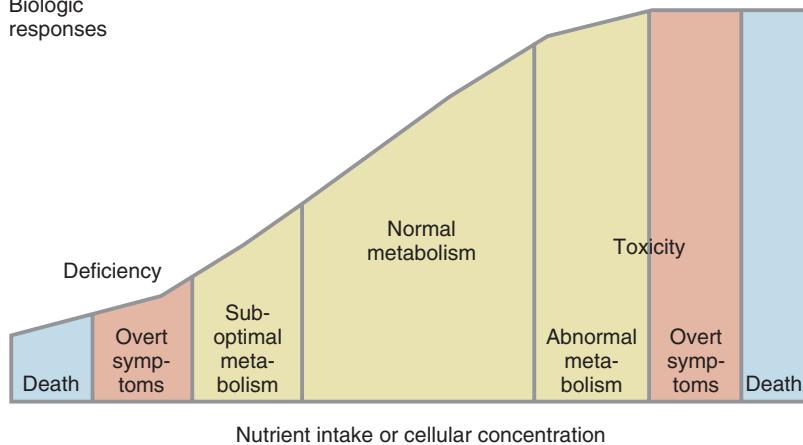

homocysteine  
macrocytic anemia  
microcytic anemia  
negative acute-phase proteins  
nutrition-specific laboratory data  
osteocalcin  
oxidative stress  
positive acute-phase proteins  
prealbumin (PAB)  
reactive oxygen species (ROS)  
retinol  
retinol-binding protein (RBP)  
static assay  
total iron-binding capacity (TIBC)  
transferrin  
transthyretin (TTHY)  
urinalysis

Laboratory tests are ordered to diagnose diseases, support nutrition diagnoses, monitor medication effectiveness, and evaluate nutrition care process (NCP) interventions. Acute illness or injury can trigger dramatic changes in laboratory test results, including rapidly deteriorating nutrition status. However, chronic diseases that develop slowly over time also influence these results, making them useful in preventive care. Laboratory test results provide objective data to use in the NCP. Furthermore, because numeric values do not themselves connote personal judgment, this data can often be shared with a patient without implicit or perceived blame.

### DEFINITIONS AND USEFULNESS OF NUTRITION LABORATORY DATA

Laboratory assessment is a stringently controlled process. It involves comparing control samples with predetermined substance or chemical constituent (**analyte**) concentrations with every patient specimen. The results obtained must compare favorably with predetermined acceptable values before the patient data can be considered valid. Laboratory data are the only objective data used in nutritional assessment that are “controlled”—that is, the validity of the

**FIGURE 8-1** The size of a nutrient pool can vary continuously from frankly deficient, to adequate, to toxic.

method of its measurement is checked each time a specimen is assayed by also assaying a sample with a known value.

Laboratory-based nutritional testing, used to estimate nutrient availability in biologic fluids and tissues, is critical for assessment of both clinical and subclinical nutrient deficiencies. As shown in Figure 8-1, the size of a nutrient pool can vary continuously from frankly deficient to adequate to toxic. Most of these states can be assessed in the laboratory so that nutritional intervention can occur before a clinical or anthropometric change or a frank deficiency occurs (Litchford, 2009). Single test results must be evaluated in light of the patient's current medical condition, medications, lifestyle choices, age, hydration status, fasting status at the time of specimen collection, and reference standards used by the clinical laboratory. Single test results are useful for screening or to confirm an assessment based on changing clinical, anthropometric, and dietary status. Comparison of current test results to historic baseline test results from the same laboratory is desirable, when available. Changes in laboratory test results that occur over time are often an objective measure of nutrition or pharmacologic interventions.

## Specimen Types

Ideally the specimen to be tested reflects the total body content of the nutrient to be assessed. However, the best specimen may not be readily available. The most common specimens for analysis for nutrients and nutrient-related substances include:

- Whole blood: Collected with an anticoagulant if entire content of the blood is to be evaluated; none of the elements are removed; contains red blood cells (RBCs), white blood cells (WBCs), and platelets suspended in plasma
- Serum: The fluid obtained from blood after the blood has been clotted and then centrifuged to remove the clot and blood cells
- Plasma: The transparent (slightly straw-colored) liquid component of blood, composed of water, blood proteins, inorganic electrolytes, and clotting factors

- Blood cells: Separated from anticoagulated whole blood for measurement of cellular analyte content
- Erythrocytes: RBCs
- Leukocytes: WBCs and leukocyte fractions
- Blood spots: Dried whole blood from finger or heel prick that is placed on paper and can be used for selected hormone tests and other tests such as infant phenylketonuria screening
- Other tissues: Obtained from scrapings or biopsy samples
- Urine (from random samples or timed collections): Contains a concentrate of excreted metabolites
- Feces (from random samples or timed collections): Important in nutritional analyses when nutrients are not absorbed and therefore are present in fecal material or to determine composition of gut flora

Less commonly used specimens include the following:

- Breath tests: Noninvasive tool to evaluate nutrient metabolism, use, and malabsorption, particularly of sugars
- Hair and nails: Easy-to-collect tissue for determining exposure to toxic metals; poor indicator of actual body levels of nutrients
- Saliva: Noninvasive medium with a fast turnover; currently is used to evaluate functional adrenal stress and hormone levels
- Sweat: Electrolyte test used to detect sweat chloride levels to determine presence of cystic fibrosis

The hair and nails specimens have significant drawbacks, including potential environmental contamination. Lack of standardized procedures exist for processing, assay, and quality control. Nutrient levels or indices may be less than the amounts that can be measured accurately. However, because these specimens can be collected at the point of care, considerable research is being done to improve their usefulness.

Hair analysis is not particularly useful for assessing levels of minerals such as sodium, magnesium, phosphorus,

potassium, calcium, iron, and iodine and good tests already exist for evaluating body functions related to these minerals. However, hair analysis may be helpful in assessing levels of trace elements such as zinc, copper, chromium, and manganese—for which measurements of functional status are not well developed—and levels of mercury, cadmium, and lead, which have negative biologic effects. Hair can be used for deoxyribonucleic acid (DNA) testing and may be useful in the future as a noninvasive methodology to predict genetic predisposition to disease and effectiveness of medical nutrition therapy (see Chapter 5 for more information).

### Assay Types

The two fundamental types of laboratory assays are static assays and functional assays. **Static assays** measure the actual level of nutrient in the specimen. Examples of this kind of assay include serum iron and white blood cell ascorbic acid. Although this kind of assay is absolutely specific for the nutrient of interest, specimen nutrient concentrations do not reflect the amount of that substance stored in body pools that are not sampled. Another major limitation of static assays is that recent dietary intake influences the amount of a nutrient found in serum, plasma, or any other fluid or tissue. This problem can be overcome, at least partially, by collecting the specimen following an overnight (8–12 hour) fast.

**Functional assays** quantitatively measure a biochemical or physiologic activity that depends on the nutrient of interest. This type of assay can be very sensitive for a nutrient at its functional site. A good example of a functional assay is serum ferritin. The concentration of ferritin released into the blood is a function of the iron present in the cellular storage pool. Unfortunately functional assays are not always specific for the nutrient of interest because many physiologic and biochemical functions depend on various biologic factors in addition to the specific nutrient.

## NUTRITION INTERPRETATION OF ROUTINE MEDICAL LABORATORY TESTS

### Clinical Chemistry Panels

Laboratory tests are ordered as panels or groupings of tests or as individual tests. The most commonly ordered groups of tests are the **basic metabolic panel (BMP)** and the **comprehensive metabolic panel (CMP)** that include groups of laboratory tests defined by the Centers for Medicare and Medicaid Services for reimbursement purposes. The BMP includes eight tests used for screening, and the CMP includes all the tests in the BMP and six additional tests (Box 8-1). Table 8-1 briefly explains these tests, but the information is not exhaustive and reference norms may vary; see Appendix 30 to obtain more detailed information. Clinical chemistry panels provide **nutrition-specific laboratory data** that are used in conjunction with health history, physical examination findings, anthropometric data, nutrition-focused physical assessment and dietary intake data to identify nutrition

### BOX 8-1

#### Two Common Groups of Laboratory Tests

##### BMP Includes

Glucose  
Calcium  
Sodium  
Potassium  
 $\text{CO}_2$  (carbon dioxide, bicarbonate)  
Chloride  
BUN  
Creatinine

##### CMP Includes

Glucose  
Calcium  
Sodium  
Potassium  
 $\text{CO}_2$  (carbon dioxide, bicarbonate)  
Chloride  
BUN  
Creatinine  
Albumin  
Total protein  
ALP  
ALT  
AST  
Bilirubin

*ALP*, Alkaline phosphate; *ALT*, alanine aminotransferase; *AST*, aspartate aminotransferase; *BMP*, basic metabolic panel; *BUN*, blood urea nitrogen; *CMP*, comprehensive metabolic panel.

diagnoses. Follow-up data are used to monitor and evaluate outcomes of various NCP interventions.

### Complete Blood Count

The **complete blood count (CBC)** provides a count of the cells in the blood and description of the RBCs. A hemogram is a CBC with a white blood cell **differential count** (often called a *differential* or *diff*). Table 8-2 provides a list of the basic elements of the CBC and differential, with reference ranges and explanatory comments.

### Stool Testing

Fecal samples may be tested for the presence of blood, pathogens, and gut flora. The fecal occult blood test is routinely ordered for adults older than age 50 and younger adults with unexplained anemia. Stool culture testing may be ordered in patients with prolonged diarrhea, especially if food-borne illness is suspected. If pathogenic bacteria are isolated in stool culture, appropriate pharmacologic interventions are initiated. Patients with chronic gastrointestinal (GI) symptoms such as maldigestion or unexplained weight loss or gain may benefit from gut flora testing to identify

**TABLE 8-1****Constituents of the Common Serum Chemistry Panels**

<b>Analytes</b>	<b>Reference Range*</b>	<b>Significance</b>
<b>Serum Electrolytes</b>		
Na <sup>+</sup>	135-145 mEq/L <sup>†</sup>	Of general interest in monitoring various patients, such as those receiving total parenteral nutrition or who have renal conditions, chronic obstructive pulmonary disease, uncontrolled DM, various endocrine disorders, ascitic and edematous symptoms, or acidotic or alkalotic conditions; decreased K <sup>+</sup> associated with diarrhea, vomiting, or nasogastric aspiration, some drugs, licorice ingestion, and diuretics; increased K <sup>+</sup> associated with renal diseases, crush injuries, infection, and hemolyzed blood specimens
K <sup>+</sup>	3.6-5 mEq/L <sup>†</sup>	
Cl <sup>-</sup>	101-111 mEq/L <sup>†</sup>	
HCO <sub>3</sub> <sup>-</sup> (or total CO <sub>2</sub> )	21-31 mEq/L <sup>†</sup>	
<b>Glucose</b>	70-99 mg/dL ; 3.9-5.5 mmol/L(fasting)	Fasting glucose >125 mg/dL indicates DM (oral glucose tolerance tests are not needed for diagnosis); fasting glucose >100 mg/dL is indicator of insulin resistance
<b>Creatinine</b>	0.6-1.2 mg/dL; 53-106 µmol/L (males) 0.5-1.1 mg/dL; 44-97 µmol/L (females)	Monitor levels along with triglycerides in those receiving total parenteral nutrition for glucose intolerance
<b>BUN or urea</b>	5-20 mg urea nitrogen/dL 1.8-7 mmol/L	Increased in those with renal disease and decreased in those with PEM (i.e., BUN/creatinine ratio >15 : 1)
<b>Albumin</b>	3.5-5 mg/dL; 30-50 g/L	
<b>Serum Enzymes</b>		
ALT	4-36 units/L at 37° C; 4-36 units/L	Increased in those with any of a variety of malignant, muscle, bone, intestinal, and liver diseases or injuries
γ-glutamyltransferase	4-27 units (females) 8-38 units (males)	AST and ALT useful in monitoring liver function in those receiving total parenteral nutrition
ALP	30-120 units/L; 0.5-2 µKat/L	
AST	10-35 IU/L; 0-0.58 µKat/L	
<b>Bilirubin</b>	Total bilirubin 0.3-1 mg/dL; 5.1-17 µmol/L Indirect bilirubin 0.2-0.8 mg/dL; 3.4-12 µmol/L Direct bilirubin 0.1-0.3 mg/dL; 1.7-5.1 µmol/L	Increased in association with drugs, gallstones, and other biliary duct diseases; intravascular hemolysis and hepatic immaturity; decreased with some anemias
<b>Total calcium</b>	8.5-10.5 mg/dL; 2.15-2.57 mmol/L Normal dependent on albumin level	Hypercalcemia associated with endocrine disorders, malignancy, and hypervitaminosis D
<b>Phosphorous (phosphate)</b>	3-4.5 mg/dL; 0.75-1.35 mmol/L	Hypocalcemia associated with vitamin D deficiency and inadequate hepatic or renal activation of vitamin D, hypoparathyroidism, magnesium deficiency, renal failure, and nephrotic syndrome
<b>Total cholesterol</b>	<200 mg/dL; 5.15 mmol/L	Hyperphosphatemia associated with hypoparathyroidism and decreased intake; hypophosphatemia associated with hyperparathyroidism, chronic antacid ingestion, and renal failure
<b>Triglycerides</b>	<100 mg/dL; <1.13 mmol/L (age and gender dependent)	Decreased in those with protein-calorie malnutrition, liver diseases, and hyperthyroidism
Increased in those with glucose intolerance (e.g., in those receiving total parenteral nutrition who have combined hyperlipidemia) or in those who are not fasting		

\*Reference ranges may vary slightly among laboratories.

<sup>†</sup>mEq/L = 1 mmol/L.ALP, Alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; Cl<sup>-</sup>, chlorine; CO<sub>2</sub>, carbon dioxide; DM, diabetes mellitus; HCO<sub>3</sub><sup>-</sup>, bicarbonate; K<sup>+</sup>, potassium; Na<sup>+</sup>, sodium; PEM, protein-energy malnutrition.

**TABLE 8-2****Constituents of the Hemogram: Complete Blood Count and Differential**

Analytes	Reference Range*	Significance
Red blood cells	$4.7\text{-}6.1 \times 10^6/\mu\text{L}$ (males); $4.7\text{-}6.1 \times 10^{12}/\text{L}$ $4.2\text{-}5.4 \times 10^6/\mu\text{L}$ (females); $4.2\text{-}5.4 \times 10^{12}/\text{L}$	In addition to nutritional deficits, may be decreased in those with hemorrhage, hemolysis, genetic aberrations, marrow failure, or renal disease or who are taking certain drugs; not sensitive for iron, vitamin B <sub>12</sub> , or folate deficiencies
Hemoglobin concentration	14-18 g/dL; 8.7-11.2 mmol/L (males) 12-16 g/dL; 7.4-9.9 mmol/L (females) >11 g/dL; >6.8 mmol/L (pregnant females) 14-24 g/dL; 8.7-14.9 mmol/L (newborns)	In addition to nutritional deficits, may be decreased in those with hemorrhage, hemolysis, genetic aberrations, marrow failure, or renal disease or who are taking certain drugs; not sensitive for iron, vitamin B <sub>12</sub> , or folate deficiencies
Hematocrit	42%-52% (males) 35%-47% (females) 33% (pregnant females) 44%-64% (newborns)	In addition to nutritional deficits, may be decreased in those with hemorrhage, hemolysis, genetic aberrations, marrow failure, or renal disease or who are taking certain drugs; not sensitive for iron, vitamin B <sub>12</sub> , or folate deficiencies
MCV	80-99 fL 96-108 fL (newborns)	Decreased (microcytic) in presence of iron deficiency, thalassemia trait and chronic renal failure, anemia of chronic disease; increased (macrocytic) in presence of vitamin B <sub>12</sub> or folate deficiency and genetic defects in DNA synthesis; neither microcytosis nor macrocytosis sensitive to marginal nutrient deficiencies
MCH	27-31 pg/cell 23-34 pg (newborns)	Causes of abnormal values similar to those for MCV
MCHC	32-36 g/dL; 32-36% 32-33 g/dL; 32-33% (newborns)	Decreased in those with iron deficiency and thalassemia trait; not sensitive to marginal nutrient deficiencies
WBC	$5\text{-}10 \times 10^9/\text{L}$ ; 5,000-10,000/mm <sup>3</sup> (2 yr-adult) $6\text{-}17 \times 10^9/\text{L}$ ; 6,000-17,000/mm <sup>3</sup> (<2 yr) $9\text{-}30 \times 10^9$ ; 9,000-30,000/mm <sup>3</sup> (newborns)	Increased (leukocytosis) in those with infection, neoplasia, and stress decreased (leucopenia) in those with PEM, autoimmune diseases, or overwhelming infections or who are receiving chemotherapy or radiation therapy
Differential	55%-70% neutrophils 20-40% lymphocytes 2-8% monocytes 1%-4% eosinophils 0.5%-1% basophils	<p><i>Neutrophilia:</i> Ketoacidosis, trauma, stress, pus-forming infections, leukemia</p> <p><i>Neutropenia:</i> PEM, aplastic anemia, chemotherapy, overwhelming infection</p> <p><i>Lymphocytosis:</i> Infection, leukemia, myeloma, mononucleosis</p> <p><i>Lymphocytopenia:</i> Leukemia, chemotherapy, sepsis, AIDS</p> <p><i>Eosinophilia:</i> Parasitic infestation, allergy, eczema, leukemia, autoimmune disease</p> <p><i>Eosinopenia:</i> Increased steroid production</p> <p><i>Basophilia:</i> Leukemia</p> <p><i>Basopenia:</i> Allergy</p>

\*Reference ranges may vary slightly among laboratories.

AIDS, Acquired immune deficiency syndrome; DNA, deoxyribonucleic acid; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; PEM, protein-energy malnutrition.

pathologic flora or an imbalance of physiologic flora. In addition, stool tests may be helpful to evaluate the effectiveness of probiotic, prebiotic, and synbiotic use.

### Urinalysis

The **urinalysis** test is used as a screening or diagnostic tool to detect substances or cellular material in the urine

associated with different metabolic and kidney disorders. Some urinalysis data have broader medical and nutritional significance e.g., glycosuria suggests abnormal carbohydrate use and possibly diabetes. The full urinalysis includes a record of (1) the appearance of the urine, (2) the results of basic tests done with chemically impregnated reagent strips (often called dipsticks) that can be read visually or by an

**TABLE 8-3****Chemical Tests in a Urinalysis**

Analyte	Expected Value	Significance
Specific gravity	1.010-1.025	Can be used to test and monitor the concentrating and diluting abilities of the kidney and hydration status; low in those with diabetes insipidus, glomerulonephritis, or pyelonephritis; high in those with vomiting, diarrhea, sweating, fever, adrenal insufficiency, hepatic diseases, or heart failure
pH	4.6-8 (normal diet)	Acidic in those with a high-protein diet or acidosis (e.g., uncontrolled DM or starvation), during administration of some drugs, and in association with uric acid, cystine, and calcium oxalate kidney stones; alkaline in individuals consuming diets rich in vegetables or dairy products and in those with a urinary tract infection, immediately after meals, with some drugs, and in those with phosphate and calcium carbonate kidney stones
Protein	2-8 mg/dL	Marked proteinuria in those with nephrotic syndrome, severe glomerulonephritis, or congestive heart failure; moderate in those with most renal diseases, preeclampsia, or urinary tract inflammation; minimal in those with certain renal diseases or lower urinary tract disorders
Glucose	Not detected (2-10 g/dL in DM)	Positive in those with DM; rarely in benign conditions
Ketones	Negative	Positive in those with uncontrolled DM (usually type 1); also positive in those with a fever, anorexia, certain GI disturbances, persistent vomiting, or cachexia or who are fasting or starving
Blood	Negative	Indicates urinary tract infection, neoplasm, or trauma; also positive in those with traumatic muscle injuries or hemolytic anemia
Bilirubin	Not detected	Index of unconjugated bilirubin; increase in those with certain liver diseases (e.g., gallstones)
Urobilinogen	0.1-1 units/dL	Index of conjugated bilirubin; increased in those with hemolytic conditions; used to distinguish among hepatic diseases
Nitrite	Negative	Index of bacteriuria
Leukocyte esterase	Negative	Indirect test of bacteriuria; detects leukocytes

DM, Diabetes mellitus; GI, gastrointestinal.

automated reader, and (3) the microscopic examination of urine sediment. Table 8-3 provides a list of the chemical tests performed in a urinalysis and their significance.

## ASSESSMENT OF HYDRATION STATUS

Disorders of fluid balance include dehydration and overhydration. Dehydration is a state of negative fluid balance caused by decreased intake, increased losses, and fluid shifts. Overhydration, or edema, occurs when there is an increase in the extracellular fluid volume. The fluid shifts from the extracellular compartment to the interstitial fluid compartment. Overhydration is caused by an increase in capillary hydrostatic pressure or capillary permeability, a decrease in colloid osmotic pressure, or physical inactivity. Laboratory measures of hydration status include serum sodium, blood urea nitrogen, serum osmolality, and urine specific gravity. Although the laboratory tests are important, decisions regarding hydration should only be made in conjunction with other information from physical examination,

nutrition-focused physical assessment, and the clinical condition of the patient (see the discussion of acid-base balance in Chapter 7).

## Bioelectrical Impedance Analysis

Bioelectrical impedance analysis (BIA) estimates body composition based on the difference in electrical conductive properties of various body tissues. BIA instruments automatically calculate total body water, fat-free mass, and percent body fat. Normal hydration is critical for results to be valid. Individuals who are overhydrated have a lower percent of body fat and a dehydrated individual has an elevated reading for percent body fat.

## ASSESSMENT OF STRESS-RELATED PROTEIN-ENERGY MALNUTRITION

Acute illness or trauma causes inflammatory stress. Hormones and cell-mediated responses trigger the breakdown of lean body mass to synthesize cytokines, **positive**

**acute-phase proteins**, lactic acid, and white blood cells (see Chapter 39). Evaluation of nutrition status of acutely ill patients exhibiting inflammatory stress is difficult because none of the standard laboratory test results consistently reflect changes in protein status at either the onset of illness or with refeeding. It is clear that the acutely ill patient loses protein rapidly because of the inflammatory process. However, increasing exogenous protein intake alone does not attenuate the loss of endogenous protein. Nutrition therapy must be combined with physical therapy to reduce loss of muscle mass (Campbell, 2007; Hays et al., 2009). The following measures should be interpreted cautiously as components of nutritional status because stress changes parameters and values may not reflect nutritional intake of protein accurately.

### C-Reactive Protein

Use of inflammatory biomarkers such as **C-reactive protein (CRP)** helps to identify when the acute hypermetabolic period of the inflammatory response wanes. **High-sensitivity CRP (hs-CRP)** is a sensitive measure of chronic inflammation seen in patients with atherosclerosis and other chronic diseases (Bajpai et al., 2010). Both CRP and hs-CRP are nonspecific markers and reflect any type of inflammation. Although the exact function of CRP is unclear, it increases in the initial stages of acute stress—usually within 4 to 6 hours of surgery or other trauma. Furthermore, its level can increase as much as 1000-fold, depending on the intensity of the stress response. When the CRP level begins to decrease, the patient has entered the anabolic period of the inflammatory response when more intensive nutrition therapy may be beneficial. Ongoing assessment and follow-up is required to address changes in nutrition status.

### Creatinine

**Creatinine** is formed from creatine, found almost exclusively in muscle tissue. Serum creatinine is used along with BUN to assess kidney function. Urinary creatinine has been used to assess somatic (muscle) protein status. Creatine is synthesized from the amino acids glycine and arginine with addition of a methyl group from the folate- and cobalamin-dependent methionine-S-adenosylmethionine (SAM)-**homocysteine** cycle. Creatine phosphate is a high-energy phosphate buffer that provides a constant supply of adenosine triphosphate (ATP) for muscle contraction. When creatine is dephosphorylated, some of it is spontaneously converted to creatinine by an irreversible, nonenzymatic reaction. Creatinine has no specific biologic function; it is continuously released from the muscle cells and excreted by the kidneys with little reabsorption.

The use of urinary creatinine to assess somatic protein status is confounded by omnivorous diets. Because creatine is stored in muscle, muscle meats are rich sources. The creatinine formed from dietary creatine cannot be distinguished from endogenously produced creatinine. When a patient follows a meat-restricted diet, the size of the somatic (muscle) protein pool is directly proportional to the amount of creatinine excreted. Therefore men generally have higher

serum levels and excrete larger amounts of creatinine than women, and individuals with greater muscular development have higher serum levels and excrete larger amounts than those who are less muscular. Total body weight is not proportional to creatinine excretion, but muscle mass is.

Daily creatinine excretion varies significantly within individuals, probably because of losses in sweat. In addition, the test is based on 24-hour urine collections, which are difficult to obtain. Because of these limitations, urinary creatinine concentration as a marker of muscle mass has limited use in health care settings and is typically used only for doing research. Creatinine excretion rate is related to muscle mass, and is expressed as a percentage of a standard value as shown by the following equation for creatinine-height index (CHI):

$$\text{CHI} = (\text{24 hr urine creatinine (mg)} \times 100) \div \text{expected 24 hr urine creatinine/cm height}$$

Calculated CHI >80% normal, 60–80% suggests mild skeletal muscle depletion, 40–60% suggests moderate depletion and <40% suggests severe depletion. See Table 8-4. (Blackburn, 1977)

Another predictive equation used to estimate skeletal muscle that does not account for height or gender was proposed by Wang (1996),

$$\begin{aligned} \text{Skeletal muscle mass (kg)} = \\ 4.1 + 18.9 \times 24\text{-hr creatinine excretion (g/day)} \end{aligned}$$

Although this equation works well for some individuals, it is not used for sick or injured patients, older adults or for body builders.

**TABLE 8-4**

**Expected Urinary Creatinine Excretions for Adults Based on Height**

<b>Adult Males*</b>		<b>Adult Females**</b>	
<b>Height (cm)</b>	<b>Creatinine (mg)</b>	<b>Height (cm)</b>	<b>Creatinine (mg)</b>
157.5	1288	147.3	830
160.0	1325	149.9	851
162.6	1359	152.9	875

193.0	1891	182.9	1240

\*Creatinine coefficient males 23 mg/kg “ideal” body weight.

\*\*Creatinine coefficient females 18 mg/kg “ideal” body weight.

## Immunocompetence

Protein-energy malnutrition (PEM) is associated with impaired immunocompetence, including depressed cell-mediated immunity, phagocyte dysfunction, decreased levels of complement components, reduced mucosal secretory antibody responses, and lower antibody affinity. Assessing immunocompetence in critically ill patients may be useful in determining the extent of the inadequate nutrition and disease. Assessing immunocompetence is also useful in the patient who is being treated for allergies.

There is no single marker for immunocompetence except for the clinical outcome of infection or allergic response. Laboratory markers with a high degree of sensitivity include vaccine-specific serum antibody production, delayed-type hypersensitivity response, vaccine-specific or total secretory immunoglobulin A in saliva, and the response to attenuated pathogens. Less sensitive markers include natural killer cell cytotoxicity, oxidative burst of phagocytes, lymphocyte proliferation, and the cytokine pattern produced by activated immune cells. Using a combination of markers is currently the best approach to measure immunocompetence (Albers et al., 2005).

## Nitrogen Balance

Nitrogen balance studies are used primarily in research studies to estimate the balance between exogenous nitrogen intake (orally, enterally, or parenterally) and renal removal of nitrogen-containing compounds (urinary, fecal, wound), and other nitrogen sources. These studies are not a measure of protein anabolism and catabolism because true protein turnover studies require consumption of labeled (stable isotope) protein to track protein use. Even if useful, nitrogen balance studies are difficult because valid 24-hour urine collections are tedious unless the patient has a catheter. In addition, changes in renal function are common in patients with inflammatory metabolism, making standard nitrogen balance calculations inaccurate without calculation of nitrogen retention (Gottschlich et al., 2001). Clinicians using nitrogen balance to estimate protein flux in critically ill patients must remember the limitations of these studies and that positive nitrogen balance may not mean that protein catabolism has decreased, particularly in inflammatory (disease and trauma) conditions. Adequate nutrition cannot circumvent the inflammatory metabolism.

## Hepatic Transport Proteins

Unlike nitrogen balance measurements that assess only short-term changes in whole-body protein status, plasma protein levels integrate protein synthesis and degradation over longer periods. Albumin, prealbumin (PAB); transthyretin [TTHY], retinol-binding protein, transferrin, and other transport proteins are synthesized in the liver and represent approximately 3% of total body protein. Serum levels of albumin and PAB have traditionally been used as part of nutrition assessment; however, levels may not reflect the patient's protein status. Albumin, PAB, retinol binding protein, and transferrin are **negative acute-phase proteins**; they plummet during inflammatory stress, injury, and illness.

Serum levels reflect the severity of illness, but may not reflect current protein status or the effects of nutrient-dense supplemental nutrition. Levels of both albumin and PAB remain nearly normal during uncomplicated starvation as redistribution from the interstitium to the plasma occurs. For these reasons, a well-nourished but stressed patient may have low levels of the hepatic transport proteins, whereas a patient who has had significant weight loss and undernutrition may have normal or close to normal levels.

## Albumin

**Albumin** accounts for approximately 60% of total serum proteins. Albumin transports major blood constituents, hormones, enzymes, medications, minerals, ions, fatty acids, amino acids, and metabolites. However, its major purpose is to maintain colloidal osmotic pressure; providing approximately 80% of colloidal osmotic pressure of the plasma. When serum albumin levels decrease, the water in the plasma moves to the interstitial compartment and promotes edema. The loss of plasma fluid results in hypovolemia; this triggers renal retention of water and sodium. Albumin has a half-life of 18–21 days, and thus does not reflect current protein intake.

## Prealbumin (Transthyretin)

**Prealbumin (PAB)**, officially **transthyretin (TTHY)**, is a hepatic protein transported in the serum as a complex of retinol-binding protein and vitamin A. It transports the thyroid hormones triiodothyronine and thyroxine (T<sub>4</sub>), along with T<sub>4</sub>-binding globulin. Because PAB has a short half-life ( $t_{1/2} = 2$  days), it has been used as an indicator of protein status. Levels of PAB fall precipitously in inflammatory stress and often do not improve with aggressive nutrition support. Serum levels decrease with inflammation, malignancy, and protein-wasting diseases of the intestines or kidneys. Serum levels also decrease in the presence of a zinc deficiency because zinc is required for hepatic synthesis and secretion of PAB. Consider zinc status from dietary intake and medical history, in addition to inflammation, when interpreting low plasma PAB levels.

PAB levels are often maintained in “uncomplicated” malnutrition and decreased in well-nourished individuals who have undergone recent stress or trauma. During pregnancy, the changed estrogen levels stimulate PAB synthesis and serum levels may increase. In nephrotic syndrome, PAB levels may also be increased. Proteinuria and hypoproteinemia are common in nephrotic syndrome; because PAB is rapidly synthesized, a disproportionate percentage of PAB can exist in the blood, whereas other proteins take longer to produce (Litchford, 2010).

## Retinol-Binding Protein

The hepatic protein with the shortest half-life ( $t_{1/2} = 12$  hr) is **retinol-binding protein (RBP)**, a small plasma protein that does not pass through the renal glomerulus because it circulates in a complex with PAB. As implied by its name, RBP binds retinol, and transport of this vitamin A metabolite seems to be its exclusive function. RBP is synthesized in the

liver and released with retinol. After RBP releases retinol in peripheral tissue, its affinity for PAB decreases, leading to dissociation of the PAB-RBP complex and filtration of apo-protein (apo)-RBP by the glomerulus. The protein is then catabolized in the renal tubule.

The plasma RBP concentration has been shown to decrease in uncomplicated protein calorie malnutrition. However, as a negative acute-phase protein, RBP levels fall in the presence of inflammatory stress and may not improve with refeeding. RBP may not reflect protein status in acutely stressed patients; however, it is not as affected by inflammatory stress as albumin, transferrin, or PAB. Simultaneous secretion of RBP and retinol from the liver means that retinol status also complicates the interpretation of reduced RBP values. RBP cannot reliably be used to assess protein status when the vitamin A status is compromised.

The use of RBP in assessing PEM is complicated by the normal catabolism of apo-RBP by the kidney. Patients with renal failure are likely to have elevated RBP levels, regardless of their protein-energy status, because the RBP is not being catabolized by the renal tubule.

RBP4 is an adipocyte-derived peptide of RBP that influences glucose homeostasis and may play a role in lipoprotein metabolism. Human clinical trials have demonstrated increased RBP4 levels in obesity, insulin resistance, gestational diabetes, proliferative diabetic retinopathy, and non-diabetic stage 5 chronic kidney disease, suggesting a possible relationship between these conditions. Larger clinical trials are needed (Axelsson, 2009; Choi, 2008; Klein, 2010; Li, 2010).

### Transferrin

**Transferrin** is a globulin protein that transports iron to the bone marrow for production of hemoglobin (Hgb). The plasma transferrin level is controlled by the size of the iron storage pool. When iron stores are depleted, transferrin synthesis increases. It has a shorter half-life ( $t_{1/2} = 8$  days) than albumin. Levels diminish with acute inflammatory reactions, malignancies, collagen vascular diseases, and liver diseases. Although the half-life of transferrin is shorter than that of albumin, it still does not respond rapidly enough to changes in nutrient intake to be useful as a measure of protein status in acute-care settings.

## LABORATORY DATA TO ASSESS FOR NUTRITIONAL ANEMIAS

Anemia is a condition characterized by a reduction in the number of erythrocytes per unit of blood volume or a decrease in the Hgb of the blood to below the level of usual physiologic need. By convention, anemia is defined as a Hgb concentration below the 95th percentile for healthy reference populations of men, women, or age-grouped children. Anemia is not a disease but a symptom of various conditions, including extensive blood loss, excessive blood cell destruction, or decreased blood cell formation. It is observed in many hospitalized patients and is often a symptom of a

disease process; its cause should be investigated. Clinical nutritionists must distinguish between anemia caused by nutritional inadequacies and that caused by other factors. See Chapter 33 for discussion of the management of anemias. For example, hydration problems can mask nutritional anemias or may result in falsely low blood values.

### Classification of Anemia

Nutritional deficits are a major cause of decreased Hgb and erythrocyte production. The initial descriptive classification of anemia is derived from the hematocrit (Hct) value or CBC as explained in Table 8-2. Anemias associated with a mean RBC volume of less than 80 fl (femtoliters) are microcytic; those with values of 80 to 99 fl are normocytic; those associated with values of 100 fl or more are macrocytic. (See Chapter 33 on Anemias.) Data from the CBC are helpful in differentiating any nutritional causes of anemia. **Microcytic anemia** is most often associated with iron deficiency, whereas **macrocytic anemia** is generally caused by either folate- or vitamin B<sub>12</sub>-deficient erythropoiesis. However, because of the low specificity of these indexes, additional data are needed to distinguish between the various nutritional causes and nonnutritional causes, such as thalassemia trait and chronic renal insufficiency. Normocytic anemia is associated with the **anemia of chronic and inflammatory diseases (ACD)**. This type of anemia is associated with rheumatic diseases, chronic heart failure, chronic infection, cancer, severe tissue injury, multiple fractures, and Hodgkin disease. ACD does not respond to iron supplementation.

Other information from the CBC that helps to differentiate the nonnutritional causes of anemia includes leukocyte, reticulocyte, and platelet counts. When these levels are low, marrow failure is indicated; high counts are associated with anemia caused by leukemia or infection. Erythrocyte sedimentation rate testing is ordered when symptoms are non-specific and if inflammatory autoimmune diseases are suspected. Reticulocytes are large, nucleated, immature RBCs that are released in small numbers with mature cells. When RBC production rates increase, reticulocyte counts also increase. Any time anemia is accompanied by a high reticulocyte count, elevated erythropoietic activity in response to bleeding should be considered. In such cases, stool specimens can be tested for occult blood to rule out chronic GI blood loss. Other causes of a high reticulocyte count include intravascular hemolysis syndromes and an erythropoietic response to therapy for iron, vitamin B<sub>12</sub>, or folic acid deficiencies.

Normocytic or microcytic anemia may be caused by chronic or acute blood loss, such as from recent surgery, injury, or positive occult stool tests. Note that in those with hemolytic anemias and early iron deficiency anemia, the RBC size may still be normal. Macrocytic anemias include megaloblastic anemia or folate deficiency and pernicious anemia or vitamin B<sub>12</sub> deficiency. The presence of macrocytic RBCs requires evaluation of both folate and vitamin B<sub>12</sub> status. Both nutrients arrest DNA synthesis resulting in impaired RBC synthesis and maturation of RBCs. These changes cause large, nucleated cells to be released into the

circulation. Although pernicious anemia is categorized as a macrocytic normochromic anemia, approximately 40% of the cases are normocytic.

## Tests for Iron Deficiency Anemias

### Hematocrit or Packed Cell Volume and Hemoglobin

**Hematocrit (Hct)** and **hemoglobin (Hgb)** are part of a routine CBC and are used together to evaluate iron status. Hct is the measure of the percentage of RBCs in total blood volume. Usually the Hct percentage is three times the Hgb concentration in grams per deciliter. The Hct value is affected by an extremely high WBC count and hydration status. Individuals living in high altitudes often have increased values. It is common for individuals older than age 50 to have slightly lower levels than younger adults.

The Hgb concentration is a measure of the total amount of Hgb in the peripheral blood. It is a more direct measure of iron deficiency than Hct because it quantifies total Hgb in RBCs rather than a percentage of total blood volume. Hgb and Hct are below normal in the four types of nutritional anemias and should always be evaluated in light of other laboratory values and recent medical history.

### Serum Ferritin

**Ferritin** is the storage protein that sequesters the iron normally gathered in the liver (reticuloendothelial system), spleen, and marrow. As the iron supply increases, the intracellular level of ferritin increases to accommodate iron storage. A small amount of this ferritin leaks into the circulation. This ferritin can be measured by assays that are available in most clinical laboratories. In individuals with normal iron storage, 1 ng/mL of serum ferritin equals approximately 8 mg of stored iron. In healthy adults, the measurement of ferritin that has leaked into the serum is an excellent indicator of the size of the body's iron storage pool.

Ferritin is a positive acute-phase protein, meaning that synthesis of ferritin increases in the presence of inflammation. Ferritin is not a reliable indicator of iron stores in patients with acute inflammation, uremia, metastatic cancer or alcoholic-related liver diseases. Cytokines and other inflammatory mediators can increase ferritin synthesis, ferritin leakage from cells, or both. Elevations in ferritin occur 1 to 2 days after the onset of the acute illness and peak at 3 to 5 days. If iron deficiency also exists, it may not be diagnosed because the level of ferritin would be falsely elevated.

ACD is the primary condition in which ferritin fails to correlate with iron stores. ACD, a common form of anemia in hospitalized patients, occurs in those with cancer or inflammatory or infectious disorders (Thomas and Thomas, 2005). It occurs during inflammation because red cell production decreases as the result of inadequate mobilization of iron from its storage sites. This is caused by the release of cytokines such as interleukin-1 and tumor necrosis factor (TNF), which also inhibit division of erythroid progenitors

and may inhibit erythropoietin production. In those with arthritis, depletion of stored iron develops partly because of reduced absorption of iron from the gut. Also the regular use of nonsteroidal antiinflammatory drugs can cause occult GI blood loss. This form of anemia is usually mild and normocytic.

In 30% to 50% of patients, hypochromic (i.e., having inadequate amounts of Hgb), microcytic red cells are made, serum iron levels and total iron-binding capacity (TIBC) are low, and iron stores are normal or elevated. Because iron stores do not decrease, normal amounts of ferritin should be present in the plasma. Although iron stores may be depleted, inflammatory mediators may cause ferritin levels to remain normal. Patients with chronic inflammatory diseases such as rheumatoid arthritis may have reduced or deficient stores. ACD has many forms and must be distinguished from iron deficiency anemia so that inappropriate iron supplementation is not initiated.

### Serum Iron

Serum iron measures the amount of circulating iron that is bound to transferrin. However, it is a relatively poor index of iron status because of large day-to-day changes, even in healthy individuals. Diurnal variations also occur, with the highest concentrations occurring midmorning (from 6 AM to 10 AM), and a nadir, averaging 30% less than the morning level, occurring midafternoon. Serum iron should be evaluated in light of other laboratory values and recent medical history to assess iron status.

### Total Iron-Binding Capacity and Transferrin Saturation

**Total iron-binding capacity (TIBC)** is a direct measure of all proteins available to bind mobile iron and depends on the number of free binding sites on the plasma iron-transport protein transferrin. Each transferrin molecule binds ferric ions at each of two binding sites and two bicarbonate ions at separate sites. Intracellular iron availability regulates the synthesis and secretion of transferrin. Therefore the plasma transferrin concentration increases in those with iron deficiency. In addition, when the amount of stored iron available for release to transferrin decreases and dietary iron intake is low, saturation of transferrin decreases.

There are exceptions to the general rule that transferrin saturation decreases and TIBC increases in patients with iron deficiency. For example, TIBC increases in those with hepatitis. It also increases in people with hypoxia, women who are pregnant, or those taking oral contraceptives or receiving estrogen replacement therapy. On the other hand, TIBC decreases in those with malignant disease, nephritis, and hemolytic anemias. Furthermore, the plasma level of transferrin may be decreased in those with PEM, fluid overload, and liver disease. Thus, although TIBC and transferrin saturation are more specific than Hct or Hgb values, they are not perfect indicators of iron status.

An additional concern about the use of serum iron, TIBC, and transferrin saturation values is that normal values persist until frank deficiency actually develops. Thus these tests

cannot detect decreasing iron stores and preanemic iron deficiencies.

### Tests for Macrocytic Anemias from B Vitamin Deficiencies

Macrocytic anemias include megaloblastic anemia from folate deficiency and pernicious anemia with vitamin B<sub>12</sub> deficiency. The nutritional causes of macrocytic anemia are related to the availability of folate and vitamin B<sub>12</sub> (cobalamin) in the bone marrow and require evaluation of both nutrient levels. Both nutrients arrest DNA synthesis by preventing the formation of thymidine monophosphate. Folate and vitamin B<sub>12</sub> are used at different steps of the synthetic pathway. Impaired RBC synthesis occurs and large, nucleated RBCs are then released into the circulation.

### Assessing Folate and Vitamin B<sub>12</sub> Status

Evaluation for macrocytic anemia includes static measurement of folate and vitamin B<sub>12</sub> deficiency in blood. They can be assayed using tests of the ability of the patient's blood specimen to support the growth of microbes that require either folate or vitamin B<sub>12</sub>, radiobinding assays, or immunoassays.

**Serum Homocysteine.** Folate and vitamin B<sub>12</sub> are required for the synthesis of SAM, the biochemical precursor involved in the transfer of one-carbon (methyl) groups during many biochemical syntheses. SAM is synthesized from the amino acid methionine by a reaction that includes the addition of a methyl group and the purine base adenine (from ATP). For example, when SAM donates a methyl group for the synthesis of thymine, choline, creatine, epinephrine, and protein and DNA methylation, it is converted to S-adenosylhomocysteine. After losing the adenosyl group, the remaining homocysteine can either be converted to cysteine by the vitamin B<sub>6</sub>-dependent transsulfuration pathway or converted back to methionine in a reaction that depends on adequate folate and vitamin B<sub>12</sub>.

When either folate or vitamin B<sub>12</sub> is lacking, the homocysteine-to-methionine reaction is virtually blocked, causing homocysteine to build up in the affected tissue and spill into the circulation. The vitamin B<sub>6</sub>-dependent transsulfuration pathway can metabolize excess homocysteine. Homocysteine has been shown to be very sensitive to folate and vitamin B<sub>12</sub> deficiency.

Therefore an elevated homocysteine level indicates either genetic defects involved in the enzymes that catalyze these reactions or a deficiency in folate, vitamin B<sub>12</sub>, or vitamin B<sub>6</sub>. Research indicates that several folate gene polymorphisms contribute risk for several chronic cardiovascular and neurologic disorders (Albert et al., 2009; Fan et al., 2010).

**Folate Assessment.** Folate is most often simultaneously measured in whole blood with its combined plasma and blood cells, and in the serum alone. The difference between whole-blood folate and serum folate levels is then used to calculate total RBC folate concentration. RBC folate concentration is a better indicator of folate status than serum folate, because folate is much more concentrated in RBCs than in the serum. RBC folate measurement more closely

reflects tissue stores and is considered the most reliable indicator of folate status. Folate is absorbed in the jejunum, and its malabsorption has several causes, but a specific test for folate absorption is not available. The presence and extent of deficiency should be assessed in patients with celiac disease, those who have had bariatric surgery, those with a history of long-term use of medications such as anticonvulsants and sulfasalazine, and chronic alcohol consumption. Chapter 5 discusses genetic markers affecting folate absorption and metabolism.

**Vitamin B<sub>12</sub> Assessment.** Vitamin B<sub>12</sub> is measured in the serum, and all indications are that the serum level gives as much information about vitamin B<sub>12</sub> status as does the RBC level. If vitamin B<sub>12</sub> status is compromised, intrinsic factor antibodies and parietal cell antibodies are measured; the presence of antibodies suggests the main cause of pernicious anemia. Historically the Schilling test was used to detect defects in vitamin B<sub>12</sub> absorption; it is rarely used today because the test requires that the patient be given radioactive vitamin B<sub>12</sub>. Methylmalonic acid (MMA) levels in serum or urine are also useful to assess B<sub>12</sub> status.

**Vitamin B<sub>12</sub> and Methylmalonic Acid.** Once a genetic cause is ruled out, the most straightforward biochemical method for differentiating between folate and vitamin B<sub>12</sub> deficiencies is to monitor the hyperhomocysteinemia by measuring the serum or urinary MMA level. MMA is formed during the degradation of the amino acid valine and odd-chain fatty acids. MMA is the side product in this metabolic pathway that increases when the conversion of methylmalonic coenzyme A (CoA) to succinyl CoA is blocked by lack of vitamin B<sub>12</sub>, a coenzyme for this reaction. Therefore deficiency leads to an increase in the MMA pool, which is reflected by the serum or urinary MMA level. The urinary MMA test is more sensitive than the serum B<sub>12</sub> test because it indicates true tissue B<sub>12</sub> deficiency. The serum MMA test may give falsely high values in renal insufficiency and intravascular volume depletion. The urinary MMA test is the only B<sub>12</sub> deficiency assay that has been validated as a screening tool (Morris et al., 2005). Homocysteine and MMA tend to detect impending vitamin deficiencies better than the static assays. This is especially important when assessing the status of certain patients such as vegans or older adults, who could have vitamin B<sub>12</sub> deficiency associated with central nervous system impairment.

## FAT-SOLUBLE VITAMINS

Fat malabsorption often results in impaired absorption of vitamins A, E, D, and K. Factors including low luminal pH, bile salts below the critical micellar concentration, and inadequate triglyceride hydrolysis can interfere with normal bile salt micelle formation, causing impaired absorption of fat-soluble vitamins. Individuals with fat malabsorptive disorders, including those who have had bariatric surgery, are at greatest risk of deficiencies of fat-soluble vitamins. See Appendix 30 for further discussion of tests for assessing specific vitamin adequacy.

## Vitamin A

Vitamin A status can be estimated using serum **retinol** and the normal level in adults is 30–80 mcg/dL. A primary deficiency of vitamin A can result from inadequate intake, fat malabsorption, or liver disorders. A secondary deficiency of vitamin A may be due to decreased bioavailability of provitamin A carotenoids or interference with vitamin A absorption, storage, or transport (e.g., celiac disease, cystic fibrosis, pancreatic insufficiency, malabsorptive weight loss surgery, or bile duct obstruction). Vitamin A deficiency is common in prolonged PEM. Because of shared absorptive mechanisms with vitamin D, serum retinol should always be assessed in the presence of vitamin D supplementation (see Chapter 3). Acute or chronic vitamin A toxicity is defined as retinol levels greater than 100 mcg/dL. Chronic vitamin A toxicities are associated with loss of hair; dry mucous membranes; dry, rough skin; and even cortical bone loss and fractures.

## Vitamin D

Individual vitamin D status can be estimated by measuring plasma **25-hydroxy vitamin D (25-[OH]D<sub>3</sub>)** levels. Current clinical practice reference ranges have been updated by the 2011 IOM (IOM, 2011). Traditional levels defining vitamin D sufficiency have been based on the lowest threshold value for plasma 25-(OH)D<sub>3</sub> (approximately 80 nmol/L or 32 ng/mL) that prevents secondary hyperparathyroidism, increased bone turnover, bone mineral loss, or seasonal variations in plasma parathyroid hormone. The IOM review concluded that individuals are at risk of deficiency at serum 25(OH)D<sub>3</sub> levels below 30 nmol or 12 ng/mL and that practically all persons have sufficient serum levels at 50 nmol or 20 ng/mL. Current clinical practice reference ranges define insufficiency as 50–80 nmol/L or 20–31 ng/mL, and deficiency is defined as less than 50 nmol/L or 20 ng/mL. Serum levels even higher at 90–100 nmol/L (36–40 ng/mL) are recommended by some (Bischoff-Ferrari et al., 2006). Optimal levels of 25(OH)D<sub>3</sub> have not been defined and the measurement of serum levels lacks standardization and calibration.

A deficiency may be caused by inadequate dietary intake, inadequate exposure to sunlight, or malabsorption. Deficiency of vitamin D can also lead to secondary malabsorption of calcium. Calcium malabsorption occurs in chronic renal failure because renal hydroxylation is required to activate vitamin D, which promotes synthesis of a calcium-binding protein in intestinal absorptive cells (Mosekilde, 2005). See Chapter 36.

## Vitamin K

Vitamin K status can be estimated using prothrombin time (PT). PT is used to evaluate the common pathway of blood clotting. The synthesis of clotting factors II, VII, IX, and X are vitamin K-dependent. **Osteocalcin** or bone G1a protein (BGP), a bone turnover marker, may also be used to assess vitamin K status. BGP is a vitamin K-dependent protein that is increased with bone formation and depressed with

increased bone loss. A reduced vitamin K status is associated with reduced BGP or serum osteocalcin levels. The relationship may explain the pathophysiologic findings of vitamin K-deficiency osteoporosis.

## WATER-SOLUBLE VITAMINS AND TRACE MINERALS

Vitamin B<sub>12</sub> and folate are the most common water-soluble vitamin deficiencies reported in adults. Frank deficiencies of other water-soluble vitamins and trace minerals are uncommon in populations that consume a variety of whole foods and fortified foods. Thiamin deficiency has been reported in individuals who chronically consume high levels of alcohol with inadequate thiamin intake, in those with persistent vomiting, and in those with impaired absorption because of disease or surgery. To assess thiamin status, thiamin diphosphate in whole blood is measured because plasma and serum levels reflect recent dietary changes and may be misleading. Subclinical deficiencies of water-soluble vitamins and other trace minerals may be present in some individuals. However the current methodologies for evaluating nutritional status of these components are both expensive and controversial. See Appendix 30 for further discussion of tests for assessing specific vitamin and trace mineral adequacy.

## CHRONIC DISEASE RISK ASSESSMENT

### Lipid Indices of Cardiovascular Risk

Serum lipoprotein and cholesterol levels are directly implicated in the development of atherosclerosis and are affected by modifiable factors, including diet. Patients undergoing lipid assessments should be fasting for 12 hours at the time of blood sampling. Fasting is necessary primarily because triglyceride levels rise and fall dramatically in the postprandial state, and low-density lipoprotein (LDL) cholesterol values are calculated from measured total serum cholesterol and high-density lipoprotein cholesterol concentrations. This calculation, based on the Friedewald equation, is most accurate when triglyceride concentrations are less than 400 mg/dL. The Friedewald equation gives an estimate of fasting LDL cholesterol levels that is generally within 4 mg/dL of the true value when triglyceride concentrations are less than 400 mg/dL.

Risk for cardiovascular disease (CVD) appears to be more related to the number of atherogenic lipoprotein particles in the serum than it is to the total volume of cholesterol. Differentiating subparticles of LDL by size and grouping by pattern has been used; however, the subparticle testing is costly and findings do not serve as independent markers for risk (Box 8-2). In patients with metabolic syndrome, lowering LDL does not reflect similar reductions in LDL particle levels (Rosenson, 2008). LDL contains the atherogenic apolipoprotein B (apoB). Some researchers propose that

**BOX 8-2****Lipid and Lipoprotein Cardiovascular Disease Risk Factors**

**LDL:** Elevated levels are atherogenic

**VLDL density:** Remnants are atherogenic

**Triglyceride concentrations:** Elevated levels are atherogenic

**Lp(a):** Elevated levels are atherogenic

**apo-protein B:** Increased concentration is atherogenic

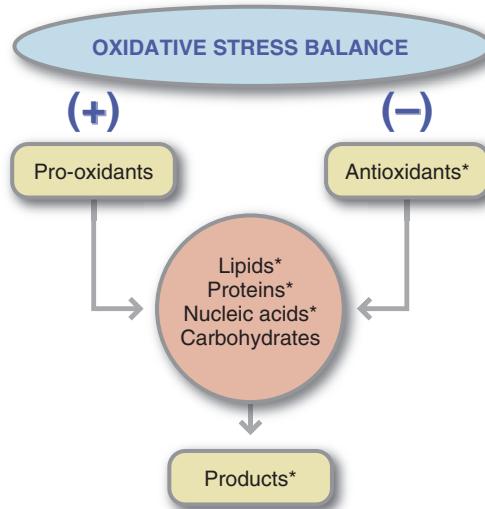

**apo-protein A-I:** Decreased concentration is atherogenic

**hs-CRP:** Elevated levels, without acute or chronic inflammatory condition, are atherogenic

**Serum homocysteine:** Increased; greater risk

**RBP4:** Elevated levels may identify early insulin resistance and associated cardiovascular risk factors

*HDL*, High-density lipoprotein; *hs-CRP*, high-sensitivity C-reactive protein; *IDL*, intermediate-density lipoprotein; *LDL*, low-density lipoprotein; *Lp(a)*, lipoprotein little a; *RBP4*, retinol-binding protein 4; *VLDL*, very low-density lipoprotein.

**FIGURE 8-2** Steps in maintaining the balance between prooxidants (reactive oxygen species) and antioxidants. The compounds marked with an asterisk (\*) have been used as markers of oxidative stress balance.

measuring the concentration of apoB provides a direct measure of the number of circulating atherogenic lipoprotein particles and is superior to LDL for predicting probability of CVD (Barter, 2006; Brunzell, 2008). Clinicians may suggest testing the genetic profile for the **apolipoprotein E (apoE) phenotype**, which precedes CVDs in some populations (Chasman et al., 2009). Other inflammatory genes are under study. See Chapter 34 for further discussion of the lipid profile and cardiovascular risk.

**Hemoglobin A1C and Diabetes**

In adults with normal glucose control, approximately 4% to 6% of the total Hgb is glycosylated. The percent of glycohemoglobin in the blood is directly related to the average blood glucose levels for the preceding 2-3 months. **Hemoglobin A1C (Hgb A1C)** does not reflect more recent changes in glucose levels. It is useful in differentiating between short-term hyperglycemia in individuals under stress or who have had an acute myocardial infarction and diabetes. It has been added as a diagnostic criteria for diagnosis of diabetes mellitus once the initial value is confirmed by a repeat Hgb A1C >6.5% or plasma glucose >200 mg/dL (11 mmol/L). Hgb A1C is not used as a diagnostic criterion for gestational diabetes because of changes in red cell turnover (American Diabetes Association [ADA], 2011).

Hgb A1C can be correlated with daily mean plasma glucose. Each 1% change in Hgb A1C represents approximately 35 mg/dL change in mean plasma glucose. Test results are useful to provide feedback to patients about changes they have made in their nutritional intakes (ADA, 2011). See Chapter 31 for further discussion of Hgb A1C and diabetes management.

**Oxidative Stress**

Aging and many diseases, including CVD, Alzheimer disease, Parkinson disease, inflammatory bowel disease, and cancer, are initiated in part by **oxidative stress** as evidenced by free radical oxidation of lipids, nucleic acids, or proteins (Figure 8-2). Oxidative stress is imposed on cells as a result of three factors: (1) an increase in oxidant generation, (2) a decrease in antioxidant protection, or (3) a failure to repair oxidative damage. Cell damage is caused by **reactive oxygen species (ROS)**. ROS are either free radicals, reactive anions containing oxygen atoms, or molecules containing oxygen atoms that can either produce free radicals or are chemically activated by them (Blanck et al., 2003). These products include the superoxide radical ( $O_2^-$ ) hydroxyl radical (OH), and hydrogen peroxide. The formation of ROS is sometimes, but not always, mediated by certain essential trace elements (e.g., iron, copper, chromium, and nickel).

In the case of CVD, the ROS react with unsaturated fatty acids in LDL, creating lipid peroxides, another free radical species. Like all free radicals, lipid peroxides initiate the oxidation of other compounds, including apolipoprotein, the protein present in lipoproteins. This oxidation leads to the formation of free radical products throughout the large, heterogeneous lipoprotein particle. Cells associated with the arterial wall ingest the resulting oxidized lipoproteins. Once present in these cells, additional metabolism of this modified complex does not seem to occur. Over time, other pathophysiological responses stabilize the deposited oxidized lipoprotein as atherosclerotic plaque.

**Antioxidant Status**

An indirect way of assessing the level of oxidative stress is to measure the levels of antioxidant compounds present in

body fluids. Oxidative stress is related to levels of the following:

- Antioxidant vitamins (tocopherols and ascorbic acid)
- Dietary phytochemicals with antioxidant properties (e.g., carotenoids)
- Minerals with antioxidant roles (e.g., selenium)
- Endogenous antioxidant compounds and enzymes (e.g., superoxide dismutase, glutathione)

More precisely, the concentration of these compounds correlates with the balance between their intake and production and their use during the inhibition of free radical compounds.

### Markers of Oxidative Stress

Biomarkers of oxidative stress status and inflammation have been associated with many chronic conditions and risk factors. Measurement of intracellular antioxidant thiols such as glutathione can be estimated using the free oxygen radical test via spectrophotometric techniques on specimens obtained from finger sticks. However, further standardization of protocols for assays and methods of combining and integrating multiple panels of biomarkers of oxidative stress and inflammation are needed to facilitate evaluation of biomarkers for risk factor prediction. Although some intervention studies examining the effects of dietary supplements, diet, and exercise on biomarkers of oxidative stress and

inflammation have been done, the data have been inconclusive, and more studies are needed to understand the underlying mechanisms.

The most commonly used chemical markers of oxidative stress are presented in Table 8-5. Some tests measure the presence of one class of free radical products, and others measure the global antioxidant capacity of plasma or a plasma fraction. These tests have been promoted on the assumption that knowledge of the total antioxidant capacity of the plasma or plasma fraction might be more useful than knowledge of the individual concentrations of free radical markers or antioxidants. This total antioxidant activity is determined by a test that assesses the combined antioxidant capacities of the constituents. Unfortunately, the results of these tests include the antioxidant capacities of compounds such as uric acid and albumin, which are not compounds of interest. In other words, no one type of assay is likely to provide a global picture of the oxidative stress to which an individual is exposed. A new noninvasive method that may become useful in the future is a method that uses Raman spectroscopy in the biophotonic antioxidant laser scanner (see *New Directions: Raman Spectroscopy Used to Measure Antioxidant Capacity*).

Despite this lack of correlation or specificity of assays of oxidative stress, two assays seem promising. One is the immunoassay myeloperoxidase used in conjunction with CRP to predict CVD mortality risk (Heslop, 2010). The second assay is the measurement of the compounds F<sub>2</sub>

## NEW DIRECTIONS

### Raman Spectroscopy Used to Measure Antioxidant Capacity

Noninvasive measurements of clinical parameters are always preferable to those requiring blood, urine, or tissue. Raman spectroscopy is just such a measurement technique and may become widely used in the future. A laser light is pointed toward the fat pad of the palm. As the laser light penetrates the skin, the amount of carotenoids (all-trans-beta-carotene, lycopene, alpha-carotene, gamma-carotene, phytoene, phytofluene, sepapreno-beta-carotene, dihydro-beta-carotene, astaxanthin, canthaxanthin, zeaxanthin, lutein, beta-apo-8' carotenal, violaxanthins, and rhodoxanthin) is measured at the cellular level. Because all carotenoids have a carbon backbone with alternating carbon double and single bonds, the vibration of these bonds can be detected with Raman spectroscopy. Raman spectroscopy has been used to assess carotenoids in precancerous skin lesions as well as in the retina to assess early stages of macular degeneration (Ermakov et al., 2005).

Carotenoids are powerful antioxidants, and because they are part of the “antioxidant network,” a measure of their presence can give a good assessment of the antioxidant capacity of the cell. The Raman spectroscopy score also correlates

inversely with urinary isoprostanes, a measure of oxidative stress (Carlson et al., 2006).

Serum carotenoids significantly correlate with skin carotenoids, as measured using Raman spectroscopy and the biophotonic laser scanner (Smidt et al., 2004; Zidichouski et al., 2004). Serum carotenoids are a good measure of the absorptive capacity of the individual (see Chapters 1 and 3). Thus an individual with a diet high in fruits and vegetables, and therefore large amounts of dietary carotenoids, usually has a high carotenoids antioxidant score. The antioxidant score, or the numeric result from this scan, can be used to determine how well a person is processing carotenoid antioxidants and whether the antioxidants are reaching the cell where they exert their protective functions. The number, which seems to be in the range of 40,000 and higher in those with optimal health, increases with greater consumption of carotenoid-containing fruits and vegetables, consumption of carotenoid-containing nutritional supplements, smoking cessation, and loss of excess body fat (Carlson et al., 2006). The measurement is quick, easy, and inexpensive, making it a possible assessment tool for nutrition professionals in the future.

**TABLE 8-5****Markers of Oxidative Stress**

Class	Functions	Comment
<b>Class I: Antioxidant Markers</b>		
Vitamin C (plasma or leukocyte)	Specific inhibitor of water-soluble radicals	Measured by chromatography, capillary electrophoresis, or an automated enzymatic assay
$\alpha$ -Tocopherol	Inhibitor of lipid peroxidation	Measured by chromatography or capillary electrophoresis
$\gamma$ -Tocopherol	An inhibitor of the nitrous oxide radical	Measured by chromatography or capillary electrophoresis
Carotenoids	Primarily inhibitors of lipid peroxidation	Measured by chromatography and spectroscopy; includes $\alpha$ - and $\beta$ -carotenes, lycopene, cryptoxanthin, zeaxanthin, and lutein
<b>Class II: Endogenous Systems</b>		
Glutathione assay	Detoxifies the ROS $H_2O_2$	Measured by plasma or erythrocyte glutathione or ratio of reduced to oxidized glutathione
<b>Class III: Global Tests of Antioxidant Capacity</b>		
LDL oxidative susceptibility	Reflects the concentration of antioxidants in LDLs	In vitro determination of the rate of formation of LDL oxidation products called <i>conjugated dienes</i>
ORAC	NA	Measures decrease in fluorescence over time; reflects the total antioxidant capacity of the specimen
TRAP	NA	Measures total antioxidant capacity; reflects the levels of uric acid and albumin
ABTS	NA	ABTS assay in commercial by available kit; also called <i>total antioxidant status</i>
8-OH-d-G	Reflects ongoing oxidative stress in body	Emerging biomarker; elevated levels associated with inadequate intake of carotenoids, antioxidant rich foods and supplemental antioxidants
<b>Class IV: Products of Free Radical Reactions</b>		
Myeloperoxidase	NA	Used in conjunction with hs-CRP to predict CVD risk
Isoprostanate	No known function	Primary form, isoprostanate $F_{2\alpha}$ , measured by chromatography or an immunoassay that is available commercially and can be rapidly performed
TBARS	NA	A colorimetric assay that is easy to perform but not specific for oxidation products; measures products of lipid peroxidation called <i>aldehydes</i> (e.g., malondialdehyde)

*ABTS*, 2,2'-Azino-bis (3-ethyl benzylazoline-sulfonic acid); *CVD*, cardiovascular disease;  $H_2O_2$ , hydrogen peroxide; *hs-CRP*, high-sensitivity C-reactive protein; *LDL*, low-density lipoprotein; *ORAC*, oxygen radical absorbance capacity; *NA*, not applicable; *ROS*, reactive oxygen species; *TBARS*, thiobarbituric acid reactive substances; *TRAP*, total peroxyl radical trapping parameter; *8-OH-d-G*, urinary 8-hydroxy-2'-deoxyguanosine.

isoprostanates either in plasma or urine (Harrison and Nieto, 2004). This test measures the presence of a continuously formed free radical compound that is produced by free radical oxidation of specific polyunsaturated fatty acids. Isoprostanates are prostaglandin-like compounds

that are produced by free radical mediated peroxidation of lipoproteins. Elevated isoprostanate levels are associated with oxidative stress, and clinical situations of oxidative stress such as hepatorenal syndrome, rheumatoid arthritis, atherosclerosis, and carcinogenesis (Roberts and Fessel, 2004).

**CLINICAL SCENARIO 1**

Clara is seen at County Hospital emergency room. She has a long history of yo-yo dieting and alcohol abuse. In the last 6 months she has had the stomach flu that lasted 4 days, seasonal flu, and colitis. She works at a retirement community as a kitchen assistant. One of the benefits of her job is one

free meal the days she works. Clara keeps snack foods, beer, and soft drinks in her apartment and eats most meals at fast-food restaurants when she is not at work. Clara has called in sick to work for the past 3 days. She has a poor work history, and her employer questions her motives for missing work.

**CLINICAL SCENARIO 1—cont'd**

Her employer told her if she is really too sick to come to work, she must see her doctor for a medical release to return to work. The emergency department doctor orders laboratory tests and Clara is admitted to the hospital. She tells the doctor that she cannot remember what has happened in the last few days. Her medical profile today is:

Age	32 years old
Height	5'9"
Weight	285 lb
Frame	Large
Glucose	142 mg/dL; 7.8 mmol/L
Calcium	9.1 mg/dL; 2.27 mmol/L
Sodium	149 mEq/L; 149 mmol/L
Potassium	3.8 mEq/L; 3.8 mmol/L
CO <sub>2</sub>	25 mEq/L/ 25 mmol/L
Chloride	106 mEq/L; 106 mmol/L
BUN	30 mg/dL; 10.7 mmol/L
Creatinine	0.9 mg/dL; 79.6 µmol/L
Albumin	4.8 g/dL; 48 g/L
Total protein	8.5 g/dL; 85 g/L
ALP	35 U/L; 0.5 µkat/L
ALT	28 units/L; 28 units/L
AST	23 units/L; 0.38 µkat/L
Bilirubin, total	1.5 mg/dL; 25.65 µmol/L
RBC	5.1 × 10 <sup>6</sup> mL; 5.1 × 10 <sup>12</sup> L
Hgb	11.5 g/dL; 7.1 mmol/L
Hct	28%; 0.28
MCV	102 mm <sup>3</sup> ; 102 fL
MCH	33 pg
MCHC	26 g/dL; 26%
WBC	12 × 10 <sup>9</sup>

Clara is referred for medical nutrition therapy. Assess her nutrition status using the data provided. Note that Clara is

scheduled for a series of tests. She is given intravenous fluids, a blood transfusion and is made NPO which means no food or fluid by mouth. The preliminary findings indicate several tumors obstructing the gall bladder. Exploratory surgery is scheduled tomorrow.

### Nutrition Diagnostic Statement

Altered laboratory values related to disordered eating pattern as evidenced by signs of nutritional anemia and dehydration.

### Nutrition Care Questions

1. Estimate Clara's energy and protein needs based on her anthropometric data.
2. Considering Clara's medical history, what does her laboratory report for hemoglobin, hematocrit, mean corpuscular volume, mean corpuscular hemoglobin, and mean corpuscular hemoglobin concentration suggest?
3. What does her laboratory report for ALP, AST, and ALT values suggest?
4. What does her laboratory report for sodium, blood urea nitrogen, and creatinine suggest about her hydration status?
5. What does her laboratory report for blood urea nitrogen and creatinine suggest about her renal status?
6. How would you expect Clara's laboratory tests to change 24 hours after major surgery?
7. What additional laboratory tests would be helpful for a comprehensive nutrition assessment?

*ALP*, Alkaline phosphate; *ALT*, alanine aminotransferase; *AST*, aspartate aminotransferase; *BUN*, blood urea nitrogen; *CO<sub>2</sub>*, carbon dioxide; *Hct*, hematocrit; *Hgb*, hemoglobin; *MCH*, mean corpuscular hemoglobin; *MCHC*, mean corpuscular hemoglobin concentration; *MCV*, mean corpuscular volume; *RBC*, red blood cell; *WBC*, white blood cell.

**CLINICAL SCENARIO 2**

Omar is seen at the Western Medical Clinic today complaining of fatigue, fluttery heart beat, and tightness in his chest after he walks up two flights of steps. He works in a high-stress job as a computer software engineer. Omar has a history of high blood pressure and takes medication daily. He is concerned about his risk for heart disease. He has gained 18 pounds after quitting smoking and getting married a year ago. Omar eats breakfast and lunch at fast-food restaurants. His favorite foods are sweet rolls and fast foods. His wife prepares the evening meal. Omar reports drinking three to five beers nightly while watching television. He does not get any regular exercise except walking up two flights of steps at his office building. His medical profile is as follows: 39-year-old male; height: 5'10"; weight: 225 lb, large frame.

### Laboratory Report

Glucose	155 mg/dL; 8.6 mmol/L
Calcium	10.1 mg/dL; 2.52 mmol/L
Sodium	142 mEq/L; 142 mmol/L
Potassium	3.2 mEq/L; 3.2 mmol/L
CO <sub>2</sub>	22 mEq/L; 22 mmol/L
Chloride	103 mEq/L; 103 mmol/L
BUN	46 mg/dL; 16.4 mmol/L
Creatinine	0.6 mg/dL; 53 µmol/L
Albumin	2.8 g/dL; 28 g/L
Total protein	6.0 g/dL; 60 g/L
ALP	30 U/L; 0.5 µkat/L
ALT	48 units/L; 48 units/L
AST	40 units/L; 0.67 µkat/L

## CLINICAL SCENARIO 2—cont'd

Bilirubin, total	1.0 mg/dL; 17.1 µmol/L
RBC	5.5 × 10 <sup>6</sup> mL; 5.5 × 10 <sup>12</sup> L
Hgb	15.5 g/dL; 9.6 mmol/L
Hct	45%; 0.45
MCV	92 mm <sup>3</sup> ; 92 fL
MCH	30 pg
MCHC	31 g/dL; 31%
WBC	7 × 10 <sup>9</sup>

**Other Labs**

Total serum cholesterol	250 mg/dL; 6.5 mmol/L
HDL cholesterol	40 mg/dL; 1.03 mmol/L
LDL cholesterol	140 mg/dL; 3.6 mmol/L
Triglycerides	350 mg/dL; 3.95 mmol/L
Homocysteine	18 µmol/L
Blood pressure	186/99 mm Hg

**Nutrition Diagnostic Statement**

Altered laboratory values related to recent weight gain and smoking cessation as evidenced by elevated blood pressure, symptoms of metabolic syndrome, and dietary history.

**Nutrition Care Questions**

- Based on the health history, social history, fasting laboratory report, and medical profile, what risk factors does Omar have for chronic diseases?
- Considering Omar's medical profile, what does his laboratory report for glucose, blood urea nitrogen, sodium, potassium, and creatinine suggest?
- What does his laboratory report for alkaline phosphate, aspartate aminotransferase, and alanine aminotransferase suggest?
- What does his lipid profile and homocysteine suggest?
- Omar is referred for medical nutrition therapy. Assess his nutrition status based on the data provided.

*ALP*, Alkaline phosphatase; *ALT*, alanine aminotransferase; *AST*, aspartate aminotransferase; *BUN*, blood urea nitrogen; *CO<sub>2</sub>*, carbon dioxide; *Hct*, hematocrit; *HDL*, high-density lipoprotein; *Hgb*, hemoglobin; *LDL*, low-density lipoprotein; *MCH*, mean corpuscular hemoglobin; *MCHC*, mean corpuscular hemoglobin concentration; *MCV*, mean corpuscular volume; *RBC*, red blood cell; *WBC*, white blood cell.

# Clinical: Food-Drug Interactions

### KEY TERMS

absorption  
acetylation  
adsorption  
bioavailability  
biotransformation  
black box warning  
cytochrome P-450 enzyme system  
distribution  
drug-nutrient interaction  
excipient  
excretion  
food-drug interaction

gastrointestinal pH  
half-life  
metabolism  
pharmacodynamics  
pharmacogenomics  
pharmacokinetics  
physical incompatibility  
polypharmacy  
pressor agents  
side effect  
therapeutically important  
unbound fraction

The management of many diseases requires drug therapy, frequently involving the use of multiple drugs. Food-drug interactions can change the effects of drugs, and the therapeutic effects or side effects of medications can affect the nutrition status of an individual. Alternatively, the diet and use of supplements, genetic makeup, or the nutritional status of the patient can decrease the efficacy of a drug or increase its toxicity.

The terms *drug-nutrient interaction* and *food-drug interaction* are often used interchangeably. In actuality, drug-nutrient interactions are some of the many possible food-drug interactions. **Drug-nutrient interactions** include specific changes to the pharmacokinetics of a drug caused by a nutrient or nutrients or changes to the kinetics of a nutrient caused by a drug. **Food-drug interaction** is a broader term that also includes the effects of a medication on nutritional status. Nutritional status may be affected by the side

effects of a medication, which could include an effect on appetite or the ability to eat.

For clinical, economic, and legal reasons, it is important to recognize food-drug interactions. Food-drug interactions that reduce the efficacy of a drug can result in longer or repeated stays in health care facilities, the use of multiple drugs, and deterioration of the patient because of the effects of the disease. Additional health problems can occur because of long-term drug-nutrient interactions. An example of this type of interaction is the long-term effects of corticosteroids on calcium metabolism and the resulting osteoporosis. Medical team members should be aware that **therapeutically important** food-drug interactions can do the following:

- Alter the intended response to the medication
- Cause drug toxicity
- Alter normal nutritional status

**BOX 9-1****Benefits of Minimizing Drug Interactions**

- Medications achieve their intended effects.
- Patients do not discontinue their drug.
- The need for additional medication is minimized.
- Fewer caloric or nutrient supplements are required.
- Adverse side effects are avoided.
- Optimal nutritional status is preserved.
- Accidents and injuries are avoided.
- Disease complications are minimized.
- The cost of health care services is reduced.
- There is less professional liability.
- Licensing agency requirements are met.

From Pronsky ZM, Crowe JP: Food-medication interactions, ed 16, Birchrunville, Pa, 2010, Food-Medication Interactions.

Awareness of these interactions enables the health care professional and patient to work together to avoid or minimize problems (Box 9-1).

## **PHARMACOLOGIC ASPECTS OF FOOD-DRUG INTERACTIONS**

Medication is administered to produce a pharmacologic effect in the body or, more specifically, in a target organ or tissue. To achieve this goal, the drug must move from the site of administration into the bloodstream and eventually to the site of drug action. In due course the drug may be changed to active or inactive metabolites and is ultimately eliminated from the body. An interaction between the drug and food, a food component, or a nutrient can alter this process at any point. Food-drug interactions may be divided into two broad types: (1) pharmacodynamic interactions, which affect the pharmacologic action of the drug; and (2) pharmacokinetic interactions, which affect the movement of the drug into, around, or out of the body.

### **Pharmacodynamics**

**Pharmacodynamics** is the study of the biochemical and physiologic effects of a drug. The mechanism of action of a drug might include the binding of the drug molecule to a receptor, enzyme, or ion channel, resulting in the observable physiologic response. Ultimately this response may be enhanced or attenuated by the addition of other substances with similar or opposing actions. **Pharmacokinetics** is the study of the time course of a drug in the body involving the absorption, distribution, metabolism (biotransformation), and excretion of the drug. **Absorption** is the process of the movement of the drug from the site of administration to the bloodstream. This process depends on (1) the route of administration, (2) the chemistry of the drug and its ability to cross biologic membranes, (3) the rate of gastric emptying (for orally administered drugs) and gastrointestinal (GI) movement, and (4) the quality of the product formulation. Food, food components, and nutrition supplements can

interfere with the absorption process, especially when the drug is administered orally.

**Distribution** occurs when the drug leaves the systemic circulation and travels to various regions of the body. Body areas of distribution vary with different drugs, depending on the drug's chemistry and ability to cross biologic membranes. The rate and extent of blood flow to an organ or tissue strongly affect the amount of drug that reaches the area. Many drugs are highly bound to plasma proteins such as albumin. The bound fraction of drug does not leave the vasculature and therefore does not produce a pharmacologic effect. Only the **unbound fraction** is able to produce an effect at a target organ.

A drug is eliminated from the body as either an unchanged drug or a metabolite of the original compound. The major organ of **metabolism**, or **biotransformation**, in the body is the liver, although other sites, such as the intestinal membrane, contribute to variable degrees. One of the more important enzyme systems that facilitate drug metabolism is the **cytochrome P-450 enzyme system**. This is a multienzyme system in the smooth endoplasmic reticulum of numerous tissues that is involved in phase I of liver detoxification (see Chapter 20). Food or dietary supplements may either increase or inhibit the activity of this enzyme system, which can significantly change the rate or extent of drug metabolism. The general tendency of the process of metabolism is to transform a drug from a lipid-soluble to a more water-soluble compound that can be handled more easily by the kidneys and excreted in the urine.

Renal **excretion** is the major route of elimination for drugs and drug metabolites either by glomerular filtration or tubular secretion. To a lesser extent drugs may be eliminated in feces, bile, and other body fluids. Under certain circumstances, such as a change in urinary pH, drugs that have reached the renal tubule may pass back into the bloodstream. This process is known as *tubular resorption*. The recommended dose of a drug generally assumes normal liver and kidney function. The dose and dosing interval of an excreted drug or active metabolite must be adjusted to meet the degree of renal dysfunction in patients with kidney disease (see Chapter 36).

## **RISK FACTORS FOR FOOD-DRUG INTERACTIONS**

Patients must be assessed individually for the effect of food on drug action and the effect of drugs on nutrition status. Interactions can be caused or complicated by **polypharmacy**, nutrition status, genetics, underlying illness, special diets, nutrition supplements, tube feeding, herbal or phytonutrient products, alcohol intake, drugs of abuse, nonnutrients in food, excipients in drugs or food, allergies, or intolerances. Poor patient compliance and physicians' prescribing patterns further complicate the risk. Drug-induced malnutrition occurs most commonly during long-term treatment for chronic disease, and older patients are at a particularly high risk for many reasons (see *Focus On: Polypharmacy in Older Adults*).

## ◎ FOCUS ON

### Polypharmacy in Older Adults

**O**lder patients are more likely to take multiple drugs, both prescription and over-the-counter, than are younger patients. They have a higher risk of food-drug interactions because of physical changes related to aging, such as the increase in the ratio of fat tissue to lean body mass, a decrease in liver mass and blood flow, and impairment of kidney function. Illness, cognitive or endocrine dysfunction, and ingestion of restricted diets also increase this risk. Malnutrition and dehydration affect drug kinetics. The use of herbal or phytonutrient products has increased significantly in all developed countries, including use by older adults. Drugs of abuse or excessive alcohol intake are often missed in the older patient.

Central nervous system side effects of drugs can interfere with the ability or desire to eat. Drugs that cause drowsiness, dizziness, ataxia, confusion, headache, weakness, tremor, or peripheral neuropathy can lead to nutritional compromise, particularly in older patients. Recognition of these problems as a drug side effect rather than a consequence of disease or aging can be overlooked. An old list known as the Beers criteria lists some medications that can cause cardiac, gastrointestinal or urinary effects, although the usefulness of the Beers criteria is now controversial (Steinman et al., 2009).

Care must be taken to evaluate intake of interacting nutrients (in the oral diet, supplements, or tube feedings) when specific drugs are used. Examples are vitamin K with warfarin (Coumadin); calcium and vitamin D with tetracycline; and potassium, sodium, and magnesium with loop diuretics such as furosemide (Lasix). Patients with Parkinson disease may be concerned with the amount and timing of protein intake because of interaction with levodopa (Sinemet, Dopar). The interdisciplinary team, which includes the physician, pharmacist, nurse, and dietitian, must work together to plan and coordinate the medication regimen and diet and nutritional supplements to preserve optimal nutrition status and minimize food-drug interactions (Figure 9-1).

Existing malnutrition places patients at greater risk for drug-nutrient interactions. Protein alterations—specifically low albumin levels—and changes in body composition secondary to malnutrition can affect drug disposition by altering protein binding and drug distribution. Patients with active cancer or human immunodeficiency virus (HIV) infection who have significant anorexia and wasting are at special risk because of the high prevalence of malnutrition and reduced intakes. Treatment modalities such as chemotherapy and radiation may also exacerbate nutritional

**FIGURE 9-1** As a result of the increased potential for illness with aging, older adults often take multiple drugs, both prescription and over-the-counter preparations. This places them at increased risk for drug-drug and food-drug interactions.

disturbances. For example, cisplatin (Platinol-AQ) and other cytotoxic agents commonly cause mouth sores, nausea, vomiting, diarrhea, anorexia, and reduced food intake.

Drug disposition can be affected by alterations in the GI tract, such as vomiting, diarrhea, hypochlorhydria, mucosal atrophy, and motility changes. Malabsorption caused by intestinal damage from disease such as cancer, celiac disease, or inflammatory bowel disease creates greater potential for food-drug interactions. Body composition is another important consideration in determining drug response. In obese or older patients, the proportion of adipose tissue to lean body mass is increased. In theory, accumulation of fat-soluble drugs such as the long-acting benzodiazepines (e.g., diazepam [Valium]) is more likely to occur. Accumulation of a drug and its metabolites in adipose tissue may result in prolonged clearance and increased toxicity (Spriet et al., 2009). In older patients this interaction may be complicated by decreased hepatic clearance of the drug.

The developing fetus, infant, and pregnant woman are also at high risk for drug-nutrient interactions. Many drugs have not been tested on these populations, making it difficult to assess the risks of negative drug effects, including food-drug interactions.

### Pharmacogenomics

Gene-nutrient interactions reflect the genetic heterogeneity among humans, environmental factors and dietary chemicals, and diverse physiologies (Wise and Kaput, 2009). Because the efficacy and safety disparity of drugs varies according to race and genetic variants, pharmacogenetic knowledge is important for the interpretation and prediction of drug interaction-induced adverse events (Bai, 2010). **Pharmacogenomics** involves genetically determined variations that are revealed solely by the effects of drugs and can be a driver for nutrigenomics, as discussed in Chapter 5

(Ghosh et al., 2007). Food-drug interaction ramifications are seen in glucose-6-phosphate dehydrogenase (G6PD) enzyme deficiency, slow inactivation of isoniazid (INH) or phenelzine (Nardil), and warfarin (Coumadin) resistance. Warfarin resistance affects individual requirements for and response to warfarin.

Slow inactivation of INH used in tuberculosis (TB) represents the effect of slow **acetylation**, a conjugation reaction that metabolizes and inactivates amines, hydrazines, and sulfonamides. “Slow acetylators” are persons who metabolize these drugs more slowly than average because of inherited lower levels of the hepatic enzyme acetyl transferase. Therefore unacetylated drug levels remain higher for longer periods in these persons than in those who are “rapid acetylators.” For example, the **half-life** of INH for fast acetylators is approximately 70 minutes, whereas the half-life is more than 3 hours for slow acetylators. A dose of drug prescribed normally for fast acetylators can be toxic for slow acetylators. Elevated blood levels of affected drugs in slow acetylators increase the potential for food-drug interactions. Slow inactivation of INH increases the risk of pyridoxine deficiency and peripheral neuropathy. Slow inactivation of phenelzine, a monoamine oxidase (MAO) inhibitor, increases the risk for hypertensive crisis if foods high in tyramine are consumed. Dapsone (DDS) and hydralazine (Apresoline) are also metabolized by acetylation and are affected by inherited differences in acetylase enzymes.

Deficiency of G6PD is an X-chromosome-linked deficiency of G6PD enzyme in red blood cells that can lead to neonatal jaundice, hemolytic anemia, or acute hemolysis. Most common in African, Middle Eastern, and Southeast Asian populations, it is also called *favism*. Intake of fava beans, aspirin, sulfonamides, and antimalarial drugs can cause hemolysis and acute anemia in G6PD-deficient persons. The potential exists for food-drug interactions in G6PD deficiency resulting from the ingestion of fava beans (broad beans), as well as vitamin C or vitamin K.

Another factor that affects drug metabolism is genetically different activity of cytochrome P450 (CYP) enzymes. Therapeutic proteins affect the disposition of drugs that are metabolized by these enzymes (Lee et al., 2010). “Slow metabolizers” may have less of a specific enzyme or their enzymes may be less active. Such individuals have a higher risk of adverse drug effects. Slow CYP2D6 metabolizers make up approximately 5% to 10% of whites, whereas approximately 20% of Asians are CYP2C19 poor metabolizers. Tests are now available to analyze deoxyribonucleic acid (DNA) to determine variations in the activity of these two enzymes. CYP2D6 and CYP2C19 metabolize approximately 25% of all drugs, including many antipsychotics, antidepressants, and narcotics. Slow metabolizers achieve a higher blood level with usual doses of such drugs, whereas fast metabolizers may have an unpredictable response as a result of rapid metabolism of the drug (Medical Letter, 2005).

Drug response genotyping helps to determine which drugs will be effective, depending on an individual’s genetic makeup (see Chapter 5). The ability to predict response to specific drugs determines more effective treatments for

cancer, mental illness, and even pain management. Genotyping will help reduce adverse drug reactions, including food-medication interactions.

## EFFECTS OF FOOD ON DRUG THERAPY

### Drug Absorption

The presence of food and nutrients in the stomach or intestinal lumen may reduce the absorption of a drug. **Bioavailability** describes the fraction of an administered drug that reaches the systemic circulation. If a medication is administered intravenously, its bioavailability is 100%, but bioavailability decreases because absorption and metabolism are incomplete when taken orally. Examples of a critically significant reduction in drug absorption are the antosteoporosis drugs alendronate (Fosamax), risedronate (Actonel), or ibandronate (Boniva). Absorption is negligible if these drugs are given with food and reduced by 60% if taken with coffee or orange juice. The manufacturer’s instructions for alendronate or risedronate are to take the drug on an empty stomach with plain water at least 30 minutes before any other food, drink, or medication. Ibandronate must be taken at least 60 minutes before any other food, drink, or medication. The absorption of the iron from supplements can be decreased by 50% if taken with food. Iron is best absorbed when taken with 8 oz of water on an empty stomach. If iron must be taken with food to avoid GI distress, it should not be taken with bran, eggs, high-phytate foods, fiber supplements, tea, coffee, dairy products, or calcium supplements, because each of these can decrease iron absorption (see Chapter 3).

Various mechanisms may contribute to the reduction in the rate or extent of drug absorption in the presence of food or nutrients. The presence and type of meal or food ingested influence the rate of gastric emptying. Gastric emptying may be delayed by the consumption of high-fiber meals and meals with high fat content. In general, a delay in drug absorption is not clinically significant as long as the extent of absorption is not affected. However, delayed absorption of antibiotics or analgesics may be clinically significant. Chelation reactions occur between certain medications and divalent or trivalent cations, such as iron, calcium, magnesium, zinc, or aluminum, and the absorption of drugs may be reduced by chelation with one of these metal ions.

The Parkinson disease drug entacapone (Comtan) chelates with iron; therefore the iron must be taken 1 hour before or 2 hours after taking the drug. The antibiotics ciprofloxacin (Cipro) and tetracycline (Achromycin-V or Sumycin) form insoluble complexes with calcium in dairy products or calcium-fortified foods and beverages; calcium, magnesium, zinc, or iron supplements; or aluminum in antacids, thus preventing or reducing the absorption of both drug and nutrient (Neuhofel et al., 2002). The optimal approach to avoid this interaction is to stop noncritical supplements for the duration of the antibiotic prescription. If this is not possible, particularly with magnesium or with

long-term antibiotic use, it is advisable to give the drug at least 2 hours before or 6 hours after the mineral.

**Adsorption**, or the adhesion to food or a food component, is another mechanism by which drug absorption is slowed or reduced. A high-fiber diet may decrease the absorption of tricyclic antidepressants such as amitriptyline (Elavil), leading to loss of therapeutic effect of the antidepressant because of the adsorption of the drug to the fiber. Likewise, the cardiovascular drug digoxin (Lanoxin) should not be taken with high-phytate foods such as wheat bran or oatmeal.

**Gastrointestinal pH** is another important factor in the absorption of drugs. Any situations resulting in changes in gastric acid pH, such as achlorhydria or hypochlorhydria, may reduce drug absorption. An example of such an interaction is the failure of ketoconazole (Nizoral) to clear a *Candida* infection in patients with HIV infection or in persons taking potent acid-reducing agents for gastroesophageal reflux disease (GERD). Ketoconazole achieves optimal absorption in an acid medium. Because of the high prevalence of achlorhydria in HIV infected patients, dissolution of ketoconazole tablets in the stomach is reduced, leading to impaired drug absorption. This is also a concern with hypochlorhydria in persons receiving chronic acid suppression therapy, such as antacids, histamine 2 ( $H_2$ ) receptor antagonists (e.g., famotidine [Pepcid]), or proton-pump inhibitors (e.g., omeprazole [Prilosec]). Ingestion of ketoconazole with an acidic liquid such as cola or a dilute hydrochloric acid (HCl) solution may improve bioavailability in these patients.

The presence of food in the stomach enhances the absorption of some medications, such as the antibiotic cefuroxime axetil (Ceftin) or the antiretroviral drug saquinavir (Invirase). These drugs are prescribed to be taken after a meal to reduce the dose that must be taken to reach an effective level. The bioavailability of cefuroxime axetil is substantially greater when taken with food, compared with taking it in the fasting state.

## Medication and Enteral Nutrition Interactions

Continuous enteral feeding is an effective method of providing nutrients to patients who are unable to swallow or eat adequately. However, use of the feeding tube to administer medication can be a problem. When liquid medications are mixed with enteral formulas, incompatibilities may occur. Types of **physical incompatibility** include granulation, gel formation, and separation of the enteral product; these frequently clog feeding tubes and interrupt delivery of nutrition to the patient. Examples of drugs that can cause granulation and gel formation are ciprofloxacin suspension (Cipro), chlorpromazine (Thorazine) concentrate, ferrous sulfate elixir, guaifenesin (Robitussin expectorant), and metoclopramide (Reglan) syrup (Wohlt et al., 2009). Emulsion breakage occurs when acidic pharmaceutical syrups are added to enteral formulas, more commonly in enteral formulas with intact protein and less so with hydrolyzed protein or free amino acids.

Most compatibility studies of medication and enteral products have focused on the effect of the drug on the

integrity of the enteral product. More important is the effect of the enteral product on the bioavailability of the drug. This area requires much more research as feeding tube placement becomes a more common practice. Bioavailability problems are common with phenytoin (Dilantin) suspension and tube feeding. Because blood levels of phenytoin are routinely performed to monitor the drug, much information exists about the reduction of phenytoin bioavailability when given with enteral feedings. Stopping the tube feeding before and after the phenytoin dose is generally suggested; a 2-hour feeding-free interval before and after the dose of phenytoin is administered can safely be recommended.

Information may not be readily available concerning a drug and enteral product interactions even though the manufacturer may have unpublished information about their drug's interaction with enteral products. Checking with the manufacturer's medical information department may yield more information for the clinician.

## Drug Distribution

Albumin is the most important drug-binding protein in the blood. Low serum albumin levels, often the result of inadequate protein intake and poor nutrition, provide fewer binding sites for highly protein-bound drugs. Fewer binding sites mean that a larger free fraction of drug will be present in the serum. Only the free fraction (unbound fraction) of a drug is able to leave the vasculature and exert a pharmacologic effect at the target organ. Patients with albumin levels below 3 g/dL are at increased risk for adverse effects from highly protein-bound drugs. Usual adult doses of highly protein-bound drugs in such persons may produce more pronounced pharmacologic effects than the same dose in persons with normal serum albumin levels. A lower dose of such drugs is often recommended for patients with low albumin levels. In addition, the risk for displacement of one drug from albumin-binding sites by another drug is greater when albumin levels are less than 3 g/dL.

The anticoagulant warfarin, which is 99.9% serum protein-bound, and the anticonvulsant phenytoin, which is greater than 90% protein-bound, are common drugs used in older patients. Low albumin levels tend to be more common in older patients and in critically ill patients. In the case of warfarin, higher levels of free drug lead to risk of excessive anticoagulation and bleeding. Phenytoin toxicity can result from higher serum levels of free phenytoin.

## Drug Metabolism

Enzyme systems in the intestinal tract and the liver, although not the only sites of drug metabolism, account for a large portion of the drug metabolizing activity in the body. Food can both inhibit and enhance the metabolism of medication by altering the activity of these enzyme systems. A diet high in protein and low in carbohydrates can increase the hepatic metabolism of the antiasthma drug theophylline (Theo-Dur).

Conversely, a substance found in grapefruit and grapefruit juice can inhibit the intestinal metabolism of drugs such as calcium channel blockers that are dihydropyridine

derivatives (felodipine [Plendil]) (Sica, 2006) and some 3-hydroxy-3-methylglutaryl (HMG)-coenzyme A (CoA) reductase inhibitors such as simvastatin (Zocor). Grapefruit inhibits the cytochrome P-450 3A4 enzyme system responsible for the oxidative metabolism of many orally administered drugs. This interaction appears to be clinically significant for drugs with low oral bioavailability, which are substantially metabolized and inactivated in the intestinal tract by the cytochrome P-450 3A4 enzyme in the intestinal wall. When grapefruit or grapefruit juice is ingested, the metabolizing enzyme is irreversibly inhibited, which reduces the normal metabolism of the drug. This reduction in metabolism allows more of the drug to reach the systemic circulation; the increase in blood levels of unmetabolized drug results in a greater pharmacologic effect and possible toxicity. Unfortunately, the effects of grapefruit on intestinal cytochrome P-450 3A4 last up to 72 hours, until the body can reproduce the enzyme. Therefore separating the ingestion of the grapefruit and the drug does not appear to alleviate this interaction.

Seville oranges (used in some marmalades but not in commercial orange juice), pomelos, and tangelos may also cause similar reactions (Egashira et al., 2003). Even a small amount of these foods may be dangerous and should be totally avoided with some drugs such as the immunosuppressant tacrolimus (Prograf) or simvastatin (Zocor). These foods may be taken in small amounts with other drugs such as fluvoxamine (Luvox). The interaction is not significant in drugs that are not metabolized by cytochrome P-450 3A4 in the intestinal wall, such as the HMG-CoA reductase inhibitors pravastatin (Pravachol) or fluvastatin (Lescol).

Competition between food and drugs such as propranolol (Inderal) and metoprolol (Lopressor) for metabolizing enzymes in the liver may alter the first-pass metabolism of these medications. Drugs absorbed from the intestinal tract by the portal circulation are first transported to the liver before they reach the systemic circulation. Because many drugs are highly metabolized during this first pass through the liver, only a small percentage of the original dose is actually available to the systemic circulation and the target organ. In some cases, however, this percentage can be increased by concurrent ingestion of food with the drug. When food and drug compete for the same metabolizing enzymes in the liver, more of the drug is likely to reach the systemic circulation, which can lead to a toxic effect if the dose of the drug is titrated to an optimal level in the fasting state.

### Drug Excretion

Food and nutrients can alter the resorption of drugs from the renal tubule. Resorption of the antimanic agent lithium (Lithobid or Eskalith) is closely associated with the resorption of sodium. When sodium intake is low or when a patient is dehydrated, the kidneys resorb more sodium. In the person treated with lithium, the kidney resorbs lithium as well as sodium under these conditions. Higher lithium levels and possible toxicity result. When excess sodium is ingested, the kidneys eliminate more sodium in the urine

and likewise more lithium. This produces lower lithium levels and possible therapeutic failure.

Drugs that are weak acids or bases are resorbed from the renal tubule into the systemic circulation only in the nonionic state. An acidic drug is largely in the nonionic state in urine with an acidic pH, whereas a basic drug is largely in a nonionic state in urine with an alkaline pH. A change in urinary pH by food may change the amount of drug existing in the nonionic state, thus increasing or decreasing the amount of drug available for tubular resorption. Foods such as milk, most fruits (including citrus fruits), and most vegetables are urinary alkalinizers (see *Clinical Insight: Urinary pH—How Does Diet Affect It?* in Chapter 36). This change can affect the ionic state of a basic drug such as the antiarrhythmic agent quinidine gluconate (Quinaglute Dura-Tabs). In alkaline urine the drug will be predominately in the nonionic state and available for resorption from the urine into the systemic circulation, which may lead to higher blood quinidine levels. The excretion of memantine (Namenda), a drug used to treat Alzheimer dementia, is also decreased by alkaline pH, thus raising the drug blood levels. Higher drug levels increase the risk of toxicity. This interaction is most likely to be clinically significant when the diet is composed exclusively of a single food or food group. Patients should be cautioned against initiating major diet changes without consulting their physician or dietitian.

Licorice, or glycyrrhizic acid, is an extract of glycyrrhiza root used in “natural” licorice candy. Approximately 100 g of licorice (the amount in two or more twists of natural licorice) can increase cortisol concentration, resulting in pseudohyperaldosteronism with increased sodium resorption, water retention, increased blood pressure, and greater excretion of potassium. The action of diuretics and antihypertensive drugs may be antagonized. The resultant hypokalemia may alter the action of some drugs (Pronsky and Crowe, 2010).

## EFFECTS OF DRUGS ON FOOD AND NUTRITION

Many of the interactions discussed in this section are the opposite of those discussed previously under the Effects of Food on Drug Therapy. For instance, the chelation of a mineral with a medication not only decreases the absorption and therefore the action of the drug, but also decreases the absorption and availability of the nutrient.

### Nutrient Absorption

Medication can decrease or prevent nutrient absorption. Chelation reactions between medications and minerals (metal ions) reduce the amount of mineral available for absorption. An example is tetracycline (Achromycin-V or Sumycin) and ciprofloxacin, which chelates calcium found in supplements or in dairy products such as milk or yogurt. This is also true for other divalent or trivalent cations such as iron, magnesium, and zinc found in individual mineral supplements or multivitamin-mineral supplements.

Standard advice is to take the minerals at least 2 to 6 hours apart from the drug.

Adsorption also can decrease nutrient absorption. Anti-hyperlipidemic, bile acid sequestrant cholestyramine (Questran) is also used to treat diarrhea. It adsorbs fat-soluble vitamins A, D, E, and K. Vitamin supplementation is recommended with long-term use of this drug, especially when it is taken more than once a day. More than 2 tbsp (30 ml) of mineral oil per day decreases absorption of fat-soluble vitamins A, D, E, and K. It is advised to take the mineral oil in the morning and the vitamins at least 2 hours later, primarily with chronic mineral oil use.

Drugs can reduce nutrient absorption by influencing the transit time of food and nutrients in the gut. Cathartic agents and laxatives reduce transit time and may cause diarrhea, leading to losses of calcium and potassium. Diarrhea may be induced by drugs containing sorbitol, such as syrup or solution forms of furosemide (Lasix), valproic acid (Depakene), carbamazepine (Tegretol), trimethoprim/sulfamethoxazole (Septra), or by drugs that increase peristalsis such as the gastric mucosa protectant misoprostol (Cytotec).

A drug also can prevent nutrient absorption by changing the GI environment. H<sub>2</sub>-receptor antagonists, such as famotidine (Pepcid) or ranitidine (Zantac), and proton-pump inhibitors, such as omeprazole (Prilosec) or esomeprazole (Nexium), are antisecretory drugs used to treat ulcer disease and GERD. They inhibit gastric acid secretion and raise gastric pH. These effects may impair absorption of vitamin B<sub>12</sub> by reducing cleavage from its dietary sources. Cimetidine (Tagamet) is an antagonist that also reduces intrinsic factor secretion; this can be a problem for vitamin B<sub>12</sub> absorption and can result in vitamin B<sub>12</sub> deficiency with long-term use. Because of the hypothesized effect on calcium absorption, protein pump inhibitors were thought to raise the risk of osteoporosis (Fournier et al., 2009) but recent information refutes this hypothesis (Targownik et al., 2010).

Drugs with the greatest effect on nutrient absorption are those that damage the intestinal mucosa. Damage to the structure of the villi and microvilli inhibits the brush-border enzymes and intestinal transport systems involved in nutrient absorption. The result is general or varying degrees of specific malabsorption, which can alter the ability of the GI tract to absorb minerals, especially iron and calcium. Damage to the gut mucosa commonly results from chemotherapeutic agents, nonsteroidal antiinflammatory drugs (NSAIDs), and long-term antibiotic therapy. NSAIDs may adversely affect the colon by causing a nonspecific colitis or by exacerbating a preexisting colonic disease (Valley et al., 2006). Patients with NSAID-induced colitis present with bloody diarrhea, weight loss, and iron deficiency anemia; the pathogenesis of this colitis is still controversial.

Drugs that affect intestinal transport mechanisms include (1) colchicine, an antiinflammatory agent used to treat gout; (2) paraaminosalicylic acid, an anti-TB drug; (3) sulfasalazine (Azulfidine), used to treat ulcerative colitis; and (4) trimethoprim (antibiotic in sulfamethoxazole-trimethoprim [Bactrim]) and antiprotozoal agent pyrimethamine

(Daraprim). The first two agents impair absorption of vitamin B<sub>12</sub>; the others are competitive inhibitors of folate transport mechanisms.

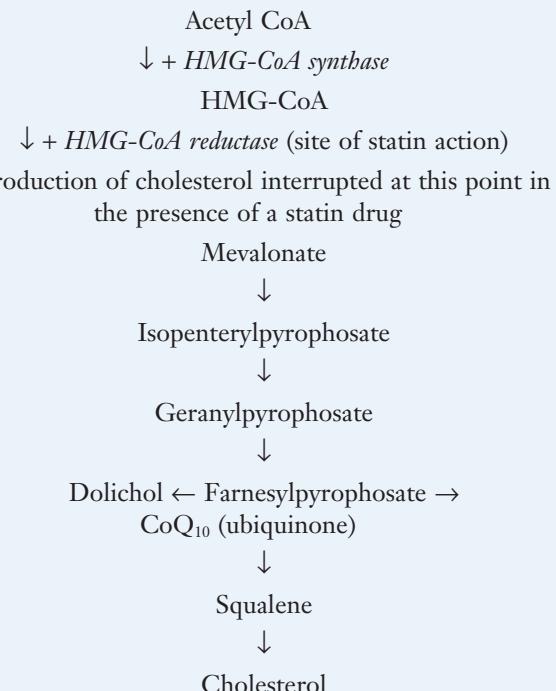

## Nutrient Metabolism

A drug may increase the metabolism of a nutrient, causing it to pass through the body faster, resulting in higher requirements; or a drug may cause vitamin antagonism by blocking conversion of a vitamin to the active form. Anticonvulsants phenobarbital and phenytoin induce hepatic enzymes and increase the metabolism of vitamins D and K, and folic acid (Crawford, 2005; Nicolaïdou et al., 2006). Supplements of these vitamins are often prescribed with these drugs. Carbamazepine (Tegretol) has been reported to affect the metabolism of biotin, vitamin D, and folic acid, leading to possible depletion. Measurement of vitamin D levels and supplementation if indicated are recommended with these anticonvulsants (Holick, 2007).

The anti-TB drug INH blocks the conversion of pyridoxine (vitamin B<sub>6</sub>) to its active form, pyridoxal 5-phosphate. Particularly in patients with low pyridoxine intake, this interaction may cause pyridoxine deficiency and peripheral neuropathy. Pyridoxine supplementation (25 to 50 mg/day) is generally recommended with the prescription of INH because it is prescribed for at least 6 months at a time. Some other drugs that function as pyridoxine antagonists are hydralazine (Apresoline), penicillamine, levodopa (Dopar), and cycloserine (Seromycin).

Methotrexate (MTX; Rheumatrex) is a folic acid antagonist used to treat cancer and rheumatoid arthritis. Without folic acid, DNA synthesis is inhibited, cell replication stops, and the cell dies. Pyrimethamine (Daraprim), used to treat malaria and ocular toxoplasmosis, is also a folic acid antagonist. These drugs bind to and inhibit the enzyme dihydrofolate reductase, preventing conversion of folate to its active form (see Chapter 3), which could lead to megaloblastic anemia from folate deficiency (see Chapter 33). Leucovorin (folinic acid, the reduced form of folic acid) is used with folic acid antagonists to prevent anemia and GI damage, especially with chemotherapy such as high-dose MTX. Leucovorin does not require reduction by dihydrofolate reductase; thus, unlike folic acid, it is not affected by folic acid antagonists. Therefore leucovorin may “rescue” normal cells from MTX damage by competing for the same transport mechanisms into the cells. Administration of daily folic acid supplements or folinic acid can lower toxicity without affecting efficacy of the drug. See also Chapter 8, “Clinical: Biochemical Assessment,” for more information on the assessment for folic acid.

Statin drugs (HMG-CoA reductase inhibitors) such as atorvastatin (Lipitor) affect the formation of coenzyme Q<sub>10</sub> (CoQ<sub>10</sub>; ubiquinone) See Box 9-2 on the mechanism of this effect. When HMG-CoA reductase is inhibited by statins, the production of cholesterol is significantly decreased. It is reasonable to conclude that the production of CoQ<sub>10</sub> is also decreased (Ghirlanda, 1993). Studies have shown that circulatory, platelet, and lymphocyte levels of CoQ<sub>10</sub> are also diminished. Although reports and small studies suggest that

**BOX 9-2****Steps in the Hepatic Production of Cholesterol**

*CoA*, Coenzyme A; *CoQ<sub>10</sub>*, coenzyme Q<sub>10</sub>; *HMG*, 3-hydroxy-3-methylglutaryl.

muscle pain and weakness can be relieved by CoQ<sub>10</sub> supplementation (Littarru 2007), further large-scale studies are still needed. It may be worthwhile to supplement patients taking HMG-CoA reductase inhibitors with at least 100 mg CoQ<sub>10</sub> daily for the preventive effect.

**Nutrient Excretion**

Some drugs can either increase or decrease the urinary excretion of nutrients. Drugs can increase the excretion of a nutrient by interfering with nutrient resorption by the kidneys. For instance, most clinicians know that loop diuretics such as furosemide (Lasix) or bumetanide (Bumex) increase the excretion of potassium; but these diuretics also increase the excretion of magnesium, sodium, chloride, and calcium. Potassium supplements are routinely prescribed with loop diuretics. In addition, clinicians need to consider supplements of magnesium and calcium, especially with long-term drug use, high doses of the diuretics, or poor dietary intake. Electrolyte and magnesium blood levels should be monitored. Prolonged use of high-dose diuretics, particularly by older patients on low-sodium diets, can cause sodium depletion. Hyponatremia may be overlooked in older patients because the mental confusion that is symptomatic of sodium depletion may be misdiagnosed as organic brain syndrome or dementia. Thiazide diuretics such as hydrochlorothiazide (HCTZ) increase the excretion of potassium and magnesium but reduce the excretion of

calcium by enhancing renal resorption of calcium. High-dose HCTZ plus calcium supplementation may result in hypercalcemia.

Potassium-sparing diuretics such as spironolactone (Aldactone) or triamterene (Dyrenium) increase excretion of sodium, chloride, and calcium. Blood levels of potassium can rise to dangerous levels if patients also take potassium supplements or suffer from renal insufficiency. Antihypertensive angiotensin-converting enzyme (ACE) inhibitors such as enalapril (Vasotec) or fosinopril (Monopril) decrease potassium excretion, leading to increased serum potassium levels. *The combination of a potassium-sparing diuretic and an ACE inhibitor increases the danger of hyperkalemia.*

Corticosteroids such as prednisone decrease sodium excretion, resulting in sodium and water retention. Conversely, enhanced excretion of potassium and calcium is caused by these drugs; so a low-sodium, high-potassium diet is recommended. Calcium and vitamin D supplements are generally recommended with long-term corticosteroid use to prevent osteoporosis, such as might be the case for a person with asthma, lupus, or rheumatoid arthritis. With corticosteroid use this risk is important because it appears that not only is calcium lost in the urine, but corticosteroids may impair intestinal calcium absorption.

Phenothiazine-class antipsychotic drugs such as chlorpromazine (Thorazine) increase excretion of riboflavin and can lead to riboflavin deficiency in those with poor dietary intake. A complication associated with the use of another drug, cisplatin, is the development of acute hypomagnesemia resulting from nephrotoxicity; hypocalcemia, hypokalemia, and hypophosphatemia are also common. Both intravenous magnesium supplementation via rectal treatment or post-treatment hydration and oral magnesium supplements taken between chemotherapeutic courses have been used to prevent magnesium depletion. Hypomagnesemia can result from cisplatin use even with high-dose magnesium replacement therapy. Hypomagnesemia can persist for months or even years after the final course. When any drugs known to cause hypomagnesemia are administered, preventive treatment is warranted (Atsmon and Dolev, 2005).

**MODIFICATION OF DRUG ACTION BY FOOD AND NUTRIENTS**

Food or nutrients can alter the intended pharmacologic action of a medication by enhancing the medication effects or by opposing it. The classic example of an enhanced drug effect is the interaction between monoamine oxidase inhibitors (MAOIs) such as phenelzine sulfate (Nardil) or tranylcypromine (Parnate) and **pressor agents** such as dopamine, histamine, and especially tyramine. These biologically active amines are normally present in many foods (Box 9-3), but they rarely constitute a hazard because they are deaminated rapidly by MAO and diamine oxidases. Inhibition of MAO by medication prevents the breakdown of tyramine and other pressor agents. Tyramine is a vasoconstrictor that raises blood pressure. Significant ingestion of high-tyramine foods such as aged cheeses and cured meats while being

**BOX 9-3**

### Pressor Agents in Foods and Beverages (Tyramine, Dopamine, Histamine, Phenylethylamine)

Avoid with MAOI medications: phenelzine (Nardil), tranylcypromine (Parnate), isocarboxazid (Marplan), selegiline (Eldepryl) in doses >10 mg/day, and the antibiotic linezolid (Zyvox).

#### **Foods That Must Be Avoided**

- Aged cheeses (e.g., cheddar, blue, Gorgonzola, Stilton)
- Aged meats (e.g., dry sausage such as salami, mortadella, Chinese dried duck)
- Soy sauce
- Fermented soya beans, soya bean paste, teriyaki sauce
- Tofu/fermented bean curd, tempeh
- Miso
- Fava (broad) beans or pods, snow pea pods (contain dopamine)
- Sauerkraut, kim chee
- Tap beer, Korean beer
- Concentrated yeast extracts (Marmite)
- Banana peel
- All casseroles made with aged cheese
- Meats, fish or poultry stored longer than 3-4 days in the refrigerator

#### **Foods That May Be Used with Caution**

- Red or white wine 2-4 oz per day
- Coffee, cola\*
- Pizza (homemade or gourmet pizzas may have higher content)
- Bottled beer, two 12-oz bottles, maximum
- Alcohol-free beer, two 12-oz bottles, maximum
- Liquors or distilled spirits (two 1½-oz servings per day)

#### **Foods Not Limited (based on current analyses)**

- Unfermented cheeses (cream, cottage, ricotta, mozzarella, processed American if refrigerated less than 2-3 weeks)
- Smoked white fish, salmon, carp, or anchovies
- Pickled herring
- Fresh meat poultry or fish
- Canned figs, raisins
- Fresh pineapple
- Beetroot, cucumber
- Sweet corn, mushrooms
- Salad dressings, tomato sauce
- Worcestershire sauce
- Baked raised products, English cookies
- Boiled egg, yogurt, junket, ice cream
- Avocado, figs, banana, raspberries
- Brewer's yeast (vitamin supplements)
- Curry powder
- Peanuts, chocolate
- Packaged or processed meats (e.g., hot dogs, bologna, liverwurst), although they should be stored in refrigerator immediately and eaten as soon as possible; histamine content is highest in improperly stored or spoiled fish, tuna

From Pronsky ZM & Crowe JP: Food medication-interactions, ed 16, Birchrunville, Pa, 2010, Food-Medication Interactions.

MAOI, Monoamine oxidase inhibitor.

\*Contains caffeine, a weak pressor agent; in quantities >500 mg/day may exacerbate reactions.

treated with an MAOI antidepressant can cause a hypertensive crisis with increased heart rate, flushing, headache, stroke, and even death. This reaction may be avoided with use of a transdermal administration method that bypasses the GI tract and omits contact with the indicated foods (Blob et al., 2007).

Caffeine in foods or beverages (see Appendix 39) increases the adverse effects of stimulant drugs such as amphetamines, methylphenidate (Ritalin, Concerta), or theophylline, causing nervousness, tremor, and insomnia. Conversely, the central nervous system (CNS) stimulatory properties of caffeine can oppose or counteract the antianxiety effect of tranquilizers such as lorazepam (Ativan).

Warfarin (Coumadin) is an oral anticoagulant that reduces the hepatic production of four vitamin K-dependent clotting factors by inhibiting the conversion of vitamin K to a usable form. Because this is a competitive interaction, the ingestion of vitamin K in the usable form will oppose the action of warfarin and allow the production of more clotting factors. To achieve an optimal level of anticoagulation, a

balance must be maintained between the dose of the drug and the ingestion of vitamin K. Counseling of a person taking oral anticoagulation therapy should include nutrition therapy to maintain a consistent dietary vitamin K intake rather than prohibiting all high-vitamin K foods, such as dark green leafy vegetables (Johnson, 2005). CoQ<sub>10</sub>, St. John's wort, or avocado may also counteract the effect of warfarin.

Ingestion of other substances may enhance the anticoagulant effect of warfarin. These substances include onions, garlic, quinine, papaya, mango, or vitamin E supplements in doses greater than 400 IU. Certain herbal products such as dong quai, which contain coumarin-like substances, or ginseng, which is a platelet inhibitor, also enhance the effect of the warfarin. Enhancement of the anticoagulation effects of warfarin may lead to serious bleeding events (Greenblatt and von Moltke, 2005). Recently there has been concern about an interaction with cranberry and warfarin (Coumadin) and the Food and Drug Administration (FDA) required a label warning change because of anecdotal reports.

However, several studies found no evidence-based information to support this warning (Ansell, 2009).

## Alcohol

Ethanol combined with certain medications produces additive toxicity, affecting various body organs and systems. Ethanol combined with CNS-depressant medications such as a benzodiazepine (e.g., diazepam [Valium]) or a barbiturate (e.g., phenobarbital) may produce excessive drowsiness, incoordination, and other signs of CNS depression.

In the GI tract ethanol acts as a stomach mucosal irritant. Combining ethanol with drugs that cause the same effect such as aspirin or other NSAIDs (ibuprofen [Advil or Motrin]) may increase the risk of GI ulceration and bleeding. Because of the hepatotoxic potential of ethanol, it should not be combined with medications that also exhibit a risk of hepatotoxicity such as acetaminophen (Tylenol), amiodarone (Cordarone), or methotrexate (Rheumatrex).

Ethanol can inhibit gluconeogenesis, particularly when consumed in a fasting state. Inhibition of gluconeogenesis will prolong a hypoglycemic episode caused by insulin or an oral hypoglycemic agent such as glyburide (Diabeta, Micronase).

The combination of disulfiram (Antabuse) and ethanol produces a potentially life-threatening reaction characterized by flushing, rapid heartbeat, palpitations, and elevation of blood pressure. Disulfiram inhibits aldehyde dehydrogenase, an enzyme necessary for the normal catabolism of ethanol by the liver. As a result of this enzyme inhibition, high levels of acetaldehyde accumulate in the blood. Symptoms such as flushing, headache, and nausea appear within 15 minutes of alcohol ingestion. Because these symptoms are unpleasant, the drug is sometimes used as an aid to prevent alcoholics from returning to drinking. However, because these symptoms may also be life threatening, candidates for this drug must be chosen carefully. Other medications, when ingested concurrently with ethanol, may produce disulfiram-like reactions. Some of these medications are the antibiotics metronidazole (Flagyl) and cefoperazone (Cefobid), the oral hypoglycemic agent chlorpropamide (Diabinese), and the antineoplastic agent procarbazine (Matulane).

Ethanol can also affect the physical characteristics of a medication. The FDA recently required a change in the labeling of the extended-release capsules of morphine sulfate (Avinza, Kadian). The label now includes a **black box warning** that patients must not consume alcoholic beverages or take morphine sulfate with medications containing alcohol. If taken with alcohol, the extended-release beads of morphine can dissolve rapidly, delivering a potentially fatal dose of morphine.

## EFFECTS OF DRUGS ON NUTRITION STATUS

The desired effects of medications often are accompanied by effects that are considered undesirable, or **side effects**. Side effects are often an extension of the desired effects, such

as bacterial overgrowth as a result of use of an antibiotic. Overgrowth of *Clostridium difficile* causes pseudomembranous colitis. Suppression of natural oral bacteria may lead to oral yeast overgrowth, or candidiasis (see Chapter 26).

## Oral, Taste, and Smell

Many drugs affect the ability to taste or smell foods (Box 9-4). Drugs can cause an alteration in taste sensation (dysgeusia), reduced acuity of taste sensation (hypogeusia), or an unpleasant aftertaste, any of which may affect food intake. The mechanisms by which drugs alter the chemical senses are not well understood. They may alter the turnover of taste cells or interfere with transduction mechanisms inside taste cells; or they may alter neurotransmitters that process chemosensory information. Common drugs that cause dysgeusia include the antihypertensive drug captopril (Capoten), the antineoplastic cisplatin (Platinol-AQ), and the anticonvulsant phenytoin. When exploring taste changes related to medication use it is always important to consider changes in zinc absorption related to the medication. An underlying zinc deficiency may affect the sense of taste (Heckmann and Lang, 2006).

Captopril (Capoten) may cause a metallic or salty taste and the loss of taste perception. The antibiotic clarithromycin (Biaxin) enters the saliva. The drug itself has a bitter taste that stays in the mouth as long as the drug is present in the body. An unpleasant or metallic taste has been reported by up to 34% of patients taking the sleep aid eszopiclone (Lunesta).

Antineoplastic drugs, used in chemotherapy for cancer, affect cells that reproduce rapidly, including the mucous membranes. Inflammation of the mucous membranes, or mucositis, occurs and is manifest as stomatitis (mouth inflammation), glossitis (tongue inflammation), or cheilitis (lip inflammation and cracking). Mucositis can be extremely painful to the point that patients are not able to eat or even drink (see Chapter 38.) Aldesleukin, also called interleukin-2 (Proleukin), paclitaxel (Taxol), and carboplatin (Paraplatin), are examples of antineoplastic agents that commonly cause severe mucositis.

Anticholinergic drugs (Box 9-5) compete with the neurotransmitter acetylcholine for its receptor sites, thereby inhibiting transmission of parasympathetic nerve impulses. This results in decreased secretions, including salivary secretions, causing dry mouth (xerostomia). Tricyclic antidepressants such as amitriptyline (Elavil), antihistamines such as diphenhydramine (Benadryl), and antispasmodic bladder control agents such as oxybutynin (Ditropan) are particularly problematic. Dry mouth immediately causes loss of taste sensation. Long-term dry mouth can cause dental caries and loss of teeth, gum disease, stomatitis, and glossitis, as well as nutritional imbalance and undesired weight loss (Friedlander et al., 2003) (see Chapter 26).

## Gastrointestinal Effects

GI irritation and ulceration are serious problems with many drugs. The antiosteoporosis drug alendronate is contraindicated in patients who are unable to sit upright for at

**NSAID**, Nonsteroidal antiinflammatory drug.

least 30 minutes after taking it because of the danger of esophagitis. NSAIDs such as ibuprofen or aspirin can cause stomach irritation, dyspepsia, gastritis, ulceration, and sudden serious gastric bleeding, sometimes leading to fatalities. Fluoxetine (Prozac) and other selective serotonin reuptake inhibitors can also cause serious gastric irritation, leading to hemorrhage, especially when aspirin or NSAIDs are also used (Yuan et al., 2006) (Box 9-6).

Antineoplastic drugs, used to treat cancer, often cause severe nausea and vomiting. Severe, prolonged nausea and vomiting, lasting as long as a week, have been reported with cisplatin (Platinol-AQ). Dehydration and electrolyte imbalances are of immediate concern. Weight loss and malnutrition are common long-term effects of these drugs, although it is often difficult to distinguish these effects from the complications of the disease itself (see Chapter 37). Serotonin antagonists such as ondansetron (Zofran) help to reduce these GI side effects.

Drugs can cause changes in bowel function that can lead to constipation or diarrhea. Narcotic agents such as codeine and morphine (MS Contin, MSIR, Avinza) cause a nonproductive increase in smooth muscle tone of the intestinal muscle wall, thereby decreasing peristalsis and causing constipation. A new parenteral drug methylnaltrexone (Relistor) is a laxative, administered subcutaneously, specifically indicated for severe opioid-induced constipation.

Drugs with anticholinergic effects decrease intestinal secretions, slow peristalsis, and cause constipation. The

atypical antipsychotic clozapine (Clozaril), tricyclic antidepressant amitriptyline (Elavil), and antihistamine diphenhydramine (Benadryl) cause constipation and possibly impaction. Patients should be closely monitored and kept adequately hydrated.

Some drugs are used to inhibit intestinal enzymes, such as the diabetic drugs acarbose (Precose) and miglitol (Glyset), which are  $\alpha$ -glucosidase inhibitors. Such action leads to a delayed and reduced rise in postprandial blood glucose levels and plasma insulin responses. The major adverse effect is GI intolerance, specifically diarrhea, flatulence, and cramping secondary to both the osmotic effect and bacterial fermentation of undigested carbohydrates in the distal bowel.

Prescription orlistat (Xenical, or over-the-counter [OTC] Alli), is a lipase inhibitor for weight loss that reduces the absorption of fat by binding to lipase in the intestine, thereby inhibiting its action. Consequently, fecal fat excretion is increased, a factor that contributes to the GI complaints associated with the drug, specifically oily spotting, increased fecal urgency, and possible fecal incontinence. A low-fat diet of no more than 30% of calories from fat is essential. Fat intake should be distributed among all three meals. Orlistat is not an appetite suppressant, and some persons may find it difficult to maintain a low-fat diet. Sufficient counseling and support is needed for success with this medication. Attention should also be given to potential malabsorption of fat soluble vitamins A, D, E, and K and carotenoids

requiring the presence of fat for optimal absorption. Obviously any of these problems, from dry mouth, to GI irritation, to constipation or diarrhea, can negatively affect food intake and nutrient absorption and nutrition status (see Chapter 22).

The use of antibiotics, particularly broad-spectrum antibiotics (Box 9-7) for long periods, destroy all sensitive bacteria of the gut flora. Intestinal flora that are not sensitive to the antibiotic will continue to grow because they are no longer inhibited by the bacteria that have been destroyed. An example of this situation is the overgrowth of *C. difficile*, causing pseudomembranous colitis with very strong-smelling yellow diarrhea (see also Chapter 29).

**Appetite Changes**

Drugs can suppress appetite (Box 9-8), leading to undesired weight changes, nutritional imbalance, and growth retardation in children. In the past the stimulant drug dextroamphetamine (Dexedrine) was used as an appetite suppressant. Because of the potential for abuse, the use of amphetamines for appetite suppression is no longer legal. Dextroamphetamine (part of Adderall) is now only indicated for treatment

of attention-deficit hyperactivity disorder (ADHD) or narcolepsy.

In general, most CNS stimulants, including the amphetamine mixture (Adderall) and methylphenidate (Ritalin, Concerta, Metadate, Daytrana), suppress appetite or cause frank anorexia. These drugs are used extensively to treat ADHD in children and may cause weight loss and inhibit growth (see Chapter 18).

Sibutramine (Meridia) and phentermine (Adipex-P, Ionamin), structurally related to amphetamines, are used as appetite suppressants. These drugs are indicated for short-term use, along with a reduced-calorie diet and exercise, in obese patients (i.e., patients with a body mass index [BMI] greater than 30) or in overweight patients (BMI greater than 27) with additional risk factors such as hypertension, diabetes, or hyperlipidemia.

A major side effect of stimulant drugs is hypertension. Thus they are often contraindicated for hypertensive patients or those who have seizures or cardiac disease. Because hypertension is common among obese persons, these contraindications may limit the use of stimulants in obese or overweight hypertensive patients.

**BOX 9-8****Examples of Drugs That Cause Anorexia****Antiinfectives**

- Amphotericin B (Abelcet, AmBisome, Amphotec, Fungizone)
- Atovaquone (Mepron)
- Cidofovir (Vistide)
- Didanosine (ddI) (Videx)
- Ethionamide (Trecator-SC)
- Fomivirsen (Vitravene)
- Foscarnet sodium (Foscavir)
- Hydroxychloroquine sulfate (Plaquenil)
- Metronidazole (Flagyl)
- Pentamidine isethionate (NebuPent, Pentam 300)
- Pyrimethamine (Daraprim)
- Sulfadiazine
- Zalcitabine (Hivid)

**Antineoplastics**

- Aldesleukin/interleukin-2 (Proleukin)
- Bleomycin sulfate (Blenoxane)
- Capecitabine (Xeloda)
- Carboplatin (Paraplatin)
- Cytarabine (ara-C) (Cytosar-U)
- Dacarbazine (DTIC-Dome)
- Fluorouracil (Adrucil) (5-FU)
- Hydroxyurea (Hydrea)
- Imatinib mesylate (Gleevec)
- Irinotecan HCl (Camptosar)
- Methotrexate (MTX)
- Vinblastine sulfate (Velban)
- Vinorelbine tartrate (Navelbine)

**Bronchodilators**

- Albuterol sulfate (Proventil, Ventolin)
- Theophylline (Elixophyllin, Slo-Phyllin, Theo-24, Theobid, Theolair, Uniphyl)

**Cardiovascular Drugs**

- Amiodarone HCl (Cordarone)
- Acetazolamide (Diamox)
- Hydralazine HCl (Apresoline)
- Quinidine (Quinaglute Dura, Quinidex Extentabs, Quinora)

**Stimulants**

- Amphetamines (Adderall, Dexedrine)
- Methylphenidate HCl (Ritalin, Concerta, Metadate, Daytrana)
- Phentermine (Adipex-P)

**Miscellaneous**

- Fluoxetine (Prozac, Sarafem)
- Galantamine (Reminyl)
- Naltrexone HCl (ReVia)
- Oxycodone (OxyContin)
- Rivastigmine (Exelon)
- Sibutramine HCl (Meridia)
- Sulfasalazine (Azulfidine)
- Topiramate (Topamax)

From Pronsky ZM & Crowe JP: Food-medication interactions, ed 16, Birchrunville, Pa, 2010, Food-Medication Interactions.

CNS side effects can interfere with the ability or desire to eat. Drugs that cause drowsiness, dizziness, ataxia, confusion, headache, weakness, tremor, or peripheral neuropathy can lead to nutritional compromise, particularly in older or chronically ill patients. Recognition of these problems as a drug side effect rather than a consequence of disease or aging is often overlooked.

Many medications stimulate appetite and lead to weight gain (Box 9-9). Antipsychotic drugs such as clozapine (Clozaril), olanzapine (Zyprexa), tricyclic antidepressant drugs such as amitriptyline (Elavil), and the anticonvulsant divalproex (Depakote) often lead to weight gain. Patients complain of a ravenous appetite and the inability to “feel full.” Weight gains of 40 to 60 lb in a few months are not uncommon. Corticosteroid use is associated with dose-dependent weight gain in many patients. Sodium and water retention, as well as appetite stimulation, causes weight increases with corticosteroids. Medical nutrition therapy (MNT) is essential, as is routine exercise.

Appetite stimulation is desirable for patients suffering from wasting (cachexia) resulting from disease states such as cancer or HIV or the acquired immunodeficiency (AIDS)

virus (Tisdale, 2006). Drugs indicated as appetite stimulants or antiwasting agents are the hormone megestrol acetate (Megace, Megace ES), human growth hormone somatropin (Serostim), the anabolic steroid oxandrolone (Oxandrin), and the marijuana derivative dronabinol (Marinol). Drugs also used as appetite stimulants, although not FDA-indicated as such, are the anabolic steroids oxymetholone (Anadrol-50) and nandrolone (Deca-Durabolin), the antihistamine cyproheptadine (Periactin), and the hormone testosterone (Androderm, Virilon). The ω-3 fatty acid, eicosapentaenoic acid has been suggested as an appetite stimulant. Although some studies have not shown improvement in appetite or weight gain (Fearon et al., 2006), one has shown improvement in cachexia (Stehr and Heller, 2006). Obviously this is an area of further study. With the successful advent of highly active antiretroviral therapy (HAART), lipodystrophy is often a problem for patients with HIV/AIDS. Debate about an accurate definition of lipodystrophy is ongoing. Redistribution of body fat, fat wasting, glucose intolerance, hypertension, and hyperlipidemia are common aspects of this syndrome. Antidiabetic drugs such as metformin (Glucophage) and rosiglitazone (Avandia) are used to

normalize glucose and insulin levels. Antihyperlipidemic drugs such as atorvastatin (Lipitor), pravastatin (Pravachol), or fenofibrate (Tricor) are used to control elevated triglycerides and cholesterol.

**Organ System Toxicity**

Drugs can cause specific organ system toxicity such as hepatotoxicity, nephrotoxicity, pulmonary toxicity, neurotoxicity, ototoxicity, ocular toxicity, pancreatitis, or cardiotoxicity. MNT may be indicated as part of the treatment of these toxicities. Although all toxicities are of concern, hepatotoxicity and nephrotoxicity are addressed here because drugs are eliminated from the body predominately through the liver and kidney.

Examples of drugs that cause hepatotoxicity (liver damage) leading to hepatitis, jaundice, hepatomegaly, or even liver failure are amiodarone (Cordarone), amitriptyline (Elavil), lovastatin (Mevacor) and other “statin” antihyperlipidemic drugs, divalproex (Depakote), carbamazepine (Tegretol), methotrexate, kava, niacin, and sulfasalazine (Azulfidine). Monitoring of hepatic function through routine blood work for liver enzyme levels is generally prescribed with use of these drugs (see Table 8-1).

Nephrotoxicity (kidney damage) may change the excretion of specific nutrients or cause acute or chronic renal

insufficiency, which may not resolve with cessation of drug use. Examples of drugs that often cause nephrotoxicity are antiinfectives amphotericin B (especially with intravenous desoxycholate form [Fungizone]) and cidofovir (Vistide), as well as antineoplastics cisplatin (Plaquenil-AQ), gentamicin (Garamycin), ifosfamide (Ifex), methotrexate, and pentamidine (Pentam 300). Adequate or extra prehydration, often administered intravenously, is prescribed to reduce renal toxicity. For example, with cidofovir, 1 L of intravenous normal saline (0.9% sodium chloride [NaCl]) is infused 1 to 2 hours before infusion of the drug. If tolerated, up to an additional liter may be infused after the drug infusion. Oral probenecid (Benemid) is also prescribed with cidofovir to reduce nephrotoxicity.

**Glucose Levels**

Many drugs affect glucose metabolism, causing hypoglycemia or hyperglycemia and in some cases frank diabetes (Box 9-10). The mechanisms of these effects vary from drug to drug and from individual to individual. Drugs may stimulate glucose production or impair glucose uptake. They may inhibit insulin secretion, decrease insulin sensitivity, or increase insulin clearance.

Glucose levels may be affected by changes in parameters, such as hypokalemia induced by thiazide diuretics or weight

gain induced by antipsychotic medications (Izzedine et al., 2005). Corticosteroids, particularly prednisone, prednisolone, and hydrocortisone, are diabetogenic because of increased gluconeogenesis, but they also cause insulin resistance and therefore inhibit glucose uptake. Second-generation antipsychotics, particularly clozapine (Clozaril) or olanzapine (Zyprexa), have been reported to cause treatment-emergent hyperglycemia. Recently the FDA added a labeling requirement on all second-generation antipsychotics to warn of the possibility of developing hyperglycemia and diabetes.

**EXCIPIENTS AND FOOD-DRUG INTERACTIONS**

An **excipient** is added to drug formulations for its action as a buffer, binder, filler, diluent, disintegrant, glidant, flavoring, dye, preservative, suspending agent, or coating. Excipients are also called inactive ingredients (Box 9-11). Hundreds of excipients are approved by the FDA for use in

pharmaceuticals. Several common excipients have potential for interactions in persons with an allergy or enzyme deficiency. Often just one brand of a drug or one formulation or strength of a particular brand may contain the excipient of concern. For example, tartrazine, listed as yellow dye No. 5, is used in a brand of clindamycin (Cleocin) capsules in the 75- and 150-mg strengths but not in the 300-mg strength. A brand of metoclopramide (Reglan) 5-mg tablets contain lactose, but the 10-mg tablets do not. Micronized progesterone (Prometrium) capsules contain peanut oil and lecithin, whereas other progesterone forms do not. Micronized progesterone labeling includes a warning that anyone allergic to peanuts should not use the drug (see Chapter 27).

Lactose is commonly used as a filler in many pills and capsules. The amount of lactose may be significant enough to cause GI problems for lactase-deficient patients, particularly those on multiple drugs throughout the day (see Chapter 29). Product information on prescription drugs and labeling on OTC drugs contain information on excipients, usually called “inactive ingredients,” including lactose.

**BOX 9-11****Examples of Potential Interactive Drug Excipients**

**Albumin (egg or human):** May cause allergic reaction.

Human albumin is a blood product.

**Alcohol (ethanol):** CNS depressant used as a solvent. All alcohol and alcohol-containing products and drugs must be avoided with medications such as disulfiram (Antabuse) or limited with other drugs to prevent additive CNS or hepatic toxicity. Most elixirs contain 4% to 20% alcohol. Some solution, syrup, liquid, or parenteral forms contain alcohol.

**Aspartame:** A nonnutritive sweetener composed of the amino acids aspartic acid and phenylalanine. Patients with PKU lack the enzyme phenylalanine hydroxylase. If patients with PKU ingest aspartame in significant quantities, accumulation of phenylalanine causes toxicity to brain tissue.

**Lactose:** Lactose is used as a filler. The natural sweetener in milk, lactose is hydrolyzed in the small intestine by the enzyme lactase to glucose and galactose. Lactose intolerance (caused by lactase deficiency) results in gastrointestinal distress when lactose is ingested. Lactose in medications may cause this reaction.

**Mannitol:** The alcohol form of the sugar mannose, used as a filler. Mannitol is absorbed more slowly, yielding half as many calories per gram as glucose. Because of slow absorption, mannitol can cause soft stools and diarrhea.

**Saccharin:** Nonnutritive sweetener. Extensive human research has found no evidence of carcinogenicity.

**Sorbitol:** The alcohol form of sucrose. Absorbed more slowly than sucrose, sorbitol inhibits the rise in blood glucose. Because of slow absorption, sorbitol can cause soft stools or diarrhea.

**Starch:** Starch from wheat, corn, or potato is added to medication as a filler, binder, or diluent. Celiac disease patients have a permanent intolerance to gluten, a protein in wheat, barley, rye, and a contaminant of oat. In celiac disease, gluten causes damage to the lining of the small intestine.

**Sucrose:** Sweetener. Significant source of simple carbohydrate and calories.

**Sulfites:** Sulfiting agents are used as antioxidants. Sulfites may cause severe hypersensitivity reactions in some people, particularly asthmatics. They include sulfur dioxide, sodium sulfite, and sodium and potassium metabisulfite. The FDA requires the listing of sulfites when present in foods or drugs.

**Tartrazine:** Tartrazine is a yellow dye No. 5 color additive, which causes severe allergic reactions in some people (1 in 10,000). The FDA requires the listing of tartrazine when it is present in foods or drugs.

**Vegetable oil:** Soy, sesame, cottonseed, corn, or peanut oil is used in some parenteral drugs as a nonaqueous vehicle. Hydrogenated vegetable oil is a tablet or capsule lubricant. May cause allergic reactions in sensitive people.

Modified from Pronsky ZM & Crowe JP: Potential interactive ingredients. In Pronsky ZM: *Food-medication interactions*, ed 16, Birchrunville, Pa, 2010, Food-Medication Interactions.

CNS, Central nervous system; FDA, Food and Drug Administration; PKU, phenylketonuria.

Patients with celiac disease have gluten sensitivity and must practice lifelong abstinence from wheat, barley, rye, and oats (which may be contaminated with gluten; see Chapter 29). They are particularly concerned with the composition and source of excipients such as wheat starch or flour, which might contain gluten. Only a few pharmaceutical companies guarantee their products to be gluten-free. Excipients such as dextrin and sodium starch glycolate are usually made from corn and potato, respectively, but can be made from wheat or barley. For example, the excipient dextromaltose, a mixture of maltose and dextrin, is produced by the enzymatic action of barley malt on corn flour (Crowe and Falini, 2001; Kibbe, 2000). The source of each drug ingredient, if not specified, should be checked with the manufacturer.

Finally, some drug brands may contain enough excipient to be nutritionally significant (see Table 9-1), magnesium in quinapril (Accupril), calcium in calcium polycarbophil (Fibercon, Fiber-Lax), and soybean oil lipid emulsion in propofol (Diprivan). Propofol is commonly used in the long

term for sedation of patients in the intensive care unit. Its formulation includes 10% emulsion, which contributes 1.1 kcal/mL. When infused at doses up to 9 mg/kg/hr in a patient weighing 70 kg, for instance, it may contribute an additional 1663 kcal/day from the emulsion. For a patient receiving total parenteral nutrition, limiting the use of long-chain fatty acids and using medium-chain triglyceride (MCT) oil may be recommended while he or she is taking propofol (Dubey and Kumar, 2005). Specific brands or formulations of a specific brand provide significant amounts of sodium and therefore may be contraindicated for patients who need to limit sodium.

**MEDICAL NUTRITION THERAPY**

MNT can be divided into prospective and retrospective care. Prospective MNT occurs when the patient first starts a drug. A diet history must be obtained, including information about the use of OTC (nonprescription) drugs, alcohol, vitamin and mineral supplements, and herbal or

**TABLE 9-1****Examples of Drugs That Contain Nutritionally Significant Ingredients**

Trade Name	Generic Name	Ingredient	Nutritional Significance
Accupril	Quinapril	Magnesium carbonate Magnesium stearate	Provides 50-200 mg magnesium daily
Accutane	Isotretinoin	Drug is related to vitamin A; contains soybean oil	Avoid vitamin A or β-carotene
Atrovent (inhaler)	Ipratropium Bromide	Soya lecithin	May cause allergic reaction May cause allergic reaction
Fibercon/ Fiber-Lax	Calcium polycarbophil	Calcium polycarbophil	100 mg Ca/tablet; up to 6 tablets/day = 600 mg calcium total
Marinol	Dronabinol	Sesame oil	May cause allergic reaction
Phazyme	Simethicone	Soybean oil in capsule	May cause allergic reaction
Prometrium	Micronized progesterone	Peanut oil	May cause allergic reaction
Diprivan	Propofol	10% soybean oil emulsion Egg yolk phospholipids	Oil is significant caloric source May cause allergic reaction
Videx	Didanosine	Sodium buffer in powder	≥2760 mg Na/adult daily dose
Zantac	Ranitidine	Sodium in <i>prescription</i> granules and tablets; Zantac 75 (nonprescription) is sodium free	350-730 mg Na/adult daily dose

Data from Pronsky ZM & Crowe JP: Food-medication interactions, ed 16, Birchrunville, Pa, 2010, Food-Medication Interactions.

phytonutrient supplements. The patient should be evaluated for genetic characteristics, weight and appetite changes, altered taste, and GI problems (see [Chapter 6](#)).

Prospective drug MNT provides basic information about the drug: the name, purpose, and duration of prescription of the drug plus when and how to take the drug. This information includes whether to take the drug with or without food. Specific foods and beverages to avoid while taking the drug and potential interactions between drug and vitamin or mineral supplements need to be emphasized. For instance, the patient taking tetracycline (Achromycin-V or Sumycin) or ciprofloxacin (Cipro) should be warned not to combine the drug with milk, yogurt, or supplements containing divalent cations, calcium, iron, magnesium, zinc, or vitamin-minerals containing any of these cations.

Potential significant side effects must be delineated, and possible dietary suggestions to relieve the side effects should be described. For instance, information about a high-fiber diet with adequate fluids should be part of MNT about an anticholinergic drug such as oxybutynin (Ditropan), which often causes constipation. Conversely, diarrhea can be controlled by the use of psyllium (Metamucil) or probiotics, such as *Lactobacillus acidophilus* (Lactinex), particularly for antibiotic-associated diarrhea even in children ([Szajewska et al., 2006](#)). Probiotics may be contraindicated for some individuals and should be prescribed and monitored by the physician.

Patients should be warned about potential nutritional problems, particularly when dietary intake is inadequate, such as hypokalemia with a potassium-depleting diuretic. Dietary changes that may alter drug action should be

included, such as the effect of an increase in foods high in vitamin K on warfarin action. Special diet information, such as a low-cholesterol, low-fat, limited-sugar diet with atorvastatin (Lipitor) or other antihyperlipidemic drugs, is essential information. Written information should list medication ingredients such as nonnutritive excipients in the medication. Examples include lactose, starch, tartrazine, aspartame, and alcohol. Patients with lactose intolerance, celiac disease, allergies, phenylketonuria, or alcoholism need to avoid or limit one or more of these ingredients.

Prospective MNT should also cover potential concerns with OTC drugs and herbal and natural products ([Herr, 2005](#)). It is important to emphasize that the pharmacokinetic and pharmacodynamic interactions explained in this chapter occur with all medications, whether obtained by prescription, OTC, or as natural or herbal products.

Retrospective MNT evaluates symptoms to determine if medical problems might be the result of food-drug interactions. To determine whether a patient's symptoms are the result of a food-drug interaction, a complete medical and nutrition history is essential, including prescription and nonprescription drugs, vitamin-mineral supplements, and herbal or phytonutrient products. The date of beginning to take the drugs versus the date of symptom onset is significant information. It is important to identify the use of nutrition supplements such as enteral products or significant dietary changes such as fad diets during the course of drug prescription. Finally it is important to investigate the reported incidence of side effects (by percentage as compared with a placebo). For example, vomiting occurs in 1.5% of those taking omeprazole (Prilosec) compared with

4.7% of those taking a placebo. Therefore in a patient treated with omeprazole, it would be appropriate to consider other causes for vomiting. A rare drug effect is less likely to be the reason for a negative symptom than an effect that is common.

In summary, although food provides energy for sustenance and physiological benefits for good health, and drugs prevent or treat many diseases, together the synergistic effects can be very positive (MacDonald et al., 2009). The nutrition therapist must assess, intervene, and evaluate the mixtures with care.

## CLINICAL SCENARIO

**H**enry is a 31-year-old man who began to suffer seizures after a head trauma injury from a motorcycle accident at the age of 18. For the first 2 years after the accident, he was prescribed various anticonvulsant regimens. The combination of phenytoin (Dilantin), 300 mg daily, and phenobarbital, 120 mg daily, has proven to be the most effective therapy to control his seizures. Henry has been stabilized on this regimen for the last 11 years.

Henry is a senior computer programmer for a large corporation. He is 6 feet 2 inches tall and weighs 182 lb. Henry admits to having an aversion for exercise and athletics. In his free time, he enjoys reading, playing computer games, and watching television. During the past year, Henry has broken his left femur and tibia on two separate occasions. He broke his femur when he missed the bottom step on the stairway in his office building. Several months later he broke his tibia when he tripped over a broken branch in his yard. Henry recently complained to his orthopedic surgeon about hip and pelvic pain of several weeks' duration. An orthopedic examination with x-ray examination, bone scan, and Dexa scan revealed that Henry is suffering from osteomalacia. A review of Henry's typical diet reveals a nutritionally marginal diet that commonly includes fast foods and frozen dinners. His diet is generally deficient in fresh fruits, vegetables, and dairy products.

### Nutrition Diagnostic Statement

Food-medication interaction related to inadequate calcium and vitamin D intake while taking anticonvulsant medications as evidenced by osteomalacia.

### Nutrition Care Questions

1. Is osteomalacia common in young men?
2. How does Henry's lifestyle contribute to the development of osteomalacia?
3. What vitamin or mineral deficiency may have contributed to the current state of Henry's bones?
4. Describe the food-drug interaction that has contributed to Henry's osteomalacia.
5. What medical nutritional therapy would you recommend for Henry?

**tertiary prevention**  
**U.S. Department of Health and Human Services (USDHHS)**

Community nutrition is an evolving area of practice with the broad focus of serving the population at large. Although this practice area encompasses the goals of public health, in the United States the current model has been shaped and expanded by prevention and wellness initiatives that evolved in the 1960s. Because the thrust of community nutrition is to be both proactive and responsive to the needs of the community, current emphasis areas include disaster and **pandemic** control, food and water safety, and controlling environmental risk factors related to obesity.

Historically *public health* was defined as “the science and art of preventing disease, prolonging life, and promoting health and efficiency through organized community effort” (Winslow, 1920). The public health approach, also known

as a *population-based* or *epidemiologic* approach, differs from the clinical or patient care model generally seen in hospitals and other clinical settings. In the public health model the client is the community, a geopolitical entity. The focus of the traditional public health approach is **primary prevention** with health promotion, as opposed to **secondary prevention** with the goal of risk reduction, or **tertiary prevention** with rehabilitation efforts. Changes in the health care system, technology, and attitudes of the nutrition consumer have influenced the expanding responsibilities of community nutrition providers.

In 1988, the Institute of Medicine published a landmark report that promoted the concept that the scope of community nutrition is a work in progress. This report

defined a mission and delineated roles and responsibilities for practicing community nutrition that are still the basis for community nutrition practice today. The scope of community-based nutrition encompasses efforts to prevent disease and promote positive health and nutritional status for individuals and groups in settings where they live and work. The focus is on well-being and building potential for the best possible quality of life. “Well-being” goes beyond the usual constraints of physical and mental health and includes other factors that affect the quality of life within the community. Community members need a safe environment and adequate housing, food, income, employment, and education. The mission of community nutrition is to promote the conditions in which people can be healthy.

Programming and services can be for any segment of the population. The program or service should reflect the diversity of the designated community, such as politics, geography, culture, ethnicity, ages, genders, socioeconomic issues, and overall health status. Along with primary prevention, community nutrition provides links to programs and services with goals of disease risk reduction and rehabilitation.

In the traditional model, funding sources for public health efforts were monies allocated from official sources (government) at the local, state, or federal level. Currently nutrition programs and services are funded alone or in partnership with a broad range of sources, including public (government), private, and voluntary health sectors. As public source funding has declined, the need for private funding has become more crucial. The potential size and diversity of a designated “community” makes collaboration critical. A single agency may be unable to fund or deliver the full range of services. In addition, it is likely that the funding will be services or product (in-kind) rather than cash. Creative funding and management skills are crucial for a community practitioner.

## NUTRITION PRACTICE IN THE COMMUNITY

Nutrition professionals recognize that successful delivery of food and nutrition services involves actively engaging people in their own community. The pool of nutrition professionals delivering medical nutrition therapy (MNT) and nutrition education in community-based or public health facilities continues to expand. In addition, the objectives of *Healthy People 2020* offer a common framework of measurable public health outcomes that can be used to assess the overall health of a community. Although the settings may vary, there are three core functions in community nutrition practice.

The three “core” functions of public health are community assessment, policy development, and public health assurance. These areas are also the components of community nutrition practice, especially community needs assessment

as it relates to nutrition. The findings of these needs assessments shape policy development and protect the nutritional health of the public.

Although there is shared responsibility for completion of the core functions of public health, official state health agencies have primary responsibility for this task. Under this model, state public health agencies, community organizations, and leaders have responsibility for assessing the capacity of their state to perform the essential functions and to attain or monitor the goals and objectives of *Healthy People 2020*. Local health agencies are charged with protecting the health of their population groups by ensuring that effective service delivery systems are in place. The federal government can support the development and dissemination of public health knowledge and provide funding. See [Box 10-1](#) for a list of various government agencies.

Typical settings for community nutrition include public health agencies (state and local) and the **Special Supplemental Nutrition Program for Women Infants and Children (WIC)**, a federal program that allocates funds to states for specific foods, health care referrals, and nutrition education for low-income, nutritionally at-risk pregnant, breastfeeding, and non-breastfeeding postpartum women, infants and children up to age five. The expansion of community-based practice beyond the scope of traditional public health has opened new employment opportunities for nutrition professionals.

Nutrition professionals often serve as consultants or may establish community-based private practices. Nutrition services also occur in programs for senior adults, community health centers, early intervention programs, Head Start (a federal program for low-income preschool children and their families), health maintenance organizations, food pantries and shelters, physicians’ offices, and schools. Effective practice in the community requires a nutrition professional who understands the effect of economic, social, and political issues on health. Because many community-based efforts are funded or guided by legislation and the resulting regulations and policies, community practice requires an understanding of the legislative process and an ability to translate policies into action. In addition, community practice requires a working knowledge of funding sources and resources at the federal, state, regional, and local level.

## NEEDS ASSESSMENT FOR COMMUNITY-BASED NUTRITION SERVICES

Nutrition services should be organized to meet the needs of a “community.” Once that community has been defined, a **community needs assessment** is developed to shape the planning, implementation, and evaluation of nutrition services. An assessment is a current snapshot of the community and is used to identify the health risks or areas of greatest

**BOX 10-1****Government Agencies Related to Food and Nutrition****Centers for Disease Control and Prevention (Department of Health and Human Services)**<http://www.cdc.gov/>**Central website for Access to All U.S. Government Information on Nutrition**<http://www.nutrition.gov>**Environmental Protection Agency**<http://www.epa.gov/>**Federal Trade Commission**<http://www.ftc.gov>**Food and Agriculture Organization of the United Nations**<http://www.fao.org>**Food and Drug Administration**<http://www.fda.gov>**Food and Drug Administration Advisory Committees**<http://www.fda.gov/nctr/>**Food and Drug Administration Center for Food Safety and Applied Nutrition**<http://www.cfsan.fda.gov>**Food and Nutrition Service—Assistance Programs**<http://www.fns.usda.gov/fns/Default.htm>**Indian Health Service—Medical and Nutrition**<http://www.his.gov/MedicalPrograms/Nutrition/>**National Cancer Institute (Department of Health and Human Services)**<http://www.nci.nih.gov>**National Health Information Center**<http://www.health.gov/nhic>**National Institutes of Health (Department of Health and Human Services)**<http://www.nih.gov>**National Institutes of Health- Office of Dietary Supplements**<http://ods.od.nih.gov>**National Marine Fisheries Service**<http://www.nmfs.noaa.gov>**USDA Center for Nutrition Policy and Promotion**<http://www.usda.gov/cnpp>**USDA Food and Nutrition Service**<http://www.fns.usda.gov/fns>**USDA Food Safety and Inspection Service**<http://www.fsis.usda.gov>**USDA National Agriculture Library**<http://www.nal.usda.gov/fnic>

concern to community well-being. To be effective, the needs assessment must be a dynamic document that is responsive to changes in the community. A plan is only as good as the research used to shape the decisions, so a mechanism for ongoing review and revision should be built into the planning.

A needs assessment is based on objective data, including demographic information and health statistics. Information should represent the community's diversity and be segmented by such factors as age, gender, socioeconomic status, disability, and ethnicity. Examples of information to be gathered include current morbidity and mortality statistics, number of low-birth-weight infants, deaths attributed to chronic diseases with a link to nutrition, and health-risk indicators such as incidence of smoking or obesity. *Healthy People 2020* outlines the leading health indicators that can be used to create target objectives. Subjective information such as input from community members and leaders and health and nutrition professionals can be useful

in supporting the objective data or in emphasizing questions or concerns. The process mirrors what the business world knows as *market research*.

Accessible community resources and services should also be catalogued. Environmental, policy, and societal changes have contributed to the rapid rise in obesity over the past few decades; walkable neighborhoods, good access to recreation facilities, and ready access to healthy foods are important measures to assess (Sallis and Glanz, 2009). In nutrition planning the goal is to determine who and what resources are available to community members when they need food- or nutrition-related products or services. For example, what services are available for nutrition therapy, nutrition and food education, and child care or homemaker skills training? Are there safe areas for exercise or recreation? Is there access to transportation? Is there compliance with disability legislation? Are mechanisms in place for emergencies that might affect access to adequate and safe food and water?

At first glance some of the data gathered in this process may not appear to relate directly to nutrition, but an experienced community nutritionist or a community-based advisory group with public health professionals can help connect this information to nutrition- and diet-related issues. Often the nutritional problems identified in a review of nutrition indicators are associated with dietary inadequacies, excesses, or imbalances that can be triggers for disease risk. Examples of trigger areas are presence of risk factors for cardiovascular disease; diabetes and stroke, including elevated blood cholesterol and lipids, inactivity, smoking, elevated blood glucose, high body mass index (BMI), and elevated blood pressure; risk factors for osteoporosis; evidence of eating disorders; high levels of teenage pregnancy; and evidence of hunger and food insecurity. Careful attention should be paid to the special needs of adults and children with disabilities or other lifestyle-limiting conditions. Access to safe and adequate amounts of food and water can be interrupted by something as simple as a power outage or as complex as a disaster. Once evaluated, the information is used to propose needed services, including MNT as discussed in other chapters, as part of the strategy for improving the overall health of the community.

### Sources for Assessment Information

It is critical that community practitioners know how to locate relevant resources and evaluate the information for validity and reliability. Knowing the background and intent of any data source and identifying the limitations and the dates when the information was collected are critical points to consider when selecting and using such sources. Census information is a starting point for beginning a needs assessment. Morbidity and mortality and other health data collected by state and local public health agencies, the Centers for Disease Control and Prevention (CDC), and the National Center for Health Statistics (NCHS) are useful. Federal agencies and their state program administration counterparts are data sources; these agencies include the [U.S. Department of Health and Human Services \(USDHHS\)](#), U.S. Department of Agriculture (USDA), and the Administration on Aging. Local providers such as community hospitals, WIC and child care agencies, health centers, and universities with a public health or nutrition department are additional sources of information. Volunteer organizations such as the March of Dimes, the American Heart Association (AHA), the American Diabetes Association, and the American Cancer Society (ACS) maintain population statistics. Health insurers are a source for current information related to health care consumers and geographic area.

## NATIONAL NUTRITION SURVEYS

Nutrition and health surveys at the federal and state level provide information on the dietary status of a population, the nutritional adequacy of the food supply, the

economics of food consumption, and the effects of food assistance and regulatory programs. Public guidelines for food selection are usually based on survey data. The data are also used in policy setting; program development; and funding at the national, state, and local levels. Until the late 1960s, the USDA was the primary source of food and nutrient consumption data. Although much of the data collection is still at the federal level, other agencies and states are now generating information that provides comprehensive information on the health and nutrition of the public.

### National Health and Nutrition Examination Survey

The [National Health and Nutrition Examination Survey \(NHANES\)](#) provides a framework for describing the health status of the nation. Sampling the noninstitutionalized population, the initial study began in the early 1960s, with subsequent studies on a periodic basis from 1971 to 1994. NHANES has been collected on a continuous basis since 1999. The process includes interviewing approximately 6000 individuals each year in their homes and following up with approximately 5000 individuals with a complete health examination. Since its inception, each successive NHANES has included changes or additions that make the survey more responsive as a measurement of the health status of the population. NHANES I to III included medical history, physical measurements, biochemical evaluation, physical signs and symptoms, and diet information using food frequency questionnaires and a 24-hour recall. Design changes added special population studies to increase information on under-represented groups. NHANES III (1988-1994) included a large proportion of persons age 65 years and older. This information enhanced understanding of the growing and changing population of senior adults. Currently, reports are released in 2-year cycles. Sampling methodology is planned to over-sample high-risk groups not previously covered adequately (low income, those older than the age of 60, blacks, and Hispanic Americans).

### Continuing Survey of Food Intake of Individuals: Diet and Health Knowledge Survey

The Continuing Survey of Food Intake of Individuals (CSFII) was a nationwide dietary survey instituted in 1985 by the USDA. In 1990 CSFII became part of the USDA National Nutrition Monitoring System. Information from previous surveys is available from the 1980s and 1990s. The Diet and Health Knowledge Survey (DHKS), a telephone follow-up to CFSII, began in 1989. The DHKS was designed as a personal interview questionnaire that allowed individual attitudes and knowledge about healthy eating to be linked with reported food choices and nutrient intakes. Early studies focused on dietary history and a 24-hour recall of adult men and women ages 19 to 50. The 1989 and 1994 surveys questioned men, women, and children of all ages

and included a 24-hour recall (personal interview) and a 2-day food diary. Household data for these studies were determined by calculating the nutrient content of foods reported to be used in the home during the survey. These results were compared with nutrition recommendations for persons matching in age and gender. The information derived from the CSFII and DHKS is still useful for decision makers and researchers in monitoring the nutritional adequacy of American diets, measuring the effect of food fortification on nutrient intakes, tracking trends, and developing dietary guidance and related programs. In 2002, both surveys merged with NHANES to become the **National Food and Nutrition Survey (NFNS)** or What We Eat in America.

### National Food and Nutrition Survey: What We Eat in America

The integrated survey, What We Eat in America, is collected as part of NHANES. Food-intake data are linked to health status from other NHANES components, allowing for exploration of relationships between dietary indicators and health status. The USDHHS is responsible for sample design and data, whereas the USDA is responsible for the survey's collection and maintenance of the dietary data. Data are released at 2-year intervals and are accessible from the NHANES website ([U.S. Department of Agriculture \[USDA\]](#) and Agricultural Research Service, 2009).

### National Nutrition Monitoring and Related Research Act

In 1990 Congress passed Public Law 101-445, the **National Nutrition Monitoring and Related Research (NNMRR) Act**. The purpose of this law is to provide organization, consistency, and unification to the survey methods that monitor the food habits and nutrition of the U.S. population, and to coordinate the efforts of the 22 federal agencies that implement or review nutrition services or surveys. Data obtained through NNMRR are used to direct research activities, develop programs and services, and make policy decisions regarding nutrition programs such as food labeling, food and nutrition assistance, food safety, and nutrition education. Reports of the various activities are issued approximately every 5 years and provide information on trends, knowledge, attitudes and behavior, food composition, and food supply determinants. They are available from the National Agricultural Library database.

### National Nutrient Databank

The **National Nutrient Databank**, maintained by the USDA, is the United States' primary resource of information from private industry, academic institutions, and government laboratories on the nutrient content of foods. Historically the information was published as the series *Agriculture Handbook 8*. Currently, the databases are available to the public on tapes and on the Internet. The bank is updated

frequently and includes supplemental sources, international databases, and links to other sites. This databank is a standard and updated source of nutrient information for commercial references and data systems. When using sources other than the USDA site, it is important to check the sources and the dates of the updates for evidence that these sources are reliable and current.

### The Centers for Disease Control and Prevention

The CDC is a component of the USDHHS. It monitors the nation's health, detects and investigates health problems, and conducts research to enhance prevention. The CDC is also a source of information on health for international travel. Housed at CDC is the NCHS, the lead agency for NHANES, morbidity and mortality, BMI, and other health-related measures. Public health threats, such as the H1N1 virus, are also monitored by CDC.

## NATIONAL NUTRITION GUIDELINES AND GOALS

*Policy development* describes the process by which society makes decisions about problems, chooses goals, and prepares the means to reach them. Such policies may include health priorities and dietary guidance.

Early dietary guidance had a specific disease approach. The 1982 National Cancer Institute (NCI) landmark report, *Diet, Nutrition and Cancer*; evolved into *Dietary Guidelines for Cancer Prevention*. These were updated and broadened, combining recommendations on energy balance, nutrition, and physical activity in 2004. The ACS and the American Institute for Cancer Research (AICR) are excellent resources along with materials from the NCI. Another federal agency, the National Heart, Lung, and Blood Institute provided three sets of landmark guidelines for identifying and treating lipid disorders between 1987 and 2010.

The AHA guidelines focused on persons at risk for hypertension and coronary artery disease; they were written in 2000 and revised in 2006 to include environmental influences on food choices. Another consumer-friendly, single health guideline was released in 1991 as a part of the "5-A-Day for Better Health" program sponsored by the NCI, the National Institutes of Health, and the Produce for Better Health Foundation. This guidance was built around fruits and vegetables being naturally low in fat and good sources of fiber, several vitamins and minerals, and phytonutrients. In keeping with evidence-based messages, the quantity was expanded to five to nine servings of fruits and vegetables a day to promote good health under the name of "Fruits and Veggies: More Matters" ([U.S. Department of Health and Human Services \[USDHHS\]](#), 2009).

### Dietary Guidelines for Americans

Senator George McGovern and the Senate Select Committee on Nutrition and Human Needs presented the first

*Dietary Goals* for the United States in 1977. In 1980 the goals were modified and issued jointly by the USDHHS and the USDA as the *Dietary Guidelines for Americans (DGA)*. The original guidelines were a response to an increasing national concern for the rise in overweight, obesity, and chronic diseases such as diabetes, coronary artery disease, hypertension, and certain cancers. The approach continues to be one of health promotion and disease prevention, with special attention paid to specific population groups.

The release of the DGA led the way for a synchronized message to the community. The common theme has been a focus on a diet lower in sodium and saturated fat, with emphasis on foods that are sources of fiber, complex carbohydrates, and lean or plant-based proteins. The message is based on food choices for optimal health using appropriate portion sizes and calorie choices related to a person's physiologic needs. Exercise, activity, and food safety guidance are standard parts of this dietary guidance. Fortunately, the current DGA are evidence-based rather than just "good advice." The expert committee report provides scientific documentation that is widely used in health practice. The DGA have become a central theme in community nutrition assessment, program planning, and evaluation; they are incorporated into programs such as *School Lunch and Congregate Meals*. Updated every 5 years, the DGA have recently undergone revision in 2010.

## Food Guides

In 1916 the USDA initiated the idea of food grouping in the pamphlet, *Food for Young Children*. Food grouping systems have changed in shape (wheels, boxes, and pyramids) and numbers of groupings (four, five, and seven groups), but the intent remains consistent: to present an easy guide for healthful eating. In 2005, an Internet-based tool called *MyPyramid.gov: Steps to a Healthier You* was released. In 2011, *MyPyramid.gov* was replaced with *chooseMyPlate.gov* along with a version for children called *chooseMyPlate.gov/kids*. These food guidance systems focus on health promotion and disease prevention, and are updated whenever DGA guidance changes.

## Healthy People and the Surgeon General's Report on Nutrition and Health

The 1979 report of the Surgeon General, *Promoting Health/Preventing Disease: Objectives for the Nation*, outlined the prevention agenda for the nation with a series of health objectives to be accomplished by 1990. In 1988, *The Surgeon General's Report on Nutrition and Health* further stimulated health promotion and disease prevention by highlighting information on dietary practices and health status. Along with specific health recommendations, documentation of the scientific basis was provided. Because the focus included implications for the individual as well as for future public health policy decisions, this report remains a useful reference and tool. *Healthy People 2000:*

*National Health Promotion and Disease Prevention Objectives* and *Healthy People 2010* were the next generations of these landmark public health efforts. Both reports outlined the progress made on previous objectives and set new objectives for the next decade.

During the evaluation phase for setting the 2010 objectives, it was determined that the United States made progress in reducing the number of deaths from cardiovascular disease, stroke, and certain cancers. Dietary evaluation indicated a slight decrease in total dietary fat intake. However, during the previous decade there has been an increase in the number of persons who are overweight or obese, a risk factor for cardiovascular disease, stroke, and other leading chronic diseases and causes of death.

Objectives for *Healthy People 2020* have specific goals that address nutrition and weight, heart disease and stroke, diabetes, oral health, cancer, and health for seniors. These goals are important for consumers and health care providers alike. The website for *Healthy People 2020* offers an opportunity to monitor the progress on past objectives as well as on the shaping of future health initiatives.

## National School Lunch Program

The National School Lunch Program (NSLP) is a federal assistance program that provides free or reduced-cost meals for low-income students in public, nonprofit private and residential institutions. It is administered at a state level through the education agencies that generally employ dietitians. In 1998 the program was expanded to include after-school snacks in schools with after-hours care. Currently the guidelines for calories, percent of calories from fat, percent of saturated fat, and the amount of protein and key vitamins and minerals must meet the DGA.

A requirement for wellness policies in schools that participate in the NSLP is in place (Edelstein et al., 2010). However, the School Nutrition Dietary Assessment Study, a nationally representative study fielded during school year 2004-2005 to evaluate nutritional quality of children's diets, identified that 80% of children had excessive intakes of saturated fat and 92% had excessive intakes of sodium (Clark and Fox, 2009). An increase in whole grains, fresh fruits, and a greater variety of vegetables is needed (Condon et al., 2009). The state of Texas made changes to their school lunches by restricting portion sizes of high-fat and high-sugar snacks and sweetened beverages, fat content of foods, and high-fat vegetables like french fries; this led to a desired reduction in energy density (Mendoza et al., 2010). For current information and updates to these programs, check the USDA website.

## The Recommended Dietary Allowances and Dietary Reference Intakes

The recommended dietary allowances (RDAs) were developed in 1943 by the Food and Nutrition Board of the National Research Council of the National Academy

of Sciences. The first tables were developed at a time when the U.S. population was recovering from a major economic depression and World War II; nutrient deficiencies were a concern. The intent was to develop intake guidelines that would promote optimal health and lower the risk of nutrient deficiencies. As the food supply and the nutrition needs of the population changed, the intent of the RDAs was adapted to prevention of nutrition-related disease. Until 1989 the RDAs were revised approximately every 10 years.

The RDAs have always reflected gender, age, and life-phase differences. There have been additions of nutrients and revisions of the age-groups. However, recent revisions are a major departure from the single list some professionals still view as the RDAs. Beginning in 1998 an umbrella of nutrient guidelines known as the dietary reference intakes (DRIs) was introduced. Included in the DRIs are RDAs, as well as new designations, including guidance on safe upper limits of certain nutrients. As a group the DRIs are evaluated and revised at intervals, making these tools reflective of current research and population base needs (see Chapter 12).

## FOOD ASSISTANCE AND NUTRITION PROGRAMS

**Public health assurance** addresses the implementation of legislative mandates, maintenance of statutory responsibilities, support of crucial services, regulation of services and products provided in both the public and private sector, and maintenance of accountability. This includes providing for food security, which translates into having access to an adequate amount of healthful and safe foods.

In the area of **food security**, or access by individuals to a readily available supply of nutritionally adequate and safe foods, programs such as the **Supplemental Nutrition Assistance Program (SNAP)** for food stamps, food pantries, and home-delivered meals, child nutrition programs, supermarkets, and other food sources should be available and used. For example, research on neighborhood food access indicates that low availability of healthy food in area stores is associated with low-quality diets of area residents (Rose et al., 2010). See Table 10-1 for a list of food and nutrition assistance programs.

## FOODBORNE ILLNESS

Each year there are an estimated 76 million cases of foodborne illness in the United States. The majority of foodborne illness outbreaks reported to the CDC result from bacteria, followed by viral outbreaks, chemical causes, and parasitic causes. Segments of the population are particularly susceptible to foodborne illnesses; vulnerable individuals are more likely to become ill and experience complications. Some of the nutritional complications associated with foodborne illness include reduced appetite and reduced nutrient absorption from the gut.

The 2000 edition of the DGA was the first to include food safety, important for linking the safety of the food and water supply with health promotion and disease prevention. This acknowledges the potential for **foodborne illness** to cause both acute illness and long-term chronic complications. Since 2000 all revisions of the DGA have made food safety a priority. Persons at increased risk for foodborne illnesses include young children; pregnant women; older adults; persons who are immunocompromised because of human immunodeficiency virus or acquired immunodeficiency syndrome, steroid use, chemotherapy, diabetes mellitus, or cancer; alcoholics; persons with liver disease, decreased stomach acidity, autoimmune disorders, or malnutrition; persons who take antibiotics; and persons living in institutionalized settings. Costs associated with foodborne illness include those related to investigation of foodborne outbreaks and treatment of victims, employer costs related to lost productivity, and food industry losses related to lower sales and lower stock prices (American Dietetic Association, 2009). Table 10-2 describes common foodborne illnesses and their signs and symptoms, timing of onset, duration, causes, and prevention.

All food groups have ingredients associated with food safety concerns. There are concerns about microbial contamination of fruits and vegetables especially those imported from other countries. An increased incidence of foodborne illness occurs with new methods of food production or distribution, and with increased reliance on commercial food sources (ADA, 2009). Improperly cooked meats can harbor organisms that trigger a foodborne illness. Even properly cooked meats have the potential to cause foodborne illness if the food handler allows raw meat juices to contaminate other foods during preparation. Sources of a foodborne illness outbreak vary, depending on such factors as the type of organism involved, the point of contamination and the duration and temperature of food during holding.

Targeted food safety public education campaigns are important. However, the model for food safety has expanded beyond the individual consumer and now includes government, the food industry, and the general public. Several government agencies provide information through websites with links to the CDC, the USDA Food Safety and Inspection Service (FSIS), the Environmental Protection Agency (EPA), the National Institute of Allergy and Infectious Diseases, and the Food and Drug Administration (FDA). A leading industry program, ServSafe®, provides food safety and training certification and was developed and administered by the National Restaurant Association. Because our food supply comes from a global market, food safety concerns are worldwide. The 2009 Country of Origin Labeling (COOL) legislation requires that retailers provide customers with the source of foods such as meats, fish, shellfish, fresh and frozen fruits and vegetables, and certain nuts and herbs. The USDA Agricultural Marketing Service has responsibility for COOL implementation. Future practice must include awareness

*Text continued on p. 244*

**TABLE 10-1****U.S. Food Assistance and Nutrition Programs**

<b>Program Name</b>	<b>Goal/Purpose</b>	<b>Services Provided</b>	<b>Target Audience</b>	<b>Eligibility</b>	<b>Funding</b>	<b>Level of Prevention*</b>
After-School Snack Program	Provides reimbursement for snacks served to students after school.	Provides cash reimbursement to schools for snacks served to students after the school day. Snacks must contain two of four components: fluid milk, meat/meat alternate, vegetable or fruit or full-strength juice, whole-grain or enriched bread.	Children younger than 18 whose school sponsors a structured, supervised after-school enrichment program and provides lunch through the NSLP.	School programs located within the boundaries of eligible low-income areas may be reimbursed for snacks served at no charge to students.	USDA	Primary, secondary
Child and Adult Care Food Program	Provides nutritious meals and snacks to infants, young children, and adults receiving day care services, as well as infants and children living in emergency shelters.	Provides commodities or cash to help centers serve nutritious meals that meet federal guidelines.	Infants, children, and adults receiving day care at childcare centers, family day care homes, and homeless shelters		USDA FNS	Primary, secondary
Commodity Supplemental Food Program	Provides no-cost monthly supplemental food packages composed of commodity foods to populations perceived to be at nutritional risk.	Provides food packages; nutrition education services are available often through Extension Service Programs; program referrals provided.	Generally children ages 5–6, postpartum nonbreastfeeding mothers from 6–12 months' postpartum, seniors	Between 130% and 185% of the poverty guideline	USDA FNS	Primary, secondary
Disaster Feeding Program	Makes commodities available for distribution to disaster relief agencies.	Commodities are provided to disaster victims through congregate dining settings and direct distribution to households.	Those experiencing a natural disaster		USDA FNS	Primary
TEFAP	Commodities are made available to local emergency food providers for preparing meals for the needy or for distribution of food packages.	Surplus commodity foods are provided for distribution.	Low-income households	Low-income households at 150% of the federal poverty income guideline	USDA FNS	Primary

EFSP	Funds are used to purchase food and shelter to supplement and extend local services.	EFSP provides funding for the purchase of food products, operation costs associated with mass feeding and shelter, limited rent or mortgage assistance, providing assistance for first month's rent, limited off-site emergency lodging, and limited utility assistance.	Those in need of emergency services	Primary	FEMA	Primary
Head Start	Provides agencies and schools with support and guidance for half- and full-day child development programs for low-income children.	Programs receive reimbursement for nutritious meals and snacks and USDA-donated commodities, support for curriculum, social services, and health screenings.	Low-income children ages 3–5; parents are encouraged to volunteer and be involved	Same as NSLP	USDA (food) USDHHS (health)	Primary Secondary
National School Breakfast Program	Provides nutritionally balanced, low-cost or free breakfasts to children enrolled in participating schools.	Participating schools receiving cash subsidies and USDA-donated commodities in return for offering breakfasts that meet same criteria as school lunch and offering free and reduced-price meals to eligible children.	Children preschool age through grade 12 in schools; children and teens 20 years of age in residential childcare and juvenile correctional institutions	Same as NSLP	USDA FNS	Primary, secondary
NSLP	Provides nutritionally balanced, low-cost or free lunches to children enrolled in participating schools.	Participating schools receive cash subsidies and USDA-donated commodities in return for offering lunches that meet dietary guidelines and $\frac{1}{3}$ of RDA for protein, iron, calcium, vitamins A and C, and calories and for offering free and reduced-price meals to eligible children.	Children preschool age through grade 12 in schools; children and teenagers 20 years of age and younger in residential childcare and juvenile correctional institutions	185% of federal poverty income guideline for reduced-price lunches; 130% for free lunches	USDA FNS	Primary, secondary

TABLE 10-1

**U.S. Food Assistance and Nutrition Programs—cont'd**

Program Name	Goal/Purpose	Services Provided	Target Audience	Eligibility	Funding	Level of Prevention*
Nutrition Program for the Elderly/ Area Agencies on Aging	Provides commodity and cash assistance to programs providing meal services to older adults.	Provides nutritious meals for older adults through congregate dining or home-delivered meals.	Older adults	No income standard applied	USDHHS administers through state and local agencies; USDA cash and commodity assistance	Primary
Seniors' Farmers Market Nutrition Program	Provides fresh, nutritious, unprepared, locally grown fruits, vegetables, and herbs from farmers' markets, roadside stands, and community-supported agriculture programs to low-income seniors.	Coupons for use at authorized farmers' markets, roadside stands, and community-supported agriculture programs (Foods that are not eligible for purchase with coupons by seniors are dried fruits or vegetables, potted plants and herbs, wild rice, nuts, honey, maple syrup, cider and molasses.)	Low-income adults older than age 60	Low-income seniors with household incomes not exceeding 195% of the federal poverty income guideline	USDA FNS	Primary
SNAP	Provides benefits to low-income people that they can use to buy food to improve their diets.	Provides assistance such as food stamps.	Any age	For households in the 48 contiguous states and the District of Columbia. To get SNAP benefits, households must meet certain tests, including resource and income tests.	USDA FNS	Primary Secondary
Special Milk Program	Provides milk to children in participating schools who do not have access to other meal programs.	Provides cash reimbursement for milk with vitamins A and D at RDA levels served at low or no cost to children; milk programs must be run on nonprofit basis.	Same target audience as school lunch and school breakfast programs	Eligible children do <i>not</i> have access to other supplemental foods programs.	USDA FNS	Primary, secondary

Summer Food Service Program	Provides healthy meals (per federal guidelines) and snacks to eligible children when school is out, using agriculture commodity foods.	Reimburses for up to two or three meals and snacks served daily free to eligible children when school is not in session; cash based on income level of local geographic area or of enrolled children.	Infants and children 18 years of age and younger served at variety of feeding sites	USDA FNS	Primary, secondary
WIC	Provides supplemental foods to improve health status of participants.	Nutrition education, free nutritious foods (protein, iron, calcium, vitamins A and C), referrals, breastfeeding promotion. FMNP food coupons for use at participating farmers' markets stands; nutrition education through arrangements with state agency.	Pregnant, breastfeeding and postpartum women up to 1 year Infants, children up to 5 yrs	185% of federal poverty income guideline nutritional risk	UDSA FNS, home state support
WIC FMNP	Provides fresh, unprepared, locally grown fruits and vegetables to WIC recipients, and to expand the awareness, use of and sales at farmers' markets.	Same as WIC recipients	Same as WIC recipients	USDA FNS	Primary

*EFSB*, Emergency Food and Shelter Program; *FEMA*, Federal Emergency Management Agency; *FMNP*, Farmers Market Nutrition Program; *FNS*, Food and Nutrition Service; *NSLP*, National School Lunch Program; *RDA*, recommended daily allowance; *SNAP*, Special Nutrition Assistance Program; *USDA*, U.S. Department of Agriculture; *USDHHS*, U.S. Department of Health and Human Services; *WIC*, Special Supplemental Nutrition Program for Women, Infants, and Children.

\*Level of prevention rationale: Programs that provide food only are regarded as primary; programs that provide food, nutrients at a mandated level of recommended dietary allowances or an educational component are regarded as secondary; and programs that used health screening measures on enrollment were regarded as tertiary.

**TABLE 10-2****Common Foodborne Illnesses**

<b>Illness</b>	<b>Signs and Symptoms</b>	<b>Onset and Duration</b>	<b>Causes and Prevention</b>	<b>Comments</b>
<i>Bacillus cereus</i>	Watery diarrhea, abdominal cramping, vomiting	6-15 hours after consumption of contaminated food; duration 24 hours in most instances	Meats, milk, vegetables, and fish have been associated with the diarrheal type; vomiting-type outbreaks have generally been associated with rice products; potato, pasta and cheese products; food mixtures such as sauces, puddings, soups, casseroles, pastries, and salads may also be a source.	<i>B. cereus</i> is a gram-positive, aerobic spore former.
<i>Campylobacter jejuni</i>	Diarrhea (often bloody), fever, and abdominal cramping	2-5 days after exposure; duration 2-10 days	Drinking raw milk or eating raw or undercooked meat, shellfish, or poultry; to prevent exposure, avoid raw milk and cook all meats and poultry thoroughly; it is safest to drink only pasteurized milk; the bacteria may also be found in tofu or raw vegetables. Hand-washing is important for prevention; wash hands with soap before handling raw foods of animal origin, after handling raw foods of animal origin, and before touching anything else; prevent cross-contamination in the kitchen; proper refrigeration and sanitation are also essential.	Top source of foodborne illness; some people develop antibodies to it, but others do not. In persons with compromised immune systems, it may spread to the bloodstream and cause sepsis; may lead to arthritis or to GBS; 40% of GBS in the United States is caused by campylobacteriosis and affects the nerves of the body, beginning several weeks after the diarrheal illness; can lead to paralysis that lasts several weeks and usually requires intensive care.
<i>Clostridium botulinum</i>	Muscle paralysis caused by the bacterial toxin: double or blurred vision, drooping eyelids, slurred speech, difficulty swallowing, dry mouth, and muscle weakness; infants with botulism appear lethargic, feed poorly, are constipated, and have a weak cry and poor muscle tone	In foodborne botulism symptoms generally begin 18-36 hours after eating contaminated food; can occur as early as 6 hours or as late as 10 days; duration days or months	Home-canned foods with low acid content such as asparagus, green beans, beets, and corn; outbreaks have occurred from more unusual sources such as chopped garlic in oil, hot peppers, tomatoes, improperly handled baked potatoes wrapped in aluminum foil, and home-canned or fermented fish. Persons who home-can should follow strict hygienic procedures to reduce contamination of foods; oils infused with garlic or herbs should be refrigerated; potatoes that have been baked while wrapped in aluminum foil should be kept hot until served or refrigerated; because high temperatures destroy the botulism toxin, persons who eat home-canned foods should boil the food for 10 minutes before eating.	If untreated, these symptoms may progress to cause paralysis of the arms, legs, trunk, and respiratory muscles; long-term ventilator support may be needed. Throw out bulging, leaking, or dented cans and jars that are leaking; safe home-canning instructions can be obtained from county extension services or from the U.S. Department of Agriculture; honey can contain spores of <i>C. botulinum</i> and has been a source of infection for infants; children younger than 12 months old should not be fed honey.

<i>Clostridium perfringens</i>	Nausea with vomiting, diarrhea, and signs of acute gastroenteritis lasting 1 day	Within 6-24 hours from the ingestion	Ingestion of canned meats or contaminated dried mixes, gravy, stews, refried beans, meat products, and unwashed vegetables. Cook foods thoroughly; leftovers must be reheated properly or discarded.	Contaminated food from poor handling. Hand washing is important.	Protozoa causes diarrhea among immune-compromised patients.
<i>Cryptosporidium parvum</i>	Watery stools, diarrhea, nausea, vomiting, slight fever, and stomach cramps	2-10 days after being infected	Contamination of water with human sewage may lead to contamination of foods; infected food handlers may also contaminate foods; dairy products such as semisoft cheeses may cause problems, but this is rare.	Undercooked ground beef and meats, from unprocessed apple cider, or from unwashed fruits and vegetables; sometimes water sources; alfalfa sprouts, unpasteurized fruit juices, dry-cured salami, lettuce, spinach, game meat, and cheese curds  Cook meats thoroughly, use only pasteurized milk, and wash all produce well.	More common with travel to other countries; in infants or debilitated elderly persons, electrolyte replacement therapy may be necessary.  Antibiotics are not used because they spread the toxin further; the condition may progress to hemolytic anemia, thrombocytopenia, and acute renal failure, requiring dialysis and transfusions; HUS can be fatal, especially in young children; there are several outbreaks each year, particularly from catering operations, church events, and family picnics. <i>E. coli</i> O157:H7 can survive in refrigerated acid foods for weeks (Mayerhauer, 2001).
<i>Enterotoxigenic Escherichia coli</i> (ETEC)	Watery diarrhea, abdominal cramps, low-grade fever, nausea and malaise	With high infective dose, diarrhea can be induced within 24 hours	Onset is slow, usually approximately 3-8 days after ingestion  Duration 5-10 days	Undercooked ground beef and meats, from unprocessed apple cider, or from unwashed fruits and vegetables; sometimes water sources; alfalfa sprouts, unpasteurized fruit juices, dry-cured salami, lettuce, spinach, game meat, and cheese curds  Cook meats thoroughly, use only pasteurized milk, and wash all produce well.	May be fatal.  Caution must be used by pregnant women, who may pass the infection on to their unborn child.
<i>Escherichia coli</i> O157:H7 Enterohemorrhagic <i>E. coli</i> (EHEC)	Hemorrhagic colitis (painful, bloody diarrhea)			Processed, ready-to-eat products such as undercooked hot dogs, deli or lunchmeats, and unpasteurized dairy products; postpasteurization contamination of soft cheeses such as feta or Brie, milk, and commercial coleslaw; cross-contamination between food surfaces has also been a problem.  Use pasteurized milk and cheeses; wash produce before use; reheat foods to proper temperatures; wash hands with hot, soapy water after handling these ready-to-eat foods; discard foods by their expiration dates.	
<i>Listeria monocytogenes</i> (LM)	Mild fever, headache, vomiting, and severe illness in pregnancy; sepsis in the immuno-compromised patient; meningoencephalitis in infants; and febrile gastroenteritis in adults	Onset 2-30 days Duration variable			

Continued

**TABLE 10-2**  
**Common Foodborne Illnesses—cont'd**

Illness	Signs and Symptoms	Onset and Duration	Causes and Prevention	Comments
<i>Norovirus</i>	Gastroenteritis with nausea, vomiting, and/or diarrhea accompanied by abdominal cramps; headache, fever/chills, and muscle aches may also be present.	24 to 48 hours after ingestion of the virus, but can appear as early as 12 hours after exposure	Foods can be contaminated either by direct contact with contaminated hands or work surfaces that are contaminated with stool or vomit or by tiny droplets from nearby vomit that can travel through air to land on food; although the virus cannot multiply outside of human bodies, once on food or in water, it can cause illness; most cases occur on cruise ships.	Symptoms are usually brief and last only 1 or 2 days; however, during that brief period, people can feel very ill and vomit, often violently and without warning, many times a day; drink liquids to prevent dehydration.
<i>Salmonella</i>	Diarrhea, fever, and abdominal cramps	12-72 hours after infection Duration usually 4-7 days	Ingestion of raw or undercooked meat, poultry, fish, eggs, unpasteurized dairy products, unwashed fruits and raw vegetables (melons and sprouts) Prevent by thorough cooking, proper sanitation, and hygiene.	There are many different kinds of <i>Salmonella</i> bacteria; <i>S. typhimurium</i> and <i>S. enteritidis</i> are the most common in the United States. Most people recover without treatment, but some have diarrhea that is so severe that the patient needs to be hospitalized; this patient must be treated promptly with antibiotics; the elderly, infants, and those with impaired immune systems are more likely to have a severe illness.
<i>Shigelllosis</i>	Bloody diarrhea, fever, and stomach cramps	24-48 hours after exposure Duration 4-7 days	Milk and dairy products; cold mixed salads such as egg, tuna, chicken, potato, and meat salads Proper cooking, reheating, and maintenance of holding temperatures should aid in prevention; careful hand washing is essential.	This is caused by a group of bacteria called <i>Shigella</i> ; it may be severe in young children and the elderly; severe infection with high fever may be associated with seizures in children younger than 2 years old. Refrigerate foods promptly during preparation and after meal service.
<i>Staphylococcus aureus</i>	Nausea, vomiting, retching, abdominal cramping, and prostration	Within 1-6 hours; rarely fatal Duration 1-2 days	Meat, pork, eggs, gravy, stuffing, tuna salad, prepared salads, gravy, cream-filled pastries Cooking does not destroy the toxin; proper handling and hygiene are crucial for prevention.	

<i>Streptococcus pyogenes</i>	Sore and red throat, pain on swallowing; tonsillitis, high fever, headache, nausea, vomiting, malaise, rhinorrhea; occasionally a rash occurs	Onset 1-3 days	Milk, ice cream, eggs, steamed lobster, ground ham, potato salad, egg salad, custard, rice pudding, and shrimp salad; in almost all cases, the foodstuffs were allowed to stand at room temperature for several hours between preparation and consumption.	Entrance into the food is the result of poor hygiene, ill food handlers, or the use of unpasteurized milk. Complications are rare; treated with antibiotics.
<i>Vibrio vulnificus</i>	Vomiting, diarrhea, or both; illness is mild	Gastroenteritis occurs about 16 hours after eating contaminated food. Duration about 48 hours	Seafood, especially raw clams and oysters, that has been contaminated with human pathogens; although oysters can only be harvested legally from waters free from fecal contamination, even these can be contaminated with <i>V. vulnificus</i> because the bacterium is naturally present.	This is a bacterium in the same family as those that cause cholera; it yields a <i>Norovirus</i> ; it may be fatal in immunocompromised individuals.
<i>Yersinia enterocolitica</i>	Common symptoms in children are fever, abdominal pain, and diarrhea, which is often bloody; in older children and adults, right-sided abdominal pain and fever may be predominant symptom and may be confused with appendicitis.	1-2 days after exposure Duration 1-3 weeks or longer	Contaminated food, especially raw or undercooked pork products; postpasteurization contamination of chocolate milk, reconstituted dry milk, pasteurized milk, and tofu are also high-risk foods; cold storage does not kill the bacteria. Cook meats thoroughly; use only pasteurized milk; proper hand washing is also important.	Infectious disease caused by the bacterium <i>Yersinia</i> ; in the United States most human illness is caused by <i>Y. enterocolitica</i> ; it most often occurs in young children. In a small proportion of cases, complications such as skin rash, joint pains, or spread of bacteria to the bloodstream can occur.

**CLINICAL INSIGHT**

## Global Food Safety

The United States imports produce, meat, and seafood from other countries to meet the consumer demands for foods that are not readily available in the country. Global importation creates potential danger to the public. Our current food supply is becoming much harder to trace back to a single source, and because of this, it is imperative that safety concerns be addressed globally, as well as in the United States. Leadership from food growers, producers, distributors and those involved in food preparation is essential to ensure a safe food supply. Protecting the food supply chain requires several safety management systems such as hazard analysis, critical control points, good manufacturing practice, and good hygiene practice (Aruoma, 2006). Food safety also includes attention to issues such as the use of toxins and pesticides in countries where standards and enforcement may be variable, as well as the importance of clean water. Finally, the effect of global warming on food production is an increasing concern.

of global food safety issues (see *Clinical Insight: Global Food Safety*).

### Hazard Analysis Critical Control Points

An integral strategy to reduce foodborne illness is risk assessment and management. **Risk assessment** entails hazard identification, characterization, and exposure. **Risk management** covers risk evaluation, option assessment and implementation, monitoring and review of progress. One formal program, organized in 1996, is the **Hazard Analysis Critical Control Points (HACCP)**, a systematic approach to the identification, evaluation, and control of food safety hazards. HACCP involves identifying any biologic, chemical, or physical agent that is likely to cause illness or injury in the absence of its control as it pertains to food production. It also involves identifying points at which control can be applied, thus preventing or eliminating the food safety hazard or reducing it to an acceptable level. Restaurants and health care facilities are obligated to use HACCP procedures in their food handling practices.

There is an increased risk to health care professionals with direct patient contact, as well as those involved in community education. Those who serve populations at the greatest risk for foodborne illness have a special need to be involved in the network of food safety education and to communicate this information to their clients. Adoption of the HACCP regulations, food quality assurance programs, handling of fresh produce guidelines, technologic advances designed to reduce contamination, increased food supply regulations, and a greater emphasis on food safety education has contributed to a substantial decline in foodborne illness.

Figure 10-1 shows a graphic used to explain HACCP to those who are cooking meals in large quantity.

## FOOD AND WATER SAFETY

Although individual educational efforts are effective in raising awareness of food safety issues, food and water safety must be examined on a national, systems-based level (ADA, 2009). Several federal health initiatives include objectives relating to food and water safety, pesticide and allergen exposure, food-handling practices, reducing disease incidence associated with water, and reducing food- and water-related exposure to environmental pollutants. Related agencies can be found in Table 10-3.

### Contamination

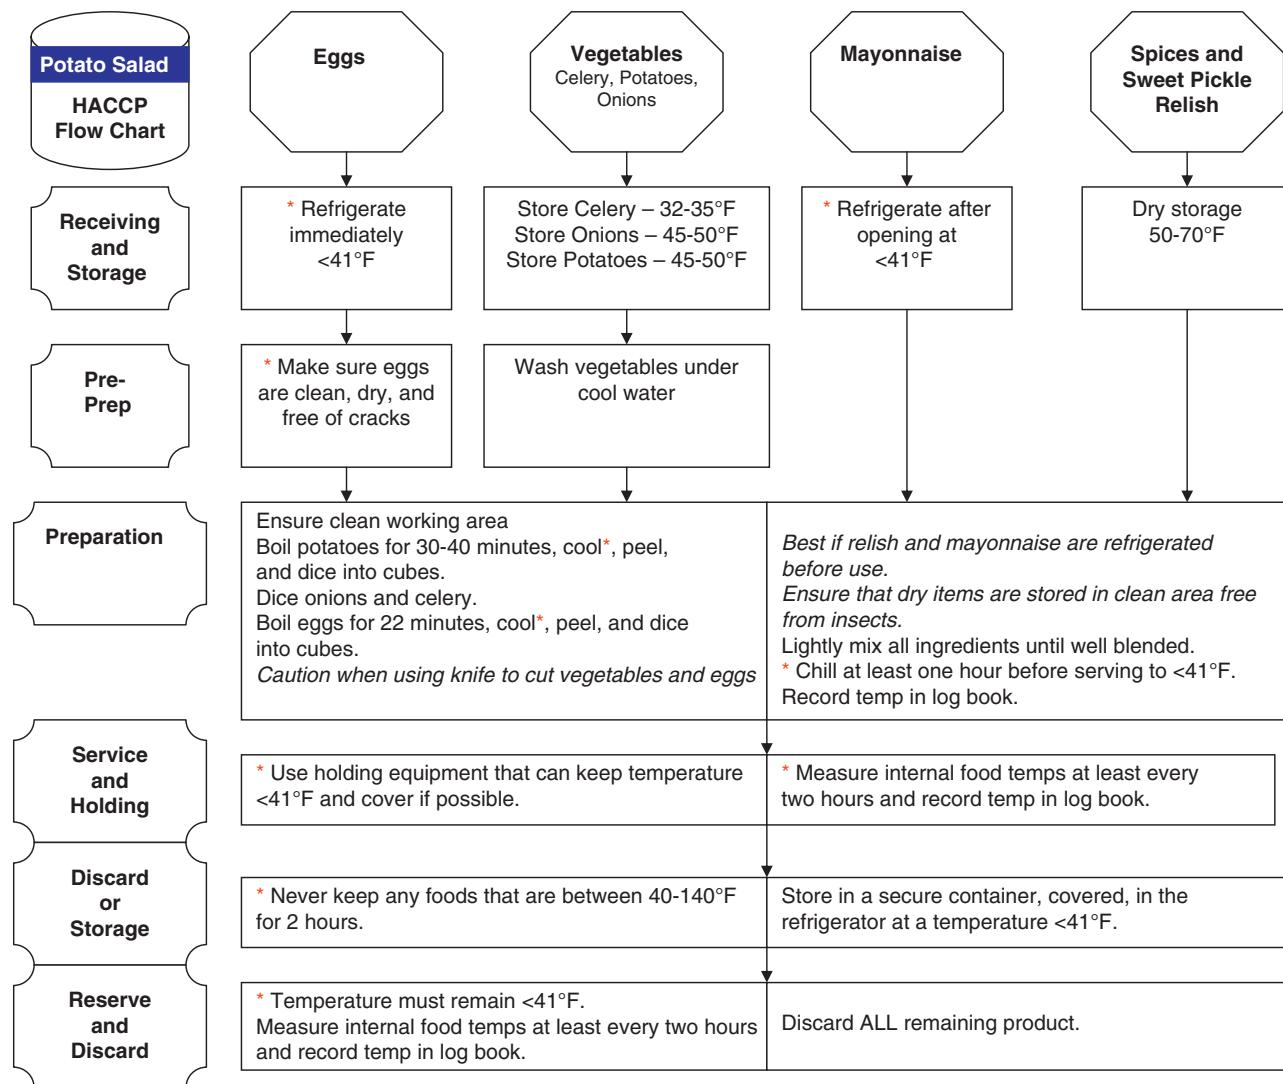

Controls and precautions in the area of limiting potential contaminants in the water supply are of continuing importance. Water contamination with arsenic, lead, pesticides, mercury, chlorine, herbicides, and *Escherichia coli* has been repeatedly highlighted by the media. It has been estimated that many public water systems, built using early twentieth-century technology, will need to invest more than \$138 billion during the next 20 years to ensure continued safe drinking water (ADA, 2009). The effect on the potential safety of foods that have contact with these contaminants is an ongoing issue being monitored by advocacy and professional groups and governmental agencies.

Of interest to many is the issue of the potential hazards of ingestion of seafood that has been in contact with methyl mercury present naturally in the environment and released into the air from industrial pollution. Mercury has accumulated in bodies of water (i.e., streams, rivers, lakes, and oceans) and in the flesh of seafood in these waters (U.S. Food and Drug Administration and Environmental Protection Agency, 2009). The body of knowledge on issues such as this is constantly being updated, and there are now recommendations to restrict the consumption of certain fish such as shark, mackerel, tilefish, tuna, and swordfish by pregnant women (Center for Food Safety and Applied Nutrition, 2009). (See Chapter 16 for further discussion.) Other contaminants in fish, polychlorinated biphenyls, and dioxin are also of concern (Mozaffarian and Rimm, 2006).

There are precautions in place at the federal, state, and local levels that need to be addressed by dietetics professionals whose roles include advocacy, communication, and education. Both members of the public and local health officials must understand the risks and the importance of carrying out measures for food and water safety and protection. Both the EPA and the Center for Food Safety and Applied Nutrition (CFSAN) provide ongoing monitoring and guidance. In addition, food and water safety and foodborne illness issues are monitored by state and local health departments.

### Organic Foods and Pesticide Use

The use of pesticides and contaminants from the water supply affect produce quality. The debate continues about

**FIGURE 10-1** The Seven Steps of HACCP and a Sample Flow Chart

1. Hazard analysis—what can go wrong?
  2. Determine the critical control points (CCPs).
  3. Establish critical limits.
  4. Establish a system to monitor CCPs.
5. Decide upon a corrective action.
6. Verify that HACCP is working properly.
7. Document and demonstrate it works.

\*Critical Control Point in food handling.

whether or not organic foods are worth the extra cost. However, the beneficial effects of organic farming also need to be considered. Most experts agree that fruit such as apples may be healthier if chosen in the organic aisle. Otherwise, fruits with a thick skin, such as banana, are acceptable in either form. See *Clinical Insight: Is Organic Produce Healthier?*

### Bioterrorism and Food-Water Safety

**Bioterrorism** is the deliberate use of microorganisms or toxins from living organisms to induce death or disease. Threats to the nation's food and water supplies have made food **biosecurity**, or precautions to minimize risk, an issue when addressing preparedness planning. The CDC has identified seven foodborne pathogens as having the potential to be used by bioterrorists to attack the food supply:

tularemia, brucellosis, *Clostridium botulinum* toxin, epsilon toxin of *Clostridium perfringens*, *Salmonella*, *E. coli*, and *Shigella*. These pathogens, along with potential water contaminants, such as mycobacteria, *Legionella*, *Giardia*, viruses, arsenic, lead, copper, methyl butyl ether, uranium, and radon, are the targets of federal systems put in place to monitor the safety of the food and water supply. Current surveillance systems are designed to detect foodborne illness outbreaks resulting from food spoilage, poor food handling practices, or other unintentional sources, but they were not designed to identify an intentional attack.

Consequences of a compromised food and water supply would be physical, psychological, political, and economic. Compromise could occur with food being the primary agent such as a vector to deliver a biologic or chemical weapon or with food being a secondary target, leaving an inadequate

 CLINICAL INSIGHT

## Is Organic Produce Healthier?

By Christine McCullum-Gómez, PhD, RD, Food and Nutrition Consultant, Houston, TX

There are a variety of reasons why organic foods facilitate the creation of a healthful, sustainable food system (McCullum-Gómez and Scott, 2009). First, some organic fruits, vegetables, and juices may contain more antioxidants and polyphenols compared with their conventionally grown counterparts (Dani et al., 2008; Mitchell et al., 2007; Olsson et al., 2006), although this is an ongoing debate (Benbrook et al., 2009; Dangour et al., 2009a; Dangour et al., 2009b; Lairon, 2009). Second, organic meat may reduce the development of human antibiotic resistance and lessen air and water pollution (American Medical Association, 2009). Third, consumption of organic versus conventional dairy products may yield a lower risk of eczema during the first two years of life, possibly from higher intake of ω-3 fatty acids or conjugated linoleic acids (Kummeling et al., 2008).

Fortunately, **organic foods** are becoming more available in the marketplace. A 2009 survey showed sales of organic food in the United States grew by almost 16 percent in 2008 over 2007, totaling \$22.9 billion in 2008 sales; 3.5 percent of all food sales (Organic Trade Association, 2009). These foods are produced following practices described in the United States Department of Agriculture (USDA) National Organic Program (NOP), a marketing program with a certification process throughout the production and manufacturing chain, required for labeling a product “organic” (U.S. Department of Agriculture, 2009). Organic foods that are certified through the USDA NOP must meet the same State and Federal food safety requirements as non-organic foods (National Organic Program, 2009; Riddle, 2009).

Although it has been suggested that organically grown fruits and vegetables may have a greater risk of pathogenic contamination than their counterparts, very few studies have confirmed these risks (Mukherjee et al., 2006). In a longitudinal survey of fresh produce grown by U.S. farmers in the upper Midwest, preharvest microbiological quality of produce from three farm types (organic, semiorganic, and conventional) was very similar during two seasons. Produce

type (leafy greens, lettuces and cabbages) influences *Escherichia coli* contamination more than the type of farm (Mukherjee et al., 2006). Indeed, the way manure is treated and stored has a large impact on *E. coli* levels. When manure is composted before it is spread on soil, it generates heat that can kill most of the *E. coli* (Semenova et al., 2009). In organic farming, raw animal manure must be composted (§205.203), unless it is applied to land used for a crop not intended for consumption or incorporated into the soil not less than 120 days prior to the harvest (Electronic Code of Federal Regulations, Title 7: Agriculture. Part 205—National Organic Program, 2010).

The Food, Conservation and Energy Act of the Farm Bill helps to fund organic certification costs and to enhance data collection on organic agriculture. Organic agriculture offers numerous opportunities to reduce exposure to detrimental pesticides from the food and water supply (Greene et al., 2009; Lu et al., 2006; Lu et al., 2008), which is particularly important for high-risk groups including pregnant women, infants, young children, and farm workers (Arcury et al., 2007; Huen et al., 2009). Organically cultivated foods can also promote a more sustainable food system by reducing soil erosion; rehabilitating poor soils; and sequestering carbon in soil, which may reduce carbon levels in the atmosphere (Greene et al., 2009; Niggli et al., 2009). Organic agriculture reduces energy requirements for production by 25 to 50 percent (Niggli et al., 2009). These lower energy inputs decrease greenhouse gas emissions (Ziesemer, 2007). In addition, biodiversity is enhanced and farms are more resilient to unpredictable weather patterns and pest outbreaks that are predicted with climate change (Niggli et al., 2009; Worldwatch Institute, 2008). Public investment in organic agriculture facilitates wider access to organic food for consumers, helps farmers capture high-value markets, and conserves natural resources, including soil and water (Greene et al., 2009).

food supply to feed a region or the nation. Intentional use of a foodborne pathogen as the primary agent might be mistaken as a routine outbreak of foodborne illness. Distinguishing normal illness fluctuation from an intentional attack depends on having in place a system for preparedness planning, rapid communication, and central analysis.

Experience with the series of hurricanes in 2005 emphasizes the need to provide access to a safe food and water supply after emergencies and disasters. Access to food and water may be limited, which, in the case of bioterrorism,

results in social disruption and self-imposed quarantine. These situations require a response different from the traditional approach to disaster relief, during which it is assumed that hungry people will seek assistance and have confidence in the safety of the food that is offered (Bruemmer, 2003). In the event of a disaster, dietetics professionals can play a key role by being aware of their environment, knowing available community and state food and nutrition resources, and participating in coordination and delivery of relief to victims of the disaster.

## DISASTER PLANNING

Dietetics and health professionals working in food service are expected to plan for the distribution of safe food and water in any emergency situation. This may include choosing food preparation and distribution sites, establishing temporary kitchens, preparing foods with limited resources, and keeping prepared food safe to eat through HACCP procedures (Puckett and Norton, 2009). To prepare for such planning, several federal agencies share the responsibility for food and water safety.

Planning, surveillance, detection, response, and recovery are the key components of public health disaster preparedness. The key agencies are the USDA, the **Department of Homeland Security (DHS)** and the Federal Emergency Management Agency (FEMA), the CDC, and the FDA. In

conjunction with DHS, USDA operates Protection of the Food Supply and Agricultural Production (PFSAP). PFSAP handles issues related to food production, processing, storage, and distribution. It addresses threats against the agricultural sector and border surveillance. PFSAP conducts food safety activities concerning meat, poultry, and egg inspection and provides laboratory support, research, and education on outbreaks of foodborne illness.

Ready.gov ([www.ready.gov](http://www.ready.gov)) is an education tool informing the public on how to prepare for a national emergency, including possible terrorist attacks. In addition, the USDA FSIS operates the Food Threat Preparedness Network (PrepNet) and the Food Biosecurity Action Team (F-Bat). PrepNet ensures effective coordination of food security efforts, focusing on preventive activities to protect the food

supply. F-Bat assesses potential vulnerabilities along the farm-to-table continuum, provides guidelines to industry on food security and increased plant security, strengthens FSIS's coordination and cooperation with law enforcement agencies, and enhances security features of FSIS laboratories (Bruemmer, 2003).

CDC has three operations relating to food security and disaster planning: PulseNet, FoodNet, and the Centers for Public Health Preparedness. PulseNet is a national network of public health laboratories that performs deoxyribonucleic acid fingerprinting on foodborne bacteria, assists in detecting foodborne illness outbreaks and tracing them back to their source, and provides linkages among sporadic cases. FoodNet is the Foodborne Diseases Active Surveillance Network, which functions as the principle foodborne disease component of the CDC's Emerging Infections Program, providing active laboratory-based surveillance. The Centers for Public Health Preparedness funds academic centers linking schools of public health with state, local, and regional bioterrorism preparedness and public health infrastructure needs (Bruemmer, 2003).

CFSAN in the FDA is concerned with regulatory issues such as seafood HACCP, safety of food and color additives, safety of foods developed through biotechnology, food labeling, dietary supplements, food industry compliance,

## CLINICAL SCENARIO

Dietitians and nutritionists play an important role in emergency preparedness. The role of qualified nutrition professionals will vary with the type of emergency or disaster (e.g., hurricane, flood, foodborne illness outbreak, ice storm). As an emerging nutrition professional, you can play a role within your own family and community by helping them to prepare safe and adequate food for an emergency.

Your family is composed of seven members: two parents, one infant on infant formula, one school-age child, one teenager, and two grandparents. The grandparents are on moderate food restrictions that reduce sugar and sodium. Review information on emergency preparedness information from the American Red Cross ([www.redcross.org](http://www.redcross.org)) and the Department of Homeland Security ([www.dhs.gov.org](http://www.dhs.gov.org)) and propose an emergency food package for your family that includes food and water and supplies, including menus for 7 days.

### Nutrition Diagnostic Statement

Lack of access to safe foods and water related to no planning as evidenced by insufficient preparation and food and water supplies for emergencies.

### Nutrition Care Questions

1. What steps can you take to design a plan?
2. How many days of food and water should be available?
3. How concerned are you about expiration dates?

and regulatory programs to address health risks associated with foodborne chemical and biologic contaminants. CFSAN also runs cooperative programs with state and local governments.

The **Federal Emergency Management Agency (FEMA)**, under the DHS, provides emergency support functions after a disaster or emergency. FEMA identifies food and water needs, arranges delivery, and provides assistance with temporary housing and other emergency services. Agencies that assist FEMA include the USDA, the Department of Defense, the USDHHS, the EPA, and the General Services Administration. Major players include voluntary agencies such as the American Red Cross, the Salvation Army, and community-based agencies and organizations. Disaster management is evolving as it is tested by both manufactured and natural disasters.

# Nutrition Diagnosis and Intervention

The type of nutrition care provided for an individual varies depending on the findings of the assessment process. The environment, surgery or trauma, food allergies, inadequate access to safe or sufficient food, stages of growth and development, harmful beliefs, lack of knowledge, and socioeconomic issues can all affect the intake of an adequate diet. In the healthy individual, omission of a specific food group or intake of high-energy, nutrient-poor foods does not lead to failed nutritional status overnight. It is the prolonged intake of such imbalances or a dramatic and acute insufficiency that leads to undesirable nutritional consequences. Indeed, inadequacy of the types or amounts of macro- or micronutrients, fluid, or even physical activity may cause a decline in health status or immunity.

The establishment of nutrition diagnoses and a standardized language helps to define and promote effective care according to specific nutrition problems. Such problems may be found in an individual, a group (such as persons who have diabetes or celiac disease), or even a community (such as sites where local produce is grown in mineral-depleted soil.) Thus step two of the nutrition care process involves identifying the appropriate diagnosis or diagnoses. It includes an analysis of the factors affecting adequacy of the current nutritional intake and overall nutritional status. In most cases,

institutions use standards of care or national practice guidelines that describe recommended actions in the nutrition care process. These standards serve as the basis for assessing quality of care provided.

Step three of the nutrition care process requires planning and goal-setting, followed by the selection of interventions that fit the cause of the problem. For example, nutrition education is an appropriate intervention for the person who has little knowledge of how to manage his or her gluten-free diet. Educating individuals about their “total diet” is a viable approach, but any other nutrition diagnoses should be addressed as well. Coordination of care may be helpful to refer the individual to available cookbooks, health services, and support groups. Manipulation of dietary components, provision of enteral or parenteral nutrition, or in-depth nutrition counseling may also be needed.

The final step of the nutrition care process is specific to the individual patient or client, and is related to the signs and symptoms identified in the assessment. A separate chapter is not written here because this fourth step (monitoring and evaluation) would be developed according to the nutrition diagnoses, assessment factors, and outcomes for the individual being served.

## CHAPTER 11

Pamela Charney, PhD, RD  
Sylvia Escott-Stump, MA, RD, LDN

# Overview of Nutrition Diagnosis and Intervention

### KEY TERMS

assessment, diagnosis, interventions, monitoring, evaluation (ADIME) format

electronic medical record (EMR)  
evidence-based guidelines (EBGs)  
Health Insurance Portability and Accountability Act (HIPAA)  
managed-care organizations (MCOs)  
nutrition care process (NCP)  
nutrition diagnosis

nutrition prescription  
palliative care  
patient-centered medical home (PCMH)  
patient-focused care  
personal health record (PHR)  
preferred-provider organization (PPO)  
problem, etiology, signs and symptoms (PES) statement  
process improvement (PI)  
protected health information (PHI)  
room service  
sentinel events  
standards of care  
Standards of Professional Performance (SOPPs)  
subjective, objective, assessment, plan (SOAP) note format  
The Joint Commission (TJC)  
utilization management

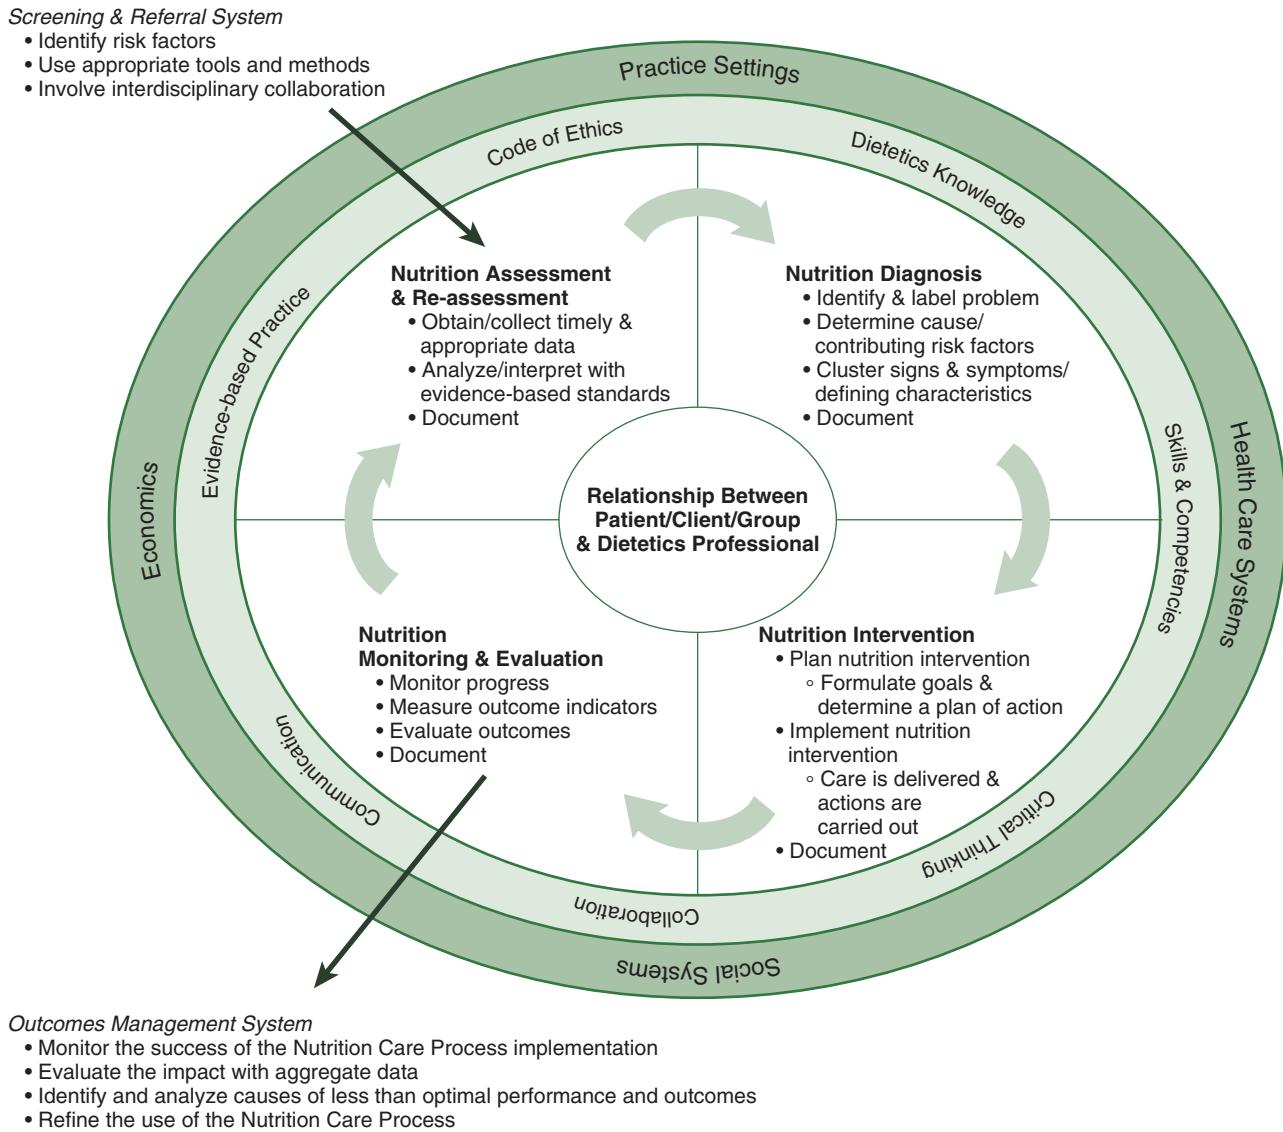

Nutrition care is an organized group of activities allowing identification of nutritional needs and provision of care to meet these needs. Comprehensive service may involve different health care providers—the physician, registered dietitian (RD), nurse, pharmacist, physical or occupational therapist, social worker, speech therapist, and case manager—who are integral in achieving desired outcomes, regardless of the care setting. A collaborative approach helps to ensure that care is coordinated and that team members and the patient are aware of all goals and priorities. Team conferences, formal or informal, are useful in all settings—a clinic, a hospital, the home, the community, a long-term care facility, or any other site where nutrition problems may be

identified. Coordinating the activities of health care professionals also requires documentation of the process and regular discussions to offer complete nutritional care.

### THE NUTRITION CARE PROCESS

The **nutrition care process (NCP)** was established by the American Dietetic Association (ADA) as a standardized process for the provision of nutrition care. The patient or client is the central focus of the NCP (Figure 11-1), and benefits from the critical thinking of the RD and effective, interdisciplinary decision-making. The NCP includes four steps to be completed by the RD: (1) nutrition assessment,

## The Nutrition Care Process and Model

**FIGURE 11-1** The nutrition care process. (©2011 American Dietetic Association. Reprinted with permission.)

(2) nutrition diagnosis, (3) nutrition intervention, and (4) monitoring and evaluation (American Dietetic Association [ADA], 2010).

## Nutrition Screening and Assessment

Nutrition screening provides a mechanism to identify patients or clients who would benefit from nutrition assessment. Most health care facilities have developed a multidisciplinary admission screening process that is completed by nursing staff during admission to the facility. One efficient mechanism for completing the nutrition screen is to incorporate the screen into this admission assessment. The nutrition risk screen should be quick, easy to administer, and cost-effective while maintaining accuracy. Patients identified as “at risk” during the admission screen should be referred to the RD for nutrition assessment. Table 11-1 lists information that is frequently included in a nutrition screen.

When the ADA's Evidence Analysis Library (EAL) team conducted a systematic review of acute care screening tools, they determined that the Malnutrition Screening Tool had acceptable reliability and validity (ADA, 2010). Rescreening should occur at regular intervals during the admission. In hospitalized patients, there may be a relationship between length of stay and worsening nutrition status. Policies for nutrition rescreening should take into account the average length of time a patient will stay at the facility. Nutrition assessment is needed when the screening highlights potential areas of concern (see Chapter 4 for methods and tools).

## Nutrition Diagnosis

After assessment of nutrition status using all of the available data, **nutrition diagnoses** (problems or needs) are identified, prioritized, and documented in the medical record. Selection of an accurate nutrition diagnosis is guided by critical

**TABLE 11-1****Nutrition Risk Screening**

<b>Responsible Party</b>	<b>Action</b>	<b>Documentation</b>
Admitting health care professional	Assess weight status—Has the patient lost weight without trying before admission?	Check yes or no on admission screen.
Admitting health care professional	Assess GI symptoms—Has the patient had GI symptoms preventing usual intake over the past 2 weeks?	Check yes or no on admission screen.
Admitting health care professional	Determine need to consult RD.	If either screening criterion is “yes,” consult RD for nutrition assessment.

GI, Gastrointestinal; RD, registered dietitian.

evaluation of each component of the assessment, combined with critical judgment and decision-making skills. Patients with nutrition diagnoses may be at higher risk for nutrition-related complications such as increased morbidity, increased length of hospital stay, and infectious complications. Nutrition-related complications can lead to a significant increase in costs associated with hospitalization, lending support to the early diagnosis of nutrition problems followed by prompt intervention.

Many facilities use standardized formats to facilitate communication of information gathered in the nutrition assessment and nutrition diagnosis phase. A nutrition diagnosis includes documentation of the **problem, etiology, signs and symptoms (PES)** in a simple, clear statement. Methods used for documenting nutrition care in the medical record are determined at the facility level. RDs in private practice should also develop a systematic method for documenting care provided. **Box 11-1** lists the nutrition diagnoses currently in use by the ADA.

### **Nutrition Intervention**

Nutrition interventions are the actions taken intended to address the nutrition problem. Because the intervention must be an action taken by the RD, assessment of the problem must focus on any nutrition-related causes of the problem rather than the medical diagnosis. Nutrition

### **BOX 11-1**

#### **Nutrition Diagnoses and Sample Codes**

##### **Intake**

NI

Defined as “actual problems related to intake of energy, nutrients, fluids, bioactive substances through oral diet or nutrition support”

##### **Caloric Energy Balance (1)**

Defined as “actual or estimated changes in energy (kcal)”

NI-1.1

- Not in use NI-1.2
- Increased energy expenditure NI-1.3
- Not in use NI-1.4
- Inadequate energy intake NI-1.5
- Excessive energy intake

##### **Oral or Nutrition Support Intake (2)**

Defined as “actual or estimated food and beverage intake from oral diet or nutrition support compared with patient goal”

NI-2.1

- Inadequate oral food or beverage intake NI-2.2
- Excessive oral food or beverage intake NI-2.3
- Inadequate intake from enteral or parenteral nutrition infusion NI-2.4
- Excessive intake from enteral or parenteral nutrition NI-2.5
- Inappropriate infusion of enteral or parenteral nutrition (use with caution)

##### **Fluid Intake (3)**

Defined as “actual or estimated fluid intake compared against patient goal”

NI-3.1

- Inadequate fluid intake NI-3.2
- Excessive fluid intake

*Continued*

**BOX 11-1****Nutrition Diagnoses and Sample Codes—cont'd**

<b>Intake</b>	<b>NI</b>
<b>Bioactive Substances (4)</b>	
Defined as "actual or observed intake of bioactive substances, including single or multiple functional food components, ingredients, dietary supplements, alcohol"

**BOX 11-1****Nutrition Diagnoses and Sample Codes—cont'd****Clinical****NC**

Defined as "nutritional findings or problems identified as related to medical or physical conditions"

**Functional (1)**

Defined as "change in physical or mechanical functioning that interferes with or prevents desired nutritional consequences"

- Swallowing difficulty NC-1.1
- Chewing (masticatory) difficulty NC-1.2
- Breastfeeding difficulty NC-1.3
- Altered gastrointestinal function NC-1.4

**Biochemical (2)**

Defined as "change in capacity to metabolize nutrients as a result of medications, surgery, or as indicated by altered lab values"

- Impaired nutrient utilization NC-2.1
- Altered nutrition-related laboratory values NC-2.2
- Food medication interaction NC-2.3

**Weight (3)**

Defined as "chronic weight or changed weight status when compared with usual or desired body weight"

- Underweight NC-3.1
- Involuntary weight loss NC-3.2
- Overweight or obesity NC-3.3
- Involuntary weight gain NC-3.4

**Behavioral-Environmental****NB**

Defined as "nutritional findings or problems identified as related to knowledge, attitudes or beliefs, physical environment, or food supply and safety"

**Knowledge and Beliefs (1)**

Defined as "actual knowledge and beliefs as observed or documented"

- Food and nutrition-related knowledge deficit NB-1.1
- Harmful beliefs or attitudes about food or nutrition-related topics (use with caution) NB-1.2
- Not ready for diet or lifestyle change NB-1.3
- Self-monitoring deficit NB-1.4
- Disordered eating pattern NB-1.5
- Limited adherence to nutrition-related recommendations NB-1.6
- Undesirable food choices NB-1.7

**Physical Activity and Function (2)**

Defined as "actual physical activity, self-care, and quality of life problems as reported, observed or documented"

- Physical inactivity NB-2.1
- Excessive exercise NB-2.2
- Inability or lack of desire to manage self-care NB-2.3
- Impaired ability to prepare foods/meals NB-2.4
- Poor nutrition quality of life NB-2.5
- Self-feeding difficulty NB-2.6

**Food Safety and Access (3)**

Defined as "actual problems with food access or food safety"

- Intake of unsafe food NB-3.1
- Limited access to food NB-3.2

intervention involves two steps: planning and implementation. During the planning phase of the nutrition intervention, the RD, patient or client, and others as needed collaborate to identify goals and objectives that will signify success of the intervention. Patient-centered goals and objectives are set, and then implementation begins. Interventions may include food and nutrition therapies, nutrition education, counseling, or coordination of care such as providing referral for financial or food resources. Because the care process is continuous, the initial plan may change as the condition of the patient changes, as new needs are identified, or if the interventions are unsuccessful.

Interventions should be specific; they are the “what, where, when, and how” of the care plan (ADA, 2010). For example, in a patient with “inadequate oral food or beverage intake,” an objective might be to increase portion sizes at two meals per day. This could be implemented through provision of portions that are initially 5% larger with a gradual increase to 25% larger portion sizes. Plans should be communicated to the health care team and the patient to ensure understanding of the plan and its rationale. Thorough communication by the RD increases the likelihood of adherence to the plan. **Box 11-2** presents the NCP applied to a sample patient, JW.

## Monitoring and Evaluation of Nutrition Care

The fourth step in the NCP involves monitoring and evaluation of the effect of nutrition interventions. This clarifies the effect that the RD has in the specific setting, whether health care, education, consulting, food services, or research. During this step, the RD first determines indicators that should be monitored. These indicators should match the signs and symptoms identified during the assessment process. For example, if excessive sodium intake was identified during the assessment, then an evaluation of the sodium intake is needed at a designated time for follow-up.

In the clinical setting the goal of nutrition care is to meet the nutritional needs of the patient or client; thus the interventions must be monitored and the meeting of the objectives evaluated frequently. This ensures that unmet objectives are addressed and that care is evaluated and modified in a timely manner. Monitoring and evaluation are not unique to nutrition practice. Evaluation of the monitored indicators provides objective data to demonstrate effectiveness of nutrition interventions, regardless of the setting or focus. If objectives are written in measurable, behavioral terms, evaluation is relatively easy because new behavior is being measured against a behavior that has already been defined.

An example in clinical practice is the sample case in **Box 11-2**. Here, monitoring and evaluation include weekly reviews of his nutritional intake, including an estimation of energy intake. If intake was less than the goal of 1800 kcal, the evaluation might be: “JW was not able to increase his calorie intake to 1800 kcal because of his inability to cook and prepare meals for himself.” A revision in the care plan at this point might include the following: “JW will be provided a referral to local agencies (Meals on Wheels) that can provide meals at home.” This new intervention is then

implemented with continued monitoring and evaluation to determine whether the new objective can be met.

When evaluation reveals that objectives are not being met or that new needs have arisen, the process begins again with reassessment, identification of new nutrition diagnoses, and formulation of a new NCP. For example, in JW’s case, during his hospitalization, high-calorie snacks were provided. However, monitoring reveals that JW’s usual eating pattern does not include snacks, and thus he was not consuming them. The evaluation showed these snacks to be an ineffective intervention. JW agrees to a new intervention—the addition of one more food to his meals. Further monitoring and evaluation will be needed to ascertain if this new intervention improves his intake.

## Evidence-Based Guidelines

Evidence-based practice is use of current “best evidence” in making decisions about the care of individual patients. “Best evidence” includes high-quality research, systematic reviews of the literature, and metaanalysis to support decisions made in practice. Comprehensive use of **evidence-based guidelines (EBGs)** leads to improved quality of care. The guides may also create new research questions.

In the 1990s, the ADA began developing nutrition practice guidelines and evaluating how their use affected clinical outcomes; diabetes management was among the first (Franz et al., 2008). These evidence-based nutrition practice guidelines are disease- and condition-specific recommendations with toolkits. Medical nutrition therapy (MNT) evidence-based guides are available to assist dietetic practitioners in providing nutrition care, especially for diabetes and prerenal failure. MNT provided by a Medicare Part B licensed provider can be reimbursed when the EBGs are used and all procedural forms are properly documented and coded (White et al., 2008).

To define professional practice by the RD, the ADA has published a Scope of Dietetics Practice Framework, a Code of Ethics, and the **Standards of Professional Performance (SOPPs)**. Specialized standards for knowledge, skills, and competencies required to provide care at the generalist, specialist, and advanced practice level for a variety of populations are now complete for many areas of practice. Benefits of nutrition therapy can be communicated to physicians, insurance companies, administrators, or other health care providers using evidence provided from these guidelines. The EBGs include major recommendations, background information, and a reference list.

Overall, the ADA’s EAL provides the best available evidence to answer questions that arise during provision of nutrition care. Use of this library is essential to protect the practitioner and the public from the consequences of ineffective care. These guidelines are extremely valuable for staff orientation, competence verification, and training of RDs anywhere in the world.

## Accreditation and Surveys

Accreditation by **The Joint Commission (TJC)**, formerly the Joint Commission on Accreditation of Healthcare

**BOX 11-2****Applying the Nutrition Care Process for Patient JW**

JW is a 70-year-old white man admitted for cardiac bypass surgery. JW lives alone in his own home. He lost his wife 3 months ago, and for the past 6 months he rarely has sat down to a cooked meal. The nutrition risk screen reveals that he has lost weight without trying and has been eating poorly for several weeks before admission, leading to referral to the RD for nutrition assessment (Step 1 of the nutrition care process).

**Assessment:** Chart review and patient interview reveals the following data:

**Laboratory Data and Medications**

Glucose and electrolytes: WNL  
Albumin: 3.8 g/dL  
Cholesterol/triglycerides: WNL  
Medications: Inderal

**Anthropometric Data**

Height: 70"  
Weight: 130 lb (15 lb weight loss over 3 months)

**Nutrition Interview Findings**

Caloric intake: 1200 kcal/day (less than energy requirements as stated in the recommended dietary allowances)  
Meals: irregular throughout the day; drinks coffee frequently

**Medical History**

History of hypertension, thyroid dysfunction, asthma, prostate surgery

**Psychosocial Data**

New widower; indicates depression and loneliness without his wife

**Nutrition Diagnosis:** JW has been consuming fewer calories than he requires and has little interest in eating. RD determines his nutrition diagnosis and establish objectives for his care.

**Nutrition Diagnostic (PES Statement):** Involuntary weight loss related to depression and poor oral food and beverage intake as evidenced by 15-lb loss in 3 months.

**Interventions:** Identification of the nutrition diagnosis allows the RD to focus the nutrition intervention on

treatment of the cause of the problem (in this case the missing meals). Goal setting is the first step, and short-term and long-term plans are established. In the education process the client and the RD must jointly establish achievable goals. Objectives should be expressed in behavioral terms and stated in terms of what the patient will do or achieve when the objectives are met. Objectives should reflect the educational level and the economic and social resources available to the patient and the family.

**Short-Term Objectives**

During the hospitalization, JW will maintain his current weight; following discharge he will begin to slowly gain weight up to a target weight of 145 lb.

While in the hospital, JW will include nutrient-dense foods in his diet, especially if his appetite is limited.

**Long-Term Objectives**

JW will modify his diet to include adequate calories and protein through the use of nutrient-dense foods to prevent further weight loss and eventually promote weight gain.

Following discharge, JW will attend a local senior center for lunch on a daily basis to help improve his socialization and caloric intake.

**Monitoring and Evaluation:** Choosing the means for monitoring if the interventions, and nutritional care activities have met the objectives or goals is important. Evaluation of the monitoring criteria will provide the RD with information on outcomes, and this should occur over time. Finally, documentation is important for each step of the process to ensure communication between all parties.

For JW, weekly weight measurements and nutrient intake analyses are required while he is in the hospital and biweekly weight measurements at the senior center or clinic when he is back at home. If nutrition status is not improving, which in this case would be evidenced by JW's weight records, and the goals are not being met, it is important to reassess JW and perhaps develop new goals and definitely create plans for new interventions.

*PES*, Problem, etiology, and signs and symptoms; *RD*, registered dietitian; *WNL*, within normal limits.

Organizations, involves a peer review process. TJC survey teams evaluate health care institutions to evaluate their compliance with established minimum standards. TJC requires that nutrition screening be completed within 24 hours of admission to acute care, but does not mandate a method to accomplish screening.

TJC focuses on the facility's actual performance of important governance, managerial, clinical, and support functions.

It also focuses on the continual **process improvement (PI)** in an organization's performance of these functions. Standards are provided in the *Accreditation Manual for Hospitals* document, which is updated and revised on a yearly basis. This document consists of three sections: (1) patient-focused functions; (2) organization-focused functions; and (3) structures with functions, which provides descriptions of the various departments and their roles. Its approach is a

functional one, and all departments and disciplines must be familiar with relevant issues found in applicable chapters. Most chapters contain standards that affect the care provided by a dietitian.

The “Care of the Patient” section contains standards that apply specifically to medication use, rehabilitation, anesthesia, operative and other invasive procedures, and special treatments, as well as nutrition care standards. The focus of the nutrition care standards is provision of appropriate nutrition care in a timely and effective manner using an interdisciplinary approach. Appropriate care requires screening of patients for nutrition needs, assessing and reassessing patient needs, developing an NCP, ordering and communicating the diet order, preparing and distributing the diet order, monitoring the process, and continually reassessing and improving the NCP. A facility can define who, when, where, and how the process is accomplished; but TJC specifies that a qualified dietitian must be involved in establishing this process. A plan for the delivery of nutrition care may be as simple as providing a regular diet for a patient who is not at nutritional risk or as complex as managing tube feedings in a ventilator-dependent patient, which involves the collaboration of multiple disciplines.

The accreditation process typically involves an on-site survey that lasts for several days. During this survey adherence to standards is ascertained through interviews, review of documents (including patient medical records), and visits to patient care and other areas. In addition, a tracer method is now being used, which identifies an issue that surveyors can follow throughout the care of a specific patient.

RDs are actively involved in the survey process. Standards set by TJC play a large role in influencing the standards of care delivered to patients in all health care disciplines. For more information, see the TJC website at [www.jointcommission.org](http://www.jointcommission.org).

Dietitians are also involved with surveys from other regulatory bodies, such as a state or local health department, a department of social services, or licensing organizations. **Sentinel events** are unintended events that are unanticipated and often unwelcome (Ash, 2007). These events must be prevented. When or if they do occur, the outcomes must be documented in the medical record. Regardless of the source of the survey, it is imperative to follow all regulations and guidelines at all times and not just when a survey is due.

## DOCUMENTATION IN THE NUTRITION CARE RECORD

MNT and other nutrition care provided must be documented in the health or medical record. The medical record is a legal document; if interventions are not recorded, it is assumed that they have not occurred. Documentation affords the following advantages:

- It ensures that nutrition care will be relevant, thorough, and effective by providing a record that identifies the problems and sets criteria for evaluating the care.

- It allows the entire health care team to understand the rationale for nutrition care, the means by which it will be provided, and the role each team member must play to reinforce the plan and ensure its success.

The medical record serves as a tool for communication among members of the health care team. Beginning in 2014, health care facilities must use electronic health records (EHRs) to document patient care, store and manage laboratory and test results, communicate with other entities, and maintain all information related to an individual's health. During the transition period, those using paper documentation maintain paper charts that typically include sections for physician orders, medical history and physical examinations, laboratory test results, consults, and progress reports. Although the format of the medical record varies depending on facility policies and procedures, in most settings all professionals document care in the medical record. The RD must ensure that all aspects of nutrition care are summarized succinctly in the medical record.

### Medical Record Charting

Problem-oriented medical records (POMRs) are used in many facilities. The POMR is organized according to the patient's primary problems. Entries into the medical record can be done in many styles. One of the most common forms is the **subjective, objective, assessment, plan (SOAP) note format** (Table 11-2).

The **assessment, diagnosis, interventions, monitoring, evaluation (ADIME) format** is used by many nutrition departments to reflect the steps of the NCP (Box 11-3; Table 11-3). See Table 11-4 for common nutrition diagnostic (PES) statements.

The important factor is the content of the documentation, not necessarily the style. All entries made by the dietitian should address the issues of nutrition status and needs. Notes must be accurate and concise, and they must be able to convey important information to the physician and other health care team members so that they might take action. In a paper-based system, the following are general guidelines for documentation in the hospital setting:

- All entries should be written in black pen or typewritten.
- Documentation should be complete, clear, concise, objective, legible, and accurate.
- Entries should include date, time, and service. Each page should include the patient's name and hospital number.
- Entries should be in chronologic order and be consecutive.
- The first word of every statement should be capitalized, with periods placed at the end of each thought. Complete sentences are not necessary, but grammar and spelling should be correct.
- All entries should be consistent and noncontradictory.

**TABLE 11-2****Evaluation of a Note in SOAP Format**

	<b>Outstanding 2 Points</b>	<b>Above Expectations 1 Point</b>	<b>Below Expectations 0 Points</b>	<b>Score</b>
<b>DATE &amp; TIME</b>		Present	Not present	
<b>S (SUBJECTIVE)</b>	Pertinent components documented.	Accurately summarizes most of the pertinent information.	One or more pertinent elements missing.	
Tolerance of current diet				
Reports of wt loss or appetite decrease				
Chewing or swallowing difficulties				
Previously unreported food allergies				
Pertinent diet hx information	Captures essence of pt's perception of medical problem.			
<b>O (OBJECTIVE)</b>	All necessary elements documented accurately.	Necessary elements documented. No more than one item missing or irrelevant data documented.	One or more pertinent elements omitted and irrelevant data documented.	
Diet order ✓ Pt dx				
Ht, wt, DBW, %DBW ✓ UBW, % UBW				
Pertinent laboratory values ✓				
Diet-related meds				
Estimated nutrient needs (EER & protein)				
<b>A (ASSESSMENT)</b>	Sophisticated assessment drawn from items documented in S & O. Appropriate conclusions drawn.	Appropriate, effective assessment, but not based on documentation in S & O.	Unacceptable assessment or no assessment. Disease pathophysiologic findings documented as assessment of nutritional status.	
S + O = A				
Nutritional status assessed				
Appropriateness of current diet order noted				
Interpretation of abnormal laboratory values (to assess nutritional status)				
Comments on diet hx (if appropriate)				
Comments of tolerance of diet (if appropriate)				
Rationale for suggested changes (if appropriate)				
<b>P (PLAN)</b>	Appropriate nutritional care plan documented reflecting pt's nutritional status.	Vague nutritional care plan documented reflecting pt's nutritional status. Minor errors in care plan. At least one necessary element missing.	MD's orders documented as nutritional care plan. More than one necessary element missing. Unacceptable and/or inappropriate care plan documented.	
Dx (if appropriate)				
Request more labs or calorie count				
Rx (if appropriate)				
Suggestions for changing diet				
Suggestions for adding supplements				
TF/TPN recs				
Recs for vitamin supplements				
Suggestions for referrals				
F/U				
Plans for future care				
Follow-up prn vs. continue to monitor nutritional status				
Monitor tolerance of TF/TPN (if approp.)				
Encourage PO (if appropriate)

**BOX 11-3****Chart Note Using ADIME****Nutrition Assessment**

- Pt is 66-year-old woman admitted with abdominal pain: Ht: 62 cm; Wt: 56 kg; IBW: 52-58 kg
- Laboratory values noted: Na 134, calcium 8, total protein 5.8, albumin 3
- EEN: 1568-1680 calories (28-30 cal/kg) and 56-73 g protein (1-1.3 g/kg)
- Current diet is low residue with pt consuming 25% of meals recorded
- Consult for education received

**Nutrition Diagnosis**

- Food- and nutrition-related knowledge deficit related to lack of prior exposure to information as evidenced by client having no prior knowledge of need for low-residue diet (NB-1.1).

**Nutrition Intervention**

- Education: Will provide pt with written and verbal instruction on low-residue diet.

- Goals: Pt will be able to develop 1-day menu using dietary restrictions.
- Pt will be able to identify good sources of calcium and protein from list of foods appropriate for low-residue diet.
- Pt will ask appropriate questions and verbalize understanding of dietary modifications.

**Monitoring and Evaluation**

- Follow up with pt regarding questions about diet indicated no further questions; good comprehension.
- Evaluation: anticipate no problems following diet at home. Gave business card/phone contact.

**TABLE 11-4****Types of Consults and Sample PES Statements**

Type of Consult	Nutrition Diagnosis Problem (P)	Related to Etiology (E)	As Evidenced by Signs and Symptoms (S)
Weight loss	Inadequate energy intake	Calorie intake not meeting caloric needs	X-lb weight loss in Y days Weight below IBW range
	Inadequate protein/energy intake	Protein/calorie intake < bodily needs	BMI <19 Decreased oral intake (X%), infection
	Inadequate oral food/beverage intake	Calorie intake < calorie expenditure	
	Involuntary weight loss	Increased caloric needs	Oral intake ≤25%
	Inadequate energy intake	Intake < calculated bodily needs	X-lb weight loss in Y days Weight < IBWR
	Inadequate oral food/beverage intake	Oral intake < recommended/calculated	X-lb weight loss in Y days Oral intake ≤50% Low total protein Low albumin Stage X pressure ulcer on
	Involuntary weight loss	Weight loss > expected or desired	Weight loss >5% in 30 days 7.5% in 90 days 10% in 180 days
	Disordered eating pattern	Attitudes related to food, eating, or weight management	Refusal to eat Y meal(s) per day X-lb weight loss in Y days
	Self-feeding difficulty	Impaired ability to place food in mouth	X-lb weight loss in Y days Rapid weight loss Advanced stages of Parkinson disease or MS Excessive shaking of hands

*Continued*

**TABLE 11-4****Types of Consults and Sample PES Statements—cont'd**

Type of Consult	Nutrition Diagnosis Problem (P)	Related to Etiology (E)	As Evidenced by Signs and Symptoms (S)
Pressure ulcer w/ poor PPO intake and weight loss	Inadequate protein/energy intake	Protein/calorie intake < calculated needs	X-lb weight loss in Y days Weight below IBWR BMI <19
	Inadequate oral food/ beverage intake	Protein/calorie intake < protein/calorie needs Increased expenditure/protein needs	Stage X pressure ulcer on
Pressure ulcer— eating well	Inadequate protein intake	Increased protein needs Oral intake not meeting needs	Reported X% intake Stage X pressure ulcer on
	Increased nutrient needs	Increased demand for energy and protein	Loss of skin integrity Stage X pressure ulcer on
Overweight/obesity	Increased protein needs	Increased demand for protein intake	Low albumin Low total protein Stage X pressure ulcer on
	Excessive oral food/beverage intake	Calorie intake > caloric expenditure	Weight > IBWR X-lb weight gain in Y month(s) Elevated BMI
	Excessive energy intake	Calorie intake exceeds calculated needs	Decreased mobility X-lb rapid weight gain in Y days Overweight
	Overweight/obesity		Obesity Morbid obesity
Weight gain	Excessive energy intake	Calorie intake > caloric expenditure	X-lb weight gain in Y month(s) X-lb weight gain in Y days
	Involuntary weight gain	Increased fluid intake Weight gain > expected or desired	Weight gain >5% in 30 days 7.5% in 90 days 10% in 180 days
	Involuntary weight gain	Calorie intake > caloric expenditure	X-lb weight gain in Y month(s) refuses activity, bed bound X-lb gradual weight gain in Y days refuses physical therapy
	Physical inactivity		
Low HgB/Hct	Inadequate mineral intake (iron)	Increased needs Iron intake not meeting needs Lower iron containing foods or substances than meets needs	Low HgB Low Hct Low RBC Anemia
Low albumin, HgB/Hct	Inadequate oral food/ beverage intake	Intake not meeting needs	Low albumin Low HgB/Hct Low RBC
	Increased nutrient needs (protein, iron)	Increase nutrient demand for acute phase proteins	Stress, trauma, inflammation, wound healing

**TABLE 11-4****Types of Consults and Sample PES Statements—cont'd**

Type of Consult	Nutrition Diagnosis Problem (P)	Related to Etiology (E)	As Evidenced by Signs and Symptoms (S)
Abnormal laboratory values	Altered nutrition-related laboratory values	Change in ability to eliminate the byproducts of metabolism	Low albumin Low albumin (edema) Low albumin (high CRP)
	Altered nutrition-related laboratory values	Change in ability to metabolize, absorb, or excrete specific nutrients	Elevated BUN, creatinine Elevated calculated osmolality Elevated Chol., TG, LDL Elevated CO <sub>2</sub> Elevated glucose Elevated glucose
	Impaired nutrient use	Change in ability to eliminate by-product of metabolism	X-lb weight loss in Y days Low albumin Low total protein Low iron Elevated glucose Low glucose
Diabetes	Excessive carbohydrate intake	Intake > needs	Uncontrolled glucose levels Need for no concentrated sweets diet
	Inadequate carbohydrate intake	Intake < needs	X-lb weight loss in Y days X-lb weight gain in Y days Elevated BUN, calc. osmo. Low calc. osmol.
	Inconsistent Carbohydrate intake	Inappropriate pattern of carbohydrate intake throughout the day	
Tube feeding	Inadequate intake from enteral/parenteral nutrition infusion	Intake < caloric needs Diet and TF do not meet needs	
	Excessive intake from enteral/parenteral nutrition	Intake > caloric needs Diet and TF exceed needs	
	Inadequate fluid intake	Intake < calculated needs Intake > calculated needs	
Dehydration	Excessive fluid intake	Lower calorie and nutrient intake than meets bodily needs	Low infusion rate X-lb weight loss in Y days
	Inadequate intake from enteral nutrition infusion	Fluid intake < bodily needs	
	Inadequate fluid intake		
Edema/fluid overload	Involuntary weight gain	Fluid intake > needs	Elevated BUN Elevated calculated osmolality Elevated BUN/creatinine ratio Elevated Na <sup>+</sup> /K <sup>+</sup>
	Excessive oral food/beverage intake	Fluid intake > body's ability to excrete fluid	X-lb weight gain in Y days Low Na <sup>+</sup> Low Hgb/Hct
Dysphagia	Excessive fluid intake	Impaired movement of food/liquid from mouth to stomach	Elevated BUN (in CHF) Choking, coughing, gurgling during meals
	Swallowing difficulty	Inability to consume regular consistency food and/or fluids	
	Inadequate oral food/beverage intake	Intake < calculated needs Inability to tolerate certain foods	Need for mechanically altered diet
GERD	Altered GI function		Reflux, sharp GI pain while eating

Constipation	Inadequate fiber intake	Low intake of fiber containing foods/substances	Constipation
SIADH	Excessive fluid intake	Intake > body's ability to excrete excess fluid	Low Na <sup>+</sup>
Medications (example: calcitonin salmon [Miacalcin] spray)	Inadequate mineral intake (calcium)	Low calcium intake	Use of calcitonin salmon spray without a calcium supplement Low oral intake of high calcium foods
Hospice	Increased energy needs	RMR > calculated requirements	Cancer
End-stage disease	Decreased energy needs	Increased RMR	Head trauma End stage disease process Weight loss expected
Financial constraints	Increased energy needs	Inability to acquire food	Homeless resident X-lb weight loss in Y days Malnutrition No income/no job

BMI, Body mass index; BUN, blood urea nitrogen; *calc. osmol.*, calculation of osmolarity; CHF, congestive heart failure; CO<sub>2</sub>, carbon dioxide; Chol, cholesterol; CRP, C-reactive protein; Hct, hematocrit; Hgb, hemoglobin; IBW, ideal body weight; IBWR, ideal body weight range; K<sup>+</sup>, potassium; LDL, low-density lipoprotein; MS, multiple sclerosis; Na<sup>+</sup>, sodium; PES, problem, etiology, and signs and symptoms; PO, by mouth; RBC, red blood cell; TF, tube feeding; G, triglyceride; w/, with.

- All entries must be signed at the end and should include credentials (e.g., *J. Wilson, RD*). No one should ever chart or sign the medical record for another individual.
- Personal opinions and comments criticizing or casting doubt on the professionalism of others should never be included.
- Documentation must be done at the time of the actual procedure or service.
- Late entries should be identified as such, including the actual date and time of the entry and the date and time it should have been recorded. *Never* add notes after the fact without accurately authenticating, dating, and referencing the original entry.
- Paper medical record entries should always be legible. When correcting an error draw a single line through the error and initial. *Never* use correction fluid, correction tape, self-adhesive labels, or thick marker strokes. *Never* remove an original and replace it with a copy.
- If information is accidentally omitted, write “see addendum” by the original entry, add the date and initial, and write the content in the medical record, identified as an addendum with the date and time of the original entry.

## Electronic Health Records and Nutrition Informatics

Prior to the early 1990s, technology advances did not meet the needs of clinicians in practice. Since then, costs for

memory space have decreased, hardware has become more portable, and system science has sufficiently advanced to make EHRs a permanent fixture in health care. Additional impetus to change standard practice came with publication of several Institute of Medicine reports that brought to light a high rate of preventable medical errors along with the recommendation to use technology as a tool to improve health care quality and safety.

Clinical information systems used in health care are known by different names; although some use electronic medical record (EMR), EHR, and personal health record (PHR) interchangeably, there are important differences. **Electronic health record (EHR)** describes information systems that contain all the health information for an individual. Another term that might be seen includes an **electronic medical record (EMR)**, which typically describes a clinical information system used by a health care organization to document patient care. Both the EHR and EMR are maintained by health care providers. In contrast, the **personal health record (PHR)** is a system that is used by the consumer to maintain health information. A PHR can be web-based, free-standing, or integrated to a facility's EMR.

EHRs include all of the information typically found in a paper-based documentation system along with tools such as clinical decision support, electronic medication records, and alert systems that will support clinicians in making decisions regarding patient care. By 2014, all health care providers will use EHRs to enter, store, retrieve, and manage information related to patient care. Dietitians must have at least a basic understanding of technology and health information

management to ensure a smooth transition from paper to EHR. Such transition will include the development of nutrition screens for patient admission, documentation, information sharing, decision support tools, and order entry. Customization capabilities vary depending on vendor contracts; RDs managing nutrition services must be involved in EHR system decisions at the very beginning, prior to communication of a request for proposals to potential vendors.

In both paper and electronic formats, medical records and the information contained are vital conduits for communicating patient care to others, providing information for quality evaluation and improvement, and as a legal document. RD documentation includes information related to NCPs. Documentation must follow the facility policy and be brief and concise while accurately describing actions taken to those authorized to view the record. Figure 11-2 shows how a computerized medical record might look when using the ADIME method.

Federal requirements mandate that provider systems be “interoperable,” meaning that information can be safely and securely exchanged between providers and facilities. Although this concept seems simple on the surface, problems with interoperability will be very difficult and expensive to overcome. The transition from paper to electronic documentation can be facilitated by thorough planning, training, and support. Many RDs in practice have little experience with technology; they may not fully understand

the practice improvement that can be realized with proper implementation and use of technology. Others may resist any change in the workplace that interrupts their current workflow. Change is never easy (Schifalacqua, 2009).

Clinical system vendors might convince administrators that the transition will be simple and that time savings will be realized immediately following implementation. Quite often this is not the case, leading to unsatisfied clinicians and an expensive tool that is not properly used (Demiris, 2007). RDs participating in implementation of EHRs in health care must be aware of possible resistance or “human issues,” ensuring that all involved are properly trained.

## INFLUENCES ON NUTRITION AND HEALTH CARE

The health care environment has undergone considerable change related to the provision of care and reimbursement in the last decade. Governmental influences, cost containment issues, changing demographics, and the changing role of the patient as a “consumer” have influenced the health care arena. The United States currently spends more on health care than any other nation, yet health care outcomes lag far behind those seen in other developed nations. Exponential increases in health care costs in the United States have been a major impetus for drives to reform how health care is provided and paid for in the United States (Ross, 2009).

The screenshot displays the NutraManager software interface. At the top, there's a navigation bar with tabs like 'Patient: Doe, John', 'Assessment Date: 10/25/2010', 'Assessment Type: Other', 'Status: Active', and a search field 'Description/Name of Problem'. Below this, several sections are visible: 'Diagnosis' (with an update button and a list of conditions: CHF, NIDDM, Hyponatremia, End Stage Renal Disease), 'Biochemical' (with an update button and a note: '10/1/2010 - BMP wnl except Glucose 118 mg/dl'), 'Anthropometric' (with an update button and a note: 'Ht: 70 in; Mo. Wt: 123.0 lbs; BMI: 17.6. Resident demonstrated a 6% weight los:'), 'Physical Examinations' (with an update button and a note: 'Skin: intact; SOB: us'), and 'Narrative Note' (with an update button). On the right side, there are sections for 'Medications' (with an update button and a list: Miralox; Nephrovite), 'Client History' (with an update button and a note: 'age: 90; DOB: 01/01/1920'), and 'Food History' (with an update button and a note: 'EN order: 50 cc continuous of XXX product per tube with 200 cc water flush'). A central window titled 'Patient Interventions' is open, showing a list of 'Patient Nutrition Diagnosis Codes' for 'Patient: Doe, John'. The list includes categories like 'ORAL OR NUTRITION SUPPORT INTAKE (2)' and 'Excessive oral intake', with specific items such as 'NI 2.1 Inadequate oral intake', 'NI 2.2 Excessive oral intake', etc. At the bottom of this window, there are buttons for 'Add', 'Exit', and 'Done'. The overall interface is designed for healthcare professionals to manage patient data and generate reports.

## Affordable Health Care for America: Reconciliation Bill

All Americans will have access to quality, affordable health care under a final package of health insurance reforms signed into law in March 2010. The law will protect Americans from insurance industry practices, offer the uninsured and small businesses the opportunity to obtain affordable health care plans, cover 32 million uninsured Americans, and reduce the deficit by \$143 billion over the next decade.

## Confidentiality and the Health Insurance Portability and Accountability Act

Privacy and security of personal information is of concern in all health care settings. In 1996 Congress passed the **Health Insurance Portability and Accountability Act (HIPAA)** (Centers for Medicare and Medicaid Services, 2010). The initial intent of HIPAA was to ensure that health insurance eligibility was maintained when people changed or lost jobs. The Administrative Simplification provisions of HIPAA require development of national standards that maintain privacy of **protected health information (PHI)**. HIPAA requires that health care facilities and providers (covered entities) take steps to safeguard PHI. Although HIPAA does not prevent sharing of patient data required for an incident of care, patients must be notified if their medical information is to be shared outside of the care process or if protected information (e.g., address, e-mail, income) is to be shared. RDs must use common sense when working with PHI; it is never appropriate to look at another person's medical record unless the RD is involved in the care of that patient. Violations of HIPAA rules have resulted in large fines and loss of jobs.

## Patient Protection and Affordable Care Act

The Patient Protection and Affordable Care Act was written in 2010. Final regulations require group health plans and health insurance issuers to provide coverage of dependent children younger than age 26.

## Payment Systems

One of the largest influences on health care delivery in the last decade has been the change in the method of payment for services provided. There are several common methods of reimbursement: cost-based reimbursement, negotiated bids, and diagnostic-related groups (DRGs). Under the DRG system, a facility receives payment for a patient's admission based on the principal diagnosis, secondary diagnosis (comorbid conditions), surgical procedure (if appropriate), and the age and gender of the patient. Approximately 500 DRGs cover the entire spectrum of medical diagnoses and surgical treatments. **Preferred-provider organizations (PPOs)** and **managed-care organizations (MCOs)** also changed health care. MCOs finance and deliver care through a contracted network of providers in exchange for a monthly premium, changing reimbursement from a fee-for-service system to one in which fiscal risk is borne by health care

organizations and physicians. New legislation will likely change the face of reimbursement even more.

## Quality Management

To contain health care costs while providing efficient and effective care that is of consistently high quality, practice guidelines or **standards of care** are used. These sets of recommendations serve as a guide for defining appropriate care for a patient with a specific diagnosis or medical problem. They help to ensure consistency and quality for both providers and clients in a health care system and, as such, are specific to an institution or health care organization. **Critical pathways**, or care maps, identify essential elements that should occur in the patient's care and define a timeframe in which each activity should occur to maximize patient outcomes. They often use an algorithm or flowchart to indicate the necessary steps required to achieve the desired outcomes. **Disease management** is designed to prevent a specific disease progression or exacerbation, and to reduce the frequency and severity of symptoms and complications. Education and other strategies maximize compliance with disease treatment. Educating a patient with type 1 diabetes regarding control of blood glucose levels would be an example of a disease management strategy aimed at decreasing the complications (nephropathy, neuropathy, and retinopathy) and the frequency with which the client needs to access the care provider. Decreasing the number of emergency room visits related to hypoglycemic episodes is a sample goal.

## Patient-Centered Care and Case Management

The **case management** process strives to promote the achievement of patient care goals in a cost-effective, efficient manner. It is an essential component in delivering care that provides a positive experience for the patient, ensures achievement of clinical outcomes, and uses resources wisely. Case management involves assessing, evaluating, planning, implementing, coordinating, and monitoring care, especially in patients with chronic disease or those who are at high risk. In some areas, dietitians have added skill sets that enable them to serve as case managers. **Utilization management** is a system that strives for cost efficiency by eliminating or reducing unnecessary tests, procedures, and services. Here, a manager is usually assigned to a group of patients and is responsible for ensuring adherence to preestablished criteria.

The **patient-centered medical home (PCMH)** is a new development that focuses on the relationship between the patient and his or her personal physician. The personal physician takes responsibility for all aspects of health care for the patient and acts to coordinate and communicate with other providers as needed. Other providers such as nurses, health educators, and allied health professionals may be called on by the patient or personal physician for preventive and treatment services. When specialty care is needed, the personal physician becomes responsible for ensuring that care is seamless and that transitions between care sites go smoothly (Backer, 2007; Ornstein 2008). The RD should be considered part of the medical home treatment plan.

Regardless of model, the facility must manage patient care prudently. Nutrition screening can be very important in identifying patients who are nutritionally compromised. Early identification of these factors allows for timely intervention and helps prevent the comorbidities often seen with malnutrition, which may cause the length of stay and costs to increase. The **Centers for Medicare and Medicaid Services (CMS)** has identified several conditions, such as heart failure, for which no additional reimbursement will be received if a patient is readmitted to acute care within 30 days of a prior admission. Although many view this rule as punitive, it does provide an opportunity for RDs to demonstrate how nutrition services, including patient education, can save money through decreased readmissions.

Other recent developments include “never events.” Never events are those occurrences that should never happen in a facility that provides high-quality, safe, **patient-focused care**. RDs must pay attention to new or worsening pressure ulcers and central line infections as potential “never events.”

### Staffing and Nutrition Coding

Staffing also affects the success of nutrition care. Clinical dietitians may be centralized (all are part of a core nutrition department) or decentralized (individual dietitians are part of a unit or service that provides care to patients), depending on the model adopted by a specific institution. Certain departments such as food service, accounting, and human resources remain centralized in most models because some of the functions for which these departments are responsible are not directly related to patient care. Dietitians should be involved in the planning for any redesign of patient care. Regardless of where dietitians work, they need to implement the NCP, use the standardized terminology of the profession, and code their services accurately (see *Focus On: Nutrition Standardized Language and Coding Practices*).

## NUTRITION INTERVENTIONS

The RD is the only licensed provider who can reliably offer food and nutrition services that are credible and highly individualized. The RD expert is able to inform, educate, and inspire his or her clients. This guidance is health-enhancing and, often, life-changing. The profession offers stringent guidelines for practice, with science-based information that is not compromised by market forces. The RD must complete continuing education and rigorous reviews of competency every 5 years to maintain that credential. In addition, there are a myriad of position papers and journal articles that keep members up to date to support the “total diet approach” to good nutritional intake.

The evaluation of general and modified diets requires in-depth knowledge of the nutrients contained in different foods. In particular, it is essential to be aware of the nutrient-dense foods that contribute to dietary adequacy. Balance and judgment are needed. Sometimes a vitamin-mineral supplement is necessary to meet the patient’s needs when the intake is limited. Chapter 3 and Appendices 46–58 provide

### © FOCUS ON

## Nutrition Standardized Language and Coding Practices

ICD codes were developed in the late 1800s as a mechanism to monitor and track mortality rates in medical practice. The ICD coding system has been revised and updated several times and is used by most countries. Medical records departments review medical records and assign codes to the medical diagnoses as well as complicating factors (“comorbidities”) to determine reimbursement rates. Commonly, pulmonary, gastrointestinal, endocrine, mental disorders, and cancer can lead to malnutrition\* as a comorbid factor. Thus coordinated nutrition care and coding for malnutrition are important elements in patient services.

Use of the nutrition codes and evidence-based guides established by the ADA should improve client outcomes and reimbursement. A study by White et al (2008) found that self-employed RDs are more likely to be reimbursed by private or commercial payers, and RDs working in clinic settings are more likely to be reimbursed by Medicare. RDs must know and be accountable for both the business and clinical side of their nutrition practices (White et al., 2008). Several members of the ADA are active on medical committees where coding and reimbursement issues are being evaluated and updated.

Using correct codes and following payers’ claims processing policies and procedures are essential. For example, an NPI is a 10-digit number that is required on claims. To apply for an NPI, registered dietitians can complete the online application at the NPPES website at <https://nppes.cms.hhs.gov/NPPES/Welcome.do>.

*ADA*, American Dietetic Association; *ICD*, International Classification of Disease; *NPI*, National Provider Identifier; *NPPES*, National Plan and Provider Enumeration System; *RD*, registered dietitian.

\*For the malnutrition identified during the nutrition care process, Code 261 is “evident malnutrition.”

detailed information on specific minerals and vitamins and the foods that contain them.

### Interventions: Food and Nutrient Delivery

The **nutrition prescription** designates the type, amount, and frequency of nutrition based on the individual’s disease process and disease management goals. The prescription may specify a caloric level or other restriction to be implemented. It may also limit or increase various components of the diet, such as carbohydrate, protein, fat, alcohol, fiber, water, specific vitamins or minerals, bioactive substances such as phytonutrients (see Chapter 3). RDs write the nutrition prescription following diagnosis of nutrition problems.

Note that a diet order differs from a nutrition prescription. In most states, only a licensed independent health care

provider can enter diet orders into a patient's medical record. Typically, physicians, physician assistants, and advanced practice nurses are considered to be licensed independent providers. In some facilities, RDs have been granted order-writing privileges. It should be remembered that the ability to enter orders does not absolve the RD of the need to communicate and coordinate care with the provider who is ultimately responsible for all aspects of patient care.

Therapeutic or modified diets are based on a general, adequate diet that has been altered to provide for individual requirements, such as digestive and absorptive capacity, alleviation or arrest of a disease process, and psychosocial factors. In general, the therapeutic diet should vary as little as possible from the individual's normal diet. Personal eating patterns and food preferences should be recognized, along with socioeconomic conditions, religious practices, and any environmental factors that influence food intake, such as where the meals are eaten and who prepares them (see "Cultural Aspects of Dietary Planning" in Chapter 12).

A nutritious and adequate diet can be planned in many ways. One foundation of such a diet is the MyPlate Food Guidance System (see Fig. 12-1). This is a basic plan; additional foods or more of the foods listed are included to provide additional energy and increase the intake of required nutrients for the individual. The Dietary Guidelines for Americans are also used in meal planning and to promote wellness. The dietary reference intakes (DRIs) and specific nutrient recommended dietary allowances are formulated for healthy persons, but they are also used as a basis for evaluating the adequacy of therapeutic diets. Nutrient requirements specific to a particular person's genetic makeup, disease state, or disorder must always be kept in mind during diet planning.

## Modifications of the Normal Diet

Normal nutrition is the foundation on which therapeutic diet modifications are based. Regardless of the type of diet prescribed, the purpose of the diet is to supply needed nutrients to the body in a form that it can handle. Adjustment of the diet may take any of the following forms:

- Change in consistency of foods (liquid diet, pureed diet, low-fiber diet, high-fiber diet)
- Increase or decrease in energy value of diet (weight-reduction diet, high-calorie diet)
- Increase or decrease in the type of food or nutrient consumed (sodium-restricted diet, lactose-restricted diet, fiber-enhanced diet, high-potassium diet)
- Elimination of specific foods (allergy diet, gluten-free diet)
- Adjustment in the level, ratio, or balance of protein, fat, and carbohydrate (diet for diabetes, ketogenic diet, renal diet, cholesterol-lowering diet)
- Rearrangement of the number and frequency of meals (diet for diabetes, postgastrectomy diet)
- Change in route of delivery of nutrients (enteral or parenteral nutrition)

## Diet Modifications in Hospitalized Patients

Food is an important part of nutrition care. Attempts should be made to honor patient preferences during illness and recovery from surgery. Imagination and ingenuity in menu planning are essential when planning meals acceptable to a varied patient population. Attention to color, texture, composition, and temperature of the foods, coupled with a sound knowledge of therapeutic diets, is required for menu planning. However, to the patient, good taste and attractive presentation are most important. When possible, patient choices of food are most likely be consumed. The ability to make food selections gives the patient an option in an otherwise limiting environment.

Hospitals have to adopt a diet manual that serves as the reference for that facility. The ADA has an online manual that can be purchased for several users per facility. All hospitals or health care institutions have basic, routine diets designed for uniformity and convenience of service. These standard diets are based on the foundation of an adequate diet pattern with nutrient levels as derived from the DRIs. Types of standard diets vary but can generally be classified as general or regular or modified consistency. The diets should be realistic and meet the nutritional requirements of the patients. The most important consideration of the type of diet offered is providing foods that the patient is willing and able to eat and that fit in with any required dietary restrictions. Shortened lengths of stay in many health care settings result in the need to optimize intake of calories and protein and this often translates into a liberal approach to therapeutic diets. This is especially true when the therapeutic restrictions might compromise intake and subsequent recovery from surgery, stress, or illness.

### Regular or General Diet

"Regular" or "general" diets are used routinely and serve as a foundation for more diversified therapeutic diets. In some institutions a diet that has no restrictions is referred to as the *regular* or *house* diet. It is used when the patient's medical condition does not warrant any limitations. This is a basic, adequate, general diet of approximately 1600 to 2200 kcal; it usually contains 60 to 80 g of protein, 80 to 100 g of fat, and 180 to 300 g of carbohydrate. Although there are no particular food restrictions, some facilities have instituted regular diets that are low in fat, saturated fat, cholesterol, sugar, and salt to follow the dietary recommendations for the general population. In other facilities the diet focuses on providing foods the patient is willing and able to eat, with less focus on restriction of nutrients. Many institutions have a selective menu that allows the patient certain choices; the adequacy of the diet varies based on the patient's selections.

### Consistency Modifications

Modifications in consistency may be needed for patients who have limited chewing or swallowing ability. Chopping, mashing, pureeing, or grinding food modifies its texture. See Chapter 41 and Appendix 35 for more information on

consistency modifications and for neurologic changes in particular.

Clear liquid diets include some electrolytes and small amounts of energy from tea, broth, carbonated beverages, clear fruit juices, and gelatin. Milk and liquids prepared with milk are omitted, as are fruit juices that contain pulp. Fluids and electrolytes are often replaced intravenously until the diet can be advanced to a more nutritionally adequate one.

There is little scientific evidence supporting the use of clear liquid diets as transition diets after surgery (Jeffery et al., 1996). The average clear liquid diet contains only 500 to 600 kcal, 5 to 10 g of protein, minimum fat, 120 to 130 g of carbohydrate, and small amounts of sodium and potassium. It is inadequate in calories, fiber, and all other essential nutrients and should be used only for short periods. In addition, full liquid diets are also not recommended for a prolonged time. If needed, oral supplements may be used to provide more protein and calories.

## Food Intake

Food served does not necessarily represent the actual intake of the patient. Prevention of malnutrition in the health care setting requires observation and monitoring of the adequacy of patient intake. If food intake is inadequate, measures should be taken to provide foods or supplements that may be better accepted or tolerated. Regardless of the type of diet prescribed, both the food served and the amount actually eaten must be considered to obtain an accurate determination of the patient's energy and nutrient intake. Nourishments and calorie-containing beverages consumed between meals are also considered in the overall intake. It is important that the RD maintain communication with nursing and food service personnel to determine adequacy of intake. Although calorie counts are often inaccurate and incomplete, they are sometimes used to justify the need for enteral or parenteral nutrition.

## Acceptance and Psychological Factors

Meals and between-meal nourishments are often highlights of the day and are anticipated with pleasure by the patient. Mealtime should be as positive an experience as possible. Whatever setting the patient is eating in should be comfortable for the patient. Food intake is encouraged in a pleasant room with the patient in a comfortable eating position in bed or sitting in a chair located away from unpleasant sights or odors. Eating with others often promotes better intake.

Arrangement of the tray should reflect consideration of the patient's needs. Dishes and utensils should be in a convenient location. Independence should be encouraged in those who require assistance in eating. The caregiver can accomplish this by asking patients to specify the sequence of foods to be eaten and having them participate in eating, if only by holding their bread. Even visually impaired persons can eat unassisted if they are told where to find foods on the tray. Patients who require feeding assistance should be fed when the foods are still at an optimal temperature. The feeding process requires about 20 minutes as a general rule.

Poor acceptance of foods and meals may be caused by unfamiliar foods, a change in eating schedule, improper food temperatures, the patient's medical condition, or the effects of medical therapy. Food acceptance is improved when personal selection of menus is encouraged. There is a revolution occurring in hospital food service. Most hospitals have a **room service**-style menu or are actively working to implement one to solve the problems related to dissatisfaction and poor intake.

Patients should be given the opportunity to share concerns regarding meals, which may improve acceptance and intake. In encouraging acceptance of a therapeutic diet, the attitude of the caregiver is important. The nurse who understands that the diet contributes to the restoration of the patient's health will communicate this conviction by actions, facial expressions, and conversation. Patients who understand that the diet is important to the success of their recovery usually accept it more willingly. When the patient must adhere to a therapeutic dietary program indefinitely, an interdisciplinary approach will help him or her achieve nutritional goals. Because they have frequent contact with patients, nurses play an important role in a patient's acceptance of nutrition care. Ensuring that the nursing staff is aware of the NCP can greatly improve the probability of success.

## Interventions: Nutrition Education and Counseling

Nutrition education is an important part of the MNT provided to many patients. The goal of nutrition education is to help the patient acquire the knowledge and skills needed to make changes, including modifying behavior to facilitate sustained change. Nutrition education and dietary changes can result in many benefits, including control of the disease or symptoms, improved health status, enhanced quality of life, and decreased health care costs.

As the average length of hospital stays has decreased, the role of the in-patient dietitian in educating inpatients has changed to providing brief education or "survival skills." This education includes the types of foods to limit, timing of meals, and portion sizes. Follow-up outpatient counseling should be encouraged to reinforce the basic counseling given during hospitalization. See Chapter 14 for managing nutrition support and Chapter 15 for counseling skills.

## Intervention: Coordination of Care

Nutrition care is part of **discharge planning**. Education, counseling, and mobilization of resources to provide home care and nutrition support are included in discharge procedures. Completing a discharge nutritional summary for the next caregiver is imperative for optimal care. Appropriate discharge documentation includes a summary of nutrition therapies and outcomes; pertinent information such as weights, laboratory values, and dietary intake; potential drug-nutrient interactions; expected progress or prognosis; and recommendations for follow-up services. Types of therapy attempted and failed can be very useful information.

The amount and type of instruction given, the patient's comprehension, and the expected degree of adherence to the prescribed diet are included. An effective discharge plan increases the likelihood of a positive outcome for the patient.

Regardless of the setting to which the patient is discharged, effective coordination of care begins on day 1 of a hospital or nursing home stay and continues throughout the institutionalization. The patient should be included in every step of the planning process whenever possible to ensure that decisions made by the health care team reflect the desires of the patient.

When needed, the RD refers the patient or client to other caregivers, agencies, or programs for follow-up care or services. For example, use of the home-delivered meal program of the Older Americans Act Nutrition Program has traditionally served frail, homebound, older adults, yet studies show that older adults who have recently been discharged from the hospital may be at high nutritional risk but not referred to this service (Sahyoun et al., 2010). Thus the RD plays an essential role in making the referral and coordinating the necessary follow-up.

## NUTRITION FOR THE TERMINALLY ILL OR HOSPICE PATIENT

Maintenance of comfort and quality of life are most typically the goals of nutrition care for the terminally ill patient. Dietary restrictions are rarely appropriate. Nutrition care should be mindful of strategies that facilitate symptom and pain control. Recognition of the various phases of dying—denial, anger, bargaining, depression, and acceptance—will help the health care practitioner understand the patient's response to food and nutrition support.

The decision as to when life support should be terminated often involves the issue of whether to continue enteral or parenteral nutrition. With **advance directives**, the patient can advise family and health care team members of his or her individual preferences with regard to end-of-life issues. Food and hydration issues may be discussed, such as whether tube feeding should be initiated or discontinued and under what circumstances. Nutrition support should be continued as long as the patient is competent to make this choice (or if specified in the patient's advance directives).

In advanced dementia, the inability to eat orally can lead to weight loss. One clear goal-oriented alternative to tube feeding may be the order for "comfort feeding only" to ensure an individualized feeding plan (Palecek et al., 2010). **Palliative care** encourages the alleviation of physical symptoms, anxiety, and fear while attempting to maintain the patient's ability to function independently.

Hospice home care programs allow terminally ill patients to stay at home and delay or avoid hospital admission. Quality of life is the critical component. Indeed, individuals have the right to request or refuse nutrition and hydration as medical treatment (ADA, 2008). RD intervention may benefit the patient and family as they adjust to issues related to the approaching death. Families who might be

## CLINICAL SCENARIO

**M**r. B, a 47-year-old man, 6 ft 2 in tall and weighing 200 lb, is admitted to the hospital with chest pain. Three days after admission, at patient care rounds, it is discovered that Mr. B has gained 30 pounds over the last 2 years. Review of the medical record reveals the following laboratory data: LDL: 240 (desirable 130), HDL 30 (desirable >50), triglyceride 350 (desirable <200). Blood pressure is 120/85. Current medications: multivitamin/mineral daily. Cardiac catheterization is scheduled for tomorrow. Diet is poor; skips meals and eats very large dinner meals.

### Nutrition Diagnostic Statement

Altered nutrition-related laboratory values related to undesirable food choices as evidenced by elevated LDL and low HDL.

### Nutrition Care Questions

1. What other information do you need to develop a nutrition care plan?
2. Was nutrition screening completed in a timely manner? Discuss the implications of timing of screening versus implementing care.
3. Develop a chart note, using ADIME format, based on this information and the interview you conduct with the patient.
4. What nutrition care goals would you develop for this patient during his hospital stay?
5. What goals would you develop for this patient after discharge? Discuss how the type of health care insurance coverage the patient has might influence this plan.

*HDL*, High-density lipoprotein; *LDL*, low-density lipoprotein.

accustomed to a modified diet should be reassured if they are uncomfortable about easing dietary restrictions. Ongoing communication and explanations to the family are important and helpful. RDs should work collaboratively to make recommendations on providing, withdrawing, or withholding nutrition and hydration in individual cases and serve as active members of institutional ethics committees (ADA, 2008). The RD, as a member of the health care team, has a responsibility to promote use of advanced directives of the individual patient and to identify their nutritional and hydration needs.

# Food and Nutrient Delivery: Planning the Diet with Cultural Competency

### KEY TERMS

adequate intake (AI)  
daily reference intake (DRI)  
daily reference values (DRVs)  
daily value (DV)  
**Dietary Guidelines for Americans (DGA)**  
dietary reference intake (DRI)  
estimated average requirement (EAR)  
estimated safe and adequate daily dietary intake (ESADDI)  
flexitarian  
food insecurity

functional food  
health claim  
**Healthy Eating Index (HEI)**  
locovore  
**MyPlate Food Guidance System**  
nutrition facts label  
phytochemicals  
**recommended dietary allowance (RDA)**  
**reference daily intakes (RDIs)**  
tolerable upper intake level (UL)  
vegan

An appropriate diet is adequate and balanced and considers the individual's characteristics such as age and stage of development, taste preferences, and food habits. It also reflects the availability of foods, socioeconomic conditions, cultural practices and family traditions, storage and preparation facilities, and cooking skills. An adequate and balanced diet meets all the nutritional needs of an individual for maintenance, repair, living processes, growth, and development. It includes energy and all nutrients in proper amounts and in proportion to each other. The presence or absence of one essential nutrient may affect the availability, absorption, metabolism, or dietary need for others. The recognition of nutrient interrelationships provides further support for the principle of maintaining food variety to provide the most complete diet.

Dietitians translate food, nutrition, and health information into food choices and diet patterns for groups and individuals. With increasing knowledge of how diet influences diseases that lead to premature disability and mortality among Americans, an appropriate diet helps reduce the risk

of developing chronic diseases and conditions. In this era of vastly expanding scientific knowledge, food intake messages for health promotion and disease prevention change rapidly. The public often hears references to functional food ingredients, which provide more benefits than just basic nutrition.

### DETERMINING NUTRIENT NEEDS

According to the Food and Nutrition Board, choosing a variety of foods should provide adequate amounts of nutrients. A varied diet may also ensure that a person is consuming sufficient amounts of **functional food** constituents that, although not defined as nutrients, have biologic effects and may influence health and susceptibility to disease. Examples include foods containing dietary fiber and carotenoids, as well as lesser known **phytochemicals** (components of plants that have protective or disease-preventive properties) such as isothiocyanates in broccoli or other cruciferous vegetables and lycopene in tomato products (see [Chapter 20](#)).

## WORLDWIDE GUIDELINES

Numerous standards serve as guides for planning and evaluating diets and food supplies for individuals and population groups. The Food and Agriculture Organization and the World Health Organization of the United Nations have established international standards in many areas of food quality and safety, as well as dietary and nutrient recommendations. In the United States the Food and Nutrition Board (FNB) of the Institute of Medicine (IOM) has led the development of nutrient recommendations since the 1940s. Since the mid-1990s, nutrient recommendations developed by the FNB have been used by the United States and Canada.

The U.S. Department of Agriculture (USDA) and U.S. Department Health and Human Services (USDHHS) have a shared responsibility for issuing dietary recommendations, collecting and analyzing food composition data, and formulating regulations for nutrition information on food products. Health Canada is the agency responsible for Canadian dietary recommendations; in Australia, the guidelines are available through the National Health and Medical Research Council. The Japan Dietetic Association updates their guidelines every four years, the latest designed as the “Spinning Top” from the Ministry of Health, Labor and Welfare. Indeed, many countries have issued guidelines appropriate for the circumstances and needs of their populations.

### Dietary Reference Intakes

American standards for nutrient requirements have been the recommended dietary allowances (RDAs) established by the FNB of the IOM. They were first published in 1941 and most recently revised between 1997 and 2002. Each revision incorporates the most recent research findings. In 1993 the FNB developed a framework for the development of nutrient recommendations, called **dietary reference intakes (DRI)**. Nutrition and health professionals should always use updated food composition databases and tables and inquire whether data used in computerized nutrient analysis programs have been revised to include the most up-to-date information. An interactive DRI calculator is available at <http://fnic.nal.usda.gov/interactiveDRI/>.

### Estimated Safe and Adequate Daily Dietary Intakes

Numerous nutrients are known to be essential for life and health, but data for some are insufficient to establish a recommended intake. Intakes for these nutrients are **estimated safe and adequate daily dietary intakes (ESADDIs)**. Most intakes are shown as ranges to indicate that not only are specific recommendations not known, but also at least the upper and lower limits of safety should be observed.

### DRI Components

The DRI model expands the previous RDA, which focused only on levels of nutrients for healthy populations to prevent deficiency diseases. To respond to scientific advances in diet and health throughout the life cycle, the DRI model now includes four reference points: adequate intake (AI),

estimated average intake (EAR), RDA, and tolerable upper intake level (UL).

The **adequate intake (AI)** is a nutrient recommendation based on observed or experimentally determined approximation of nutrient intake by a group (or groups) of healthy people when sufficient scientific evidence is not available to calculate an RDA or an EAR. Some key nutrients are expressed as an AI, including calcium (see Chapter 3). The **estimated average requirement (EAR)** is the average requirement of a nutrient for healthy individuals; a functional or clinical assessment has been conducted, and measures of adequacy have been determined. An EAR is the amount of a nutrient with which approximately one half of individuals would have their needs met and one half would not. The EAR should be used for assessing the nutrient adequacy of populations, but not for individuals.

The **recommended dietary allowance (RDA)** presents the amount of a nutrient needed to meet the requirements of almost all (97% to 98%) of the healthy population of individuals for whom it was developed. An RDA for a nutrient should serve as a goal for intake for individuals, not as a benchmark for adequacy of diets of populations. Finally the **tolerable upper intake level (UL)** was established for many nutrients to reduce the risk of adverse or toxic effects from consumption of nutrients in concentrated forms—either alone or combined with others (not in food)—or from enrichment and fortification. A UL is the highest level of daily nutrient intake that is unlikely to have any adverse health effects on almost all individuals in the general population. The DRIs for the macronutrients, vitamins and minerals, including the ULs are presented on the inside front cover and opening page of this text. The acceptable macronutrient distribution ranges are based on energy intake by age and sex. See Table 12-1 and the DRI tables on the inside front cover of this text.

### Target Population

Each of the nutrient recommendation categories in the DRI system is used for specific purposes among individuals or populations. The EAR is used for evaluating the nutrient intake of populations. The AI and RDA can be used for individuals. Nutrient intakes between the RDA and the UL may further define intakes that may promote health or prevent disease in the individual.

### Age and Gender Groups

Because nutrient needs are highly individualized depending on age, sexual development, and the reproductive status of females, the DRI framework has 10 age groupings, including age-group categories for children, men and women 51 to 70 years of age, and those older than 70 years of age. It separates three age-group categories each for pregnancy and lactation—younger than 18 years, 19 to 30 years, and 31 to 50 years of age.

### Reference Men and Women

The requirement for many nutrients is based on body weight, according to reference men and women of

**TABLE 12-1****Acceptable Macronutrient Distribution Ranges**

Nutrient	AMDR (Percentage of Daily Energy Intake)			AMDR Sample Diet Adult, 2000-kcal/day Diet	
	1-3 Years	4-18 Years	>19 Years	% Reference*	g/Day
Protein <sup>†</sup>	5-20	10-30	10-30	10	50
Carbohydrate	45-65	45-65	45-65	60	300
Fat	30-40	25-35	20-35	30	67
α-Linolenic acid (*ω-3) <sup>‡</sup>	0.6-1.2	0.6-1.2	0.6-1.2	0.8	1.8
Linolenic acid (ω-6)	5-10	5-10	5-10	7	16
Added sugars <sup>§</sup>	≤25% of total calories			500	125

Modified from Food and Nutrition Board, Institute of Medicine: Dietary reference intakes for energy, carbohydrate, fiber, fat, fatty acids, cholesterol, protein, and amino acids, Washington DC, 2002, National Academies Press.

AMDR, Acceptable macronutrient distribution range; DHA, docosahexaenoic acid; DRI, dietary reference intake; EPA, eicosapentaenoic acid.

\*Suggested maximum.

<sup>†</sup>Higher number in protein AMDR is set to complement AMDRs for carbohydrate and fat, not because it is a recommended upper limit in the range of calories from protein.

<sup>‡</sup>Up to 10% of the AMDR for α-linolenic acid can be consumed as EPA, DHA, or both (0.06%-0.12% of calories).

<sup>§</sup>Reference percentages chosen based on average DRI for protein for adult men and women, then calculated back to percentage of calories. Carbohydrate and fat percentages chosen based on difference from protein and balanced with other federal dietary recommendations.

designated height and weight. These values for age-sex groups of individuals older than 19 years of age are based on actual medians obtained for the American population by the third National Health and Nutrition Examination Survey, 1988 to 1994. Although this does not necessarily imply that these weight-for-height values are ideal, at least they make it possible to define recommended allowances appropriate for the largest number of people.

## NUTRITIONAL STATUS OF AMERICANS

### Food and Nutrient Intake Data

Information about the diet and nutritional status of Americans and the relationship between diet and health is collected by 22 federal agencies. This effort is coordinated by the USDA and USDHHS through the National Nutrition Monitoring and Related Research Program, (See Chapter 10). Overall, analysis of the American diet shows that the population is slowly changing eating patterns and adopting more healthy diets. Intake of total fat, saturated fatty acids, and cholesterol has decreased in some segments of the population; servings of fruits and vegetables have risen to four per day. Hospitals have even taken on the challenge for healthier food intake (see *Focus On: The “Healthy Food In Health Care” Pledge*).

Unfortunately, gaps still exist between actual consumption and government recommendations in certain population subgroups. Nutrition-related health measurements indicate that overweight and obesity are increasing from lack of physical activity. Hypertension remains a major public health problem in middle-age and older adults and

in non-Hispanic blacks in whom it increases the risk of stroke and coronary heart disease. Osteoporosis develops more often among non-Hispanic whites than non-Hispanic blacks. Finally, in spite of available choices, many Americans experience **food insecurity**, meaning that they lack access to adequate and safe food for an active, healthy life. Table 12-2 provides a list of food components and public health concerns related to those components.

### Healthy Eating Index

The Center for Nutrition Policy and Promotion of the USDA releases the **Healthy Eating Index (HEI)** to measure how well people's diets conform to recommended healthy eating patterns. The index provides a picture of foods people are eating, the amount of variety in their diets, and compliance with specific recommendations in the Dietary Guidelines for Americans (DGA). The HEI is designed to assess and monitor the dietary status of Americans by evaluating 10 components, each representing different aspects of a healthy diet. The dietary components used in the evaluation include grains, vegetables, fruits, milk, meat, total fat, saturated fat, cholesterol, sodium, and variety. Data from the HEI over time show that Americans are reducing total and saturated fat and eating a wider variety of foods. The 2005 report suggests that milk intake is still low (Guenther et al., 2008). The overall HEI score ranges from 0 to 100. Interestingly, women generally have scores higher than men, and toddlers have the highest scores.

### Nutrition Monitoring Report

At the request of the USDHHS and USDA, the Expert Panel on Nutrition Monitoring was established by the Life Sciences Research Office of the Federation of American

## © FOCUS ON

### The “Healthy Food in Health Care” Pledge

Health care facilities across the nation have recognized that their systems of purchasing, producing and distributing food are misaligned with the U.S. dietary guidelines and have joined a movement to change their practices. The organization promoting this plan is called “Health Care Without Harm.” In 2009, The American Medical Association (AMA) approved a new policy resolution in support of practices and policies within health care systems that promote and model a healthy and ecologically sustainable food system. The resolution also calls on the AMA to work with health care and public health organizations to educate the health care community and the public about the importance of healthy and ecologically sustainable food systems. Hospitals are using the online pledge form to commit to these eight steps:

1. Work to source locally (see *Focus On*: What is a Locovore?).
2. Encourage vendors to supply foods without harmful chemicals and antibiotics and to support the health of farmers and the environment.
3. Implement a program to adopt sustainable food procurement.
4. Communicate to group purchasing organizations a desire to source locally and to source foods that do not contain harmful chemicals.
5. Educate patients and the community about nutritious, socially just, and ecologically sustainable food practices and procedures.
6. Minimize or beneficially reuse food waste and support the use of food packaging that is ecologically protective.
7. Develop a program to promote and source from producers and processors that uphold the dignity of family, farmers, and their communities, and support humane and sustainable agriculture systems.
8. Report annually.

Modified from Health Care without Harm. Accessed 24 May 2010 from <http://www.noharm.org>.

Societies for Experimental Biology to review the dietary and nutritional status of the American population. In general, the committee concluded that the food supply in the United States is abundant, although some people may not receive enough nutrients for various reasons. Nutrient intakes are most likely to be low in persons living below the poverty level. Intakes of nutrients reported to be low in the general population are even lower in the poverty group. Chapter 10 describes this report more fully.

## NATIONAL GUIDELINES FOR DIET PLANNING

Eating can be one of life’s greatest pleasures. People eat for enjoyment and to obtain energy and nutrients. Although many genetic, environmental, behavioral, and cultural factors affect health, diet is equally important for promoting health and preventing disease. Yet within the past 40 years, attention has been focused increasingly on the relationship of nutrition to chronic diseases and conditions. Although this interest derives somewhat from the rapid increase in number of older adults and their longevity, it is also prompted by the desire to prevent premature deaths from diseases such as coronary heart disease, diabetes mellitus, and cancer. Approximately two thirds of deaths in the United States are caused by chronic disease.

### Current Dietary Guidance

In 1969 President Nixon convened the White House Conference on Nutrition and Health ([AJCN, 1969](#)). Increased attention was being given to prevention of hunger and disease. The development of dietary guidelines in the United States is discussed in Chapter 10. Guidelines directed toward prevention of a particular disease, such as those from the National Cancer Institute; the American Diabetes Association; the American Heart Association; and the National Heart, Lung, and Blood Institute’s cholesterol education guidelines, contain recommendations unique to particular conditions. The American Dietetic Association supports a total diet approach, in which the overall pattern of food eaten, consumed in moderation with appropriate portion sizes and combined with regular physical activity, is key. Various guidelines that can be used by health counselors throughout the developed world are summarized in Box 12-1.

### Implementing the Guidelines

The task of planning nutritious meals centers on including the essential nutrients in sufficient amounts as outlined in the newest DRIs, in addition to appropriate amounts of energy, protein, carbohydrate (including fiber and sugars), fat (especially saturated and *trans*-fats), cholesterol, and salt. Suggestions are included to help people meet the specifics of the recommendations. When specific numeric recommendations differ, they are presented as ranges.

To help people select an eating pattern that achieves specific health promotion or disease prevention objectives, nutritionists should assist individuals in making food choices (e.g., to reduce fat, to increase fiber). Although numerous federal agencies are involved in the issuance of dietary guidance, the USDA and USDHHS lead the effort. The [Dietary Guidelines for Americans \(DGA\)](#) were first published in 1980 and are revised every five years; the most recent guidelines were released in 2010 (Box 12-2). The DGA are designed to motivate consumers to change their eating and activity patterns by providing them with positive, simple messages. Using consumer research, the DGA develop messages that expand the influence of the dietary guidelines to encourage

**TABLE 12-2****Food Components and Public Health Concerns**

<b>Food Component</b>	<b>Relevance to Public Health</b>
Energy	The high prevalence of overweight indicates that an energy imbalance exists among Americans because of physical inactivity and underreporting of energy intake or food consumption in national surveys.
Total fat, saturated fat, and cholesterol	Intakes of fat, saturated fatty acids, and cholesterol among all age groups older than 2 years of age are above recommended levels. Cholesterol intakes are generally within the recommended range of 300 mg/dL or less.
Alcohol	Intake of alcohol is a public health concern because it displaces food sources of nutrients and has potential health consequences.
Iron and calcium	Low intakes of iron and calcium continue to be a public health concern, particularly among infants and females of childbearing age. Prevalence of iron deficiency anemia is higher among these groups than among other age and sex groups. Low calcium intake is a particular concern among adolescent girls and adult women in most racial and ethnic groups.
Sodium*	Sodium intake exceeds government recommendations of 2300 mg/day in most age and sex groups. Strategies to lower intake can be found at the Institute of Medicine website at <a href="http://www.iom.edu/Reports/2010/Strategies-to-Reduce-Sodium-Intake-in-the-United-States.aspx">http://www.iom.edu/Reports/2010/Strategies-to-Reduce-Sodium-Intake-in-the-United-States.aspx</a>
Other nutrients at potential risk	Some population or age groups may consume insufficient amounts of total carbohydrate and carbohydrate constituents such as dietary fiber; protein; vitamin A; carotenoids; antioxidant vitamins C and E; folate, vitamins B <sub>6</sub> and B <sub>12</sub> ; magnesium, potassium, zinc, copper, selenium, phosphorus, and fluoride. Studies also suggest that vitamin D deficiency is very common.
Unbalanced Nutrients	Intakes of polyunsaturated and monounsaturated fatty acids, <i>trans</i> -fatty acids, and fat substitutes are often excessive.

\*Recommended intake of 1500 mg or less in at-risk populations defined as African-Americans, people with hypertension, and anyone 40 years or older (IOM, 2004).

**BOX 12-1****Universal Prescription for Health and Nutritional Fitness**

- Adjust energy intake and exercise level to achieve and maintain appropriate body weight.
- Eat a wide variety of foods to ensure nutrient adequacy.
- Increase total carbohydrate intake, especially complex carbohydrates.
- Eat less total fat and less saturated fat.
- Eat more fiber-rich foods, including whole grains, fruits, and vegetables.
- Eat fewer high cholesterol foods.
- Limit or omit high-sodium foods.
- Reduce intake of concentrated sugars.
- Drink alcohol in moderation or not at all.
- Meet the recommendations for calcium, especially important for adolescents and women.
- Meet the recommendation for iron, especially for children, adolescents, and women of childbearing age.
- Limit protein to no more than twice the recommended dietary allowance.
- If using a daily multivitamin, choose dietary supplements that do not exceed the dietary reference intake.
- Drink fluoridated water.

consumers to adopt them and ultimately change their behaviors. The messages reach out to consumers' motivations, individual needs, and life goals, and can be used in education, counseling, and communications initiatives (USDA, 2005).

The **MyPlate Food Guidance System**, shown in Figure 12-1, replaces the MyPyramid and offers a guide for daily food choices and portions. Consumers can use [chooseMyPlate.gov](http://chooseMyPlate.gov) as a resource.

For comparison, see the Eating Well with Canada's Food Guide as shown in *Clinical Insight: Nutrition Recommendations for Canadians* and Figure 12-2.

**FOOD AND NUTRIENT LABELING**

To help consumers make choices between similar types of food products that can be incorporated into a healthy diet, the Food and Drug Administration (FDA) established a voluntary system of providing selected nutrient information on food labels. The regulatory framework for nutrition information on food labels was revised and updated by the USDA (which regulates meat and poultry products and eggs) and the FDA (which regulates all other foods) with enactment of the Nutrition Labeling and Education Act (NLEA) in 1990. The labels became mandatory in 1994.

**Mandatory Nutrition Labeling**

As a result of the NLEA, nutrition labels must appear on most foods except products that provide few nutrients (such as coffee and spices), restaurant foods, and ready-to-eat

**BOX 12-2****The 2010 Dietary Guidelines for Americans—Focal Points**

Unlike previous Dietary Guidelines, reduction of calories in general, and reduction of dietary components that most contribute these excess calories, such as solid fats, added sugars, and refined grains, is the underlying message.

The emphasis is placed more on dietary patterns instead of individual nutrients and food groups to enable diverse approaches to complying with the Dietary Guidelines.

Whenever possible, the goal should be to encourage consumption of whole, minimally processed foods as the source of nutrients. The following concepts form the basis of the 2010 Dietary Guidelines for Americans Committee report:

- Reduce calorie consumption.
- Shift food intake patterns to a more plant-based diet that emphasizes vegetables, cooked dry beans and peas, fruits, whole grains, and nuts and seeds.
- Reduce intake of foods containing added sugars, solid fats, refined grains, and sodium.
- Meet the Physical Activity Guidelines for Americans by reducing sedentary behavior and screen time, and increasing physical activity at school, work, and community.
- Prevent excessive maternal weight gain and obesity in young children through attention to breastfeeding, early advice to parents, changes in school food offerings and physical activity, and preventive measures from the White House Task Force on Obesity.

Accessed 24 May 2010 from <http://www.healthierus.gov/dietaryguidelines>.

foods prepared on site, such as supermarket bakery and deli items. Providing nutrition information on many raw foods is voluntary. However, the FDA and USDA have called for a voluntary point-of-purchase program in which nutrition information is available in most supermarkets. Nutrition information is provided through brochures or point-of-purchase posters for the 20 most popular fruits, vegetables, and fresh fish and the 45 major cuts of fresh meat and poultry.

Nutrition information for foods purchased in restaurants is widely available at the point of purchase or from Internet sites or toll-free numbers. New legislation may require chains with 20 or more locations to disclose on their menus or menu board the number of calories per menu item, with additional nutrition information including total calories and calories from fat, and amounts of fat, saturated fat, cholesterol, sodium, total carbohydrates, complex carbohydrates, sugars, dietary fiber, and protein available upon request.

Ready-to-eat unpackaged foods in delicatessens or supermarkets may provide nutrition information voluntarily. However, if nutrition claims are made, nutrition labeling is

 **CLINICAL INSIGHT**
**Nutrition Recommendations for Canadians**

The revision to Canada's Food Guide to Healthy Eating was released in 2007 and developed age- and gender-specific food intake patterns. These age- and gender-specific suggestions include 4 to 7 servings of vegetables and fruits, 3 to 7 servings of grain products, 2 to 3 servings of milk or milk alternatives, and 1 to 3 servings of meat or meat alternatives. Canada's Eating Well with Canada's Food Guide contains four food groupings presented in a rainbow shape ([Health Canada, 2007](#)).

Tips include:

- Consume no more than 400-450 mg of caffeine per day.
- Eat at least one dark green and one orange vegetable each day.
- Make at least half of grain products consumed each day whole grain.
- Compare the Nutrition Facts table on food labels to choose products that contain less fat, saturated fat, *trans* fat, sugar, and sodium.
- Drink skim, 1% or 2% milk, or fortified soy beverages each day. Check the food label to see if the soy beverage is fortified with calcium and vitamin D.
- Include a small amount (30-45 mL [2-3 Tbsp]) of unsaturated fat each day to get the fat needed.
- Limit the intake of soft drinks, sports drinks, energy drinks, fruit drinks, punches, sweetened hot and cold beverages, and alcohol.
- Eat at least two Food Guide Servings of fish each week.
- Build 30-60 minutes of moderate physical activity into daily life for adults and at least 90 minutes a day for children and youth.

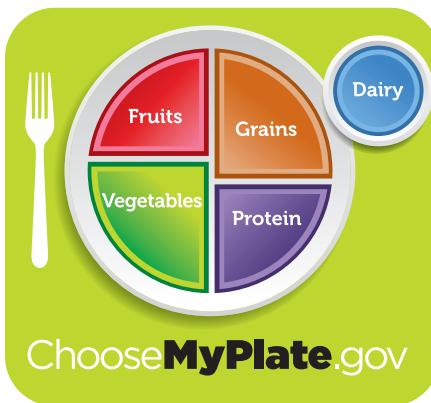

The Canadian Food Guide recognizes the cultural, spiritual, and physical importance of traditional Aboriginal foods as well as the role of nontraditional foods in contemporary diets, with a First Nations, Inuit, and Métis guide available. The guide is available in 12 languages.

Data from Health Canada: Eating well with Canada's food guide, Her Majesty the Queen in Right of Canada, represented by the Minister of Healthy Canada, 2007. Accessed 17 January 2010 from <http://www.hc-sc.gc.ca/fn-an/food-gu>.

required at the point of purchase. If a food makes the claim of being organic, it also must meet certain criteria and labeling requirements.

**Standardized Serving Sizes on Food Label**

Serving sizes of products are set by the government based on reference amounts commonly consumed. For example, a serving of milk is 8 oz, and a serving of salad dressing is

### Balancing Calories

- Enjoy your food, but eat less.
- Avoid oversized portions.

### Foods to Increase

- Make half your plate fruits and vegetables.
- Make at least half your grains whole grains.
- Switch to fat-free or low-fat (1%) milk.

### Foods to Reduce

- Compare sodium in foods like soup, bread, and frozen meals – and choose the foods with lower numbers.
- Drink water instead of sugary drinks.

**FIGURE 12-1** MyPlate showing the five essential food groups. (From the United States Department of Agriculture (USDA). Accessed June 10, 2011 from <http://www.chooseMyPlate.gov/>.)

2 tbsp. Standardized serving sizes make it easier for consumers to compare the nutrient contents of similar products (Figure 12-3).

### Nutrition Facts Label

The **nutrition facts label** on a food product provides information on its per-serving calories and calories from fat. The label must list the amount (in grams) of total fat, saturated fat, trans fat, cholesterol, sodium, total carbohydrate, dietary fiber, sugar, and protein. For most of these nutrients the label also shows the percentage of the **daily value (DV)** supplied by a serving, showing how a product fits into an overall diet by comparing its nutrient content with recommended intakes of those nutrients. DVs are not recommended intakes for individuals; they are simply reference points to provide some perspective on daily nutrient needs. DVs are based on a 2000-kcal diet. For example, individuals who consume diets supplying more or fewer calories can still use the DVs as a rough guide to ensure that they are getting adequate amounts of vitamin C but not too much saturated fat.

The DVs exist for nutrients for which RDAs already exist (in which case they are known as **reference daily intakes**

[RDIs]) (Table 12-3) and for which no RDAs exist (in which case they are known as **daily reference values [DRVs]** [Table 12-4]). However, food labels use only the term *daily value*. RDIs provide a large margin of safety; in general, the RDI for a nutrient is greater than the RDA for a specific age-group. The term *RDI* replaces the term *U.S. RDAs* used on previous food labels. The previously mentioned nutrients must be listed on the food label.

As new DRIs are developed in various categories, labeling laws are updated. Figure 12-4 shows a sample nutrition facts label, and Box 12-3 provides tips for reading and understanding food labels. The FDA has a helpful website to assist consumers with reading labels (<http://www.fda.gov/Food/LabelingNutrition/ConsumerInformation/UCM078889.htm>).

### Nutrient Content Claims

Nutrient content terms such as *reduced sodium*, *fat free*, *low calorie*, and *healthy* must now meet government definitions that apply to all foods (Box 12-4). For example, *lean* refers to a serving of meat, poultry, seafood, or game meat with less than 10 g of fat, less than 4 g of saturated fat, and less than 95 mg of cholesterol per serving or per 100 g. Extra

Data from Health Canada: *Eating well with Canada's food guide*, Her Majesty the Queen in Right of Canada, represented by the Minister of Healthy Canada, 2007. Accessed 22 May 2010 from [www.hc-sc.gc.ca/fn-an/food-guide-aliment](http://www.hc-sc.gc.ca/fn-an/food-guide-aliment).

**Make each Food Guide Serving count...**  
wherever you are – at home, at school, at work or when eating out!

\* Health Canada provides advice for limiting exposure to mercury from certain types of fish. Refer to [www.healthcanada.gc.ca](http://www.healthcanada.gc.ca) for the latest information.

### Advice for different ages and stages...

**Children**

Following Canada's Food Guide helps children grow and thrive.

Young children have small appetites and need calories for growth and development.

- Serve small nutritious meals and snacks each day.
- Do not restrict nutritious foods because of their fat content. Offer a variety of foods from the four food groups.
- Most of all... be a good role model.

**Women of childbearing age**

All women who could become pregnant and those who are pregnant or breastfeeding need a multivitamin containing folic acid every day. Pregnant women need to ensure that their multivitamin also contains iron. A health care professional can help you find the multivitamin that's right for you.

Pregnant and breastfeeding women need more calories. Include an extra 2 to 3 Food Guide Servings each day.

Here are two examples:

- Have fruit and yogurt for a snack, or
- Have an extra slice of toast at breakfast and an extra glass of milk at supper.

**Men and women over 50**

The need for vitamin D increases after the age of 50.

In addition to following Canada's Food Guide, everyone over the age of 50 should take a daily vitamin D supplement of 10 µg (400 IU).

Canada's Physical Activity Guide recommends building 30 to 60 minutes of moderate physical activity into daily life for adults and at least 90 minutes a day for children and youth. You don't have to do it all at once. Add it up in periods of at least 10 minutes at a time for adults and five minutes at a time for children and youth.

### Eat well and be active today and every day!

#### The benefits of eating well and being active include:

- Better overall health.
- Feeling and looking better.
- Lower risk of disease.
- More energy.
- A healthy body weight.
- Stronger muscles and bones.

#### Be active

To be active every day is a step towards better health and a healthy body weight.

Canada's Physical Activity Guide recommends building 30 to 60 minutes of moderate physical activity into daily life for adults and at least 90 minutes a day for children and youth. You don't have to do it all at once. Add it up in periods of at least 10 minutes at a time for adults and five minutes at a time for children and youth.

Start slowly and build up.

#### Take a step today...

- ✓ Have breakfast every day. It may help control your hunger later in the day.
- ✓ Walk wherever you can – get off the bus early, use the stairs.
- ✓ Benefit from eating vegetables and fruit at all meals and as snacks.
- ✓ Spend less time being inactive such as watching TV or playing computer games.
- ✓ Request nutrition information about menu items when eating out to help you make healthier choices.
- ✓ Enjoy eating with family and friends!
- ✓ Take time to eat and savor every bite!

### How do I count Food Guide Servings in a meal?

#### Here is an example:

Vegetable and beef stir-fry with rice, a glass of milk and an apple for dessert	
250 mL (1 cup) mixed broccoli, carrot and sweet red pepper	= 2 Vegetables and Fruit Food Guide Servings
75 g (2½ oz.) lean beef	= 1 Meat and Alternatives Food Guide Serving
250 mL (1 cup) brown rice	= 2 Grain Products Food Guide Servings
5 mL (1 tsp) canola oil	= part of your Oils and Fats intake for the day
250 mL (1 cup) 1% milk	= 1 Milk and Alternatives Food Guide Serving
1 apple	= 1 Vegetables and Fruit Food Guide Serving

#### Read the label

- Compare the Nutrition Facts table on food labels to choose products that contain less fat, saturated fat, trans fat, sugar and sodium.
- Keep in mind that the calories and nutrients listed are for the amount of food listed at the top of the Nutrition Facts table.

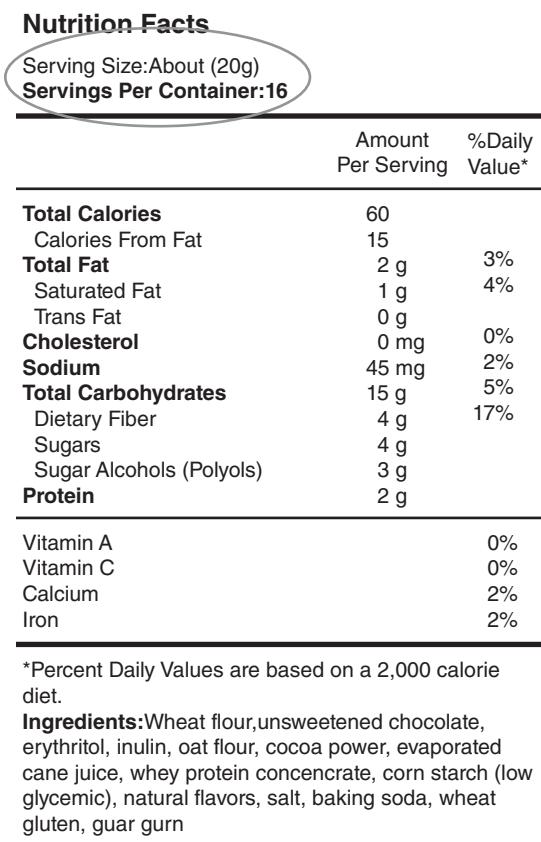

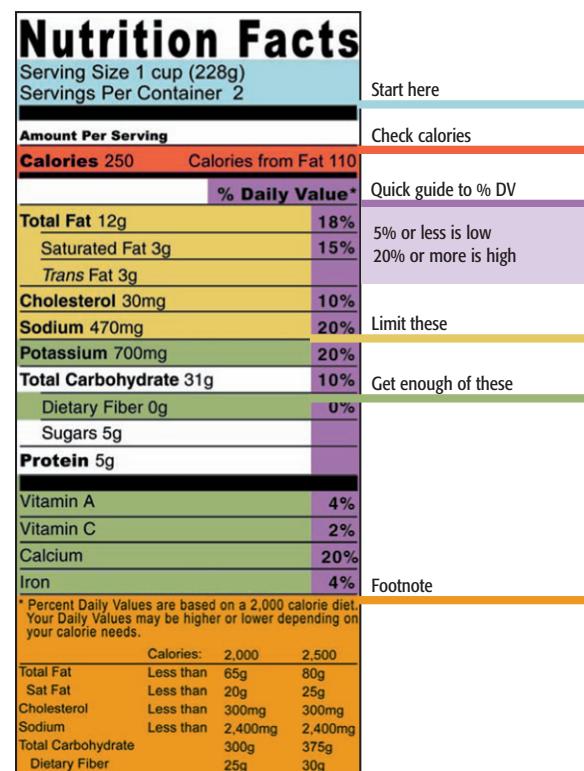

#### Limit trans fat

When a Nutrition Facts table is not available, ask for nutrition information to choose foods lower in trans and saturated fats.

#### Nutrition Facts

Amount	% Daily Value
Calories: 0	0 %
Fat: 0 g	0 %
Saturates: 0 g	0 %
+ Trans: 0 g	0 %
Cholesterol: 0 mg	0 %
Sodium: 0 mg	0 %
Carbohydrate: 0 g	0 %
Fibre: 0 g	0 %
Sugars: 0 g	0 %
Protein: 0 g	0 %
Vitamin A: 0 %	Vitamin C: 0 %
Calcium: 0 %	Iron: 0 %

**TABLE 12-4****Daily Reference Values**

Food Component	DRV	Calculation
Fat	65 g	30% of kcal
Saturated fat	20 g	10% of kcal
Cholesterol	300 mg	Same regardless of kcal
Carbohydrates	300 g (total)	60% of calories
Fiber	25 g	11.5 g per 1000 kcal
Protein	50 g	10% of kcal
Sodium	2400 mg	Same regardless of kcal
Potassium	3500 mg	Same regardless of kcal

DRV, Daily reference value.

NOTE: The DRVs were established for adults and children over 4 years old. The values for energy yielding nutrients below are based on 2,000 calories per day.

## BOX 12-3

### Tips for Reading and Understanding Food Labels

Interpret the Percent Daily Value.

Nutrients with %DV of 5 or less are considered low.

Nutrients with %DV of 10-19 or less are considered moderate or “good sources.”

Nutrients with %DV of 20 or more are considered high or “rich sources.”

Prioritize nutrient needs and compare %DV levels accordingly. For example, if a consumer wishes to lower osteoporosis risk versus limiting sodium, a packaged food containing 25%DV calcium and 15%DV sodium may be considered a sensible food selection.

Note the calories per serving and the servings per container. Consider how the energy value of a specific food fits into the total energy intake “equation.” Be conscious of the portion size that is consumed and “do the math” as to how many servings per container that portion would be.

Be aware of specific nutrient content claims. As shown in Box 12-4, there are many nutrient content claims, but only specific ones may relate to personal health priorities. For example, if there is a positive family history for heart disease, the “low fat” nutrient claim of 3 grams or less per serving may serve as a useful guide during food selection.

Review the ingredient list. Ingredients are listed in order of prominence. Pay particular attention to the top five items listed. Ingredients that contain sugar often end in -ose. The term *hydrogenated* signals that processed, trans, or saturated fats may have been incorporated. Sodium-containing additives may be present in multiple forms. In an effort to lower the amount of heavily processed food consumed, look for ingredient lists containing more nutrient-dense food items and fewer additives.

## BOX 12-4

### Nutrient Content Claims

**Free:** *Free* means that a product contains no amount of, or only trivial or “physiologically inconsequential” amounts of, one or more of these components: fat, saturated fat, cholesterol, sodium, sugar, or calories. For example, *calorie-free* means the product contains fewer than 5 calories per serving, and *sugar-free* and *fat-free* both mean the product contains less than 0.5 g per serving.

Synonyms for *free* include *without*, *no*, and *zero*. A synonym for *fat-free* milk is *skim*.

**Low:** *Low* can be used on foods that can be eaten frequently without exceeding dietary guidelines for one or more of these components: fat, saturated fat, cholesterol, sodium, and calories. Synonyms for *low* include *little*, *few*, *low source of*, and *contains a small amount of*.

- **Low fat:** 3 g or less per serving
- **Low saturated fat:** 1 g or less per serving
- **Low sodium:** 140 mg or less per serving
- **Very low sodium:** 35 mg or less per serving
- **Low cholesterol:** 20 mg or less and 2 g or less of saturated fat per serving
- **Low calorie:** 40 calories or less per serving

**Lean and extra lean:** *Lean* and *extra lean* can be used to describe the fat content of meat, poultry, seafood, and game meats.

**Lean:** less than 10 g fat, 4.5 g or less saturated fat, and less than 95 mg cholesterol per serving and per 100 g

**Extra lean:** less than 5 g fat, less than 2 g saturated fat, and less than 95 mg cholesterol per serving and per 100 g

**Reduced:** *Reduced* means that a nutritionally altered product contains at least 25% less of a nutrient or of calories than the regular, or reference, product. However, a *reduced* claim cannot be made on a product if its

reference food already meets the requirement for a “low” claim.

**Less:** *Less* means that a food, whether altered or not, contains 25% less of a nutrient or of calories than the reference food. For example, pretzels that have 25% less fat than potato chips could carry a *less* claim. *Fewer* is an acceptable synonym.

**Light:** *Light* can mean two things:

- First, that a nutritionally altered product contains one-third fewer calories or half the fat of the reference food. If the food derives 50% or more of its calories from fat, the reduction must be 50% of the fat.
- Second, that the sodium content of a low-calorie, low-fat food has been reduced by 50%. In addition, *light in sodium* may be used on food in which the sodium content has been reduced by at least 50%.

The term *light* still can be used to describe such properties as texture and color, as long as the label explains the intent (e.g., *light brown sugar* and *light and fluffy*).

**High:** *High* can be used if the food contains 20% or more of the daily value for a particular nutrient in a serving.

**Good source:** *Good source* means that one serving of a food contains 10% to 19% of the daily value for a particular nutrient.

**More:** *More* means that a serving of food, whether altered or not, contains a nutrient that is at least 10% of the daily value more than the reference food. The 10% of daily value also applies to *fortified*, *enriched*, *added*, *extra*, and *plus* claims, but in these cases the food must be altered.

Data from Food and Drug Administration. Accessed 18 January 2010 from <http://www.fda.gov/Food/GuidanceComplianceRegulatoryInformation/GuidanceDocuments/FoodLabelingNutrition/FoodLabelingGuide/default.htm>.

lean meat or poultry contains less than 5 g of fat, less than 2 g of saturated fat, and the same cholesterol content as lean, per serving, or per 100 g of product.

## Health Claims

A **health claim** is allowed only on appropriate food products that meet specified standards. The government requires that health claims be worded in ways that are not misleading (e.g., the claim cannot imply that the food product itself helps prevent disease). Health claims cannot appear on foods that supply more than 20% of the DV for fat, saturated fat, cholesterol, and sodium. The following is an example of a health claim for dietary fiber and cancer: “Low-fat diets rich in fiber-containing grain products, fruits, and vegetables may reduce the risk of some types of cancer, a disease associated with many factors.” **Box 12-5** lists health claims that manufacturers can use to describe food-disease relationships.

## DIETARY PATTERNS AND COUNSELING TIPS

### Vegetarian Diet Patterns

Vegetarian diets are popular. Those who choose them may be motivated by philosophic, religious, or ecologic concerns, or by a desire to have a healthier lifestyle. Considerable evidence attests to the health benefits of a vegetarian diet. Studies of Seventh-Day Adventists indicate that the diet results in lower rates of type 2 diabetes, breast and colon cancer, and cardiovascular and gallbladder disease.

Of the millions of Americans who call themselves vegetarians, many eliminate “red” meats but eat fish, poultry, and dairy products. A lactovegetarian does not eat meat, fish, poultry, or eggs, but does consume milk, cheese, and other dairy products. A lactoovovegetarian also consumes eggs. A **vegan** does not eat any food of animal origin. The vegan diet is the only vegetarian diet that has any real risk of providing inadequate nutrition, but this risk can be avoided by careful planning (American Dietetic Association [ADA], 2009). A new type of semivegetarian is known as a **flexitarian**. Flexitarians generally adhere to a vegetarian diet for the purpose of good health and do not follow a specific ideology. They view an occasional meat meal as acceptable.

Vegetarian diets tend to be lower in iron than omnivorous diets, although the nonheme iron in fruits, vegetables, and unrefined cereals is usually accompanied either in the food or in the meal by large amounts of ascorbic acid that aids in iron assimilation. Vegetarians do not have a greater risk of iron deficiency than those who are not vegetarians (ADA, 2009). Vegetarians who consume no dairy products may have low calcium intakes, and vitamin D intakes may be inadequate among those in northern latitudes where there is less exposure to sunshine. The calcium in some vegetables is inactivated by the presence of oxalates. Although phytates in unrefined cereals also can inactivate calcium, this is not a problem for Western vegetarians, whose diets tend to be based more on fruits and vegetables

than on the unrefined cereals of Middle Eastern cultures. Long-term vegans may develop megaloblastic anemia because of a deficiency of vitamin B<sub>12</sub>, found only in foods of animal origin. The high levels of folate in vegan diets may mask the neurologic damage of a vitamin B<sub>12</sub> deficiency. Vegans should have a reliable source of vitamin B<sub>12</sub> such as fortified breakfast cereals, soy beverages, or a supplement. Although most vegetarians meet or exceed the requirements for protein, their diets tend to be lower in protein than those of omnivores. This lower intake may help vegetarians retain more calcium from their diets. Furthermore, lower protein intake usually results in lower dietary fat because many high-protein animal products are also rich in fat (ADA, 2009).

Well-planned vegetarian diets are safe for infants, children, and adolescents and can meet all of their nutritional requirements for growth. They are also adequate for pregnant and lactating females. The key is that the diets be well planned. Vegetarians should pay special attention to ensure that they get adequate calcium, iron, zinc, and vitamins B<sub>12</sub> and D. Calculated combinations of complementary protein sources is not necessary, especially if protein sources are reasonably varied. **Table 12-5** highlights many of the phytochemicals and functional components rich in many vegetable-based diets. A useful website on vegetarian meal planning is available at <http://www.eatright.org/> through the American Dietetic Association. See also *Focus On: The “Healthy Food In Health Care” Pledge* earlier in the chapter.

## CULTURAL ASPECTS OF DIETARY PLANNING

To plan diets for individuals or groups that are appropriate from a health and nutrition perspective, it is important that registered dietitians and health providers use resources that are targeted to the specific client or group. Numerous population subgroups in the United States and throughout the world have specific cultural, ethnic, or religious beliefs and practices to consider. These groups have their own set of dietary practices or beliefs, which are important when considering dietary planning (Diabetes Care and Education Dietetic Practice Group, 2010). The IOM report entitled *Unequal Treatment* recommends that all health care professionals receive training in cross-cultural communication to reduce ethnic and racial disparities in health care; indeed, cultural competence is central to professionalism and quality (Betancourt and Green, 2010).

Attitudes, rituals, and practices surrounding food are part of every culture in the world and there are so many cultures in the world that it defies enumeration. Many world cultures have influenced American cultures as a result of immigration and intermarriage. This makes planning a menu that embraces cultural diversity and is sensitive to the needs of a specific group of people a major challenge. It is tempting to simplify the role of culture by attempting to categorize dietary patterns by race, ethnicity, or religion. However, this type of generalizing can lead to inappropriate labeling and misunderstanding.

**BOX 12-5****Health Claims for Diet-Disease Relationships****(APPROVED CLAIM [MODEL CLAIM, STATEMENTS AND CLAIM REQUIREMENTS])**

**Calcium and Osteoporosis** (Regular exercise and a healthy diet with enough calcium helps teens and young adult white and Asian women maintain good bone health and may reduce their high risk of osteoporosis later in life.)  
**Sodium and Hypertension** (Diets low in sodium may reduce the risk of high blood pressure, a disease associated with many factors.)

**Sodium and Hypertension** (Diets low in sodium may reduce the risk of high blood pressure, a disease associated with many factors.)

**Dietary Fat and Cancer** (Development of cancer depends on many factors. A diet low in total fat may reduce the risk of some cancers.)

**Dietary Saturated Fat and Cholesterol and Risk of Coronary Heart Disease** (Although many factors affect heart disease, diets low in saturated fat and cholesterol may reduce the risk of this disease.)

**Fiber-Containing Grain Products, Fruits, and Vegetables and Cancer** (Low-fat diets rich in fiber-containing grain products, fruits, and vegetables may reduce the risk of some types of cancer, a disease associated with many factors.)

**Fruits, Vegetables and Grain Products that contain Fiber, particularly Soluble Fiber, and Risk of Coronary Heart Disease** (Diets low in saturated fat and cholesterol and rich in fruits, vegetables, and grain products that contain some types of dietary fiber, particularly soluble fiber, may reduce the risk of heart disease, a disease associated with many factors.)

**Fruits and Vegetables and Cancer** (Low-fat diets rich in fruits and vegetables [*foods that are low in fat and may contain dietary fiber, vitamin A, or vitamin C*] may reduce the risk of some types of cancer, a disease associated with many factors. Broccoli is high in vitamin A and C, and it is a good source of dietary fiber.)

**Folate and Neural Tube Defects** (Healthful diets with adequate folate may reduce a woman's risk of having a child with a brain or spinal cord defect.)

**Dietary Noncariogenic Carbohydrate Sweeteners and Dental Caries** (Full claim: Frequent between-meal consumption of foods high in sugars and starches promotes tooth decay. The sugar alcohols in [*name of food*] do not promote tooth decay; Shortened claim on small packages only: Does not promote tooth decay.)

**Soluble Fiber from Certain Foods and Risk of Coronary Heart Disease**

Soluble fiber from foods such as [*name of soluble fiber source, and, if desired, name of food product*], as part of a diet low in saturated fat and cholesterol, may reduce the risk of heart disease. A serving of [*name of food product*] supplies \_\_ grams of the [*necessary daily dietary intake for the benefit*] soluble fiber from [*name of soluble fiber source*] necessary per day to have this effect.)

**Soy Protein and Risk of Coronary Heart Disease** (1. 25 grams of soy protein a day, as part of a diet low in saturated fat and cholesterol, may reduce the risk of heart disease. A serving of [*name of food*] supplies \_\_ grams of soy protein. 2. Diets low in saturated fat and cholesterol that include 25 grams of soy protein a day may reduce the risk of heart disease. One serving of [*name of food*] provides \_\_ grams of soy protein.)

**Plant Sterol and Stanol Esters and Risk of Coronary Heart Disease**

Foods containing at least 0.65 gram per of vegetable oil sterol esters, eaten twice a day with meals for a daily total intake of least 1.3 grams, as part of a diet low in saturated fat and cholesterol, may reduce the risk of heart disease. A serving of [*name of food*] supplies \_\_ grams of vegetable oil sterol esters. 2. Diets low in saturated fat and cholesterol that include two servings of foods that provide a daily total of at least 3.4 grams of plant stanol esters in two meals may reduce the risk of heart disease. A serving of [*name of food*] supplies \_\_ grams of plant stanol esters.)

**Whole Grain Foods and Risk of Heart Disease and Certain Cancers** (“Diets rich in whole grain foods and other plant foods and low in total fat, saturated fat, and cholesterol may reduce the risk of heart disease and some cancers.”)

**Potassium and the Risk of High Blood Pressure and Stroke** (“Diets containing foods that are a good source of potassium and that are low in sodium may reduce the risk of high blood pressure and stroke.”)

**Fluoridated Water and Reduced Risk of Dental Carries** (“Drinking fluoridated water may reduce the risk of [*dental caries or tooth decay*].”)

**Saturated Fat, Cholesterol, and *Trans* Fat, and Reduced Risk of Heart Disease** (“Diets low in saturated fat and cholesterol, and as low as possible in *trans* fat, may reduce the risk of heart disease.”)

Data from Food and Drug Administration. Accessed 18 January 2010 from <http://www.fda.gov/Food/GuidanceComplianceRegulatoryInformation/GuidanceDocuments/FoodLabelingNutrition/FoodLabelingGuide/ucm064919.htm>.

## © FOCUS ON

### What is a Locovore?

There is a growing movement in the United States fueled by books like the Omnivore's Dilemma (Pollan et al., 2006). One component of this movement is a collaborative effort to build a more locally based, self-reliant food economy—one in which sustainable food production, processing, distribution, and consumption are integrated to enhance the economic, environmental, and social health of a particular place. **Locovores** are those who eat food grown or produced locally or within a certain radius. The locovore movement encourages consumers to buy from farmers' markets or even to produce their own food. They argue that locally produced food is fresher and more nutritious and uses less fossil fuel to grow and transport. Another component of this movement is the condemnation of the factory farming method of grain feeding animals. These operations are known as concentrated animal feeding operations. There is a growing demand for meat that is grass or range fed and not transported long distances.

To illustrate this point, consider the case of Native Americans. There are more than 500 different tribes spread across all 50 states. The food and customs of the tribes in the Southwest are drastically different than those of the Northwest. When discussing traditional foods among Native Americans, the situation is further complicated by the fact that many tribes were removed from their traditional lands by the U.S. government. Thus a Montana tribe that once depended on hunting bison and gathering local roots and berries may now be living in Oklahoma.

Another example of the complexity of diet and culture in the United States is that of African Americans. "Soul food" is commonly identified with African Americans from the South. Traditional food choices include grits, collard greens prepared with ham hocks and lard, with a side of corn bread. But this by no means represents the diet of all African Americans. African Americans may be eating the foods of their homeland. An Ethiopian meal might consist of a vegetable stew served atop bread known as *injera*, whereas someone eating the food of Ghana would probably be eating a stew atop rice or yams.

When faced with planning a diet to meet the needs of an unfamiliar culture, it is important to avoid forming opinions that are based on inaccurate information or stereotyping

**TABLE 12-5**

#### Phytochemicals and Functional Components in Foods

Compound	Function	Food Sources
<b>Carotenoids</b>		
$\beta$ -carotene	May neutralize free radicals that damage cells, boost antioxidant defenses	Carrots, dark orange fruits, butternut squash, cantaloupe
Lutein	Much discovered about its role in protecting the eyes from oxidation; also being investigated for potentially reducing the risk of colon, breast, lung, and skin cancer ( <a href="http://www.luteininfo.com">www.luteininfo.com</a> )	Deep green vegetables, kale, spinach, collards, corn, eggs, citrus
Lycopene	Protects prostate health by reducing risk of prostate cancer; may also aid in preserving bone health	Processed tomato products, guava, pink grapefruit, watermelon
Diallyl sulfides	Along with promoting heart health, boosts production of enzymes that benefit the immune system	Onions, garlic, scallions, leeks, chives
Ellagic acid	May block body's production of enzymes needed for tumor growth; causes cancer cell death in the test tube; functions as antioxidant; possible antiviral and antibacterial activities	Strawberries, raspberries, pomegranates, cranberries, walnuts
<b>Flavonoids</b>		
Anthocyanins	Most studied; may neutralize free radicals, bolster antioxidant defenses, especially at the DNA level; contributes to heart health and vision and brain function by reducing oxidation of LDL cholesterol	Berries, (especially dark-colored), cherries, red grapes
Lignans	Acting as phytoestrogens, may boost immune function and contribute to maintaining heart health; may also help block some hormone related cancers	Flax seed, rye, some vegetables

*Continued*

**TABLE 12-5****Phytochemicals and Functional Components in Foods—cont'd**

<b>Compound</b>	<b>Function</b>	<b>Food Sources</b>
Limonene	Boosts levels of naturally occurring liver enzymes involved in detoxification of carcinogens	Essential oils of citrus fruits and other plants
Phytic acid	May suppress oxidation reactions in the colon that produce free radicals; reduces rate of starch digestion and thus blood glycemic response; converted to related compounds in body involved in cellular communication; may be effective in slowing tumor growth	Wheat bran, flax seed, sesame seeds, beans and other high-fiber foods
Proanthocyanidins (condensed tannins or procyanidins)	The active component of cranberries that contributes to urinary tract health but may also have a role in heart health	Cranberries, cocoa, cinnamon, peanuts, wine, grapes, strawberries, peanut skins
Phenols	May boost antioxidant defense while maintaining healthy vision	Apples, pears, citrus fruits, parsley, carrots, broccoli, cabbage, cucumbers, squash, yams, tomatoes
Phytoestrogens	Genistein and daidzein; may contribute to healthy bones, brain function, and immune function; relationship of phytoestrogens and cancers is still being debated	Soybeans, soybean products
Plant stanols and sterols	May help bolster the benefits of a heart-healthy diet with exercise, thus reducing the risk of heart disease	Corn, soy, wheat, fortified foods, beverages, fortified table spreads, fortified chocolate, peanut oil
<b>Prebiotics</b>		Whole grains (especially oatmeal), flax and barley; greens; berries, bananas, and other fruits; legumes; onions, garlic, honey, leeks
<b>Probiotics</b>		Yogurt (with active, live culture), kefir, buttermilk and other fermented dairy products; fermented vegetables such as kim chi and sauerkraut; and fermented soy products such as miso and tempeh
Organosulfuric compounds	Believed to fight cancer cell growth; may be useful in treating arthritic joints	Garlic, onions, chives, citrus fruits, broccoli, cabbage, cauliflower, Brussels sprouts

From Center for Food Safety & Applied Nutrition: A Food Labeling Guide, College Park, Md, 1994, U.S. Dept of Agriculture, revised 1999.  
*DNA*, Deoxyribonucleic acid; *LDL*, low-density lipoprotein.

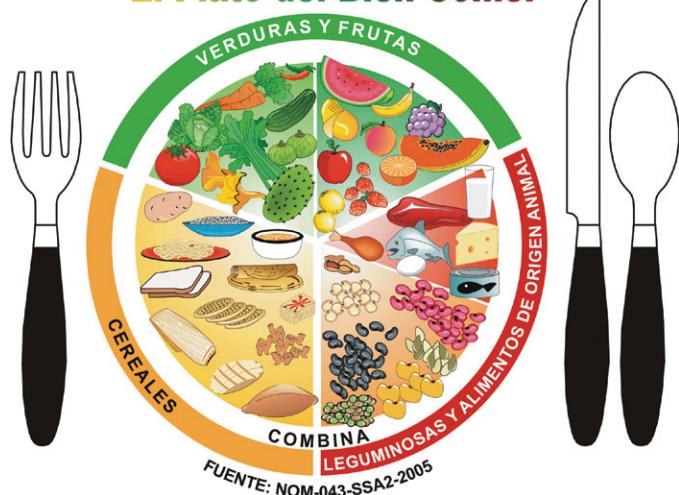

(see Chapter 15). Some cultural food guides have even been developed for specific populations (Figure 12-5) for helping to manage disease conditions.

### Religion and Food

Dietary practices have been a component of religious practice for all of recorded history. Some religions forbid the eating of certain foods and beverages; others restrict foods and drinks during holy days. Specific dietary rituals may be assigned to members with designated authority or with special spiritual power (e.g., medicine men, priests). Sometimes dietary rituals or restrictions are observed based on gender. Dietary and food preparation practices (e.g., halal and kosher meat preparation) can be associated with rituals of faith.

Fasting is practiced by many religions. It has been identified as a mechanism that allows one to improve one's body, to earn approval (as with Allah or Buddha), or to understand and appreciate the sufferings of others. Attention to specific eating behaviors such as overeating, use of alcoholic or stimulant-containing beverages, and vegetarianism are also considered by some religions. Before planning menus for members of any religious group, it is important to gain an understanding of some traditions or dietary practices (Table 12-6). In all cases, discussing the personal dietary preferences of an individual is imperative (Kittler and Sucher, 2008).

Escott-Stump S: *Nutrition and diagnosis-related care*, ed 7, Baltimore, Md, 2011, Lippincott Williams & Wilkins.

+, Practiced; A, avoided by the most devout; O, permitted, but may be avoided at some observances; R, some restrictions regarding types of foods or when a food may be eaten; X, prohibited or strongly discouraged.

\*Fasting varies from partial (abstention from certain foods or meals) to complete (no food or drink).

## CLINICAL SCENARIO

Marty is a 45-year-old Jewish male who emigrated from Israel to the United States 3 years ago. He follows a strict kosher diet. In addition, he does not drink milk but does consume other dairy products. He has a body mass index of 32 and a family history of heart disease. He has come to you for advice on increasing his calcium intake.

### Nutrition Diagnostic Statement

Knowledge deficit related to calcium as evidenced by request for nutrient and dietary information.

### Nutrition Care Questions

1. What type of dietary guidance would you offer Marty?
2. What type of dietary plan following strict kosher protocols would meet his daily dietary needs and promote weight loss?
3. What suggestions would you offer him about dietary choices for a healthy heart?
4. Which special steps should Marty take to meet calcium requirements without using supplements?
5. How can food labeling information be used to help Marty meet his weight loss and nutrient goals and incorporate his religious dietary concerns?

subluxation  
traditional Oriental medicine

### INTEGRATIVE MEDICINE

Integrative medicine focuses on healing-oriented medicine that considers the whole person (body, mind, spirit) and all aspects of lifestyle. Emphasis is placed on the therapeutic relationship and appropriate therapies, both conventional and alternative. A multidisciplinary approach that moves beyond conventional medicine practitioners is needed; here, patients and health care providers are partners in promoting wellness. The scope of care includes wellness and prevention, and, when illness does occur, a reliance on less invasive approaches is emphasized. Yet integrative care is evidence-based by critically evaluating all medical and healing approaches.

**Complementary and alternative medicine (CAM)** refers to those practices that are not a customary part of conventional medicine. This includes such treatment methodologies as

acupuncture, meditation, naturopathy, and chiropractic care. **Integrative medicine** is slightly different than CAM in that it is focused on the combined use of conventional and CAM approaches, and is defined as the comprehensive integration of appropriate complementary approaches along with conventional medical approaches into the care of the whole person, with the goal of achieving optimal health outcomes (Kiefer, 2009).

CAM and integrative therapies are not new. In fact, their roots can be traced to early Greek and Chinese cultures. Although natural therapies are often described as being “cutting edge,” they are actually much older than conventional Western medical interventions. Experts estimate that herbal remedies and ayurveda, the traditional medicine of India, are more than 5000 years old. CAM therapies are **holistic therapies**, derived from the Greek word *holos*,

meaning *whole*. They are based on the theory that health is a vital dynamic state, reflecting a profound will and wisdom to maintain wellness rather than just the absence of disease. *Vis medicatrix naturae*, the healing force of nature, is the underlying precept of holistic medicine. According to this precept, all living things can self-heal, and organisms have inherent self-defense mechanisms against illness. According to the National Center for Complementary and Alternative Medicine (NCCAM) classification scheme, CAM can be grouped as (1) alternative medical systems such as naturopathy, traditional Chinese Medicine, ayurveda, and homeopathy; (2) mind-body therapies such as meditation, prayer, art or music therapy, and cognitive behavior therapy; (3) biologically based therapies such as the use of herbs, whole-foods diets, and nutrient supplementation; (4) manipulative therapies such as massage, chiropractic medicine, osteopathy, and yoga; and (5) medical systems based on energy therapies such as qi gong, magnetic therapy, or reiki.

**Functional medicine** has some components of CAM therapy, but shifts the disease-centered focus of traditional medical practice to a more patient-centered approach (Institute of Functional Medicine, 2011). The goal is to evaluate the whole person rather than individual symptoms, and to consider care in relation to prevention as well as long-term support for health. Diet, nutrition, and exercise are considered central to “best medical practice” in the delivery of functional medicine. The philosophy also embraces biochemical individuality, hormonal and neurotransmitter imbalance, oxidative stress and detoxification, immune enhancement, and the overall dynamic balance of internal and external factors important to health and longevity.

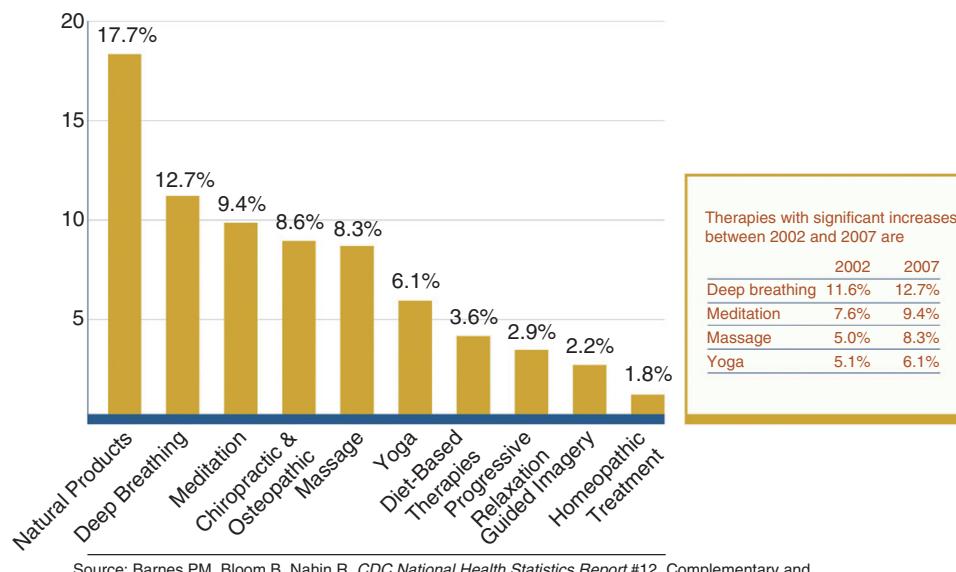

Increasingly, health care practitioners, including dietetics professionals, are involved in the provision of care based

on an integrative approach. For example, **functional nutrition assessment** (as defined in *New Directions: Functional Nutrition Assessment* in Chapter 6) is being included more frequently as part of a complete health evaluation. As the cost of health care escalates, providers are actively seeking integrative care as a plausible approach to reducing costs and enhancing client satisfaction (Maizes, 2009; Ullman, 2009). Diet therapy and dietary supplementation are modalities commonly practiced in the context of CAM and integrative and functional medicine. Several diet-based therapies are listed as CAM modalities, including the Ornish, Zone, Atkins, and Pritikin diets, as well as macrobiotic and vegetarian diets. See Table 13-1 for descriptions of modalities identified as within the scope of CAM.

### Use of Complementary and Alternative Therapies

The use of CAM therapies to enhance conventional medical practices has increased in the United States since the 1960s. A significant number of Americans use some form of CAM therapy even more frequently than they see a primary care physician. Figure 13-1 shows the frequency of use of CAM therapies.

Data from the Alternative Health/Complementary and Alternative Medicine supplement to the 2007 National Health Interview Survey (NHIS), administered by the Centers for Disease Control and Prevention, showed that among the 29,266 American households and 75,764 people surveyed, 38.3% of adults and one in nine children reported use of CAM within the previous 12 months (Barnes et al., 2008). Use has been shown to be greatest among women, people ages 30-69, people with higher education, those residing in the western United States, and people who were hospitalized in the previous 12 months (National Center for Complementary and Alternative Medicine, 2005). By race

**TABLE 13-1****Description of Commonly Used Complementary and Alternative Medicine Therapies**

	<b>Description</b>
<b>Naturopathy</b> (natural medicine)	<p>Based on the concept of the healing force of nature that emphasizes the prevention of disease and the maintenance of health.</p> <p>Derived from the Hippocratic precept, “First do no harm.”</p> <p>Naturopathic physicians avoid therapies that weaken the body’s innate ability to self-heal or that take over a function of the body; instead, naturopathic practice emphasizes the concepts of wellness, prevention, and the role of the health care provider as a teacher.</p> <p>Diagnosis and treatment based on natural laws.</p> <p>May prescribe medications.</p> <p>Licensure required in most states.</p> <p>Training includes pathology, microbiology, histology, and physical and clinical diagnosis; <b>pharmacognosy</b> (clinical training in botanical medicine), hydrotherapy, physiotherapy, therapeutic nutrition, and homeopathy.</p> <p>Modalities include phytotherapy (treatment with plant-based preparations), electrotherapy, physiotherapy, minor surgery, mechanotherapy, and therapeutic manipulation.</p> <p>Nutrition and dietary supplementation routinely used.</p>
<b>Chiropractic</b>	<p>Embraces many of the same principles as naturopathy, particularly the belief that the body has the ability to heal itself and that the practitioner’s role is to assist the body in doing so; like naturopathy, chiropractic focuses on wellness and prevention and favors noninvasive treatments.</p> <p>Chiropractors do not prescribe drugs or perform surgery.</p> <p>Focus on locating and removing interferences to the body’s natural ability to maintain health, called <b>subluxations</b> (specifically musculoskeletal problems that lead to interference with the proper function of the nervous system).</p> <p>The central approach is the manual manipulation of the body, such as spinal adjustment and muscle work, with support from physiologic approaches to healing such as lifestyle modification.</p> <p>Two fundamental precepts: (1) the structure and condition of the body influence how well the body functions, and (2) the mind-body relationship is important in maintaining health and in promoting healing.</p> <p>Licensed and regulated in all 50 states and in some 30 countries.</p> <p>Must complete a 4-year program from a federally accredited college of chiropractic and, like other licensed practitioners, successfully pass an examination administered by a national certifying body.</p>
<b>Homeopathy</b>	<p>The root words of <i>homeopathy</i> are derived from the Greek <i>homios</i>, meaning <i>like</i> and <i>pathos</i>, meaning <i>suffering</i>. Homeopathy is a medical theory and practice advanced to counter the conventional medical practices of 200 years ago. It endeavors to help the body heal itself by treating like with like, commonly known as the “law of similars”; the law of similars is based on the theory that, if a large amount of a substance causes symptoms in a healthy person, a smaller amount of the same substance can be used to treat an ill person</p> <ul style="list-style-type: none"> <li>• Samuel Hahnemann, an 18th-century German physician, is credited with founding homeopathy.</li> <li>• The amounts of the remedies used in homeopathic medicines are extremely diluted; according to homeopathic principles, remedies are potentized (i.e., they become more powerful through shaking).</li> <li>• A tincture is made directly from the source material. One drop of the tincture is then mixed with 99 drops of water or alcohol to make the first potency. The mixture is vigorously shaken more than 100 times, a process called <i>succussion</i>.</li> <li>• The minimum-dose principle means that many homeopathic remedies are so dilute that no actual molecules of the healing substance can be detected by chemical tests.</li> <li>• The goal of homeopathy is to select a remedy that will bring about a sense of well-being on all levels—physical, mental, and emotional—and that will alleviate physical symptoms and restore the patient to a state of wellness and creative energy.</li> <li>• Clinical evidence on the efficacy of homeopathy is highly contradictory.</li> </ul>

*Continued*

**TABLE 13-1****Description of Commonly Used Complementary and Alternative Medicine Therapies—cont'd**

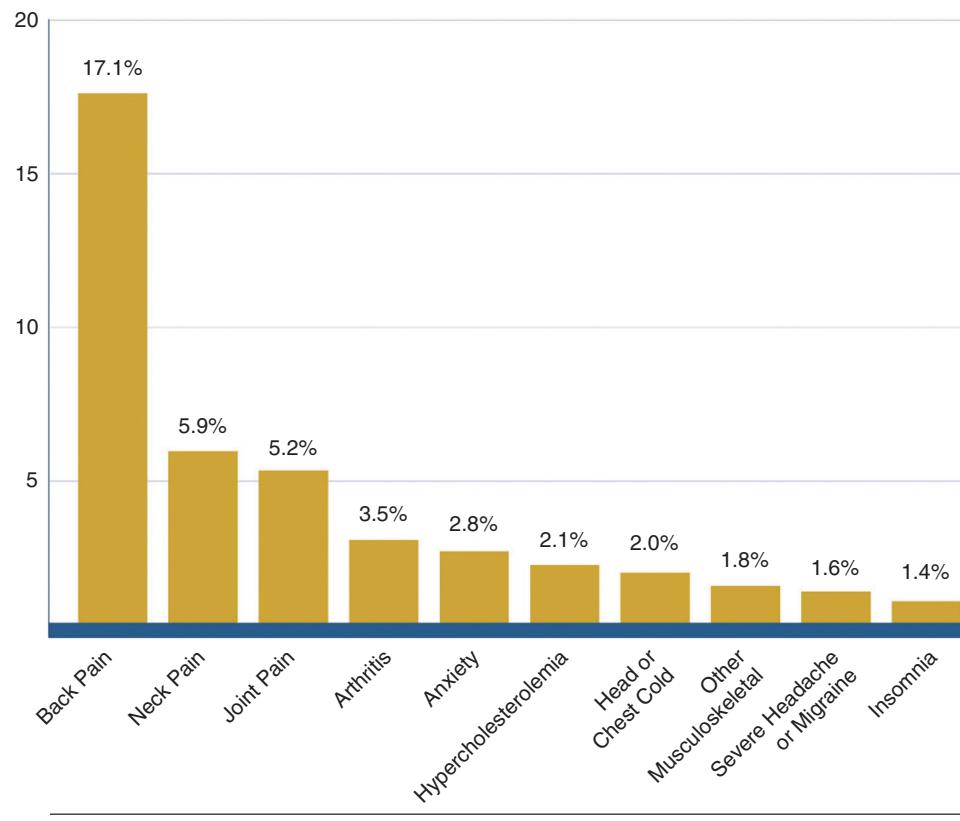

Description	
<b>Traditional Oriental medicine</b>	<p>Based on the concept that energy, also termed <b>chi (Qi)</b> or life-force energy, is the center of body functions. Chi is the intangible force that animates life and enlivens all activity. Wellness is a function of the balanced and harmonious flow of chi, whereas illness or disease results from disturbances in its flow; wellness also requires preserving equilibrium between the contrasting states of yin and yang (the dual nature of all things). The underlying principle is preventive in nature, and the body is viewed as a reflection of the natural world.</p> <p>Four substances—blood, jing (essence, substance of all life), shen (spirit), and fluids (body fluids other than blood)—constitute the fundamentals.</p> <p>The nutritional modality has several components: food as a means of obtaining nutrition, food as a tonic or medicine, and the abstention from food (fasting); foods are classified according to taste (sour, bitter, sweet, spicy, and salty) and property (cool, cold, warm, hot, and plain) to regulate yin, yang, chi, and blood.</p> <p>The <b>meridians</b> are channels that carry chi and blood throughout the body; these are not channels per se, but rather they are invisible vertical networks that act as energy circuits, unifying all parts of the body and connecting the inner and the outer body; organs are not viewed as anatomic concepts but as energetic fields.</p>
<b>Acupuncture</b>	<p>Acupuncture is the use of thin needles, inserted into points on the meridians, to stimulate the body's chi, or vital energy. <b>Moxibustion</b>, the application of heat along meridian acupuncture points for the purpose of affecting chi and blood so as to balance substances and organs, is related to acupuncture. This therapy is used to treat disharmony in the body, which leads to disease. Disharmony, or loss of balance, is caused by a weakening of the yin force in the body, which preserves and nurtures life, or a weakening of the yang force, which generates and activates life. The concept of yin and yang expresses the dual nature of all things, the opposing but complementary forces that are interdependent on each other and must exist in equilibrium.</p>
<b>Massage therapy/ body work</b>	<p>The philosophy behind massage therapy and body work is that there is a healing that occurs through the action of touching. Massage therapy became a profession in the United States in the 1940s and has grown in use over the last several decades. The key principles of body work are the importance of increasing blood circulation, moving lymphatic tissue to remove waste and release toxins, calming of the spirit, enhancing physiologic functions of body systems, and improving musculoskeletal function. This therapy has also been widely used to reduce stress and increase energy.</p>

or ethnicity, Native Americans (50.3%) and Hawaiians and Pacific Islanders (43.2%) report the highest use of CAM, followed by non-Hispanic whites (43.1%). Factors associated with greater CAM use among children include adolescence, college-educated parents, concurrent prescription medication use, and reported anxiety or stress, as well as dermatologic conditions, sinusitis, and musculoskeletal conditions (Birdee, 2010).

Between 2002 and 2007, use of CAM therapies acupuncture, deep breathing, massage therapy, meditation, naturopathy, and yoga increased. Vegetarian diets were most commonly used (3.5% of adults), followed by the Atkins Diet (1.7%), macrobiotic (0.2%), and Zone diets (0.2%). Megavitamin therapy was reportedly used by 2.8% of the adult population surveyed (Barnes et al., 2008).

Those who use these therapies believe that these options are beneficial to their overall health and are more congruent

with their values about health than conventional therapies. Frequently, there is an increased reliance on CAM therapies when conventional medicine has little to offer in terms of effective treatment, or when the current conventional approach has significant risks and side effects that motivate patients to explore alternatives. CAM therapies are also often considered when conventional therapies or diagnostic workups are not deemed effective by the patient (as in insomnia, pain, anxiety), when CAM approaches have been shown to be effective (chiropractic medicine for back pain, acupuncture for pain relief, select dietary supplementation for joint pain associated with osteoarthritis), and when CAM approaches are supported by significant historical evidence of efficacy. The recent NHIS survey also suggested that CAM use increases when conventional treatments are too costly. Figure 13-2 shows the frequency of CAM use by medical diagnosis.

Source: Barnes PM, Bloom B, Nahin R. *CDC National Health Statistics Report #12. Complementary and Alternative Medicine Use Among Adults and Children: United States, 2007*. December 2008.

**FIGURE 13-2** Diseases for which complementary and alternative medicine therapies are most often used by adults. (Source: <http://nccam.nih.gov/news/camstats/2007/graphics.htm>. Accessed 24 May 2010.)

As a result of the increased interest in these therapies, the Office of Alternative Medicine of the National Institutes of Health (NIH) was created in 1992 to evaluate their effectiveness. This office became the 27th institute or center within the NIH in 1998. Renamed NCCAM, the Center explores complementary and alternative healing practices scientifically, using research, training, outreach, and integration. (Ahn et al., 2010) In addition to research funding, there has been an increased awareness of expanding training needs as well as medical reimbursement for provision of CAM therapies in the context of conventional medical systems. Increasingly, nursing and medical curricula include CAM training.

## DIETARY SUPPLEMENTATION

Dietary supplementation is common practice among Americans, particularly among those at risk or diagnosed with clinical conditions such as cancer, cardiovascular disease, diabetes, or hypertension. Consumers and health professionals should be aware that there is limited information on the effects of dietary supplements taken concurrently with prescription and other over-the-counter medications (Farmer Miller et al., 2008).

Historically, dietetics professionals focused their assessment, care plan, and counseling on diet or food-related

recommendations. The 2007 NHIS survey of CAM use indicated that nonvitamin, nonmineral, natural products are the most common form of CAM. The demand for information in this area from dietetics professionals remains high. In fact, the 2009 Position Paper of the American Dietetic Association on nutrient supplementation calls on registered dietitians to be the “first source” of information on nutrient supplementation (Marra et al., 2009).

**Dietary supplements** have been officially defined under the **Dietary Supplement Health and Education Act (DSHEA)** of 1994 as products intended to supplement the diet that contain one or more of the following ingredients: a vitamin, mineral, herb or other botanical, amino acid, concentrate, metabolite, constituent, extract, or combinations of these ingredients. Dietary supplements are intended for ingestion in pill, capsule, tablet, or liquid form and are not to be represented for use as a conventional food or as the sole item of a meal or diet. They should be labeled as a *dietary supplement* and carry the dietary supplement facts label (Figure 13-3). Dietary supplements must be differentiated from drugs, cosmetics, and foods; see Figure 13-4.

**Botanicals**, plants (including their leaves, flowers, stems, rhizomes, or roots) that are used for medicinal purposes, are formulated in a wide variety of forms, including teas, infusions, and decoctions (concentrated beverage made from boiling plant root), as well as extracts (including

tinctures, alcohol solvent, and glycerite-glycerol solvent) and pill forms (capsules, tablets, lozenges, soft gels) (see Botanical Formulations in Box 13-1). Topical application of botanicals or nutrients in the form of creams or essential oils such as are used in aromatherapy are not classified as dietary supplements under the current regulatory definition. Created in Germany, the **Commission E Monographs** on phytomedicines were developed by an expert commission of

scientists and health care professionals as references for practice of **phytotherapy**, the science of using plant-based medicines to prevent or treat illness.

In recent years the Office of Dietary Supplements has worked collaboratively with several organizations and experts to develop a database of dietary supplements used in the United States. Because the database provides specific information on the nutrient, herbal, or other constituents contained in a supplement, it allows clinicians to more accurately assess the appropriate use of select supplements by their patients. The database includes dietary supplement label information for more than 4000 supplements, including the structure and function claims. The information is linked to PubMed, allowing clinicians access to peer-reviewed information on use in human trials, **adverse events (AEs)** associated with use, and information regarding the mechanism of action (National Institutes of Health, 2010).

<b>Supplement Facts</b>	
Serving Size 1 Capsule	
Amount Per Capsule	% Daily Value
Calories 20	
Calories from Fat 20	
Total Fat 2 g	3%*
Saturated Fat 0.5 g	3%*
Polyunsaturated Fat 1 g	†
Monounsaturated Fat 0.5 g	†
Vitamin A 4250 IU	85%
Vitamin D 425 IU	106%
Omega-3 fatty acids 0.5 g	†

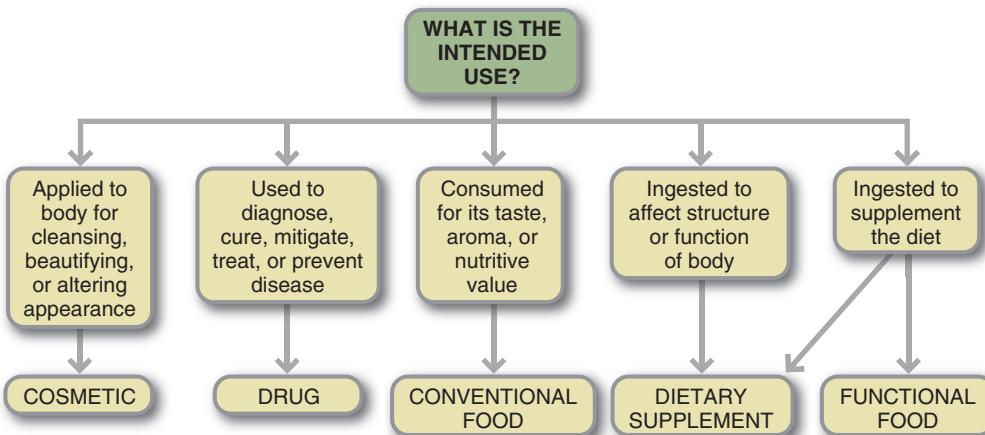

\* Percent Daily Values are based on a 2,000 calorie diet.  
† Daily Value not established.

Ingredients: Cod liver oil, gelatin, water, and glycerin.

**FIGURE 13-3** A dietary supplement facts label per Food and Drug Administration regulation as defined under the Dietary Supplement Health Education Act. (Source: <http://www.fda.gov/Food/DietarySupplements/ConsumerInformation/ucm110493.htm>. Accessed 24 May 2010.)

### Trends in Dietary Supplement Use

Dietary supplement use is common among adults in the United States and is growing among children as well. About one third of adults use a multivitamin and mineral supplement regularly (American Dietetic Association, 2009). The NHIS CAM survey showed the most common nonvitamin, nonmineral supplements consumed were fish oils, glucosamine, echinacea, flaxseed, and ginseng (Barnes et al., 2008). Children commonly consume the same dietary supplements taken by adults. Use of dietary supplements has been shown to increase with advancing age, white race, and female gender. Reports find that use of dietary supplements is highest among those in the best state of health; most frequently supplements are taken by those with a body mass index less than  $25 \text{ kg/m}^2$  who are nonsmokers, are physically active, report good health, adhere to a healthy diet, and use food labels in making food choices, as well as among those with high incomes and education (Archer, 2005).

**FIGURE 13-4** Use of dietary supplementation in clinical practice requires use of a credible resource for evaluation and application. (From Thomson CA, Newton T: Dietary supplements: evaluation and application in clinical practice, *Topics Clin Nutr* 20(1):32, 2005. Reprinted with permission.)

**BOX 13-1****Botanical Formulations**

Type	Form
<b>Bulk Herbs</b>	Sold loose to be used as teas, in cooking, and to prepare capsules; rapidly lose potency; should be stored in opaque containers, away from heat and light
<b>Beverages</b>	
Teas	Beverage weak in concentration; steep fresh or dried herbs in a cup of hot water for a few minutes, strain, and drink
Infusions	More concentrated than teas; steep fresh or dried herbs for approximately 15 min to allow more of the active ingredients to be extracted than for teas
Decoctions	Most concentrated of the beverages, made by boiling the root, rhizome, bark or berries for 30-60 min to extract the active ingredients
<b>Extracts</b>	Herbs are extracted with an organic solvent to dissolve the active components; forms a concentrated form of the active ingredients
Tinctures	Extract in which the solvent is alcohol
Glycerites	Extract in which the solvent is glycerol or a mixture of glycerol, propylene glycol, and water; more appropriate for children than a tincture
<b>Pill Forms</b>	
Capsules	Pills should be taken with at least 4-8 oz of water to avoid leaving residue in the esophagus
Tablets	Herbal material is enclosed in a hard shell made from animal-derived gelatin or plant-derived cellulose
	Herbal material is mixed with filler material to form the hard tablet; may be uncoated or coated with films
Lozenges	Also called <i>troches</i> ; method of preparation allows the active components to be readily released in the mouth when chewed or sucked
Soft gels	Soft capsule used to encase liquid extracts such as ω-3 fatty acids or vitamin E
Essential oils	Fragrant, volatile plant oils; used for aromatherapy, bathing; concentrated form and not to be used internally unless specifically directed (such as enteric-coated peppermint oil)

Use of herbal products has been more difficult to evaluate; products are often taken intermittently to treat specific health care problems, and use can be quite variable. Some herbal products commonly consumed include St. John's wort, echinacea, garlic, saw palmetto and ginkgo biloba, ginseng, soy, valerian, cranberry, and black cohosh (Ernst, 2005). For several dietary supplements enough evidence has accumulated to justify an evidence assessment report by multidisciplinary teams of scientific experts under the Agency for Healthcare Research and Quality or the preparation of a Cochrane Database Review (CDR). A CDR is published as a summation of efficacy and safety of the use of a select supplement in specific medical conditions. Table 13-2 presents commonly used dietary supplements and related information regarding clinical efficacy in the form of CDR.

### Potentially At-Risk Populations

Although dietary supplementation is most common among those who are likely to be at lowest risk for nutrient deficiency, select groups within the population are more likely

to require dietary supplementation. For example, dietary intake inadequacies have been reported among the elderly (Chernoff, 2005), those of lower socioeconomic status (Karp et al., 2005), and those on energy- or fat-restricted diets (Dwyer et al., 2005). In addition, select physiologic states such as pregnancy and lactation increase requirements for select nutrients (e.g., iron, calcium, folate) that are sometimes difficult to meet through dietary changes alone. Furthermore, chronic illness may result in either increased requirements for certain nutrients (e.g., malabsorptive disorders and general supplementation, osteoporosis and bone-related nutrients, elevated serum homocysteine levels in cardiac disease, and increased B vitamin requirements). Finally, lifestyle choices may increase nutrient needs (e.g., increased vitamin C requirement in smokers, increased folate requirement in alcohol users, and increased iron requirements in iron-deficient athletes). Thus clinicians should be aware of these at-risk subgroups and complete a nutrition assessment to determine the need for supplementation on an individual basis. See Chapters 6 and 8.

**TABLE 13-2****Select Cochrane Database Reviews of Nutrient and Botanical Supplementation Efficacy**

Dietary Supplement	Use	Sufficient Evidence of Therapeutic Benefit?	Reference
<b>Nutrients</b>			
Antioxidant supplements (mixed)	Gastrointestinal cancer prevention	NO	Bjelakovic G et al: <i>Cochrane Database Syst Rev</i> 18(4):CD004183, 2008.
	Macular degeneration	YES with antioxidant mixture plus zinc	Evans JR: <i>Cochrane Database Syst Rev</i> (2):CD000254, 2009.
	Preeclampsia	NO	Rumbold et al: <i>Cochrane Database Syst Rev</i> CD004227, 2008.
	Mortality	NO	Bjelakovic G et al: <i>Cochrane Database Syst Rev</i> CD007176, 2008.
Calcium	Colorectal cancer and polyps	YES, for recurrent adenomatous polyps, not CRC specifically	Weingarten MA et al: <i>Cochrane Database Syst Rev</i> (1):CD003548, 2008.
	Hypertension	YES, with pregnancy; 50% reduction in preeclampsia	Hofmeyr GT et al: <i>Cochrane Database Syst Rev</i> (1):CD001059, 2010.
		NO, adults with HTN	Dickinson HO et al: <i>Cochrane Database Syst Rev</i> (2):CD004639, 2009.
DHEA	Cognitive function in healthy elderly	NO	Evans JG: <i>Cochrane Database Syst Rev</i> (2):CD006221, 2006.
Folic acid	Cognition and dementia	NO, with or without B <sub>12</sub> , possible in people with elevated homocysteine	Malouf R et al: <i>Cochrane Database Syst Rev</i> (4):CD004514, 2008.
Omega-3 fatty acids	Cardiovascular disease treatment and prevention	NO, inconclusive	Hooper L et al: <i>Cochrane Database Syst Rev</i> 14(3):CD003177, 2009.
	Crohn disease	NO	Turner D et al: <i>Cochrane Database Syst Rev</i> CD006320, 2009.
	Intermittent claudication	NO	Sommerfield T, et al: <i>Cochrane Database Syst Rev</i> (3):CD003833, 2007.
Probiotics	Infectious diarrhea	YES	Allen SJ et al: <i>Cochrane Database Syst Rev</i> (2):CD003048, 2009.
Selenium	Critical illness (adult)	NO	Avenell et al: <i>Cochrane Database Syst Rev</i> 18(4):CD003703, 2007.
	Asthma	Somewhat	Allam MF, Lucane RA: <i>Cochrane Database Syst Rev</i> (2):CD003538, 2005.
Vitamin C	Asthma	NO	Ram et al: <i>Cochrane Database Syst Rev</i> (4):CD000993, 2004.
	Common cold	NO, maybe with severe physical exercise or cold environment	Hemila H et al: <i>Cochrane Database Syst Rev</i> 18(3):CD000980, 2007.
	Pneumonia	NO, general population	Hemila H, Louhiala P: <i>Cochrane Database Syst Rev</i> 24(1):CD005532, 2007.
		YES, those with low plasma concentrations	Avenell A et al: <i>Cochrane Database Syst Rev</i> (1):CD000227, 2009.
Vitamin D	Fractures w/ osteoporosis	NO, possibly with calcium, likely in deficient people	Jepson RG and Craig JC: <i>Cochrane Database Syst Rev</i> (2):CD001321, 2008.
<b>Botanicals</b>			
Cranberry	Urinary tract infections	YES, in women with recurrent UTIs	Linde K et al: <i>Cochrane Database Syst Rev</i> (2):CD000530, 2006.
Echinacea	Common cold	YES, with <i>Echinacea purpurea</i>	Zeng X et al: <i>Cochrane Database Syst Rev</i> 19(4):CD003691, 2005.
Ginkgo biloba	Ischemic stroke recovery	NO	

**TABLE 13-2****Select Cochrane Database Reviews of Nutrient and Botanical Supplementation Efficacy—cont'd**

Dietary Supplement	Use	Sufficient Evidence of Therapeutic Benefit?	Reference
	Dementia/cognition	NO, not convincing	Birks J, Evans JG: <i>Cochrane Database Syst Rev</i> (4):CD003120, 2009.
Garlic	Peripheral arterial occlusive disease	NO	Jepson RG et al: <i>Cochrane Database Syst Rev</i> (2):CD000095, 2008.
Kava	Anxiety	YES	Pittler MH, Ernst E: <i>Cochrane Database Syst Rev</i> (1):CD003383, 2009.
Milk thistle	Alcoholic liver disease or hepatitis B and C	Somewhat; trials needed	Rambaldi A et al: <i>Cochrane Database Syst Rev</i> (2):CD003620, 2007.
Saw palmetto	Benign prostatic hyperplasia	NO; trials needed	Tacklind J et al: <i>Cochrane Database Syst Rev</i> (3):CD001423, 2009.
St. John's wort	Depression	YES, with hypericum	Linde K et al: <i>Cochrane Database Syst Rev</i> (2):CD000448, 2008.

Cochrane Database reviews can be found online at: [www.cochrane.org/reviews](http://www.cochrane.org/reviews) and are also listed in MedLine and PubMed peer-review citation indexes. CRC, Colorectal cancer; DHEA, dehydroepiandrosterone; HTN, hypertension; UTI, urinary tract infection.

Routine use of multivitamin-mineral supplements may be an appropriate recommendation to ensure dietary adequacy. Because many American adults do not meet even the estimated average requirement for vitamin C, D, and E or minerals such as calcium, many suggest that adults in the United States should regularly take a multivitamin-mineral supplement. To further address this issue, the NIH convened a Conference on Multivitamin/Mineral Supplements and Chronic Disease Prevention in 2006 to develop a consensus statement. Even though the panel report states that there is insufficient evidence to show that multivitamin-mineral supplements will reduce the risk for certain chronic diseases (see full report at [http://ods.od.nih.gov/news/Results\\_of\\_MultivitaminMineral\\_Supplements\\_2006.aspx](http://ods.od.nih.gov/news/Results_of_MultivitaminMineral_Supplements_2006.aspx); Neuhouser, 2009), many nutrition practitioners and health care providers continue to recommend a daily multivitamin-mineral supplement to their patients on a routine basis. In some instances supplementation is considered standard of practice. An example is the recommendation that all women of childbearing age take a multivitamin with 400 mcg of folic acid to reduce the risk for neural tube defects in unborn children.

In the area of botanical supplementation there is less evidence of the existence of at-risk populations who require supplementation. Rather, botanical supplements are more generally used to alleviate symptoms of illness or disease. There can be wide variability in response, and routine recommendations for all patients may not be appropriate. For example, although there is some support for the use of garlic to reduce serum cholesterol levels, routine supplementation with garlic for all patients with hypercholesterolemia is not appropriate. The patient may be taking prescription

medications to treat the elevated cholesterol, may be at risk for increased bleeding time with long-term garlic use, or may be intolerant of the potential gastrointestinal discomfort of supplemental garlic.

In addition to reviewing the available evidence, an assessment of each patient's clinical situation is important. If the therapy is both effective and safety has been demonstrated, recommending a dietary supplement or a CAM therapy may make sense. Unfortunately, either the evidence for CAM therapy is not clear and consistent (especially in regard to general lack of studies) or safety is a concern. These gray areas are challenging for clinicians when making specific recommendations. Certainly the use of a CAM or dietary supplement that has not been shown to be effective and carries a safety risk should be discouraged.

## **DIETARY SUPPLEMENT REGULATION**

Botanical products are regulated in the United States as dietary supplements. The DSHEA of 1994 clarifies marketing regulations for botanicals and reclassifies them as dietary supplements, distinct from food or drugs. A variety of potential labeling approaches are used by the dietary supplement industry to market supplements. These include qualified health claims; unqualified health claims; claims based on an authoritative statement; nutrient content claims; dietary guidance statements; and structure-function claims, which is the most commonly used approach.

A **health claim** is a written claim on the dietary supplement label that has two essential components: (1) a *substance* and (2) a *disease* or health-related condition. It describes the

relationship between these two components; a statement lacking either of these components does not meet the regulatory definition of a health claim. Furthermore, it must meet the significant scientific agreement standard and requires prenotification of the Food and Drug Administration (FDA). Although it does require approval by the FDA, a general health claim does not require the level of scientific evidence of a qualified health claim.

A **qualified health claim** is a label health claim based on emerging scientific evidence that, on review of this evidence by the FDA, is approved for use on a food or dietary supplement label, given sufficient evidence exists to make the requested label claim (see Chapter 12 for more details). Remember that qualified health claims must be petitioned for by a body outside the FDA such as the supplement manufacturer; thus, although evidence may exist for use of select dietary supplements for select health symptoms, unless a request is formally made to FDA, such a claim will not be developed. Other types of health claims are the *authoritative statement* (FDA Modernization Act of 1997) and *dietary guidance statements*, which are based on published statements from authoritative organizations and agencies, as well as statements found within the body of the dietary guidelines.

Of greatest concern is the set of **structure-function claims**. Under DSHEA, the physiologic effects of a product can be noted, but no claims about prevention or cure of specific conditions can be made. A product manufacturer cannot claim that a dietary supplement “prevents heart disease,” but it can state that the product “helps increase blood flow to the heart.” Such subtle differences are unlikely to be discerned by the average consumer, leading to misinterpretation and potentially inappropriate use of the products. Furthermore, these claims do not require FDA prenotification, and the manufacturer assumes responsibility for ensuring the accuracy and truthfulness of the statement. All products must display the following disclaimer: “This statement has not been evaluated by the Food and Drug Administration. This product is not intended to diagnose, treat, cure, or prevent any disease.” However, there is no research as to the awareness or interpretation of this statement by consumers. Consumers must educate themselves about the appropriate application of each dietary supplement they choose to use and about selection of quality products.

A report from the International Food Information Council (IFIC) suggests that consumers cannot clearly distinguish qualified from unqualified health claims and that they prefer structure-function claims for their positive focus and brevity. Among the more common problems that have been reported since the passage of DSHEA are misrepresentation of product contents; variable potency and recommended dosages among products; inadequate information about how a company’s herbs are grown and processed; and poor standards of quality, product safety, or activity of ingredients. Although rare, herb contamination and misidentification do occur. Governmental and industry entities have

developed high-quality manufacturing guidelines (good manufacturing practices [GMPs]) for all dietary supplements, including botanical products. Under the GMP rule manufacturers are required to establish and meet specifications for identity, purity, quality, strength and composition of dietary supplements (Food and Drug Administration, 2007).

In December 2006 the Dietary Supplement and Nonprescription Drug Consumer Protection Act was signed into law, setting requirements for both labeling and mandatory (rather than voluntary) AE reporting related to dietary supplement and over-the-counter (OTC) medication interactions (Frankos, 2009).

Another agency has international significance. The **Codex Alimentarius Commission (Codex)** was created in 1963 by two U.N. organizations, the Food and Agriculture Organization and the World Health Organization, to protect the health of consumers and to ensure fair practices in international food trade (Food and Drug Administration, 2010). Codex participants work on the development of food standards, codes of practice, and guidelines for products such as dietary supplements. Codex standards and guidelines are developed by committees from 180 member countries, where they voluntarily review and provide comments on standards at several stages in the development process (Crane et al., 2010).

## ASSESSMENT OF DIETARY SUPPLEMENT USE

Popular interest in the use of dietary supplements for health applications is widespread in the United States. Health care professionals should be aware that, although nutrient supplementation is generally recommended to enhance the relative adequacy of the diet or to meet increased requirements associated with illness or disease, the therapeutic action of many botanical products is similar to that of drugs; so the potential for harmful interactions exists. Consumers may not be well informed about the safety and efficacy of supplements and some have difficulty interpreting product labels (American Dietetic Association, 2009).

Health care professionals should also be aware that their patients typically do not inform them of their use of botanicals or other dietary supplements; practitioners must inquire about the use of supplements by their patients. To facilitate obtaining information, health care providers should approach patients in an open, nonjudgmental manner. Key items and issues to be inquired about are summarized in Box 13-2. Not only should all dietary supplements be reviewed, but it is recommended that patients bring all supplements into the clinic to be evaluated. In this way the health care provider can review dose, dosage form, additive sources of the same nutrient or botanical, frequency of use, rationale for use, any identified side effects, and the patient-perceived efficacy of each supplement. This should be done on a regular basis. It is particularly important

**BOX 13-2**

## Evaluating Dietary Supplement Use: The Patient–Health Care Provider Information Exchange

**Ask**

- What dietary supplements are you taking (type: vitamin, mineral, botanical, amino acid, fiber)?
- What antacids or other OTC medications or food products are you taking that provide supplemental nutrients, herbals, fiber, etc.?
- Why are you taking these dietary supplements? Include review of patient's medical diagnosis and symptoms for reasons why he or she may be taking supplements (e.g., osteoarthritis, heart disease, high blood pressure, night sweats, loss of memory, fatigue).
- How long have you been taking these dietary supplements?
- What dose or how much are you taking? For each, include chemical form and review and photocopy labels.
- With what frequency are you taking each supplement?
- What are the sources of the supplements (e.g., OTC or prescribed, Internet, health care provider) and manufacturers of the supplements?
- Is it touted as being preventive or to have treatment effects? What does the label claim? Supplemental brochures or materials?
- Who recommended the supplement (e.g., media, physician, nurse, dietitian, alternative medicine practitioner, friend, family)?

**Evaluate**

- Dietary intake (including intake of fortified foods, energy or sports bars, or beverages)
- Health status and health history—include lifestyle habits (e.g., smoking, alcohol, exercise)
- Biochemical profile, laboratory data
- Prescribed and OTC medications
- Clinical response
- Adverse events, symptoms

**Educate**

- Scientific evidence of benefit and effectiveness
- Potential interaction with foods, nutrients, and medications or other dietary supplements
- Appropriate dose, brand, and chemical form; duration of supplementation; appropriate follow-up
- Quality of products, manufacturers, good manufacturing practices (USP, Consumer Labs)
- Mechanism of action of the primary active ingredient
- Appropriate storage of the dietary supplement
- Administration instructions: with food? Without food? Potential food-supplement interactions?
- Awareness and reporting of any side effects or adverse events, symptoms
- Recommend necessary dietary changes
- Remind that a nutritional *supplement* should supplement the diet

**Document**

- List specific supplements and brand names of each supplement being taken.
- Record batch number from bottle in case of an adverse event.
- Record patient perception and expected level of compliance.
- Monitor efficacy and safety, including health outcomes and adverse effects.
- Record medication-supplement or supplement-supplement interactions.
- Plan for follow-up.

From Practice Paper of the American Dietetic Association: Dietary supplements, J Am Diet Assoc 105(3):466, 2005. Reprinted with permission.  
OTC, Over the counter.

that dietary supplement use be reviewed before surgery because some dietary supplements and botanicals alter the rate of blood coagulation. **Table 13-3** provides specific recommendations regarding the discontinuation of dietary supplements before surgery to avoid complications associated with prolonged bleeding time.

Although a listing of efficacy and safety issues of select supplements is provided in the form of Cochrane database reviews in this chapter (see **Table 13-3**), the list is somewhat limited. A more extensive list is not provided because it is imperative that practitioners seek current data sources for this information, which is expanding rapidly.

Practitioners should use the most up-to-date information when formulating recommendations for their patients. See **Box 13-3** for a listing of reliable and comprehensive data sources.

Intake and follow-up information about these therapies provides important pharmacologic and treatment information for the health care provider. In particular, dietary supplements that have similar actions to prescription and OTC medications should generally not be combined, because the effects can be additive and cause harm (DeBusk, 2000). Conversely, dietary supplements that counter the effects of prescription and OTC medications should not be

**TABLE 13-3****Recommended Times for Preoperative Discontinuation of Select Common Dietary Supplements**

Dietary Supplement	Recommended Discontinuation Time Before Surgery
Echinacea	Insufficient data
Garlic	7 days
Ginkgo	36 hours
Ginseng	7 days
Kava	24 hours
St. John's wort	5 days
Valerian	Insufficient data
Vitamin E	7 days

Data from Ang-Lee MK et al: Herbal medicines and perioperative care, *JAMA* 286:208, 2001.

combined, such as taking a blood pressure-lowering medication along with a botanical that can raise blood pressure. Funding studies that evaluate botanical-drug interactions is a priority of the NCCAM.

Beyond evaluating the efficacy of dietary supplements, safety must also be addressed. Although select safety issues have been identified, some may go unreported and use of that supplement discontinued, with no formal report of the AE being filed. As an example, more than 4 million Americans are taking antithrombotic therapy. Approximately 180 dietary supplements have been identified as having anticoagulation, antiplatelet, antagonistic, or drug-metabolizing activity. AEs should be reported to the health care institutions, poison control centers, and MedWatch. Manufacturers of dietary supplements should also maintain their own reporting system for AEs (Talati and Gurnani, 2009).

AEs should be reported to MedWatch. Reports can be filed by the individual, health care provider, or industry. AE reports are forwarded to the Center for Food Safety and Applied Nutrition where they are further evaluated by qualified reviewers. In 2008 a total of 1,080 reports were filed—the majority from mandatory rather than voluntary sources. The majority were related to use of vitamins or mixed-nutrient products (Frankos, 2009).

Many health care professionals remain uncomfortable recommending dietary supplements. Guidelines for recommending and selling dietary supplements and a clinical practice paper have been previously published (Thomson et al., 2005). Internet resources are listed at the end of this chapter. An algorithm for assessing and recommending dietary supplements is presented. Practitioners must take the initiative to develop the appropriate knowledge, skills, and resources to provide optimal care in the area of dietary supplementation.

## **GUIDELINES FOR COUNSELING**

The goal of CAM counseling is to determine which supplements clients are using and the health goals they hope to achieve through the use of these products. People typically do not divulge their use of dietary supplements or CAM use to their health care practitioners. This is especially true for minority racial and ethnic groups. It is imperative that the practitioner establish rapport with the client to enhance disclosure of CAM use (Chao, 2008). Being nonjudgmental of the client's practices fosters a constructive dialogue. The health care practitioner's role is as a coach who helps clients assess the need for supplements and helps them to become more knowledgeable about their options (see Box 13-2).

For discussion of dietary supplement use, clients should bring with them all prescriptions, OTC medications, and dietary supplements they are using. In addition, a dietary supplement intake assessment form should be completed by each patient or client and reviewed in detail by the health care provider. Note that, in addition to a listing of specific supplements, nutrients, and botanicals, the form also identifies the health conditions that motivated the use of supplements. In the case of calcium, it is also imperative to collect information about antacid use because this is a major source of calcium supplementation.

Each supplement should be discussed individually in terms of what the client hopes to achieve by using that supplement, whether the preparation is appropriate for the client's health goals, and whether the dosage being taken and the length of time for supplementation is supported by published clinical trials. How to recognize a quality preparation for each supplement (in particular if the manufacturer is compliant with GMPs), any known safety concerns and contraindications, and any known or potential interactions between each supplement and prescription or OTC medications and other dietary supplements or foods should also be reviewed (see Chapter 9).

The client should be instructed to use the dosage commonly recommended for that specific botanical. A low starting dose, even less than the recommended dose, should be encouraged and the response monitored to minimize the chances of an adverse reaction. Dietary supplement use by clients provides an excellent platform for teaching consumers analytic skills that will serve them well in their pursuit of increased self-management of their health.

The Office of Dietary Supplements has developed facts sheets for an extensive list of dietary supplements that can be used by health care professionals to educate patients. The FDA has published tips for the dietary supplement user in making informed choices regarding which supplements to consider taking. Tips include advice regarding (1) assessment of present diet, (2) informing health care providers of dietary supplement use, (3) potential medication–dietary supplement interactions, (4) reporting of AEs, and (5) assessment of the validity of information. See Box 13-4 for issues to consider when choosing a botanical.

## **Resources for Clinicians**

As awareness of dietary supplement use expands within the health care community, the number of evidence-based resources available to clinicians is also growing considerably. It is advisable that clinicians have access to at least one online resource that is updated at regular intervals. Resources that provide reference to the original research are preferable. In addition, accessing available medical literature is advised, given that there are a growing number of studies being published in peer-reviewed literature. Finally, contacting health care providers and researchers who are actively working in this area can be invaluable in terms of increasing awareness of safety issues, understanding mechanisms of biologic activity, and assessing the level of evidence for clinical efficacy.

## **CLINICAL SCENARIO**

Ellen is 66 years old and has been diagnosed as having hypertension, hypercholesterolemia, and type 2 diabetes. She has been referred by her physician for nutritional counseling, with a specific request from the referring physician that you evaluate any herbal preparations she is taking. At the initial consult, Ellen tells you she is taking the following dietary supplements: garlic pills, ginseng, ginkgo, and St. John's wort, along with the following medications: warfarin, a tricyclic antidepressant, and blood pressure–lowering medication.

### **Nutrition Diagnostic Statement**

Bioactive substance intake related to daily intake of multiple supplements as evidenced by intake of supplements that conflict with medications (warfarin, garlic, St. John's wort).

### **Nutrition Care Questions**

1. What recommendations would you make about Ellen's diet?
2. What additional questions would you ask regarding Ellen's supplements?
3. List potential adverse interactions between the botanicals and the prescription drugs.
4. How would you counsel Ellen?

**BOX 13-4****Guidelines for Choosing Botanical Products**

1. Be sure the choice of a botanical is appropriate to the health care goals and compatible with any prescription and over-the-counter medications or other dietary supplements. Information is available at [www.consumerlab.com](http://www.consumerlab.com) for validation of specific product brands on the market.
2. Investigate the quality of the manufacturer whose product is being considered. At a minimum, it is important to know that the retail suppliers carry only manufacturers that adhere to high-quality standards or that the health care professional recommending a product is knowledgeable about the quality of dietary supplements. Some of the questions to ask are how herbs are grown, selected, stored, and processed to ensure absence of microbial contamination, proper identification, and potency.
3. Investigate the potential for pesticide contamination, which can be minimized by choosing organically grown herbs whenever possible.
4. Investigate the claims being made about the products and avoid products with exaggerated claims associated with them.
5. Use the dietary supplement label to obtain important information, including:
  - The complete botanical name of the product to confirm that this is the appropriate botanical
  - The part of the plant used to prepare the product, confirming that it is the part that contains the active components
  - The concentration of the botanical or nutrient and whether the concentration is appropriate for obtaining the reported benefits of the product (i.e., neither too weak nor too strong)
  - The daily dosage needed to obtain the desired effect
  - A lot number, which is helpful if problems arise because it allows the product to be tracked through each stage of the manufacturing process
  - An expiration date
  - A recognized seal of approval that indicates good manufacturing practices have been used in the production of the product and that the product has passed independent analyses confirming that the label accurately represents the product
  - A toll-free number for contacting the manufacturer in the event of adverse reactions
6. After determining that a manufacturer and its product meet these standards, compare prices among products of similar quality. Prices can vary widely.

Nutrition support is the delivery of formulated enteral or parenteral nutrients for the purpose of maintaining or restoring nutritional status. **Enteral nutrition (EN)** refers to the provision of nutrients into the gastrointestinal tract (GIT) through a tube or **catheter**. In certain instances EN may include the use of formulas as oral supplements or meal

replacements. **Parenteral nutrition (PN)** is the provision of nutrients intravenously.

### RATIONALE AND CRITERIA FOR APPROPRIATE NUTRITION SUPPORT

Sections of this chapter were written by Charles Mueller, PhD, RD, CNSD, CDN and Abby S. Bloch, PhD, RD, FADA for the previous edition of this text.

When patients are unable to eat enough to support their nutritional needs for more than a few days, nutrition support

should be considered. EN should be the first consideration. Using the gut for nutrition versus using only PN is preferable for preserving the mucosal barrier function and integrity. The act of feeding the GIT has been shown to attenuate the catabolic response and preserve immunologic function (ASPEN, 2010). EN decreases the incidence of hyperglycemia when compared with PN. At this time, there

is insufficient evidence to draw conclusions about the effect of EN versus PN on length of stay and mortality (American Dietetic Association, 2010).

Criteria must be applied to select appropriate candidates for nutrition support (Table 14-1). PN should be used in patients who are or will become malnourished and who do not have sufficient gastrointestinal function to

**TABLE 14-1****Conditions That Often Require Nutrition Support**

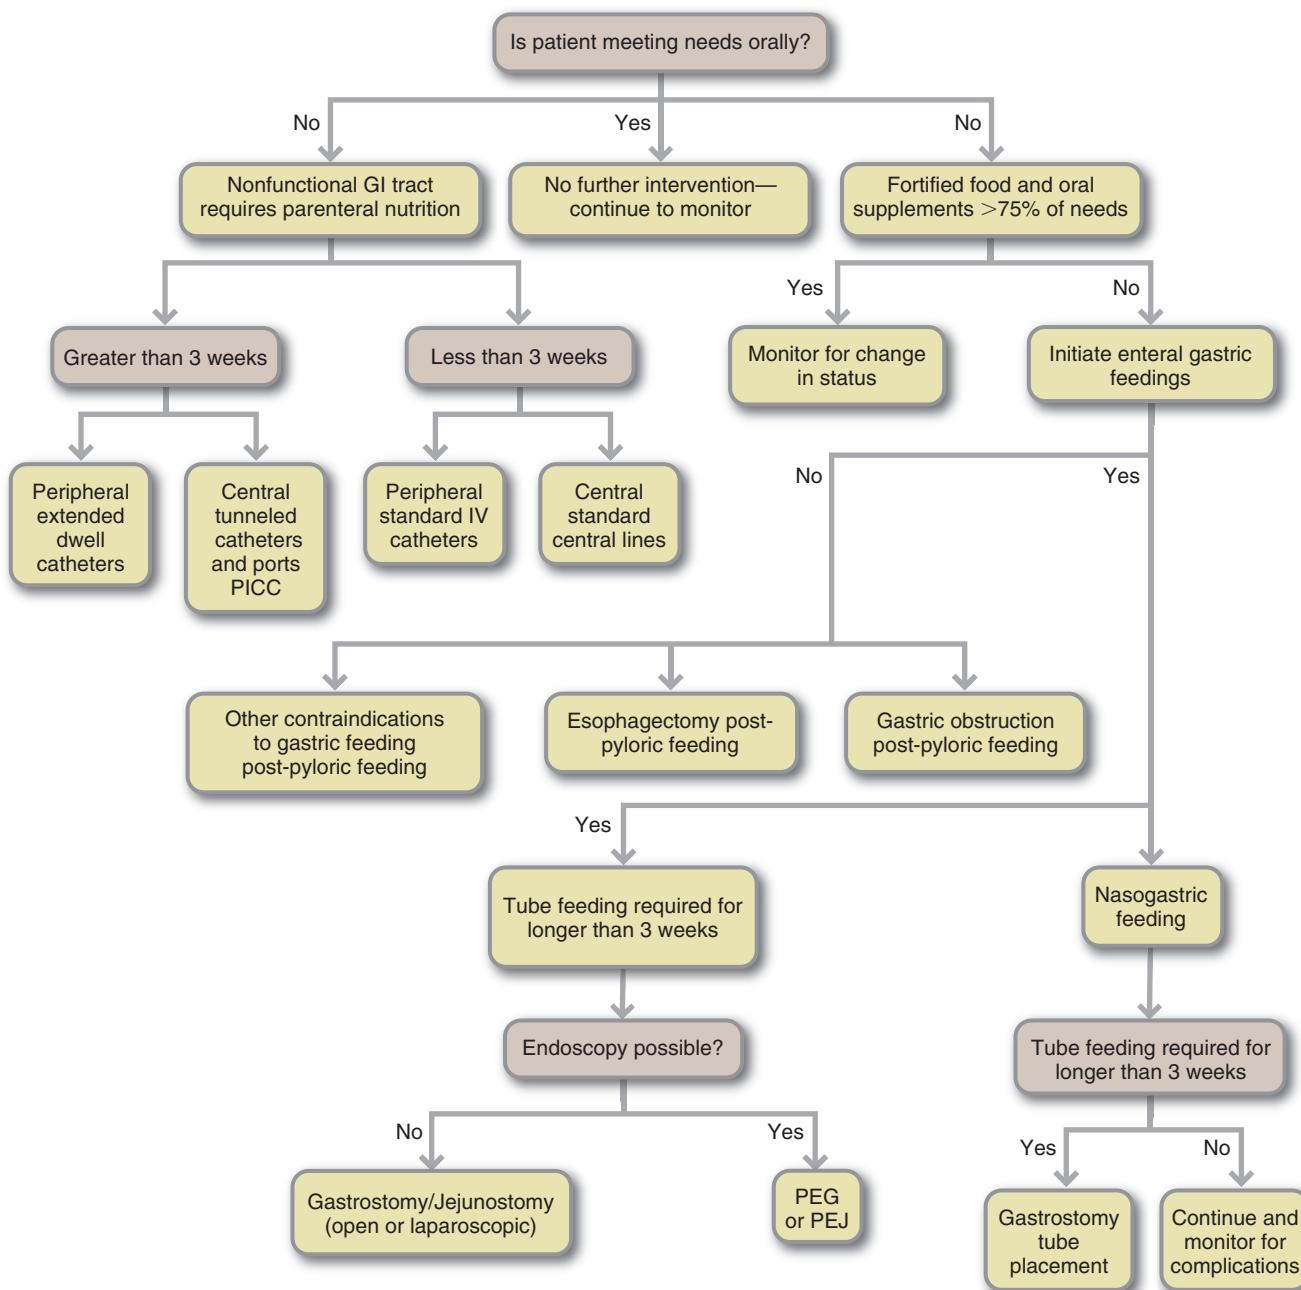

<b>Recommended Route of Feeding</b>	<b>Condition</b>	<b>Typical Disorders</b>
Enteral nutrition	Inability to eat	Neurologic disorders (dysphagia) Facial trauma Oral or esophageal trauma Congenital anomalies Respiratory failure (on a ventilator) Traumatic brain injury Comatose state GI surgery (e.g., esophagectomy)
	Inability to eat enough	Hypermetabolic states such as with burns Cancer Heart failure Congenital heart disease Impaired intake after orofacial surgery or injury Anorexia nervosa HIV/AIDS Failure to thrive Cystic fibrosis
	Impaired digestion, absorption, metabolism	Severe gastroparesis Inborn errors of metabolism Crohn disease Short bowel syndrome with minimum resection Pancreatitis
Parenteral nutrition	Gastrointestinal incompetency	Short bowel syndrome—major resection Severe acute pancreatitis with intolerance to enteral feeding Severe inflammatory bowel disease Small bowel ischemia Intestinal atresia Severe liver failure Persistent postoperative ileus Intractable vomiting/diarrhea refractory to medical management Distal high-output fistulas Severe GI Bleeding
	Critical illness with poor enteral tolerance or accessibility	Multorgan system failure Major trauma or burns Bone marrow transplantation Acute respiratory failure with ventilator dependency and gastrointestinal malfunction Severe wasting in renal failure with dialysis Small bowel transplantation, immediate after surgery

AIDS, Acquired immune deficiency syndrome; GI, gastrointestinal; HIV, human immunodeficiency virus.

be able to restore or maintain optimal nutritional status (McClave et al., 2009). Figure 14-1 presents an algorithm for selecting EN and PN routes. Although these guidelines can assist with the selection of the best type of nutrition, the choice is not always easy. For example, access methods are not universally available in every health care setting. Therefore, if a specific type of small bowel access is not available for EN, PN may be the only realistic option. Often PN is used temporarily until adequate gastrointestinal function can support either EN or oral intake. In this situation a combination of feeding methods is used (see “Transitional Feeding” later in the chapter).

In a **computerized prescriber order entry (CPOE)**, the prescriber enters orders directly into a computer system, usually aided by decision-support technology (Bankhead et al., 2009). Although methods of nutrition support can be standardized for the course of certain disease states or treatments, every patient presents an individual challenge. Nutrition support must often be adapted to unanticipated developments or complications. The optimal treatment plan requires interdisciplinary collaboration that is closely aligned with the overall patient care plan. In a few instances nutrition support may be warranted but physically impossible to implement within the overall care plan.

**FIGURE 14-1** Algorithm for route selection for nutrition support.

Conversely, nutrition support may be achievable but not warranted because of the prognosis, unacceptable risk, or the patient's right to self-determination. In all cases, it is important to prevent errors in ordering, delivery, and monitoring of nutrition support to prevent undesirable risks or outcomes (**sentinel events**) such as an unexpected death, serious physical injury with loss of limb or function, or psychological injury (Joint Commission, 2010).

## ENTERAL NUTRITION

By definition, *enteral* implies using the GIT, primarily via "tube feeding." When a patient has been determined to be a candidate for EN, the location of nutrient administration and type of enteral access device is selected. Enteral access selection depends on the (1) anticipated length of time enteral feeding will be required, (2) degree of risk for aspiration or tube displacement, (3) patient's clinical status, (4) presence or absence of normal digestion and absorption, (5) patient's anatomy (e.g., feeding tube placement is not possible in some very obese patients), and (6) whether a surgical intervention is planned.

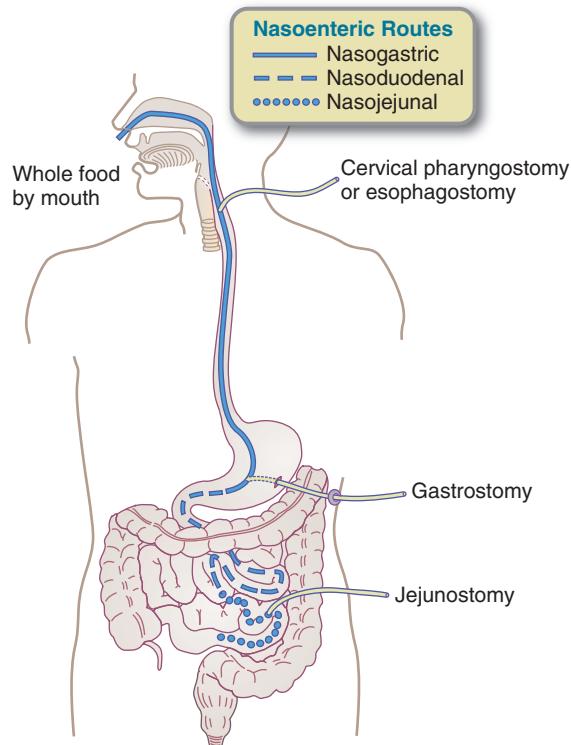

In a **closed enteral system** the container or bag is pre-filled with sterile liquid formula by the manufacturer, and is ready to administer. In an **open enteral system**, the person administering the feeding must open and pour the feeding into the container or bag. Both systems are effective when sanitation is a priority. **Hang time** is the length of time an enteral formula is considered safe for delivery to the patient; most facilities allow a 4 hour hang time before the product is changed for open systems and 24-48 hours for closed systems.

### Short-Term Enteral Access

#### Nasogastric Route

**Nasogastric tubes (NGTs)** are the most common way to access the GIT. They are generally appropriate only for those requiring short-term EN, which is defined as 3 or 4 weeks. Typically, the tube is inserted at the bedside by a nurse or dietitian. The tube is passed through the nose into the stomach (Figure 14-2). Patients with normal gastrointestinal function tolerate this method, which takes advantage of normal digestive, hormonal, and bactericidal processes in the stomach. Rarely, complications can occur (Box 14-1).

NG feedings can be administered by bolus injection or by intermittent or continuous infusions (see "Administration" later in this chapter). Soft, flexible, and well-tolerated polyurethane or silicone tubes of various diameters, lengths, and design features may be used, depending on formula characteristics and feeding requirements. Tube placement is verified by aspirating gastric contents in combination with auscultation of air insufflation into the stomach or by radiographic confirmation of the tube tip location. Techniques for placing a tube are described by Metheny and Meert (2004).

**FIGURE 14-2** Diagram of enteral tube placement.

### BOX 14-1

#### Potential Complications of Nasoenteric Tubes

- Esophageal strictures
- Gastroesophageal reflux resulting in aspiration pneumonia
- Incorrect position of the tube leading to pulmonary injury
- Mucosal damage at the insertion site
- Nasal irritation and erosion
- Pharyngeal or vocal cord paralysis
- Rhinorrhea, sinusitis
- Ruptured gastroesophageal varices in hepatic disease
- Ulcerations or perforations of the upper gastrointestinal tract and airway

Adapted from McClave SA et al: Guidelines for the provision and assessment of nutrition support therapy in the adult critically ill patient, JPEN J Parenter Enteral Nutr 33: 277, 2009.

### Gastric versus Small-Bowel Feeding

The decision to use a small-bowel feeding tube versus a gastric tube is multifaceted. It is much easier to place tubes into the stomach; therefore gastric feedings generally result in a patient being fed sooner. However, ease of access is only one consideration. Gastric feedings may not be well tolerated, especially in critically ill patients (see Chapter 39).

Signs and symptoms of intolerance to gastric feeding include abdominal distention and discomfort; vomiting; and persistent, high gastric residuals (defined as more than 400 mL). Patients receiving gastric feedings are often thought to be at higher risk of aspiration pneumonia, but this is debatable (Bankhead et al., 2009).

### Nasoduodenal or Nasojejunal Route

For those patients unable to tolerate gastric feedings who require relatively short-term nutrition support, a **nasoduodenal tube (NDT)** or a **nasojejunal tube (NJT)** is indicated. This requires that the tip of the tube pass through the pylorus and into the duodenum or pass all the way through the duodenum and into the jejunum. Positioning of these tubes requires one of the following techniques: (1) intraoperative placement (generally not just for the purpose of placing a feeding tube), (2) endoscopic or fluoroscopic guidance, (3) spontaneous placement that depends on a gastric tube migrating into the duodenum by peristalsis, or (4) bedside placement using a computer guidance system (Figure 14-3). Spontaneous migration of a gastric tube cannot be used for an NJT. Confirmation that the tube has migrated to the correct position can take several days and requires x-ray confirmation. This can result in delayed feedings.

### Long-Term Enteral Access

#### Gastrostomy or Jejunostomy

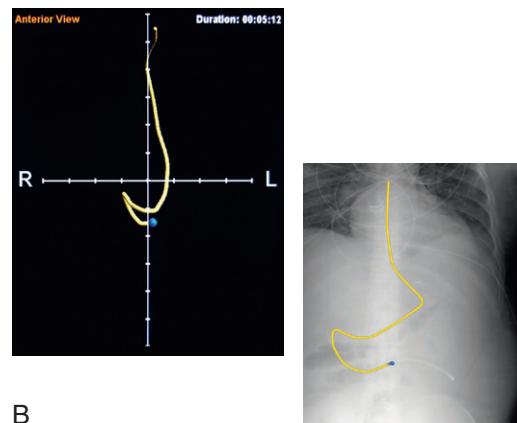

When enteral feedings are necessary for more than 3-4 weeks, gastrostomy or jejunostomy should be considered to prevent some of the complications related to nasal and upper GIT irritation (see Box 14-1) and for the general comfort of the patient (Figure 14-4). These procedures can be done surgically and this may be the most efficient method if the patient is otherwise undergoing surgery (e.g., patients undergoing esophagectomies commonly have jejunal feeding tubes placed at the time of surgery). Nonoperative procedures are now far more common.

The **percutaneous endoscopic gastrostomy (PEG)** is a nonsurgical technique for placing a tube directly into the stomach through the abdominal wall; the technique is performed using an endoscope, with the patient under local anesthesia. Tubes are endoscopically guided from the mouth into the stomach or the jejunum and then brought out through the abdominal wall. The short procedural time required for insertion, limited need for anesthesia, and minimum wound complications also make it preferable for the physician and others caring for the patient.

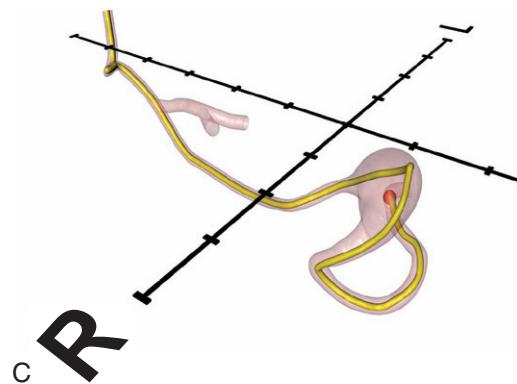

PEG tubes used are generally large bore (feeding tubes are measured as **french size**), making clogging less likely. It is possible to convert a PEG to a **gastrojejunostomy** by threading a small-bore tube through the PEG tube into the jejunum using either fluoroscopy or endoscopy. PEGs may have a short piece of tubing that can be used to inject feedings with a syringe or to connect to a feeding bag. PEGs that are “low profile” are flush to the skin. These feeding tubes, also known as “buttons”, are a good choice

(From Oley Foundation, Albany NY [www.oley.org](http://www.oley.org).)

for those patients prone to pulling on their tubes (e.g., children, older adults with dementia). They are also beneficial for those who are active and want to avoid the bulkiness of a feeding tube under their clothing.

### Other Minimally Invasive Techniques

High-resolution video cameras have made percutaneous radiologic and laparoscopic gastrostomy and jejunostomy enteral access an option for patients in whom endoscopic procedures are contraindicated. Using fluoroscopy, a radiologic technique, tubes can be guided visually into the stomach or the jejunum and then brought out through the abdominal wall to provide the access route for enteral feedings. Laparoscopic or fluoroscopic techniques are used in some facilities and offer alternative options for enteral access (Nikolaidis, 2005).

### Multiple Lumen Tubes

Gastrojejunal dual tubes are available for either endoscopic or surgical placement. These tubes are designed for patients in whom prolonged **gastrointestinal decompression** is anticipated. The **multiple lumen tube** has one **lumen** for decompression and one to feed into the small bowel. These tubes are used for early postoperative feeding.

### Formula Content and Selection

A wide variety of enteral feeding products are commercially available. A **modular enteral feeding** is created by combining separate nutrient sources or by modifying existing formulas. For the most sterile product, it is best to use standardized commercial products and to avoid using multiple additives or drugs. The less the products are handled, the safer they are for the patient.

Enteral formulas can be classified as (1) standard **polymeric formula**; (2) elemental, predigested, or chemically defined; or 3) specialized. Many formulas are available within each of these categories. Hospitals and other health care institutions generally have a product formulary that determines which products can be used in that facility. The suitability of an enteral formula for a specific patient should be based on the functionality of the GIT, the clinical status of the patient, and the patient's nutrient needs. In some situations the cost of the formula is a major factor. In the past, **osmolality** was considered key to patient tolerance and the goal was to provide feedings that were the same osmolality as body fluids (290 mOsm/kg). However, studies done in the mid-1980s showed that patients can tolerate feedings with a wide variance of osmolarity.

Formulas are classified in a variety of ways, usually based on protein or overall macronutrient composition. Most patients with a variety of clinical conditions tolerate standard formulas intended to meet the nutritional requirements of general patient populations. The formulas are lactose-free, contain 1 to 1.2 kcal/mL, and are used as over-the-counter oral supplements and tube-feeding formulas. Some standard formulas are more concentrated to provide 1.5 to 2 kcal/mL when fluid restriction is required for patients with cardiopulmonary, renal, and hepatic failure, or for patients who have trouble tolerating high-volume feedings. Formulas intended for use as supplements to oral diets are flavored and contain simple sugars for palatability. See **Appendix 32**.

The Food and Drug Administration states that enteral formulas are a food; thus they are not under regulatory control. Manufacturers do not need to register their products with FDA nor get FDA approval before producing or selling them. Products are often introduced with little scientific evidence to support claims that are made. Evaluation of the suitability and efficacy of products, whether for individual or institutional use, is increasingly complex. A product making claims of pharmacologic effects must be evaluated using clinical evidence before a decision is made to use it (**Box 14-2**).

### Protein

The amount of protein in enteral formulas varies from 6% to 25% of total kilocalories. The protein is typically derived from casein, whey, or soy protein isolate. Standard formulas provide intact protein, whereas elemental or predigested formulas have protein as di- and tripeptides and amino acids. The latter require less digestion. Specialized formulas may have the protein as crystalline amino acids for conditions such as renal or hepatic failure. These truly elemental formulas may also be used in the case of severe allergies. (Gottschlich 2006). In some cases specific amino acids have been added to enteral formulas. For example, arginine is added to renal products and critical care products because it is considered to be a conditionally essential amino acid in those clinical situations. See **Chapter 39** for further discussion.

**BOX 14-2****Factors to Consider When Choosing an Enteral Formula**

- Ability of the formula to meet the patient's nutritional requirements
- Caloric and protein density of the formula (i.e., kcal/mL, g protein/mL, kcal:nitrogen ratio)
- Gastrointestinal function of the patient
- Presence of lactose, which may not be tolerated
- Sodium, potassium, magnesium, and phosphorus content of the formula, especially in cardiopulmonary, renal, or hepatic failure
- Type of protein, fat, carbohydrate, and fiber in the formula tolerable for the patient's digestive and absorptive capacity
- Viscosity of the formula related to tube size and method of feeding

**Carbohydrate**

The percentage of total calories provided as carbohydrates in enteral formulas varies from 30% to 85% of kilocalories. Corn syrup solids are usually the carbohydrate found in standard formulas. Sucrose is added to flavored formulas that are meant for oral consumption. Hydrolyzed formulas have carbohydrate from cornstarch or maltodextrin. A recent innovation in the carbohydrate component of enteral formulas is fructooligosaccharides (FOS). These oligosaccharides are fermented to short-chain fatty acids and used as fuel by colonocytes (Charney, 2006).

Formulas are lactose-free. Lactose is not used as a carbohydrate source in most formulas because lactase deficiency is common in acutely ill patients. Fiber or carbohydrate that cannot be digested by human enzymes, although digested by colonic microflora into short-chain fatty acids, is frequently added to enteral formulas. Fibers are classified as water soluble (pectins and gums) or water insoluble (cellulose or hemicellulose) (see Chapters 1 and 3). The effectiveness of different fibers in enteral formulas used to treat gastrointestinal symptoms in acutely ill patients is controversial (see Chapter 39).

**Lipid**

Lipid varies from 1.5% to 55% of the total kilocalories in enteral formulas; between 15% and 30% of the total kilocalories of standard formulas are provided by lipids, usually from corn, soy, sunflower, safflower, or canola oils. Elemental formulas usually have minimum amounts of long-chain fat. Approximately 2% to 4% of daily energy intake from linoleic and linolenic acid is necessary to prevent **essential fatty acid deficiency (EFAD)**. The remainder of the fat in enteral formulas is in the form of long-chain and medium-chain triglycerides (MCTs). Formulas contain a combination of  $\omega$ -3 fatty acids and  $\omega$ -6 fatty acids. The  $\omega$ -3 fatty

acids include eicosapentaenoic acid and docosahexanoic acid. These are considered advantageous compared with  $\omega$ -6 fatty acids because of their antiinflammatory effect; see Chapter 6.

MCTs can be added to enteral formulas because they do not require bile salts or pancreatic lipase for digestion and are absorbed directly into the portal circulation. Most formulas provide 0% to 85% of fat as MCTs. MCTs do not provide the essential linoleic or linolenic acids; they must therefore be provided in combination with long-chain triglycerides.

**Vitamins, Minerals, and Electrolytes**

Most, but not all available formulas are designed to meet the dietary reference intakes (DRIs) for vitamins and minerals if a sufficient volume is taken. However, DRIs are intended for healthy populations, not for acute or chronically ill people. Formulas intended for use in renal and hepatic failure are intentionally low in specific vitamins, minerals, and electrolytes. In contrast, disease-specific formulas often are supplemented with antioxidant vitamins and minerals with the intention of improving immune function and accelerating wound healing. Electrolytes are provided in relatively modest amounts compared with the oral diet and may require supplementation when diarrhea or drainage losses occur.

**Fluid**

Fluid needs for adults can be estimated at 1 mL of water per kilocalorie consumed, or 30 to 35 mL/kg of usual body weight (see Chapter 7). Without an additional source of fluid, tube-fed patients may not get enough free water to meet their needs, particularly when concentrated formulas are used. Standard (1 kcal/mL) formulas contain approximately 85% water by volume, but concentrated (2 kcal/mL) formulas contain only approximately 70% water by volume. All sources of fluid being given to a patient receiving EN, including feeding tube flushes, medications, and intravenous fluids, should be considered when determining and calculating a patient's intake. Additional water can be provided through the feeding tube as needed.

**Administration**

The three common methods of tube-feeding administration are (1) bolus feeding, (2) intermittent drip, and (3) continuous drip. Method selection is based on the patient's clinical status, living situation, and quality-of-life considerations. One method can serve as a transition to another method as the patient's status changes.

**Bolus**

The feeding modality of choice when patients are clinically stable with a functional stomach is the syringe bolus method (see Figure 14-4). Syringe **bolus feedings** administered in 5 to 20 minutes are more convenient and less expensive than pump or gravity bolus feedings, and should be encouraged when tolerated. A 60-mL syringe is used to infuse the formula. If bloating or abdominal discomfort develops, the

patient is encouraged to wait 10 to 15 minutes before proceeding with the remainder of formula allocated for that feeding. Patients with normal gastric function can usually tolerate 500 mL of formula at each feeding. People receiving home EN may tolerate greater volumes of formula over time. Three or four bolus feedings per day can provide the daily nutritional requirements for most patients. Feedings should be at room temperature because cold formula can cause gastric discomfort.

### Intermittent Drip

Quality-of-life issues are often the reason for the initiation of **intermittent drip feeding** regimens, which allow mobile patients more free time and autonomy compared with continuous drip infusions. These feedings can be given by pump or gravity drip. Gravity feeding is done by pouring formula into a feeding bag with a roller clamp. The clamp is adjusted to the desired drips per minute. A schedule is based on four to six feedings per day administered for 20 to 60 minutes. Formula administration is initiated at 100 to 150 mL per feeding and increased incrementally as tolerated. Success with this method of feeding depends largely on the degree of mobility, alertness, and motivation of the patient to tolerate the regimen.

### Continuous Drip

**Continuous drip infusion** of formula requires a pump. This method is appropriate for patients who do not tolerate large-volume infusions during a given feeding such as those occurring with bolus or intermittent methods. Patients with compromised gastrointestinal function because of disease, surgery, cancer therapy, or other physiologic impediments are candidates for continuous drip infusion. Patients that are being fed into the small intestine should be fed only by continuous drip infusion. The feeding rate goal, in milliliters per hour, is set by dividing the total daily volume by the number of hours per day of administration (usually 18 to 24 hours). Feeding is started at one quarter to one half of the goal rate and is advanced every 8 to 12 hours to the final volume.

Formulas can generally be started at full strength; however, high osmolality formulas may require more time to achieve tolerance and should be advanced conservatively. Dilution of formulas is not necessary and can lead to underfeeding.

Modern enteral pumps are small and easy to handle. Many pumps are battery operated for up to 8 hours in addition to being electrically powered, allowing flexibility and mobility for the patient. Most pumps have a complete delivery system available, including bags and tubing compatible with proper pump operation.

## Monitoring and Evaluation

### Monitoring for Complications

Abdominal leakage of gastric contents from a gastrostomy site can cause skin erosion and skin breakdown, leading to infection and peritonitis; however, fewer than 10% of

patients experience serious complications. Other complications can be prevented or managed with careful patient monitoring. **Box 14-3** provides a comprehensive list of complications associated with EN.

Aspiration is a concern for patients receiving EN and is also a controversial topic because many experts believe

### BOX 14-3

#### Complications of Enteral Nutrition

##### Access Problems

- Leakage from ostomy/stoma site
- Pressure necrosis/ulceration/stenosis
- Tissue erosion
- Tube displacement/migration
- Tube obstruction

##### Administration Problems

- Microbial contamination
- Misplacement of tube, causing infection or aspiration pneumonia or peritonitis
- Regurgitation

##### Gastrointestinal Complications

- Constipation
- Delayed gastric emptying
- Diarrhea
- Osmotic diarrhea, especially if sorbitol is given in liquid drug preparations
- Secretory
- Distention/bloating/cramping
- Formula choice/rate of administration
- High gastric residuals
- Intolerance of nutrient components
- Maldigestion/malabsorption
- Medications
- Nausea/vomiting
- Treatment/therapies

##### Metabolic Complications

- Drug-nutrient interactions
- Glucose intolerance/hyperglycemia
- Hydration status—dehydration/overhydration
- Hypoalbuminemia
- Hyponatremia
- Hypoglycemia
- Hyperkalemia/hypokalemia
- Hyperphosphatemia/hypophosphatemia
- Micronutrient deficiencies
- Refeeding syndrome

Data from Hamaoui E, Kodsi R: Complications of enteral feeding and their prevention. In Rombeau JL, Rolandelli RH, editors: Clinical nutrition: enteral tube feeding, Philadelphia, 1997, Saunders; Merck Manual online. Accessed 29 May 2010 from <http://www.merckmanuals.com/professional/sec01/ch003/ch003b.html>.

the issue is not aspiration of formula into the airway, but aspiration of throat contents and saliva. To minimize the risk of aspiration, patients should be positioned with their heads and shoulders above their chests during and immediately after feeding (ASPEN, 2010, Bankhead et al., 2009).

There is confusion in the literature as to the efficacy of checking gastric residuals, because procedures are not standardized and the practice of checking residuals does not protect the patient from aspiration. Stable patients, especially those who have been fed by tube for long periods, do not need residuals checked regularly. Also, it is difficult to aspirate the stomach contents, and the residuals may contain more secretions and gastric fluids than formula. In critically ill patients the best methods for decreasing the risk of aspiration are elevating the head of the bed, continuous subglottic suctioning, and oral decontamination (American Dietetic Association, 2010; Bankhead et al., 2009).

Diarrhea is a common complication, often from colonic bacterial overgrowth, antibiotic therapy, and gastrointestinal motility disorders associated with acute and critical illness. Hyperosmolar medications such as magnesium-containing antacids, sorbitol-containing elixirs, and electrolyte supplements can also contribute to diarrhea. Adjustment of medications or administration methods can frequently correct the diarrhea. The addition of FOS, pectin, and other fibers, bulking agents, and antidiarrheal medications can also be beneficial. Use of a predigested formula can also be considered when managing diarrhea in a tube-fed patient.

Among stable patients receiving EN, constipation can become a problem. Fiber-containing formulas or stool-bulking medication may be helpful, and adequate fluid must be provided. Again, medications should be reviewed. Narcotic pain relievers have the side effect of slowing GIT activity. Gastrointestinal motility should be assessed because diarrhea can coexist with constipation, usually when there is also a fecal impaction.

### Monitoring for Tolerance and Nutritional Intake Goals

Monitoring the patient's actual intake and tolerance is necessary to ensure that nutrition goals are achieved and maintained. Monitoring of metabolic and gastrointestinal tolerance, hydration status, and nutritional status is extremely important (Box 14-4). It is important to avoid use of blue dye to evaluate the contents of aspirate; the risks outweigh any perceived benefit (American Dietetic Association, 2010). Another concern is gastroparesis or high gastric residuals. In these cases, a promotility drug may be beneficial to increase gastrointestinal transit, improve EN delivery, and improve feeding tolerance (American Dietetic Association, 2010). The development and use of practice guidelines, institutional protocols, and standardized ordering procedures are helpful to ensure optimal, safe monitoring of EN (ASPEN, 2010).

It is important to monitor actual intake compared with prescribed intake. During routine patient care, feeding time

### BOX 14-4

#### Monitoring the Patient Receiving Enteral Nutrition

- Abdominal distention and discomfort
- Fluid intake and output (daily)
- Gastric residuals (every 4 hr) if appropriate
- Signs and symptoms of edema or dehydration (daily)
- Stool output and consistency (daily)
- Weight (at least 3 times/wk)
- Nutritional intake adequacy (at least 2 times/wk)
- Serum electrolytes, blood urea nitrogen, creatinine, (2-3 times/wk)
- Serum glucose, calcium, magnesium, phosphorus, (weekly or as ordered)

Adapted from McClave SA et al: Guidelines for the provision and assessment of nutrition support therapy in the adult critically ill patient, JPEN J Parenter Enter Nutr 33: 277, 2009.

is commonly lost from the prescribed feeding schedule as a result of (1) a dislodged tube, (2) gastrointestinal intolerance, (3) medical procedures requiring discontinuation of feeding, and (4) difficulties with the feeding tube position. When feedings must be turned off for long periods of time the result can be inadequate nutrition and adjustment in the tube feeding regimen should be made. For example, if tube feedings are being turned off for 2 hours every afternoon for physical therapy, the rate on the feeding should be turned up and the length of feeding time decreased to accommodate the therapy schedule.

### PARENTERAL NUTRITION

PN provides nutrients directly into the bloodstream intravenously. PN is indicated when the patient requires nutrition support but is unable or unwilling to take adequate nutrients orally or enterally. PN may be used as an adjunct to oral or EN to meet nutrient needs. Alternatively, PN may be the sole source of nutrition during recovery from illness or injury, or may be a life-sustaining therapy for patients who have lost the function of their intestine for nutrient absorption. The practitioner must choose between central and peripheral access. *Central access* refers to catheter tip placement in a large, high-blood-flow vein such as the superior vena cava; this is **central parenteral nutrition (CPN)**. **Peripheral parenteral nutrition (PPN)** refers to catheter tip placement in a small vein, typically in the hand or forearm.

The osmolarity of the PN solution dictates the location of the catheter; central catheter placement allows for the higher caloric PN formulation and therefore greater osmolarity (Table 14-2). The use of PPN is limited in that it is short-term therapy with a minimum effect on nutritional status; the type and amount of fluids that can be provided peripherally do not fully meet nutrition requirements.

**TABLE 14-2****Osmolarity of Nutrients in PN Solutions**

Nutrient	Osmolarity (mOsm/mL)	Sample Calculations
Dextrose 5%	0.25	500 mL = 125 mOsm
Dextrose 10%	0.505	500 mL = 252 mOsm
Dextrose 50%	2.52	500 mL = 1260 mOsm
Dextrose 70%	3.53	500 mL = 1765 mOsm
Amino Acids 8.5%	0.81	1000 mL = 810 mOsm
Amino Acids 10%	0.998	1000 mL = 998 mOsm
Lipids 10%	0.6	500 mL = 300 mOsm
Lipids 20%	0.7	500 mL = 350 mOsm
Electrolytes	Varies by additive	
Multitrace elements	0.36	5 mL = 1.8 mOsm
Multivitamin concentrate	4.11	10 mL = 41 mOsm

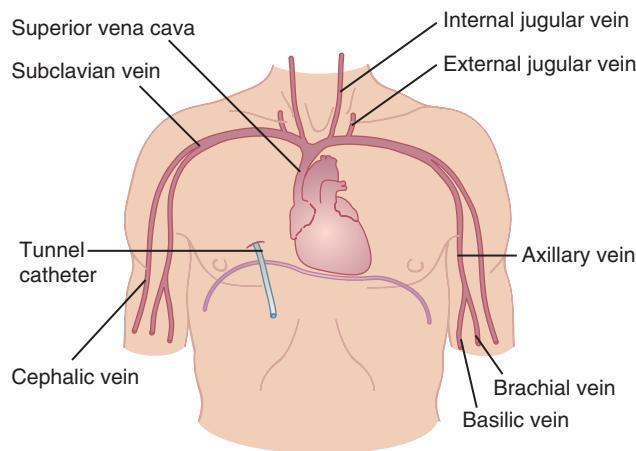

Data from RxKinetics: Calculating osmolarity of an IV admixture. Accessed 29 May 2010 from [http://www.rxkinetics.com/iv\\_osmolarity.html](http://www.rxkinetics.com/iv_osmolarity.html).

Volume-sensitive patients such as those with cardiopulmonary, renal, or hepatic failure are not good candidates for PPN. PPN may be appropriate when used as a supplemental feeding or in transition to enteral or oral feeding, or as a temporary method to begin feeding when central access has not been initiated. Calculation of the osmolarity of a parenteral solution is important to ensure venous tolerance (Kumpf et al., 2005). **Osmolarity**, or mOsm/mL is used to calculate IV fluids rather than osmolality which is used for body fluids.

**Access****Peripheral Access**

Nutrient solutions not exceeding osmolalities of 800 to 900 mOsm/kg of solvent can be infused through a routine peripheral intravenous angiocatheter placed in a vein in good condition (Matarese and Steiger, 2006). Protocols for dressing changes and rotation of the site are used to prevent thrombophlebitis, the principal complication of peripheral catheters.

A beneficial development in peripheral catheter technology is the **extended dwell catheter**. These catheters are sometimes called *midline* or *midclavicular catheters*, depending on their position. Extended dwell catheters require a vein large enough to advance the catheter 5 to 7 inches into the vein. These catheters can remain at the original site for 3 to 6 weeks and make PPN a more feasible option in patients with veins large enough to tolerate the catheter (Krzywda et al., 2005).

**FIGURE 14-5** Venous sites from which the superior vena cava may be accessed.

**Short-Term Central Access**

Catheters used for CPN ideally consist of a single lumen. If central access is needed for other reasons, such as hemodynamic monitoring, drawing blood samples, or giving medications, multiple-lumen catheters are available. To reduce the risk of infection, the catheter lumen used to infuse CPN should be reserved for that purpose only. Catheters are most commonly inserted into the subclavian vein and advanced until the catheter tip is in the superior vena cava, using strict aseptic technique. Alternatively, an internal or external jugular vein catheter can be used with the same catheter tip placement. However, the motion of the neck makes this site much more difficult for maintaining the sterility of a dressing. Radiologic verification of the tip site is necessary before infusion of nutrients can begin. Strict infection control protocols should be used for catheter placement and maintenance (Krzywda et al., 2005). Figure 14-5 shows alternative venous access sites for CPN; femoral placement is also possible.

A **peripherally inserted central catheter (PICC or PIC)** may be used for short- or moderate-term infusion in the hospital or in the home. This catheter is inserted into a vein in the antecubital area of the arm and threaded into the subclavian vein with the catheter tip placed in the superior vena cava. Trained nonphysicians can insert a PICC, whereas placement of a tunneled catheter is a surgical procedure (Krzywda et al., 2005). All catheters must have radiologic confirmation of the placement of the catheter tip prior to initiating any infusion.

**Long-Term Central Access**

A commonly used long-term catheter is a “tunneled” catheter. This single- or multiple-lumen catheter is placed in the cephalic, subclavian, or internal jugular vein and fed into the superior vena cava. A subcutaneous tunnel is created so that the catheter exits the skin several inches from its venous entry site. This allows the patient to care for the catheter more easily as is necessary for long-term infusion. Another type of long-term catheter is a surgically

implanted port under the skin where the catheter would normally exit at the end of the subcutaneous tunnel. A special needle must access the entrance port. Ports can be single or double; an individual port is equivalent to a lumen. Both tunneled catheters and PICCs can be used for extended therapy in the hospital or for home infusion therapy. Care of long-term catheters requires specialized handling and extensive patient education.

## PARENTERAL SOLUTIONS

### Protein

Commercially available standard PN solutions are composed of all the essential amino acids and only some of the nonessential crystalline amino acids. Nonessential nitrogen is provided principally by the amino acids alanine and glycine, usually without aspartate, glutamate, cysteine, and taurine. Specialized solutions with adjusted amino acid content that contain taurine are available for infants, for whom taurine is thought to be conditionally essential.

The concentration of amino acids in PN solutions ranges from 3% to 20% by volume. Thus a 10% solution of amino acids supplies 100 g of protein per liter (1000 mL). The percentage of a solution is usually expressed at its final concentration after dilution with other nutrient solutions. The caloric content of amino acid solutions is approximately 4 kcal/g of protein provided. Approximately 15% to 20% of total energy intake should come from protein (Kumpf et al., 2005).

Specialized solutions for patients with renal or liver disease are available, but are used infrequently because of their expense and the lack of conclusive research data supporting their efficacy. Recently, the amino acid glutamine has been suggested as an additive for patients requiring PN in the critical care setting (Martindale, 2009). Glutamine is not yet readily available in a commercial form and is therefore not routinely added to PN formulations.

### Carbohydrates

Carbohydrates are supplied as dextrose monohydrate in concentrations ranging from 5% to 70% by volume. The dextrose monohydrate yields 3.4 calories per gram. As with amino acids, a 10% solution yields 100 g of carbohydrates per liter of solution. The use of carbohydrates (100 g daily for a 70-kg person) ensures that protein is not catabolized for energy during conditions of normal metabolism.

Maximum rates of carbohydrate administration should not exceed 5 to 6 mg/kg/min in critically ill patients. When PN solutions provide 15% to 20% of total calories as protein, 20% to 30% of total calories as lipid, and the balance from carbohydrate (dextrose), infusion of dextrose should not exceed this amount. Excessive administration can lead to hyperglycemia, hepatic abnormalities, or increased ventilatory drive (see Chapter 35).

### Lipid

Lipid emulsions, available in 10%, 20%, and 30% concentrations, are composed of aqueous suspensions of soybean

or safflower oil, with egg yolk phospholipid as the emulsifier. Lipid emulsions should not be used when a patient has an egg allergy. The three-carbon molecule, glycerol, which is water soluble, is added to the emulsion. Glycerol is oxidized and yields 4.3 kcal/g.

Dietitians may be asked to calculate what the patient is receiving. A 10% emulsion provides 1.1 kcal/mL, a 20% emulsion provides 2 kcal/mL, and 30% emulsion provides 2.9 kcal/mL. Providing 20% to 30% of total calories as lipid emulsion should result in a daily dosage of approximately 1 g of fat per kilogram of body weight. Administration should not exceed 2.5 g of lipid emulsion per kilogram of body weight per day. In the hospital lipid is infused during 24 hours when mixed with the dextrose and amino acids. Alternatively, lipids can be provided separately by infusion via an infusion pump. For adult patients receiving PN at home, the PN will most often be infused during 10-12 hours per day with the lipid as part of the PN solution.

Approximately 10% of calories per day from fat emulsions provide the 2% to 4% of calories from linoleic acid required to prevent EFAD. Soybean and safflower oils are rich sources of linoleic acid, providing approximately 40%. Linoleic acid alters prostaglandin metabolism, thereby producing both proinflammatory and immunosuppressive effects, particularly at high doses and at faster infusion rates (Mizock and DeMichele, 2004). Therefore it is important not to use high doses of linoleic acid in the solutions.

### Electrolytes, Vitamins, Trace Elements

General guidelines for daily requirements for electrolytes are given in Table 14-3, for vitamins in Table 14-4, and for trace elements in Table 14-5. Parenteral solutions also represent a significant portion of total daily fluid and electrolyte intake. Once a solution is prescribed and initiated, adjustments for proper fluid and electrolyte balance may be necessary, depending on the stability of the patient. The choice of the salt form of electrolytes (e.g., chloride, acetate) affects acid-base balance.

**TABLE 14-3**

#### Daily Electrolyte Requirements During Total Parenteral Nutrition—Adults

Electrolyte	Standard Intake/Day
Calcium	10-15 mEq
Magnesium	8-20 mEq
Phosphate	20-40 mmol
Sodium	1-2 mEq/kg + replacement
Potassium	1-2 mEq/kg
Acetate	As needed to maintain acid-base balance
Chloride	As needed to maintain acid-base balance

From McClave SA et al: Guidelines for the provision and assessment of nutrition support therapy in the adult critically ill patient, JPEN J Parenter Enteral Nutr 33:277, 2009.

**TABLE 14-4****Adult Parenteral Multivitamins: Comparison of Guidelines and Products**

Vitamin	NAG-AMA Guidelines	FDA Requirements	MVI-12	MVI-13 (Infuvite) Baxter
A (retinol)	3300 units (1 mg)	3300 units (1 mg)	3300 units (1 mg)	3300 units (1 mg)
D (ergocalciferol cholecalciferol)	200 units (5 mcg)	200 units (5 mcg)	200 units (5 mcg)	200 units (5 mcg)
E (mcg-tocopherol)	10 units (10 mg)	10 units (10 mg)	10 units (10 mg)	10 units (10 mg)

**TABLE 14-5****Daily Trace Element Supplementation for Adult Parenteral Formulations**

Trace Element	Intake
Chromium	10-15 mcg
Copper	0.3-0.5 mg
Manganese	60-100 mcg
Zinc	2.5-5.0 mg
Selenium	20-60 mcg

Because parenterally administered vitamins and trace elements do not go through the digestive and absorptive processes, these recommendations are lower than the DRIs. Recently a review of the micronutrient needs of patients receiving PN, especially those receiving long-term home parenteral nutrition (HPN), has raised awareness of the need for careful review of patient requirements compared with the content of current trace element formulations. Monitoring of manganese and chromium status is recommended for patients receiving PN for longer than 6 months (Buchman, 2009). Iron is not normally part of parenteral infusions because it is not compatible with lipids and may enhance certain bacterial growth. Additionally, care must be taken to ensure that a patient can tolerate the separate iron infusion. When patients receive iron on an outpatient basis, the first dose should be done in a controlled setting (such as an outpatient infusion suite) to observe for any reactions that the patient might experience.

**Fluid**

Fluid needs for PN or EN are calculated similarly. Maximum volumes of CPN rarely exceed 3 L, with typical prescriptions of 1.5 to 3 L daily. In critically ill patients volumes of prescribed CPN should be closely coordinated with their overall care plan. The administration of other medical therapies requiring fluid administration, such as intravenous medications and blood products, necessitates careful monitoring. Patients with cardiopulmonary, renal, and hepatic failure are especially sensitive to fluid administration. For HPN, higher volumes may be best provided in separate infusions. For example, if additional fluid is required as a result of high output by the patient, then a liter bag of intravenous fluid containing minimal electrolytes may be infused during a short time during the day if the PN is infused over night. See Appendix 32 on calculating PN prescriptions.

**Compounding Methods**

PN prescriptions have historically required preparation or compounding by competent pharmacy personnel under laminar airflow hoods using aseptic techniques. Hospitals may have their own compounding pharmacy or may purchase PN solutions that have been compounded outside the hospital in a central location, and then returned to the hospital for distribution to individual patients. A third method of providing PN solutions is to utilize multichamber bag technology whereby solutions are manufactured in a quality-controlled environment using good manufacturing processes. These PN solutions are standardized but are available in multiple formulas with varying amounts of dextrose and amino acids, making them suitable for CPN or

PPN infusion. They contain conservative amounts of electrolytes or may be electrolyte free. These products have a shelf life of 2 years and do not need to be refrigerated unless the product covering has been opened to reveal the infusion bag (Figure 14-6). Institutions frequently use standardized solutions, which are compounded in batches, thus saving labor and lowering costs; however, flexibility for individualized compounding should be available when warranted (Kumpf et al., 2005).

Prescriptions for PN are compounded in two general ways. One method compounds all components except the fat emulsion, which is infused separately. Solutions are usually mixed in one bag at a 1:1 dextrose-to-amino acid volume ratio. The second method combines the lipid emulsion with the dextrose and amino acid solution and is referred to as a **total nutrient admixture** or **3-in-1** solution. The PN Safe Practices Guidelines provide practitioners with information on many techniques and procedures that enhance safety and prevent mistakes in the preparation of PN (Seres, 2006).

A number of medications, including antibiotics, vaso-pressors, narcotics, diuretics, and many other commonly administered drugs, can be compounded with PN solutions. In practice this occurs infrequently because it requires specialized knowledge of physical compatibility or incompatibility of the solution contents. The most common drug additives are insulin for persistent hyperglycemia and histamine-2 antagonists to avoid gastroduodenal stress ulceration (Kumpf et al., 2005). One other consideration is that the PN usually is ordered 24 hours prior to its administration, and patient status may have changed.

## Administration

The methods used to administer PN are addressed after the goal infusion rate, based on calculations, has been established. PN calculations and orders are inherently complex and protocols for ordering PN vary considerably among institutions. Nevertheless, general considerations as listed in Box 14-5 can be applied to almost any protocol.

## Continuous Infusion

Parenteral solutions are usually initiated below the goal infusion rate via a volumetric pump and then increased incrementally over a 2- or 3-day period to attain the goal infusion rate. Some practitioners start PN based on the amount of dextrose, with initial prescriptions containing 100 to 200 g daily and advancing over a 2- or 3-day period to a final goal. With high dextrose concentrations, abrupt cessation of CPN should be avoided, particularly if the patient's glucose tolerance is abnormal. If CPN is to be stopped, it is prudent to taper the rate of infusion in an unstable patient to prevent **rebound hypoglycemia**, low blood sugar levels resulting from abrupt cessation. For most stable patients this is not necessary.

## Cyclic Infusion

Individuals who require PN at home will benefit from a cyclic infusion; this entails infusion of PN for 8- to 12-hour periods, usually at night. This allows the person to have a free period of 12 to 16 hours each day, which may improve quality of life. The goal cycle for infusion time is established incrementally when a higher rate of infusion or a more concentrated solution is required. Cycled infusions should not be attempted if glucose intolerance or fluid tolerance is a problem. The pumps used for home infusion of PN are small and convenient, allowing mobility during daytime infusions. Administration time may be decreased because of patient ambulation and bathing, tests or other treatments, intravenous administration of medications, or other therapies.

## Monitoring and Evaluation

As with enteral feeding, routine monitoring of PN is necessary more frequently for the patient receiving PN in the hospital. For patients receiving HPN, initial monitoring is done on a weekly basis or less frequently as the patient becomes more stable on PN. Monitoring is done not only to evaluate response to therapy, but to ensure compliance with the treatment plan.

The primary complication associated with PN is infection (Box 14-6). Therefore strict adherence to protocols and monitoring for signs of infection such as chills, fever, tachycardia, sudden hyperglycemia, or elevated white blood cell count are necessary. Monitoring of metabolic tolerance is also critical. Electrolytes, acid-base balance, glucose tolerance, renal function, and cardiopulmonary and **hemodynamic stability** (maintenance of adequate blood pressure) can be affected by PN and should be monitored

**BOX 14-5**

## Nutrition Care Process for Enteral and Parenteral Nutrition

### **Assessment**

1. Clinical status, including medications
2. Fluid requirement
3. Route of administration
4. Energy (kcal) requirement
5. Protein requirement
6. Carbohydrate/lipid considerations
7. Micronutrient considerations
8. Formula selection or PN solution considerations
  - A. Concentration (osmolarity)
  - B. Protein content
  - C. Carbohydrate/lipid content
  - D. Micronutrient content
  - E. Special formula considerations
9. Calculations
  - A. Energy: use kcal/mL formula
  - B. Protein: use g/1000 mL
  - C. Fat and micronutrient considerations: units/1000 mL
  - D. Fluid considerations: extra water, IV fluids (including medications)

### **Nutrition Diagnosis**

1. Identify the problems affecting oral nutritional intake.
2. Identify problems related to access or administration of tube feedings.
3. Write PES statements. These may include inadequate or excess infusion of enteral or parenteral nutrition, or other nutrition diagnoses.

### **Intervention**

1. Each problem should have an intervention and a way to evaluate it.
2. Recommend what method and how to begin feedings.
3. Recommend how to advance feedings.
4. Determine how fluids will be given in adequate amounts.
5. Calculate final feeding prescription.

### **Monitoring and Evaluation**

1. Describe clinical signs and symptoms to monitor for feeding tolerance.
2. List laboratory values and other measurements to be monitored.
3. Determine how feeding outcomes will be evaluated.

*IV*, Intravenous; *PES*, problem, etiology, and signs and symptoms; *PN*, parenteral nutrition.

**BOX 14-6**

## Parenteral Nutrition Complications

### **Mechanical Complications**

- Air embolism
- Arteriovenous fistula
- Brachial plexus injury
- Catheter fragment embolism
- Catheter misplacement
- Cardiac perforation
- Central vein thrombophlebitis
- Endocarditis
- Hemothorax
- Hydromediastinum
- Hydrothorax
- Pneumothorax or tension pneumothorax
- Subcutaneous emphysema
- Subclavian artery injury
- Subclavian hematoma
- Thoracic duct injury

### **Infection and Sepsis**

- Catheter entrance site
- Catheter seeding from bloodborne or distant infection
- Contamination during insertion
- Long-term catheter placement
- Solution contamination

### **Metabolic Complications**

- Dehydration from osmotic diuresis
- Electrolyte imbalance
- Essential fatty acid deficiency
- Hyperosmolar, nonketotic, hyperglycemic coma
- Hyperammonemia
- Hypercalcemia
- Hyperchloremic metabolic acidosis
- Hyperlipidemia
- Hyperphosphatemia
- Hypocalcemia
- Hypomagnesemia
- Hypophosphatemia
- Rebound hypoglycemia on sudden cessation of PN in patient with unstable glucose levels
- Uremia
- Trace mineral deficiencies

### **Gastrointestinal Complications**

- Cholestasis
- Gastrointestinal villous atrophy
- Hepatic abnormalities

Adapted from McClave SA et al: Guidelines for the provision and assessment of nutrition support therapy in the adult critically ill patient, JPEN J Parenter Enteral Nutr 33: 277, 2009.

*PN*, Parenteral nutrition.

**TABLE 14-6****Inpatient Parenteral Nutrition Monitoring**

Variable to Be Monitored	Suggested Frequency	
	Initial Period*	Later Period*
Weight	Daily	Weekly
Serum electrolytes	Daily	1-2/wk
Blood urea nitrogen	3-wk	Weekly
Serum total calcium or ionized Ca <sup>+</sup> , inorganic phosphorus, magnesium	3-wk	Weekly
Serum glucose	Daily	3-wk
Serum triglycerides	Weekly	Weekly
Liver function enzymes	3-wk	Weekly
Hemoglobin, hematocrit	Weekly	Weekly
Platelets	Weekly	Weekly
WBC count	As indicated	As indicated
Clinical status	Daily	Daily
Catheter site	Daily	Daily
Temperature	Daily	Daily
I&O	Daily	Daily

McClave SA et al: Guidelines for the provision and assessment of nutrition support therapy in the adult critically ill patient, JPEN J Parenter Enteral Nutr 33:277, 2009.

*I&O*, Intake and output; *WBC*, white blood cell.

\*Initial period is that period in which a full glucose intake is being achieved. Later period implies that the patient had achieved a steady metabolic state. In the presence of metabolic instability, the more intensive monitoring outlined under initial period should be followed.

*I&O* refers to all fluids going into the patient: oral, intravenous, medication; and all fluid coming out: urine, surgical drains, exudates.

carefully. Table 14-6 lists parameters that should be monitored routinely.

The CPN catheter site is a potential source for introduction of microorganisms into a major vein. Protocols to prevent infection vary and should follow Centers for Disease Control Prevention guidelines (Centers for Disease Control and Prevention [CDC] and O'Grady, 2002). Catheter care and prevention of catheter-related bloodstream infections are of utmost importance in both the hospital and alternate settings. These infections are not only costly but may be life-threatening. Catheter care is dictated by the site of the catheter and the setting in which the patient receives care.

## REFEEDING SYNDROME

Patients who require enteral or PN therapies may have been eating poorly prior to initiating therapy because of the disease process and may be moderately to severely malnourished. Aggressive administration of nutrition, particularly via the intravenous route, can precipitate **refeeding syndrome** with severe, potentially lethal electrolyte fluctuations involving metabolic, hemodynamic, and neuromuscular problems. Refeeding syndrome occurs when energy substrates, particularly carbohydrate, are introduced into the plasma of anabolic patients (Parrish, 2009).

Proliferation of new tissue requires increased amounts of glucose, potassium, phosphorus, magnesium, and other nutrients essential for tissue growth. If intracellular

electrolytes are not supplied in sufficient quantity to keep up with tissue growth, low serum levels of potassium, phosphorus, and magnesium develop. Low levels of these electrolytes are the hallmark of refeeding syndrome, especially hypokalemia. Carbohydrate metabolism by cells also causes a shift of electrolytes to the intracellular space as glucose moves into cells for oxidation. Rapid infusion of carbohydrate stimulates insulin release, which reduces salt and water excretion and increases the chance of cardiac and pulmonary complications from fluid overload.

Patients starting on PN who have received minimal nutrition for a significant period should be monitored closely for electrolyte fluctuation and fluid overload. A review of baseline laboratory values, including glucose, magnesium, potassium, and phosphorus should be completed and any abnormalities corrected prior to initiating nutrition support, particularly PN. Conservative amounts of carbohydrate and adequate amounts of intracellular electrolytes should be provided. The initial PN formulation should usually contain 25% to 50% of goal dextrose concentration and be increased slowly to avoid the consequences of hypophosphatemia, hypokalemia, and hypomagnesemia. PN compatibilities must be assessed when very low levels of dextrose are provided with higher levels of amino acids and electrolytes. The syndrome also occurs in enterally fed patients, but less often because of the effects of the digestive process.

In managing the nutrition care process, refeeding syndrome is an undesirable outcome that requires monitoring

and evaluation. Most often, the nutrition diagnosis may be “excessive carbohydrate intake” or “excessive infusion from enteral or parenteral nutrition” in the undernourished patient. Thus, in the early phase of refeeding, nutrient prescriptions should be moderate in carbohydrate and supplemented with phosphorus, potassium, and magnesium (Kraft et al., 2005).

## TRANSITIONAL FEEDING

All nutrition support care plans strive to use the GIT when possible, either with EN or by a total or partial return to oral intake. Therefore patient care plans frequently involve **transitional feeding**, moving from one type of feeding to another, with several feeding methods used simultaneously while continuously administering estimated nutrient requirements. This requires careful monitoring of patient tolerance and quantification of intake from parenteral, enteral, and oral routes. Most experts advise that initial oral diets be low in simple carbohydrates and fat, as well as lactose free. These provisions make digestion easier and minimize the possibility of osmotic diarrhea. Attention to individual tolerance and food preferences also helps maximize intake.

### PARENTERAL TO ENTERAL FEEDING

To begin the transition from PN to EN, introduce a minimal amount of enteral feeding at a low rate of 30 to 40 mL/hr to establish gastrointestinal tolerance. When there is severe gastrointestinal compromise, predigested formula to initiate enteral feedings may be better tolerated. Once formula has been given during a period of hours, the parenteral rate can be decreased to keep the nutrient levels at the same prescribed amount. As the enteral rate is increased by 25 to 30 mL/hr increments every 8 to 24 hours, the parenteral prescription is reduced accordingly. Once the patient is tolerating about 75% of nutrient needs by the enteral route, the PN solution can be discontinued. This process ideally takes 2 to 3 days; however, it may become more complicated, depending on the degree of gastrointestinal function. At times the weaning process may not be practical, and PN can be stopped sooner, depending on overall treatment decisions and likelihood for tolerance of enteral feeding.

### PARENTERAL TO ORAL FEEDING

The transition from parenteral to oral feeding is ideally accomplished by monitoring oral intake and concomitantly decreasing the PN to maintain a stable nutrient intake. Approximately 75% of nutrient needs should be met consistently by oral intake before the PN is discontinued. The process is less predictable than the transition to enteral feeding. Variations include the patient’s appetite, motivation, and general well being. It is important to continue monitoring the patient for adequate oral intake once PN has been stopped and to initiate alternate nutrition support if necessary. Generally patients are transitioned from clear liquids to a diet that is low in fiber and fat and is lactose

free. It takes several days for the GIT to regain function; during that time, the diet should be composed of easily digested foods.

Special nutrient needs may be employed, especially when transitioning a patient with gastrointestinal disorders such as short bowel syndrome. Specialized nutrients, optimized drug therapy, and nutrition counseling should be comprehensive to improve outcome. Some PN patients may not be able to fully discontinue PN, but may be able to use PN less than 7 days per week, necessitating careful attention to nutrient intake. A skilled registered dietitian (RD) can coordinate diet and PN needs for this type of patient (Matarese and Steiger, 2006).

### ENTERAL TO ORAL FEEDING

A stepwise decrease is also used to transition from EN to oral feeding. It is effective to move from continuous feeding to a 12- and then an 8-hour formula administration cycle during the night; this reestablishes hunger and satiety cues for oral intake during daytime. In practice, oral diets are often tried after inadvertent or deliberate removal of a naso-enteric tube. This type of interrupted transition should be monitored closely for adequate oral intake. Patients receiving EN who desire to eat and for whom it is not contraindicated can be encouraged to do so. A transition from liquids to easy-to-digest foods may be necessary during a period of days. Patients who cannot meet their needs by the oral route can be maintained by a combination of EN and oral intake.

### ORAL SUPPLEMENTS

The most common types of oral supplements are commercial formulas meant primarily to augment the intake of solid foods. They often provide approximately 250 kcal/8-oz or 240-mL portion and approximately 8 to 14 g of intact protein. Some products have 360 or 500 or as much as 575 kcal in a can. There are different types of products for different disease states.

Fat sources are often long-chain triglycerides, although some supplements contain MCTs. More concentrated and thus more nutrient-dense formulas are also available. A variety of flavors, consistencies, and modifications of nutrients are appropriate for various disease states. Some oral supplements provide a nutritionally complete diet if taken in sufficient volume.

The form of carbohydrate is a key factor to patient acceptance and tolerance. Supplements with appreciable amounts of simple carbohydrate taste sweeter and have higher osmolalities, which may contribute to gastrointestinal intolerance. Individual taste preferences vary widely, and normal taste is altered by certain drug therapies, especially chemotherapy. Concentrated formulas or large volumes can contribute to taste fatigue and early satiety. Thus both oral dietary intake and the actual intake of prescribed supplements should be monitored.

Oral supplements that contain hydrolyzed protein and free amino acids such as those developed for patients with renal, liver, and malabsorptive diseases tend to be mildly to markedly unpalatable, and acceptance by the patient

depends on motivation. Some of these formulas also lack sufficient vitamins and minerals and are not nutritionally complete.

Although commercially available supplements are most commonly used for convenience, modules of protein, carbohydrate, or fat or commonly available food items can produce highly palatable additions to a diet. As examples, liquid or powdered milk, yogurt, tofu, or protein powders can be used to enrich cereals, casseroles, soups, or milk shakes. Thickening agents are now used to add variety, texture, and aesthetics to pureed foods, which are used when swallowing ability is limited (see Chapter 41). Imagination and individual tailoring can increase oral intake, avoiding the necessity for more complex forms of nutrition support.

## NUTRITION SUPPORT IN LONG-TERM AND HOME CARE

### Long-Term Care

*Long-term care (LTC)* generally refers to a skilled nursing facility. Health care provided in this environment focuses on quality of life, self-determination, and management of acute and chronic disease. Indications for EN and PN are generally the same for older patients as for younger adults, and varies according to the age, gender, and disease state of the individual. PN and EN are often provided to these facilities by offsite pharmacies that specialize in LTC. These providers may employ dietitians and specially trained nurses to assist the facilities with education and training on PEN.

**Advance directives** are legal documents that residents use to state their preferences about aspects of care, including those regarding the use of nutrition support. These directives may be written in any setting, including acute or home care, but are especially useful in LTC to guide interventions on behalf of long-term care residents when they are no longer able to make decisions.

Differentiation between the effects of advanced age versus malnutrition is an assessment challenge for dietitians working in long-term care (Raymond, 2006). This is an area of active research, as is the influence that nutrition support has on the quality of life among long-term care residents. Studies generally show that use of nutrition support in older adults is beneficial, especially when used in conjunction with physical activity. However, when there is a terminal illness or condition, starting nutrition support may have no advantage and may prolong suffering in some cases. It is prudent for dietitians to be involved in ethical decisions according to the policies of their institutions.

### Home Care

**Home enteral nutrition (HEN)** or **home parenteral nutrition (HPN)** support usually entails the provision of nutrients or formulas, supplies, equipment, and professional clinical services. Resources and technology for safe and effective management of long-term enteral or parenteral therapy are widely available for the home-care setting. Although

home nutrition support has been available for more than 20 years, few outcome data have been generated. Because mandatory reporting requirements do not exist in the United States for patients receiving home nutrition support, the exact number of patients receiving this support is unknown.

The elements needed to implement home nutrition successfully include identification of appropriate candidates and a feasible home environment with responsive caregivers, a choice of a suitable nutrition support regimen, training of the patient and family, and a plan for medical and nutritional follow-up by the physician as well as by the home infusion provider (Box 14-7). These objectives are best achieved through coordinated efforts of an interdisciplinary team (see *Clinical Insight: Home Tube Feeding—Key Considerations*).

Patients receiving HEN may receive supplies only, or formula and supplies with or without clinical oversight by the provider. Many enteral patients receive services from a **durable medical equipment (DME) provider** that may or may not provide clinical services. A home infusion provider provides intravenous therapies, including home PN, intravenous antibiotics, and other therapies. Home nursing agencies may be associated with a DME company or a home infusion agency to provide nursing services to home EN or PN patients. Often the patient's reimbursement source for home therapy plays a major role in determining the type of home infusion provider. In fact, reimbursement is a key component of a patient's ability to receive home therapy of any kind and should be evaluated early in the care plan so that appropriate decisions can be made prior to discharge or initiating a therapy (Wojtylak, 2007).

Companies that provide home infusion services for EN or PN may be private or affiliated with acute care facilities. Criteria for selecting a home-care company to provide nutrition support should be based on the company's ability

### BOX 14-7

#### Considerations When Deciding on Home Nutrition Support

Sanitation of the home environment to preserve the patient's health and reduce risk of infection

Potential for improvement in quality of life and nutritional status

The financial and time commitment needed by patient or family; potential loss of income outside the home in some cases

Ability to understand the techniques for administration of the product and safe use of all equipment and supplies

Any physical limitations that prevent the implementation of HEN or HPN therapy

Capacity for patient or caregiver to contact medical services when needed

HEN, Home enteral nutrition; HPN, home parenteral nutrition.

 CLINICAL INSIGHT

## Home Tube Feeding—Key Considerations

### What Is the Best Kind of Tube?

In general, nasal tubes should be avoided because they are more difficult to manage, clog easily, are easily dislodged, and over time can cause tissue irritation and even erosion. PEG tubes are now the most common and preferred method for home tube feedings. They can be either low-profile (flat to the abdomen), button-type tubes, or they can have a short piece of tubing attached through the abdomen and into the stomach. The button tubes require some manual dexterity to access and can be difficult to use for patients who are very obese. **Percutaneous endoscopic jejunostomy (PEJ)** tubes are best for patients who require postpyloric feedings as a result of intolerance of gastric feeding, but PEJ feedings require a pump, which severely limits mobility of the patient.

### What Is the Best Method of Administration?

Bolus feeding is the easiest administration method and should generally be tried first. It should be started slowly at half of an 8-oz can four to six times a day. If bolus feeding is not tolerated, gravity feeding is a second option. It does require a bag and pole, but can be accomplished fairly quickly and requires less manual dexterity than bolus feeding.

Pump feeding is sometimes necessary when a patient requires small amounts of formula delivered slowly. Although

it is well tolerated, it has major implications for a patient at home because even the simplest pump is often viewed as “high tech.” Its use greatly limits mobility, and, like any piece of equipment, it can break and interrupt feeding schedules.

### What is the Best Way to Educate the Patient and Caregiver?

Directions should be written in common measurements such as cups, tablespoons, and cans rather than milliliters. The enteral nutrition regimen should be as simple as possible; use whole cans of formula rather than partial cans.

Additives to the feedings should be minimized to avoid confusion and clogging of the feedings tubes.

Provide clear directions for gradually increasing to the goal feeding rate.

Provide clear directions for water flushing of the tube and for additional water requirements to prevent dehydration.

Discuss common problems that may come up and provide guidance for resolving them.

Make sure that the patient or caregiver can demonstrate understanding of the feeding process by either explaining it or by doing it.

### CLINICAL SCENARIO

A 24-year-old has newly diagnosed type 1 diabetes mellitus and Crohn's disease. She recently had surgery for removal of one third of her ileum. She is 75% of her usual weight, which is 125 lb; she is 65 inches tall. She requires specialized nutrition support for several months until her body adapts to the shortened bowel.

#### Nutrition Diagnostic Statements

- Involuntary weight loss related to poor intake, surgery, and pain during flare-up of Crohn's disease as evidenced by 25% weight loss.
- Inadequate oral food and beverage intake related to recent ileal resection as evidenced by 75% of usual weight and need for artificial nutrition.

#### Nutrition Care Questions

1. What immediate nutrition support method would be recommended?
2. What long-term nutrition support plan is likely to be designed?
3. What specialty products, if any, might be beneficial?
4. What parameters would you monitor to determine tolerance and response to the nutrition plan?

## ETHICAL ISSUES

Whether to provide or withhold nutrition support is often a central issue in “end-of-life” decision making. For patients who are terminally ill or in a persistent vegetative state, nutrition support can extend life to the point that issues of quality of life and the patient's right to self-determination come into play. Often surrogate decision makers are involved in treatment decisions. The nutrition support practitioner has a responsibility to know whether documentation, such as a living will regarding the patient's wishes for nutrition support, is in the medical record and whether counseling and support resources for legal and ethical aspects of patient care are available to the patient and his or her significant others.

# Education and Counseling: Behavioral Change

### KEY TERMS

alignment  
ambivalence  
**behavior change**  
**behavior modification**  
**cognitive behavioral therapy (CBT)**  
**cultural competency**  
discrepancy  
**double-sided reflection**  
empathy  
**health belief model (HBM)**  
**health literacy**  
maleficence

**motivational interviewing (MI)**  
negotiation  
normalization  
peer educator  
reflective listening  
reframing  
self-efficacy  
self-management  
self-monitoring  
**social cognitive theory (SCT)**  
**stages of change**  
**theory of planned behavior (TPB)**  
**transtheoretical model (TTM)**

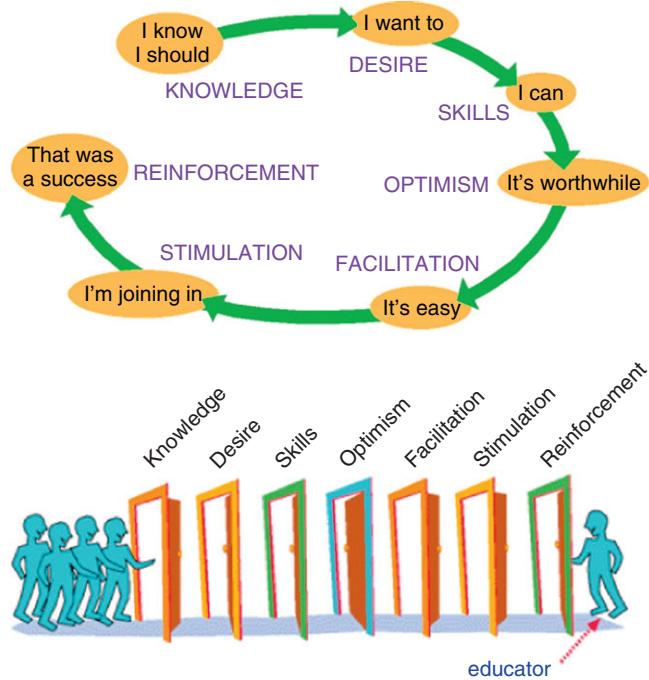

Key factors in changing nutrition behavior are the person's awareness that a change is needed and the motivation to change. Nutrition education and nutrition counseling both provide information and motivation, but they do differ. *Nutrition education* can be individualized or delivered in a group setting; it is usually more preventive than therapeutic, and there is a transmission of knowledge. *Counseling* is most often used during medical nutrition therapy, one on one. In the one-on-one setting, the nutritionist sets up a transient support system to prepare the client to handle social and personal demands more effectively while identifying favorable conditions for change. The goal of nutrition counseling is to help individuals make meaningful changes in their dietary behaviors.

Sections of this chapter were written by Linda Snetselaar, PhD, RD for the previous edition of this text

### BEHAVIOR CHANGE

Although there are differences between education and counseling as intervention techniques, the distinctions are not as important as the desired outcome, behavior change.

**Behavior change** requires a focus on the broad range of activities and approaches that affect the individual choosing food and beverages in his or her community and home environment. **Behavior modification** implies the use of techniques to alter a person's behavior or reactions to environmental cues through positive and negative reinforcement, and extinction of maladaptive behaviors. In the context of nutrition, both education and counseling can assist the individual in achieving short-term or long-term health goals. Education provides the knowledge and skills needed to change; counseling is aimed at the other steps shown in Figure 15-1.

**FIGURE 15-1** Seven steps to behavior change. (Accessed 31 May 2010 from <http://www.comminit.com/en/node/201090>.)

## Factors Affecting the Ability to Change

Multiple factors affect a person's ability to change, the educator's ability to teach new information, and the counselor's ability to stimulate and support small changes. Inability to afford nutrition counseling, unstable living environments, inadequate family or social support, expensive food costs, insufficient transportation, and low literacy are some of the socioeconomic factors that may be barriers for obtaining and maintaining a healthy diet. With a population that is culturally diverse, it is imperative to appreciate the differences in beliefs or understanding that may lead to the inability to change.

Physical and emotional factors also make it hard to change, especially for seniors. Older adults need education and counseling programs that address low vision, poor hearing, limited mobility, decreased dexterity, and memory problems or cognitive impairments (Kamp et al., 2010).

Trust and respect are essential for all helping relationships. The quality of the provider-patient relationship can have either a positive or a negative effect on the outcome of the sessions. If a treatment plan is complex and not understood, decreased adherence is likely. When uncertain of comprehension, asking a few questions can be quite helpful to identify gaps in the patient's knowledge, understanding, or motivation.

## Cultural Competency

The health care community was the first to promote **cultural competency** and, although there is no agreement on its exact definition, it is fair to say it involves cultural sensitivity or awareness. It requires respecting and understanding the attitudes, values, and beliefs of others; willingness to use

cultural knowledge while interacting with clients; and consideration of culture during discussions and recommendations (Ulrey and Amason, 2001). Culture encompasses more than race, religion, or ethnicity; it includes community perspectives and perceptions. Care must be taken not to label people with a stereotype (Stein, 2009).

Gregg et al. (2006) define the following five tenets as the basis for cultural competency:

- Understanding the role of culture. Learning the skills to elicit patients' individual beliefs and interpretations and to negotiate conflicting beliefs is important to good patient care, regardless of the social, ethnic, or racial backgrounds of the patient.
- Learning about culture and becoming "culturally competent" is not a panacea for health disparities.
- *Culture, race, and ethnicity* are distinct concepts. Just learning about the culture will not eliminate racism.
- Culture is mutable and multiple; any understanding of a particular cultural context is always incompletely true, always somewhat out of date, and partial.
- Context is critical. Because culture is so complex, so shape-shifting, and so ultimately inseparable from its social and economic context, it is impossible to consider it as an isolated or static phenomenon.

Multicultural awareness is the first step toward establishing rapport and becoming a competent nutrition educator or counselor. It is important to evaluate one's own beliefs and attitudes and become comfortable with differences among racial, ethnic, or religious beliefs, culture, and food practices (*Clinical Insight: The Counselor Looks Within*). Heightening awareness of personal biases and increasing sensitivity allows the counselor to be more effective in understanding what the client may need to move forward.

Implementation of a cultural competency in interactions with patients or clients may seem like a very time-consuming challenge, without readily available resources in some cases. However, having this skill will in the end result in a more thorough communication with the patient or client and ultimately a better outcome. The Joint Commission continues to strengthen guidelines related to communication and cultural competency with guidelines and roadmaps for hospitals (The Joint Commission, 2010). Cultural competency is expected to be added as a Joint Commission standard in the future (Stein, 2009).

## Communication

One of the most essential competencies in the delivery of health care is effective multicultural communication. The United States will continue to become more diverse. By the year 2050, it is estimated that almost 25% of the total U.S. population will be Hispanic. Of those who are non-Hispanic, projections for 2050 reflect a population that is 72.1% white, 14.6% black, and 8% Asian (Shrestha, 2010). Each culture has values, ideas, assumptions, and beliefs about life and a common system of encoding and decoding verbal and nonverbal messages (Ulrey and Amason, 2001).

Language is always important in communication. Although knowing several languages can be an asset, many will rely on translators. Unofficial translators, such as family or friends, are not usually a good choice because of a lack of understanding of nutrition and health. Using professional translators is also not without limitations in that the educator needs to understand not only the client but also the interpreter. The educator should maintain contact with the client and explain the role of the interpreter (Mossavar-Rahmani, 2007). When working with clients who

have limited ability to speak and understand English, always use common terms, avoiding slang and words with multiple meanings. Always speak directly to the client, even when using a translator, and watch the client for nonverbal responses during the translation.

Communication not only encompasses language but also the context in which words are interpreted, including posture, gestures, concepts of time, spatial relationships, the role of the individual within a group, status and hierarchy of persons, and the setting (Satia-About et al., 2002). Nonverbal messages convey information about relationships. The way in which cultures combine verbal and nonverbal messages to transmit a message determines the context of the communication (Kittler and Sucher, 2007). Spatial relationships vary among cultures and among individuals. Movements such as gestures, facial expressions, and postures are often the cause of confusion and misinterpretations in intercultural communication. Good posture is an important sign of respect in nearly all cultures. Rules regarding eye contact are usually complex and vary according to issues such as gender, distance apart, and social status (*Clinical Insight: Body Language and Communication Skills*).

All counselors should be empathetic, genuine, and respectful. A good way to begin communication is by finding out how the client prefers to be addressed. Although in America it is common to call strangers and acquaintances by their given names, nearly all other cultures expect a more respectful approach. Listening sensitively, sharing control, accepting differences, demonstrating sincere concern, respecting other cultures, seeking feedback, and being natural and honest are strategies important to achieving client compliance and satisfaction (Patterson, 2004). Use of these techniques helps make the counseling sessions more effective and satisfying for both parties.

## CLINICAL INSIGHT

### The Counselor Looks Within

Before entering a counseling relationship and after reflecting on the session, the nutritionist should look inward and consider any factors that affect his or her own thinking and how they might affect the client. The nutritionist should reflect on ethical issues, such as the autonomy of the client, and beneficence versus **maleficence** (harm). An example may be when a female client decides not to set goals for her blood glucose levels and not to learn the amounts of carbohydrates in foods (autonomy). These choices serve as barriers to the benefit the counselor would make in teaching these **self-management** tools (beneficence) and the need for nonmaleficence (do no harm). Whenever clients decide a behavior change is not right for them, the counselor's role is not to force the issue but to encourage its future consideration.

## CLINICAL INSIGHT

### Body Language and Communication Skills

Active listening forms the basis for effective nutrition counseling. There are two aspects to effective listening: nonverbal and verbal. Nonverbal listening skills consist of varied eye contact, attentive body language, a respectful but close space, adequate silence, and encouragers. Eye contact is direct yet varied. Lack of eye contact implies that the counselor is too busy to spend time with the client. When the counselor leans forward slightly and has a relaxed posture and avoids fidgeting and gesturing, the client will be more at ease. Silence can give the client time to think and provide time for the counselor to contemplate what the client has said. Shaking one's head in agreement can be a positive encourager, leading to more conversation. Moving forward slightly toward the client is an encourager that allows for more positive interaction.

Verbal components of listening include keeping the focus on the client by demonstrating a willingness to listen. Often

the nutritionist feels obligated to solve a problem or give advice. These two desires can decrease the time left for active listening. Emphasize questions that are open to detailed descriptions. Use questions that begin with "what," "how," "why," and "could."

Two types of encouragers are important in counseling: paraphrasing and summarizing. Paraphrasing is a brief repeat of the essence of what the speaker has said, using fresh and concise wording. It is not parroting or word swapping. Paraphrasing is not easy and requires careful listening and caring. Summarizing is lengthier than paraphrasing because it uses more information and summarizes what has been said during a longer period. In general, it is important to establish the interactive relationship before beginning the actual process of nutrition counseling.

## Message Framing

The way in which a message is framed can influence its persuasiveness and effectiveness. Framing a message in a positive way focuses on the positive aspects of change; framing it with a negative spin highlights what could be lost without the change. By observing the community in which one practices, the counselor can adjust his or her comments accordingly. Visiting a grocery store, restaurants in the neighborhood, schools, or social centers will help the nutritionist understand the client's perspective. For example, knowing that fresh produce is not readily available from the local grocery store, the counselor may discuss the benefits of using canned or frozen vegetables instead of praising only the benefits of raw vegetables.

Messages and materials must be available for various educational levels, English language proficiencies, geographic locations, sexual orientation (lesbian, gay, bisexual, transgender), and folk customs and beliefs. Instructional information should be simple, clear, and free from bias in content and use of graphics or pictures.

## Health Literacy

Low **health literacy** is common among older adults, minorities, and those who are medically underserved or have a low socioeconomic status (Health Resources and Services Administration, 2010). This problem can lead to poor management of chronic health conditions, as well as low adherence to recommendations. The counselor should be careful

to avoid jargon and to use language or examples that have relevance to the client. Although there are many guidelines for writing health materials at lower literacy levels, oral communication requires interactive dialogue for assessment of the client's understanding and ability to absorb potentially complex concepts. Relying on the client's educational attainment provides some guidance, but asking the client to repeat explanations in his or her own words can also help the nutrition educator evaluate the client's level of understanding. Useful resources from the Agency on Healthcare Research and Quality are *Rapid Estimate of Adult Health Literacy in Medicine (REALM)* and *Short Assessment of Health Literacy for Spanish Adults (SAHLSA-50)* (Agency on Healthcare Research and Quality, 2010).

## Models for Behavior Change

Changing behavior is the ultimate goal for nutrition counseling and education. Simply providing a pamphlet or a list of foods usually does not change eating behavior. Because so many different factors influence what someone eats, nutritionists have been learning from behavioral scientists to identify and intervene based on mediators of people's eating behavior. Health professionals can support individuals in deciding what and when to change by using a variety of health behavior theories. Some of the most common theories for behavior change are listed in **Table 15-1**, with examples described in the following paragraphs.

**TABLE 15-1**

### Overview of Behavior Theories Used in Nutrition Education and Counseling

Health Belief Model (HBM)	Perceived susceptibility: an individual's belief regarding the chance that he or she may get a condition or disease Perceived severity: an individual's belief of how serious a condition and its consequences are Perceived benefits: an individual's belief in the positive effects of the advised action in the reducing risk or the seriousness of a condition Perceived barriers: an individual's belief about the tangible and psychological costs of the advised action Self-efficacy: an individual's belief that he or she is capable of performing the desired action Cues to action: strategies to activate one's readiness to change a behavior
Social Cognitive Theory (SCT)	Personal factors: outcome expectations, self-efficacy, reinforcements, impediments, goals and intentions, relapse prevention Behavioral factors: knowledge and skills, self-regulation and control, and goal setting Environmental factors: include imposed, selected, and created environments Subjective norms: the people who may influence the patient Attitudes: what the patient thinks about the behavior
Theory of Planned Behavior (TPB)	Perceived control: how much control the patient has to change things that affect the behavior Behavioral intention: whether the patient plans to perform the behavior Precontemplation: The individual has not thought about making a change. Contemplation: The individual has thought about making a change but has done no more than think about it.
Transtheoretical Model (TM), or Stages of Change Model	Preparation: The individual has taken some steps to begin to make the desired change. Action: The individual has made the change and continues it for less than 6 months. Maintenance: The individual has continued the behavior for longer than 6 months. Termination: The individual no longer thinks about the change; it has become a habit.

## Health Belief Model

The **health belief model (HBM)** focuses on a disease or condition, and factors that may influence behavior related to that disease (Contento, 2007). The HBM has been used most with behaviors related to diabetes and osteoporosis, focusing on barriers to and benefits of changing behaviors (Sedlak et al., 2007; Tussing and Chapman-Novakofski, 2005).

## Social Cognitive Theory

**Social cognitive theory (SCT)** represents the reciprocal interaction among personal, behavioral, and environmental factors (Bandura, 1977, 1986). This theory is quite extensive and includes many variables; some of the most important to counseling include self-efficacy, goal setting, and relapse prevention.

## Transtheoretical Model of Change

The **transtheoretical model (TTM)**, or **stages of change** model, has been used for many years to alter addictive behaviors. TTM describes behavior change as a process in which individuals progress through a series of six distinct stages of change, as shown in Table 15-1 (Prochaska et al., 1992; Prochaska and DiClemente, 1982; Sigman-Grant, 1996). The value of the TTM is in determining the individual's current stage, then using change processes matched to that stage (Resnicow et al., 2006). Recently, however, the effectiveness of the TTM has been questioned (Salmela et al., 2009).

## Theory of Planned Behavior

The **theory of planned behavior (TPB)** is based on the concept that intentions predict behavior (Ajzen, 1991). Intentions are predicted by attitudes, subjective norms (important others), and perceived control. This theory is most successful when a discrete behavior is targeted (e.g. milk consumption), but has also been used for healthy diet consumption (Brewer et al., 1999; Pawlak et al., 2009).

## COUNSELING STRATEGY: COGNITIVE BEHAVIORAL THERAPY

**Cognitive behavior therapy (CBT)** can be used to help individuals develop skills to achieve healthier eating habits. Instead of helping to decide *what* to change, it helps to identify *how* to change thinking, behavior, and communication. Lifestyle modification can be time-consuming and skill-intensive, but new methods include use of the Internet and cognitive therapy to alter distorted thinking. CBT can be used for obesity treatment to promote and encourage self-care among patients, or for managing chronic diseases such as diabetes or cardiovascular disease.

Many textbooks describe the CBT process. For example, for a textbook on eating disorders describes steps such as shaping concerns and mindsets, managing dietary restraint and rules, and handling events and moods related to eating

(Fairburn et al., 2003). CBT counselors can help clients explore troubling themes, strengthen their coping skills, and focus on their well being. The CBT process is practical, action-oriented, and goal-directed. CBT training is available from many universities or centers for cognitive therapy (National Alliance on Mental Illness, 2010).

## COUNSELING STRATEGY: MOTIVATIONAL INTERVIEWING

**Motivational interviewing (MI)** has been used to encourage clients to identify discrepancies between how they would like to behave and how they are behaving, and then motivate them to change (Miller and Rollnick, 2002). Studies point to the positive influence of MI on changes in dietary behavior, either alone or in combination with other strategies. These include increases in self-efficacy in relation to dietary changes, increased fruit and vegetable intake, and decreased body mass index. As with any strategy, better outcomes were associated with longer interventions and increased number of counseling session (Martins and McNeil, 2009). The following are principles used in MI to enhance behavior change.

### Expressing Empathy

**Empathy**, nutrition counselor acceptance of what a client feels in times of turmoil, can often result in change. Acceptance facilitates change. Beyond this acceptance is a skillful form of **reflective listening**, which allows the client to describe thoughts and feelings, while the nutritionist reflects back understanding. Many clients have no one with whom to discuss problems in their lives. This opportunity to have someone listen and understand the emotions behind the words is crucial to eventual dietary change.

As clients review situations in their lives and lack of time for dietary changes, the nutrition counselor will hear **ambivalence**. On the one hand, clients want to make changes; on the other hand, they want to pretend that change is not important. Ambivalence is normal.

*Client: I feel totally worthless. On one hand, I want to follow this new eating pattern, and on the other; I want to eat spontaneously, not worrying about decreasing my fat intake.*

*Nutrition Counselor: Your feelings are normal. You are having a difficult time merging new and old habits. This happens to many people.*

### Developing Discrepancy

An awareness of consequences is important. Identifying the advantages and disadvantages of modifying a behavior, or developing **discrepancy**, is a crucial process in making changes.

*Client: I want to follow the new eating pattern, but I just can't afford it.*

*Nutrition Counselor: Let's look at your diet record and discuss some healthy, low-cost changes.*

## Rolling with Resistance (Legitimation, Affirmation)

Invite new perspectives without imposing them. The client is a valuable resource in finding solutions to problems. Perceptions can be shifted, and the nutrition counselor's role is to help with this process. For example, a client who is wary of describing why she is not ready to change may become much more open to change if she sees openness to her resistive behaviors. When it becomes okay to discuss resistance, the rationale for its original existence may seem less important.

*Client: I just feel that my level of enthusiasm for following the diet is low. It all seems like too much effort.*

*Nutrition Counselor: I appreciate your concerns. At this point in following a new diet, many people feel the same way. Tell me more about your concerns and feelings.*

## Supporting Self-Efficacy

Belief in one's own capability to change is an important motivator. The client is responsible for choosing and carrying out personal change. However, the nutrition counselor can support **self-efficacy** by having the client try behaviors or activities while the counselor is there.

*Client: I just don't know what to buy once I get to the grocery store. I end up with hamburger and potato chips.*

*Nutrition Counselor: Let's think of one day's meals right now. Then we can make a grocery list from that.*

## First Session

The first session of a one-on-one educational intervention establishes the counseling relationship. The environment should be conducive to privacy, and there should be a plan for reduction of interruptions (e.g., no telephone calls). The counselor should be seated in a manner that reflects interest in the client, such as sitting directly across from one another in chairs without a desk as a barrier. In this first session, it is most important to establish rapport and invite input from the client.

### Establishing Rapport

To build rapport, one begins by asking how the client prefers to be addressed.

*"Good afternoon Mrs. Jones. My name is Ms. Kathy Smith. Please call me Kathy. Do you prefer I use Mrs. Jones, or your first name as we talk?"*

It is acceptable to ask one or two questions that are relevant to important aspects of the client's life or conversational to allow the client to adjust.

*"I see you live in \_\_\_\_\_. Have you always lived there?"*

*"The traffic has been really bad with all the road repair. Did you have a difficult time getting here?"*

Some clients may choose very little conversation, while others are quite talkative. At some point, the nutrition counselor needs to move the conversation to the point of the visit.

*"We have about \_\_\_\_\_ minutes to meet today. I thought we might talk about how you're doing with your dietary changes. How does this sound to you?"*

In an initial visit, the counselor introduces the subject of the session and invites the client to contribute. The following are sample conversations:

*"The purpose of this visit is to see how you are doing in covering your dietary carbohydrate intake with insulin." (SCT, self-efficacy)*

*"In looking at your monitoring tools, it seems that you have had excellent progress at some times and at other times it may have been more difficult. Is there an area in particular that you'd like to work on?"*

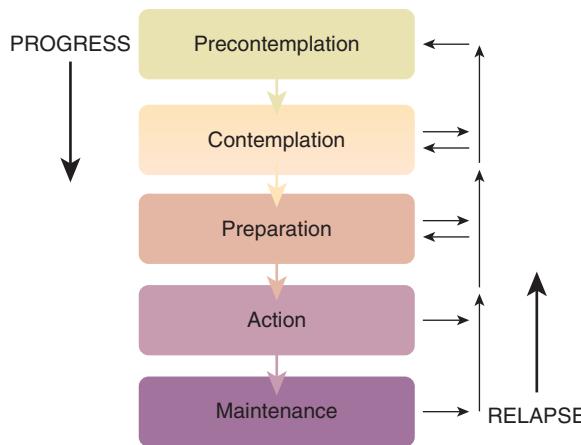

*"Could we talk about your diet records to identify problems we could solve?" (HBM, perceived barriers)*

Although not every first session lends itself to an assessment of the client's readiness to change, at some point after the topic has been agreed upon, the counselor must assess if the client is ready to change. To identify in which of these three stages a client is, see Figure 15-2.

It may be difficult to build rapport with some clients. Someone who appears hostile, unusually quiet, or dismissive may have more success with either a different nutritionist or with someone with whom he or she has background in common. In those cases, working with a peer educator may be most effective. The **peer educator** should ideally share similarities with the target population in terms of age or ethnicity, and have primary experience in the nutrition topic (e.g., has breastfed her infant) (Pérez-Escamilla et al., 2008). Peer educators are usually community health workers or paraprofessionals. The Expanded Food and Nutrition Education Program (EFNEP) has demonstrated the effectiveness and cost efficiency of peer educators (Dollahite et al., 2008). In prenatal or WIC clinics, breastfeeding peer counselors are often highly effective in helping new mothers with their questions and concerns.

## Assessment Results: Choosing Focus Areas

The purpose of assessment is to identify the client's stage of change and to provide appropriate help in facilitating change. The assessment should be completed in the first visit if possible. If conversation extends beyond the designated time for the session, the assessment steps should be completed at the next session. The nutritional assessment requires gathering the appropriate anthropometric, biochemical, clinical, dietary, and economic data relating to the

**FIGURE 15-2** A model of the stages of change. In changing, a person progresses down these steps to maintenance. If relapse occurs, he or she gets back on the steps at some point and works down them again.

client's condition. The nutritional diagnosis then focuses on any problems related to food or nutrient intake.

Determining present eating habits provides ideas on how to change in the future. It is important to review the client's eating behavior, to identify areas needing change, and to help the client select goals that will have the most effect on health conditions. For instance, if the nutrition diagnosis includes excessive fat intake (nutrient intake [NI]-5102), inappropriate intake of food fats (NI-51.3), excessive energy intake (NI-1.5), inadequate potassium intake (NI-55.1), food- and nutrition-related knowledge deficit (nutrition behavior [NB]-1.1), and impaired ability to prepare foods or meals (NB-2.4), the counselor may need to focus on the last diagnosis before the others. If all other diagnoses are present except impaired ability to prepare foods or meals (NB-2.4), the nutritionist may want to have a discussion about whether excessive fat intake, inappropriate intake of types of food fats, or excessive energy intake are more appealing or possible for the client to focus on first.

### Assessment of Readiness to Change

Once the nutrition diagnosis is selected for intervention, it is important to assess readiness for changes. Using a ruler that allows the client to select his or her level of intention to change is one method of allowing client participation in the discussion. The counselor asks the client, "On a scale of 1 to 12, how ready are you right now to make any new changes to eat less fat? (1 = not ready to change; 12 = very ready to change)." The nutritionist may use this method with each nutrition diagnosis to help the client decide where to focus first.

Three possibilities for readiness exist: (1) not ready to change; (2) unsure about change; (3) ready to change. These three concepts of readiness have condensed the six distinct stages of change described in this chapter to assist the counselor in determining the level of client readiness. There are many concepts to remember, and readiness to change may

fluctuate during the course of the discussion. The counselor must be ready to move back and forth between the phase-specific strategies. If the client seems confused, detached, or resistant during the discussion, the counselor should return and ask about readiness to change. If readiness has lessened, tailoring the intervention is necessary. Not every counseling session has to end with the client's agreement to change; even the decision to think about change can be a useful conclusion.

## NOT-READY-TO-CHANGE COUNSELING SESSIONS

In approaching the "not-ready-to-change" stage of intervention, there are three goals: (1) facilitate the client's ability to consider change, (2) identify and reduce the client's resistance and barriers to change, and (3) identify behavioral steps toward change that are tailored to each client's needs. At this stage identifying barriers (HBM), the influence of subjective norms and attitudes (TPB), or personal and environmental factors (SCT) that may have negative influences on the intention to change can be helpful. To achieve these goals, several communication skills are important to master: asking open-ended questions, listening reflectively, affirming the patient's statements, summarizing the patient's statements, and eliciting self-motivational statements.

### Asking Open-Ended Questions

Open-ended questions allow the client to express a wider range of ideas, whereas closed questions can help in targeting concepts and eliminating tangential discussions. For the person who is not ready to change, targeted discussions around difficult topics can help focus the session. The nutritionist asks questions that must be answered by explaining and discussing, not by one-word answers. This is particularly important for someone who is not ready to change, because it opens the discussion to problem areas that keep the client from being ready. The following statements and questions are examples that create an atmosphere for discussion:

- "We are here to talk about your dietary change experiences to this point. Could you start at the beginning and tell me how it has been for you?" (SCT, personal factors)
- "What are some things you would like to discuss about your dietary changes so far? What do you like about them? What don't you like about them?" (TPB, attitudes)

### Reflective Listening

Nutrition counselors not only listen but also try to tag the feelings that surface as a client is describing difficulties with an eating pattern. Listening is not simply hearing the words spoken by the client and paraphrasing them back. Figure 15-3 shows a nutrition counselor listening reflectively to her client.

**FIGURE 15-3** This nutrition counselor is using reflective listening techniques with her client.

Reflective listening involves a guess at what the person feels and is phrased as a statement, not a question. By stating a feeling, the nutrition counselor communicates understanding. The following are three examples of listening reflectively:

*Client: "I really do try, but I am retired and my husband always wants to eat out. How can I stay on the right path when that happens?"*

*Nutrition Counselor: "You feel frustrated because you want to follow the diet, but at the same time you want to be spontaneous with your husband. Is this correct?" (reflective listening; TPB, subjective norms; HBM, barriers; SCT, personal factors)*

*Client: "I feel like I let you down every time I come in to see you. We always discuss plans and I never follow them. I almost hate to come in."*

*Nutrition Counselor: "You are feeling like giving up. You haven't been able to modify your diet, and it is difficult for you to come into our visits when you haven't met the goals we set. Is this how you are feeling?" (reflective listening) Can you think of a specific time when you feel that you had an opportunity to achieve your plan, but didn't?" (HBM, barriers)*

*Client: "Some days I just give up. It is on those days that I do very badly in following my diet."*

*Nutrition Counselor: "You just lose the desire to try to eat well on some days and that is very depressing for you. Do I have that right?" (rephrasing) "Are those days when something in particular has happened? (HBM, barriers)*

## Affirming

Counselors often understand the idea of supporting a client's efforts at following a new eating style but do not put those thoughts into words. When the counselor affirms someone, there is alignment and normalization of the client's issues. In **alignment** the counselor tells the client that he or she understands these difficult times. **Normalization**

means telling the client that he or she is perfectly within reason and that it is very normal to have such reactions and feelings. The following statements indicate affirmation:

- "I know that it is hard for you to tell me this. But thank you."
- "You have had amazing competing priorities. I feel that you have done extremely well, given your circumstances."
- "Many people I talk with express the same problems. I can understand why you are having difficulty."

## Summarizing

The nutrition counselor periodically summarizes the content of what the client has said by covering all the key points. Simple and straightforward statements are most effective, even if they involve negative feelings. If conflicting ideas arise, the counselor can use the strategy exemplified by the statement, "On the one hand you want to change, but love those old eating patterns." This helps the client recognize the dichotomy in thinking that often prevents behavior change.

## Eliciting Self-Motivational Statements

The four communication strategies (asking open-ended questions, listening reflectively, affirming, and summarizing) are important when eliciting self-motivational statements. The goal here is for the client to realize that a problem exists, that concern results, and that positive steps in the future can be taken to correct the problem. The goal is to use these realizations to set the stage for later efforts at dietary change. Examples of questions to use in eliciting self-motivational feeling statements follow.

### Problem Recognition

- "What things make you think that eating out is a problem?"
- "In what ways has following your diet been a problem?"

### Concern

- "How do you feel when you can't follow your diet?"
- "In what ways does not being able to follow your diet concern you?"
- "What do you think will happen if you don't make a change?"

### Intention to Change

- "The fact that you're here indicates that at least a part of you thinks it's time to do something. What are the reasons you see for making a change?"
- "If you were 100% successful and things worked out exactly as you would like, what would be different?"
- "What things make you think that you should keep on eating the way you have been?" And in the opposite direction, "What makes you think it is time for a change?"

## Optimism

- “What encourages you that you can change if you want to?”
- “What do you think would work for you if you decided to change?”

Clients in this “not-ready-to-change” category have already told the counselor they are not doing well at making changes. Usually if a tentative approach is used by asking permission to discuss the problem, the client will not refuse. One asks permission by saying, “Would you be willing to continue our discussion and talk about the possibility of change?” At this point, it is helpful to discuss thoughts and feelings about the current status of dietary change by asking open-ended questions:

- “Tell me why you picked \_\_\_\_\_ on the ruler.” (Refer to previous discussion on the use of a ruler.)
- “What would have to happen for you to move from a \_\_\_\_\_ to a \_\_\_\_\_ (referring to a number on the ruler)? How could I help get you there?”
- “If you did start to think about changing, what would be your main concern?”

To show real understanding about what the client is saying, it is beneficial to summarize the statements about his or her progress, difficulties, possible reasons for change, and what needs to be different to move forward. This paraphrasing allows the client to rethink his or her reasoning about readiness to change. The mental processing provides new ideas that can promote actual change.

## Ending the Session

Counselors often expect a decision and at least a goal-setting session when working with a client. However, it is important in this stage to realize that traditional goal setting will result in feelings of failure on both the part of the client and the nutritionist. If the client is not ready to change, respectful acknowledgment of this decision is important. The counselor might say, “I can understand why making a change right now would be very hard for you. The fact that you are able to indicate this as a problem is very important, and I respect your decision. Our lives do change, and, if you feel differently later on, I will always be available to talk with you. I know that, when the time is right for you to make a change, you will find a way to do it.” When the session ends, the counselor will let the client know that the issues will be revisited after he or she has time to think. Expression of hope and confidence in the client’s ability to make changes in the future, when the time is right, will be beneficial. Arrangements for follow-up contact can be made at this time.

With a client who is not ready to change it is easy to become defensive and authoritarian. At this point, it is important to avoid pushing, persuading, confronting, coaxing, or telling the client what to do. It is reassuring to

## → NEW DIRECTIONS

### Dietitian Counselor as Life Coach

By Marjorie Geiser, RD, NSCA-CPT

More and more registered dietitian (RD) nutrition counselors are turning to life coaching to enhance nutrition counseling skills and increase client success. Coaching moves the focus away from the RD as the expert who tells the client what to do, to realizing that clients do know how they want to accomplish their goals. Many clients already know the information the RD provides, but the RD can be most valuable by helping them apply that information. Life coaching involves asking questions to help clients look within to answer the questions they didn’t think of. It is not therapy; it is simply asking questions without an agenda. It is taking the client from where he or she is currently to where he or she wants to be. It is helping the client accomplish more sooner.

a nutritionist to know that change at this level will often occur outside the office. The client is not expected to be ready to do something during the visit (see *New Directions: Dietitian Counselor as Life Coach*).

## UNSURE-ABOUT-CHANGE COUNSELING SESSIONS

The only goal in the “unsure-about-change” session is to build readiness to change. This is the point at which changes in eating behavior can escalate. This “unsure” stage is a transition from not being ready to deal with a problem eating behavior to preparing to continue the change. It involves summarizing the client’s perceptions of the barriers to a healthy eating style and how they can be eliminated or circumvented to achieve change. Heightened self-efficacy may provide confidence that goals can be achieved. A restatement of the client’s self-motivational statements assists in setting the stage for success. The client’s ambivalence is discussed, listing the positive and negative aspects of change. The nutritionist can restate any statements that the client has made about intentions or plans to change or to do better in the future.

One crucial aspect of this stage is the process of discussing thoughts and feelings about current status. Use of open-ended questions encourages the client to discuss dietary change progress and difficulties. Change is promoted through discussions focused on possible reasons for change. The counselor might ask the question: “What would need to be different to move forward?”

This stage is characterized by feelings of ambivalence. The counselor should encourage the client to explore

ambivalence to change by thinking about “pros” and “cons.” Some questions to ask are:

- “What are some of the things you like about your current eating habits?”
- “What are some of the good things about making a new or additional change?”
- “What are some of the things that are not so good about making a new or additional change?”

By trying to look into the future, the nutrition counselor can help a client see new and often positive scenarios. As a change facilitator, the counselor helps to tip the balance away from being ambivalent about change toward considering change by guiding the client to talk about what life might be like after a change, anticipating the difficulties as well as the advantages. An example of an opening to generate discussion with the client might be: “I can see why you’re unsure about making new or additional changes in your eating habits. Imagine that you decided to change. What would that be like? What would you want to do?” The counselor then summarizes the client’s statements about the “pros” and “cons” of making a change and includes any statements about wanting, intending, or planning to change.

The next step is to negotiate a change. There are three parts to the **negotiation** process. The first is setting goals. Set broad goals at first and hold more specific nutritional goals until later. “How would you like things to be different from the way they are?” and “What is it that you would like to change?”

The second step in negotiation is to consider options. The counselor asks about alternative strategies and options and then asks the client to choose from among them. This is effective because, if the first strategy does not work, the client has other choices. The third step is to arrive at a plan, one that has been devised by the client. The counselor touches on the key points and the problems and then asks the client to write down the plan.

To end the session the counselor asks about the next step, allowing the client to describe what might occur next in the process of change. The following questions provide some ideas for questions that might promote discussion:

- “Where do you think you will go from here?”
- “What do you plan to do between now and the next visit?”

## RESISTANCE BEHAVIORS AND STRATEGIES TO MODIFY THEM

Resistance to change is the most consistent emotion or state when dealing with clients who have difficulty with dietary change. Examples of resistance behaviors on the part of the client include contesting the accuracy, expertise, or integrity of the nutrition counselor; or directly challenging the accuracy of the information provided (e.g., the accuracy of

the nutrition content). The nutrition counselor may even be confronted with a hostile client. Resistance may also surface as interrupting, when the client breaks in during a conversation in a defensive manner. In this case, the client may speak while the nutrition counselor is still talking without waiting for an appropriate pause or silence. In another, more obvious manner, the client may break in with words intended to cut off the nutrition counselor’s discussion.

When clients express an unwillingness to recognize problems, cooperate, accept responsibility, or take advice, they may be denying a problem. Some clients blame other people for their problems (e.g., a wife may blame her husband for her inability to follow a diet). Other clients may disagree with the nutrition counselor when a suggestion is offered, but they frequently provide no constructive alternative. The familiar “Yes, but ...” explains what is wrong with the suggestion but offers no alternative solution.

Clients try to excuse their behavior. A client may say, “I want to do better, but my life is in a turmoil since my husband died 3 years ago.” An excuse that was once acceptable is reused even when it is no longer a factor in the client’s life.

Some clients make pessimistic statements about themselves or others. This is done to dismiss an inability to follow an eating pattern by excusing poor compliance as just a given resulting from past behaviors. Examples are “My husband will never help me” or “I have never been good at sticking with a goal. I’m sure I won’t do well with it now.”

In some cases, clients are reluctant to accept options that may have worked for others in the past. They express reservations about information or advice given. “I just don’t think that will work for me.” Some clients will express a lack of willingness to change or an intention not to change. They make it very clear that they want to stop the dietary regimen.

Often clients show evidence that they are not following the nutrition counselor’s advice. Clues that this is happening include using a response that does not answer the question, providing no response to a question, or changing the direction of the conversation.

These types of behavior can occur within a counseling session as clients move from one stage to another. They are not necessarily stage-specific, although most are connected with either the “not ready” or “unsure-about-change” stages. A variety of strategies are available to assist the nutrition counselor in dealing with these difficult counseling situations. These strategies include reflecting, double-sided reflection, shifting focus, agreeing with a twist, emphasizing personal choice, and reframing. Each of these options is described in the following paragraphs.

### Reflecting

In reflecting, the counselor identifies the client’s emotion or feeling and reflects it back. This allows the client to stop and reflect on what was said. An example of this type of counseling is, “You seem to be very frustrated by what your husband says about your food choices.”

## Double-Sided Reflection

In **double-sided reflection**, the counselor uses ideas that the client has expressed previously to show the discrepancy between the client's current words and the previous ones. For example:

*Client: "I am doing the best I can." (Previously this client stated that she sometimes just gives up and doesn't care about following the diet.)*

*Nutrition Counselor: "On the one hand you say you are doing your best, but on the other hand I recall that you said you just felt like giving up and didn't care about following the diet. Do you remember that? How was that point in time different than now?"*

## Shifting Focus

Clients may hold onto an idea that they think is getting in the way of their progress. The counselor might question the feasibility of continuing to focus on this barrier to change when other barriers may be more appropriate targets. For example:

*Client: "I will never be able to follow a low-saturated fat diet as long as my grandchildren come to my house and want snacks."*

*Nutrition Counselor: "Are you sure that this is really the problem? Is part of the problem that you like those same snacks?"*

*Client: "Oh, you are right. I love them."*

*Nutrition Counselor: "Could you compromise? Could you ask your grandchildren which of this long list of low-saturated fat snacks they like and then buy them?"*

## Agreeing with a Twist

This strategy involves offering agreement, then moving the discussion in a different direction. The counselor agrees with a piece of what the client says but then offers another perspective on his or her problems. This allows the opportunity to agree with the statement and the feeling, but then to redirect the conversation onto a key topic. For example:

*Client: "I really like eating out, but I always eat too much, and my blood sugars go sky high."*

*Nutrition Counselor: "Most people do like eating out. Now that you are retired it is easier to eat out than to cook. I can understand that. What can we do to make you feel great about eating out so that you can still follow your eating plan and keep your blood glucose values in the normal range?"*

## Reframing

With **reframing** the counselor changes the client's interpretation of the basic data by offering a new perspective. The counselor repeats the basic observation that the client has

provided and then offers a new hypothesis for interpreting the data. For example:

*Client: "I gave up trying to meet my dietary goals because I was having some difficulties when my husband died, and I have decided now that I just cannot meet those strict goals."*

*Nutrition Counselor: "I remember how devastated you were when he died and how just cooking meals was an effort. Do you think that this happened as a kind of immediate response to his death and that you might have just decided that all of the goals were too strict at that time?" (Pause)*

*Client: "Well, you are probably right."*

*Nutrition Counselor: "Could we look at where you are now and try to find things that will work for you now to help you in following the goals we have set?"*

These strategies help by offering tools to ensure that nutrition counseling is not ended without appropriate attempts to turn difficult counseling situations in a more positive direction.

## Self-Efficacy and Self-Management

Counselors should always emphasize that any future action belongs to the client, that the advice can be taken or disregarded. This emphasis on personal choice (autonomy) helps clients avoid feeling trapped or confined by the discussion. Belief in the ability to change through his or her own decisions is an essential and worthy goal. A sense of self-efficacy reflects the belief about being capable of influencing events and choices in life. These beliefs determine how individuals think, feel, and behave. If people doubt their capabilities, they will have weak commitments to their goals. Success breeds success, and failure breeds a sense of failure. Having resilience, positive role models, and effective coaching can make a significant difference.

## READY-TO-CHANGE COUNSELING SESSIONS

The major goal in the “ready-to-change” session is to collaborate with the client to set goals that include a plan of action. The nutrition counselor provides the client with the tools to use in meeting nutrition goals. This is the stage of change that is most often assumed when a counseling session begins. To erroneously assume this stage means that inappropriate counseling strategies set the stage for failure. Misaligned assumptions often result in lack of adherence on the part of the client and discouragement on the part of the nutritionist. Therefore it is important to discuss the client's thoughts and feelings about where he or she stands relative to the current change status. Use of open-ended questions helps the client confirm and justify the decision to make a change and in which area. The following questions may elicit information about feelings toward change:

- “Tell me why you picked \_\_\_\_ on the ruler.”
- “Why did you pick (nutrition diagnosis 1) instead of (other nutrition diagnoses)?”

In this stage, goal setting is extremely important. Here the counselor helps the client set a realistic and achievable short-term goal: “Let’s do things gradually. What is a reasonable first step? What might be your first goal?”

### Action Plan

Following goal setting, an action plan is set to assist the client in mapping out the specifics of goal achievement. Identifying a network to support dietary change is important. What can others do to help?

Early identification of barriers to adherence is also important. If barriers are identified, plans can be formed to help eliminate these roadblocks to adherence.

Many clients fail to notice when their plan is working. Clients can be asked to summarize their plans and identify markers of success. The counselor then documents the plan for discussion at future sessions and ensures that the clients also have their plans in writing. The session should be closed with an encouraging statement and reflection about how the client identified this plan personally. Indicate that each person is the expert about his or her own behavior. Compliment the client on carrying out the plan. Ways to express these ideas to clients are:

- “You are working very hard at this, and it’s clear that you’re the expert about what is best for you. You can do this!”
- “Keep in mind that change is gradual and takes time. If this plan doesn’t work, there will be other plans to try.”

The key point for this stage is to avoid telling the client what to do. Clinicians often want to provide advice. However, it is critical that the client express ideas of what will work best: “There are a number of things you could do, but what do you think will work best for you?” The next contact may be in person, online, or by phone.

Following up with clients by phone or online has become a popular counseling method for many nutritionists. When behavior and counseling theories are combined with phone counseling, the results have been effective in managing weight, type 2 diabetes, and hypertension (Eakin et al., 2009; Kim et al., 2009). Online weight reduction programs have also been successful, especially when the websites are interactive and communication with counselors is available (Krukowski et al., 2009).

### EVALUATION OF EFFECTIVENESS

Clinicians need to evaluate their services. Just completing the process does not mean that outcomes will match the goals. The sessions must be confidential, empowering, and personalized. When the American Dietetic Association Evidence Analysis Library Nutrition Counseling Workgroup

### CLINICAL SCENARIO

Mrs. Lee is originally from mainland China. She has been living in your area for several years and has numerous health problems, including high blood pressure and glaucoma. You have been asked to counsel her about making changes in her diet. Because her vision is poor, she will not be able to use printed materials that you have in your office that have been translated into Chinese.

#### Nutrition Diagnostic Statement

Impaired ability to prepare food and meals related to inability to see as evidenced by client report and history of glaucoma

#### Nutrition Care Questions

1. What steps should you take to make her comfortable with this session?
2. Should you invite family members to attend the counseling session? Why or why not?
3. What tools might be useful to help Mrs. Lee understand portions or types of food that she should select?
4. Would a supermarket tour be useful? Why or why not?
5. What other types of information will be needed to help Mrs. Lee?

conducted a review of literature related to behavior change theories and strategies used in nutrition counseling, they found the following (Spahn et al., 2010):

1. Strong evidence supports the use of a CBT in facilitating modification of targeted dietary habits, weight, and cardiovascular and diabetes risk factors.
2. MI is a highly effective counseling strategy, particularly when combined with CBT.
3. Few studies have assessed the application of the TTM or SCT on nutrition-related behavior change.
4. **Self-monitoring**, meal replacements, and structured meal plans are effective; financial reward strategies are not.
5. Goal setting, problem solving, and social support are effective strategies.
6. Research is needed in more diverse populations to determine the most effective counseling techniques and strategies.

# Nutrition in the Life Cycle

The importance of nutrition throughout the life cycle cannot be refuted. However, the significance of nutrition during specific times of growth, development, and aging is becoming increasingly appreciated.

Health professionals have recognized for quite some time the effects of proper nutrition during pregnancy on the health of the infant and mother, even after her childbearing years. Maternal nutrition and possibly even paternal nutrition before conception affect the health of the newborn. “Fetal origin” has far more lifelong effects than originally thought.

Establishing good dietary habits during childhood lessens the possibility of inappropriate eating behavior later in life. Although the influence of proper nutrition on morbidity and mortality usually remains unacknowledged until adulthood, dietary practices aimed at preventing the degenerative diseases that develop later in life should be instituted in childhood.

During early adulthood many changes begin that lead to the development of diseases of aging years later. Many of these changes can be accelerated or slowed over the years, depending on the quality of the individual’s nutritional intake, the health of the gut, and the function of the immune system.

With the rapid growth of the population of older adults has evolved a need to expand the limited nutrition data currently available for these individuals. Although it is known that energy needs decrease with aging, little is known about whether requirements for specific nutrients increase or decrease. Identifying the unique nutritional differences among the various stages of aging is becoming even more important.

## CHAPTER 16

Miriam Erick, MS, RD, CDE, LDN

# Nutrition in Pregnancy and Lactation

### KEY TERMS

amenorrhea  
amylophagia  
assisted reproductive technology (ART)  
colostrum  
congenital anomalies  
eclampsia  
epigenetic effects  
failure to thrive (FTT)  
fetal alcohol syndrome (FAS)  
fetal origins of disease  
geophagia  
gestational diabetes mellitus (GDM)  
gestational hypertension  
gravida  
hyperemesis gravidarum (HG)

intrauterine fetal demise (IUFD)  
intrauterine growth restriction (IUGR)  
lactation  
let-down  
macrosomia  
nausea and vomiting in pregnancy (NVP)  
neural tube defect (NTD)  
oxytocin  
perinatal mortality  
pica  
pre-eclamptic toxemia (PET)  
pregnancy-induced hypertension (PIH)  
pregorexia  
prolactin  
ptyalism  
teratogenicity

Optimal preconceptual nutrition supports successful conception when it includes adequate amounts of all of the required vitamins, minerals, and energy-providing macronutrients. Because the developing fetus depends solely on the transfer of substrates from its host, there is simply no other means to acquire nutrition in utero. The cliché that the “fetus is the perfect parasite” implies the fetus takes entirely what it requires at the expense of the host. However, at some point nutritional deficiency can result in premature labor, relieving the host of an ongoing nutritional debt. After birth, quality nutrition during **lactation** continues the process of providing nutritional building blocks for maximal cerebral development, and growth of all body organs in the neonate.

This time period in the human experience—creating a new human being—sets the stage for the health of future generations. The quality and quantity of in-utero nourishment on the developing zygote, then fetus, then neonate, then adult emerges as one explanation for diseases that manifest in adulthood. This concept is known as **fetal origins of disease** or *developmental origins of health and disease* (Niland, 2008; Solomons, 2009).

### **PRECONCEPTION AND FERTILITY**

Traditional pregnancy partners were usually “man and wife,” or mother and father. Advances in **assisted reproductive**

**technology (ART)** mean that “parents” may be egg or sperm donors. ART can involve in vitro fertilization (IVF), cryo embryo transfer, IVF with donor oocytes, intracytoplasmic sperm injection, a gestational carrier, or surrogate mother.

## Reproductive Readiness and Fertility

Preconceptual guidance is based on findings that many women enter pregnancy with suboptimal nutrition intake. One study of 249 pregnant women who reported for their first prenatal visit found low dietary intakes of vitamin E, folate, iron, and magnesium in the preconceptual period and during pregnancy (Pinto et al., 2009). Although current public health recommendations promote mostly folate supplementation, there is some evidence that other nutrients also reduce the risk of congenital defects, such as vitamins B<sub>12</sub>, B<sub>6</sub>, and niacin, iron, and magnesium (Gaber et al., 2007). Thus a preconceptual multinutrient supplement confers more benefit than single supplements for a pregnant woman, or **gravida**.

Causes of infertility can be male factor (25% to 40%), ovulation defect (20% to 30%), fallopian tube defect (20% to 30%), unexplained causes (10% to 20%), endometriosis (5% to 10%), and other causes (4%). Infertility may also be due to extremes in body mass index (BMI) in either partner. Women with less than 17% body fat often do not menstruate, and those with less than 22% often do not ovulate. Women at risk include those with excessive exercise regimens, eating disorders, or both.

Dietary changes have been shown to decrease ovulatory disorders and improve fertility. Vitamin D deficiency in both men and women can be associated with infertility (Ozkan et al., 2009). Calcium has been shown to be important in males for spermatogenesis, sperm motility, hyperactivation, and acrosome (area of the sperm that contains digestive enzymes to break down the outer layers of the ovum) reactions. Recommendations include eating a lower glycemic diet (including high-fat dairy products, but reducing *trans-fats*), obtaining iron from plant sources, consuming a multivitamin daily, and being moderately physically active (Chavarro et al., 2007).

## Toxins

Exposure to environmental chemicals such as dioxins, polybrominated biphenyls, phthalate esters, and other industrial products (endocrine disruptors) and heavy metals are known to damage sperm health (Meeker et al., 2008). Healthier sperm counts are associated with avoidance of tobacco and alcohol as well as an optimal diet with zinc, folic acid, and antioxidants (Gaur et al., 2010).

Screening is critical in women for occupational toxin exposure as well as for alcohol, tobacco, and intravenous and recreational drug use (Hannigan et al., 2009). Women with high fish consumption are at risk for entering pregnancy with toxic levels of mercury. Mercury levels decline once fish consumption is reduced. Unfortunately, even when a medical university in Taiwan advised women that fish containing high levels of mercury might be harmful to the brains of their developing fetuses, more than two thirds of

the women indicated they would not change their fish intake (Chien et al., 2010).

Maternal caffeine intake and infertility relationships are often debated (Cochrane Update, 2009). A few studies have associated caffeine with increased rates of miscarriage or adverse pregnancy outcome (Jahanfar and Sharifah, 2009). However, caffeinated beverages are not considered to be of high nutritional quality and moderation is encouraged to ensure consumption of fluids with better nutrients, such as soy milk, low-fat dairy, and 100% fruit juices.

## Obesity, Endocrine Conditions, and Oxidative Stress

Obesity is often correlated with poor prepregnancy health care, inaccurate self-categorization of weight, unsuccessful weight loss attempts, and insufficient advice regarding the importance of prepregnancy weight loss (Callaway et al., 2009a). In men elevated BMI is associated with lower testosterone levels (Chavarro et al., 2007). Obese women have a higher likelihood of prediabetes, undiagnosed diabetes preconceptually, or prolonged hyperglycemia; they also often have higher rates of fetal **congenital anomalies** (Selvaraj et al., 2008). Thus reducing obesity preconceptually may lower the risk of birth defects (American Dietetic Association, 2009; Biggio, 2010; Dheen, 2009).

Polycystic ovary syndrome (PCOS) affects 5% to 10% of women of reproductive age. These ovarian cysts alter the testosterone-estrogen balance, which results in insulin resistance and infertility. PCOS is often treated successfully with metformin (Grassi, 2008). See Chapter 32.

Hypothyroidism is also associated with reduced fertility (Hoy-Rosas, 2009). The thyroid hormone requirement increases 20% to 40% during gestation (Yassa et al., 2010). Pregnant women with treated hypothyroidism must increase their T4 levels to prevent transient hypothyroxinemia, associated with preterm birth or low birth weight (LBW) (Yassa et al., 2010). See Chapter 32.

Finally, oxidative stress depletes nutrient stores and contributes to a host of pregnancy complications. A healthy, antioxidant-rich diet and an exercise program help women prepare for an optimal pregnancy outcome. Box 16-1 lists some risk factors for birth defects.

## CONCEPTION

Conception involves a complex series of endocrine events in which a healthy sperm fertilizes a healthy ovum (egg) within 24 hours of ovulation (see Table 16-1). An optimal environment is needed, including adequate nutrition and the absence of hostile factors. Conception itself does not guarantee successful pregnancy outcome. Low levels of copper and zinc adversely affect the development of the oocyte. Cloning experiments have shown that once the oocyte is fertilized, there is no further genetic material that is incorporated into the genetic sequence of that embryo. Exposures of the embryo or fetus to specific maternal nutrients can turn on or off the imprinting genes that control growth and development.

**BOX 16-1****Potential Risk Factors for Development of Birth Defects**

- Assisted reproductive technologies
- Birth trauma
- Bacterial or viral infection during pregnancy
- Genetic alterations
- Gene-environmental interactions, such as maternal smoking
- Hormonal conditions (hypothyroidism, PCOS)
- Hyperglycemia
- Hypoxia during pregnancy
- In utero exposure to toxins (lawn chemicals, formaldehyde, endocrine disruptors, agricultural products, pesticides, carbon monoxide)
- Maternal alcohol ingestion
- Maternal medication or substance exposure (phenytoin, antihypertensive medications, aspirin), illicit recreational substances
- Mother born in a different country
- Nutrient deficits during pregnancy, such as iodine, vitamin B<sub>12</sub>, vitamin D, vitamin A, vitamin K, copper, zinc, folic acid, choline
- Obesity
- Older mother
- Oxidative stress
- Premature birth
- Radiation exposure

Adapted from Erick M: Gestational malnutrition. Lecture at Brigham and Women's Hospital, Boston, Mass., December 2008.

PCOS, Polycystic ovary syndrome.

**PREGNANCY**

The eventual infant from a gestational carrier's womb will not be the same as one that had been carried by the biologic mother, even though the genes themselves are the same (Wilkins-Haug, 2009). This phenomenon reflects the effects of deoxyribonucleic acid (DNA) methylation from the maternal diet, known as epigenetics. **Epigenetic effects** involve the mechanisms by which DNA transcription is altered in various tissues and at different times without changing the underlying gene sequence. Unfortunately, the biologic changes of early pregnancy are difficult to visualize without sophisticated equipment.

**Physiologic Changes of Pregnancy****Blood Volume and Composition**

Blood volume expands approximately 50% by the end of pregnancy. This results in decreased levels of hemoglobin, serum albumin, other serum proteins, and water-soluble vitamins. The decline in serum albumin may be the result of fluid accumulation. The decrease in water-soluble vitamin

concentrations makes determination of an inadequate intake or a deficient nutrient state difficult. In contrast, serum concentrations of fat-soluble vitamins and other lipid fractions such as triglycerides, cholesterol, and free fatty acids increase.

**Cardiovascular and Pulmonary Function**

Increased cardiac output accompanies pregnancy, and cardiac size increases by 12%. Diastolic blood pressure decreases during the first two trimesters because of peripheral vasodilatation, but returns to prepregnancy values in the third trimester. Mild lower extremity edema is a normal condition of pregnancy resulting from the pressure of the expanding uterus on the inferior vena cava. Blood return to the heart decreases, leading to decreased cardiac output, a fall in blood pressure, and lower-extremity edema. Mild physiologic lower extremity edema is associated with slightly larger babies and a lower rate of prematurity.

Maternal oxygen requirements increase and the threshold for carbon dioxide lowers, making the pregnant woman feel dyspneic. Adding to this feeling of dyspnea is the growing uterus pushing the diaphragm upward. Compensation results from more efficient pulmonary gas exchange.

**Gastrointestinal Function**

During pregnancy the function of the gastrointestinal (GI) tract changes in several ways that affect nutritional status. In the first trimester nausea and vomiting may occur, followed by a return of appetite that may be ravenous (see “[Nausea, Vomiting, and Hyperemesis Gravidarum](#)”). Cravings for and aversions to foods are common. Increased progesterone concentrations relax the uterine muscle to allow for fetal growth while also decreasing GI motility with increased reabsorption of water. This often results in constipation. In addition, a relaxed lower esophageal sphincter and pressure on the stomach from the growing uterus can cause regurgitation and gastric reflux (see “[Heartburn](#)”).

Gallbladder emptying becomes less efficient because of the effect of progesterone on muscle contractility. Constipation, dehydration, a low-calorie diet, or poor intake are risk factors for gallstone development. During the second and third trimesters, the volume of the gallbladder doubles and its ability to empty efficiently is reduced. Gallbladder disease affects approximately 3.5% of pregnant women.

Celiac disease affects approximately 1 in 333 people, more than previously thought. It adversely affects fertility and absorption of nutrients. Women with celiac disease are at high risk of spontaneous abortion and premature deliveries. Some prenatal supplements may contain gluten or wheat binders and should be avoided. See [Chapter 29](#).

**Placenta**

The placenta produces several hormones responsible for regulating fetal growth and development of maternal support tissues. It is the conduit for exchange of nutrients, oxygen, and waste products. Placental insults compromise the ability to nourish the fetus, regardless of how well nourished the

*Text continued on p. 349*

**TABLE 16-1****The Carnegie Criteria**

<b>Carnegie Stage</b>	<b>Time Postovulation</b>	<b>Structure Size</b>	<b>Major Events</b>	<b>Other Events</b>
Stage 1 Oocyte (egg) is fertilized.	1 day	0.1-0.15 mm— Approximately the size of a pencil point	Fertilization begins when the sperm penetrates the oocyte. This requires the sperm, which can survive up to 48 hours, to travel 10 hours up the female reproductive track. Then the sperm must successfully penetrate the zona pellucida, a tough membrane surrounding the egg. This process takes approximately 20 minutes. Once the fertilization is successful, the structure now becomes a zygote. This is the end of the fertilization process.	Optimal amounts of folate are needed for cell division and formation of DNA.
Stage 2 Cleavage First Cell Division	1.5-3 days	0.1-0.2 mm	Zygote begins to divide. Division begins to occur approximately every 24 hours. When cell division generates a mass of approximately 16 cells, the zygote now becomes a morula. (This structure is mulberry shaped.)	The newly created morula (formerly a zygote, which is less than 16 cells) leaves the fallopian tube and enters the uterine cavity 3-4 days after fertilization.
Stage 3 Early Blastocyst	4 days	0.1-0.2 mm	The morula enters the uterus and cell division continues. A cavity (hole) forms in the middle of the morula. This structure is now called a blastocoele. Cells are flattening and compacting inside the cavity. The zona pellucida remains the same size as it was after fertilization of the egg by the sperm, with the cavity (hole) in the center.	The presence of the blastocoele indicates two cell types are being formed: embryoblasts (which are on the <i>inside</i> of the blastocoele) and trophoblasts, which are on the outside portion of the blastocoele.
Stage 4 Implantation Begins HCG levels rise	5-6 days	0.1-0.2 mm	Pressure from the blastocoele expanding in the middle of the blastocoele against the rigid wall of the zona pellucida creates a “hatching” of the blastocoele from this zona pellucida. Separation of these two elements is complete.	The outer layers of the trophoblast cells secrete an enzyme that erodes the epithelial lining of the uterine cavity so the blastocoele can implant. Trophoblast cells secrete HCG. HCG stimulates the corpus luteum to continue progesterone production. Progesterone is a C21 steroid secreted by the corpus luteum and in the placenta; important intermediate in steroid biosynthesis to support the pregnancy. Progesterone has a short half-life and is metabolized by the liver.

*Continued*

**TABLE 16-1****The Carnegie Criteria—cont'd**

Carnegie Stage	Time Postovulation	Structure Size	Major Events	Other Events
Stage 5 Implantation Complete	7–12 days	0.1–0.2 mm	Trophoblast cells continue to engulf and destroy cells of the uterine lining, creating blood pools and stimulating new capillaries to grow. This begins the growth of the placenta. Ectopic pregnancies are those that do not implant in the uterus at this time and can develop up until 16 weeks before eventually becoming a life-threatening problem.	Blastocyst layer: forming two inner cell masses, which differentiate into two layers: epiblast: top layer of cells, which becomes the embryo and the amniotic cavity hypoblast: lower layer of cells, which become the yolk sac
Stage 6 Primitive Streak	13 days	0.2 mm	Placental formation: Chorionic villi “fingers” form in the placenta, anchoring the embryo to the uterus. Blood vessels begin appearing first in the placenta surrounding the embryo.	Ectoderm: Top layer of the embryonic disc will later form skin, hair, lenses of the eye, lining of the internal and external ear, nose, sinuses, mouth, anus, tooth enamel (Vello et al., 2009), pituitary and mammary glands, and all parts of the nervous system. Mesoderm: Middle cell layer of the embryonic disc and precursor to the muscles, bones, lymphatic tissue, spleen, blood cells, heart, lungs, reproductive, and excretory systems. Endoderm: Inner cell layer of the embryonic disc, which will eventually form the lining of the lungs, the tongue, tonsils, urethra and associated glands, the bladder, and the digestive tract.
Stage 7 Neurulation	16 days	0.4 mm	Stalk Formation: The embryo is attached to the developing placenta by a stalk, which later becomes part of the umbilical cord. Gastrulation: A narrow line of cells appear on the surface of the formerly two-layered embryonic disc, which is called the <i>primitive streak</i> , which marks the bilateral symmetry in the embryo. Cells now migrate from the outer edges of the disc into the primitive streak and down, creating a new third layer. These three layers (see right column) are the ectoderm, mesoderm and the endoderm. Formation of a new cell layer—the ectoderm, which changes the two-layer disc into a three-layer disc.	Consider vitamins A, E, C. Neural crest cells originate at the top of the neural tube and mitigate extensively, differentiating into many cell types such as neurons, glial cells, pigmented cells of the epidermis, epinephrine producing cells of the adrenal glands, and various skeletal (Wai-Man See et al., 2008) and connective tissues of the head.

Rho B and Slug protein are the proteins now present in stage 7, which promote migration. The loss of N-cadherin, a protein required for left-right symmetry, also helps to initiate the migration of the neural crest cells.

Crest cells are important because they travel along to many areas of the developing embryo and give rise to multiple parts of the mature body, including sensory ganglia and melanocytes. These cells migrate from the neural plate, to the forebrain and mandibular and hyoid arches. They travel around the developing eye in three main pathways, forming the maxillary, mandibular, median, and lateral nasal processes. These cells develop into a variety of tissues, such as connective tissue, cartilage, and bone.

The ectoderm has thickened to form the neural plate, which then flattens out to form the neural groove. This groove is the precursor of the embryo's nervous system and it is one of the first organs to develop.

**Consider vitamin B<sub>12</sub>, ω-3 fatty acids, folate, and choline.**

Stage 8	17-19 days	1-1.5 mm	<p>Primitive pit, notochordal canal, and neuroenteric canals. The embryonic area is now shaped like a pear and the head region is broader than the tail region.</p> <p>By stage 8, the blood cells are already developed and begin to form channels alongside the epithelial cells, which form at the same time.</p>	<p><i>Sonic hedgehog (SHH)</i> is the name of a series of three genes that are forming and look like a hedgehog. These genes encode for signalling molecules that are involved in patterning processes during embryogenesis. SHH are secreted from the notochord. Various levels of SHH result in different types of cells formed in the developing fetus.</p>	<p>Some roles of SHH:</p> <ul style="list-style-type: none"> <li>purkinje neuron development</li> <li>involved in separation of the single eye field into two bilateral fields</li> <li>implicated in hair development</li> <li>important in limb development</li> </ul>	<p>Somites, which look like “bumps,” are forming on this comma-shaped structure. Somites are composed of tissue and are considered the mesoderm and appear on either side of the neural groove.</p> <p>A head ridge rises on either side of the primitive streak, which is now <math>\frac{1}{4}</math> to <math>\frac{1}{3}</math> the length of the embryo.</p>
Stage 9	19-21 days postovulation	1.5-2.1 mm	<p>Appearance of Somites</p>	<p>Every ridge, bump, and recess now indicates cellular differentiation.</p>		<i>Continued</i>

**TABLE 16-1****The Carnegie Criteria—cont'd**

Carnegie Stage	Time Postovulation	Structure Size	Major Events	Other Events
			Secondary blood vessels now appear in the chorion and placenta. Hematopoietic cells appear on the yolk sac simultaneously with endothelial cells, which evolve to form blood vessels for the newly emerging blood cells.	Endocardial (muscle) cells begin to fuse and form into the early embryo's two heart tubes.
Stage 10	21-23 days postovulation	1.5-3 mm	Neural folds and heart folds begin to fuse. On each side of the neural tube, between 4 and 12 pairs of somites can exist by the end of stage 10. The cells, which will become eyes, appear as thickened circles just off the neural folds. Other newly differentiated cells will become the ears. At this time, the embryo looks like an old fashioned key-hole with a big oval top, with an ear of corn in the bottom $\frac{2}{3}$ of the structure.	Rapid cellular growth and changes elongate the embryo and expand the yolk sac. The neural folds are rising and fusing at several points along the neural tube, as the budding somites appear to "zip" the neural tube closed. Failure of the neural tube to close results in spina bifida, which varies in severity. Neural crest cells eventually contribute to the skull and face of the embryo. The two endocardial tubes, formed during stage 9, now fuse in stage 10. Together they form one single tube generated from the cells in the "roof" of the neural tube. The heart tube takes on an S shape, establishing the asymmetry of the heart.
Stage 11	23-25 days postovulation	2.5-3 mm	Major event: two pharyngeal arches appear.	A primitive S-shaped heart is beating and peristaltic muscle contractions begin. This is <i>not</i> true circulation because blood vessel development is incomplete. Consider <b>Vitamin A</b> . Upper limb buds appear.
Stage 12	26-30 days postovulation	4-6 mm; size of the head of a pencil eraser	Beginning cells of the liver are forming. First thin surface layer of skin appears to cover the embryo.	
Stage 13	31-35 days postovulation	5-7 mm	Esophagus is forming.	
Stage 14			Future cerebral hemispheres are distinct.	
Stage 15				

Stage 16	9-11 mm	Future lower jaw now visible.	Hind brain begins to develop.
Stage 17		Heart separates into four distinct chambers.	
Stage 18		Kidneys begin to produce urine.	
Stage 19		Semicircular canals are forming in the inner ear.	Gonads are forming.
Stage 20		Spontaneous movement begins.	
Stage 21		Intestines begin to recede into the abdominal cavity. Failure to recede results in a condition known as <i>gastroschisis</i> .	
Stage 22	56-60 days postovulation	Limbs begin to ossify. In the head and neck, the head is erect and round. External ear is completely developed. Eyes are closed but retina is fully pigmented. Eyelids begin to unite and are half-closed.	<b>Consider the bone nutrients.</b> Taste buds begin to form on the surface of the tongue. Primary teeth are at cap stage. Bones of the palate begin to fuse. <b>For bone, consider vitamins A, D, and K.</b> <b>For eyes, consider vitamin A and ω-3 fatty acids.</b>
Stage 23	23-26 mm	Intestines begin to migrate from the umbilical cord into the body cavity.	Upper and lower limbs are well formed. Fingers get bigger and toes are no longer webbed. All digits are separate and distinct. The “tail” has disappeared.
First Trimester End of Embryonic Period		Layers of rather flattened cells—the precursor of the layer of skin—replaces the thin ectoderm.	The brain from weeks 12-23 has a smooth surface, with two to three layers differentiated in the cerebral cortex. <b>For the brain, consider folate, iodine, choline, ω-3 fatty acid, vitamin D.</b> <b>For the face, consider various B vitamins.</b> Genitals begin to show sex-specific characteristics.
Second Trimester	31-42 mm	In the head and neck, the basic brain structure is complete and the brain mass is rapidly dividing. Sockets for all 20 teeth are formed in the gum line. Face has human appearance.	Fingernails begin to grow from nail buds. Skin develops reflexes and is reportedly very sensitive. <b>For the thyroid, consider iodine.</b>
	61-68 days postovulation	In the abdomen, the intestines have migrated into the abdomen from the umbilical cord. Digestive tract muscles are functional and practice contractions. Liver begins to secrete bile, bile pigments, cholesterol and inorganic salts. Bile is stored in the gallbladder. The development of the thyroid and pancreas are complete. Insulin begins to be secreted.	

Continued

**TABLE 16-1**

<b>The Carnegie Criteria—cont'd</b>				
<b>Carnegie Stage</b>	<b>Time Postovulation</b>	<b>Structure Size</b>	<b>Major Events</b>	<b>Other Events</b>
Second Trimester: Approximately 14 Weeks		Length: crown-rump 2.5 inches (61 mm). Length is a better measure at this time. Weight: 0.3–0.5 oz or 8 to 14 g.	In the head and neck, the fetal head is 50% of the structure. Sucking muscles of mouth fill out cheeks. Tooth buds continue to develop and salivary glands start functioning. Hair pattern starting to be discernible.	In the thorax, heart tones can be detected with sensitive equipment. The lungs start to develop further as the fetus inhales and exhales amniotic fluid essential for proper lung development. <b>Consider vitamin A.</b>
Second Trimester: 16 weeks postovulation		Length: 4.3–4.6 inches (108– 111 mm) Weight: approximately 2.3 oz (80 g)	Able to identify gender. Sweat glands begin to develop.  Mother has approximately 7.5 oz or 250 mL of amniotic fluid surrounding the conceptus.	In the abdomen, the spleen now assumes removal of old red blood cells and production of antibodies begins. Fingerprints and toe prints begin. Eyes now straight-forward in final position and start blinking. Ears move into final places at side of head.
			In the blood and nervous system, circulation is functionally complete. Placenta is now almost same size as fetus. Nerves are beginning to be coated in myelin, which is a fatty substance that surrounds nerve fibers to speed nerve cell transmission and insulates them for uninterrupted impulses.	In the abdomen, meconium begins to develop in the fetal bowels. Meconium is the product of cell loss, digestive secretions, and swallowed amniotic fluid. <b>For myelin, consider iron.</b> <b>For kidneys, consider vitamin A.</b>

Adapted from The Visible Embryo. Accessed 18 June 2010 from [www.visembryo.com](http://www.visembryo.com).

DNA, Deoxyribonucleic acid; HCG, human chorionic gonadotropin; SHH, sonic hedgehog.

mother. Placental insults can be the result of poor placenta from early pregnancy or small infarcts associated with preeclampsia (PE) or hypertension disorders. Placental size can be 15% to 20% lower than normal in fetuses with **intrauterine growth restriction (IUGR)**. A small placenta has a smaller surface area of placental villi, with a reduced functional capacity. Important research about the role of imprinting and epigenetics in placental function is underway (Wilkins-Haug, 2009).

## Renal Function

The glomerular filtration rate (GFR) increases by 50% during pregnancy, although the volume of urine excreted each day is not increased. The blood volume increases because of the increased GFR with lower serum creatinine and blood urea nitrogen concentrations. Renal tubular resorption is less efficient than in the nonpregnant state, and glucosuria may occur, along with increased excretion of water-soluble vitamins. Small amounts of glucosuria increase the risk for urinary tract infections. Pregnant women who present with acute pyelonephritis are hospitalized for aggressive antibiotic treatment, as this infection can easily affect the respiratory system.

## Uterine Environment

A less than ideal intrauterine environment resulting from maternal infection, stressful events, poor nutrition, or excess saturated fat intake can negatively influence the development of different cell types and organs (Tamashiro and Moran, 2010). Nonetheless, the goal is to support a healthy environment through a proper balance of nutrients and the avoidance of teratogens.

A system depicting embryonic changes was compiled by scientists and embryologists in 1913. This system is known as the “Carnegie criteria,” with 23 stages of developmental milestones. For example, multiple nutrients are involved in the creation of bone (see Box 16-2). Specific nutrients are involved at the different Carnegie stages, see *The Visible Embryo* from [www.visembryo.com](http://www.visembryo.com)

Optimizing outcomes includes adequate prenatal care, minimizing stress, and ensuring a healthy pregnancy diet (Rifas-Shiman et al., 2009). Fortunately, women with poor socioeconomic status can improve their diet quality with nutrition education. Women with preexisting depression are at risk for poor pregnancy outcome and postpartum depression, which not only puts the mother at risk but also the newborn. Inadequate nutrient intake (such as ω-3 fatty acids), poor self-care, or a combination of both, are complex causes but are important to distinguish (Leung et al., 2009).

The effect of poor maternal nutrition follows both infant and mother for decades (Cox and Phelan, 2008). Maternal nutritional status has been evaluated primarily for infant birth weight, risk of **neural tube defects (NTDs)**, and fetal alcohol syndrome (FAS), a major cause of mental retardation and learning disorders. Birth weight is highly correlated with infant mortality and morbidity. Infants born small for gestational age are known to have major organs that are

## BOX 16-2

### Bone Nutrients

#### Protein

Forms organic matrix, for collagen, production of hormones, growth factors.

#### Minerals

Boron: Considered to have minor role in bone function.

Calcium: Main bone-forming mineral; 99% in skeleton.

Copper: Functions in lysyl oxidase, an enzyme essential for cross-linking of collagen fibrils.

Fluoride: Can replace hydroxyl groups in hydroxyapatite to form less soluble fluoroapatite..

Iron: Cofactor in enzyme involved in collagen bone matrix synthesis, cofactor in 25-hydroxycholecalciferol hydroxylase.

Magnesium: 60% of this mineral is in bone; it has an indirect role in ATP metabolism.

Manganese: For biosynthesis of mucopolysaccharides in bone matrix, cofactor for several enzymes in bone tissue.

Phosphorous: Essential bone-forming mineral.

Zinc: For osteoblastic activity, collagen synthesis, alkaline phosphatase activity.

#### Fat-Soluble Vitamins

Vitamin A: Essential in bone remodeling process: osteoblasts and osteoclasts have receptors for retinoic acid.

Vitamin D: Maintains calcium levels.

Vitamin K: Cofactor for gamma carboxylation of glutamic acid residues, including osteocalcin, the noncollagenous protein of bone.

#### Water-Soluble Vitamins

Folic acid: Coenzyme mediating variety of reactions critical to nucleic and amino acid metabolism critical to bone development.

Riboflavin: Needed to convert vitamin B<sub>6</sub> and folate into active forms.

Vitamin B<sub>6</sub>: Essential Cofactor for enzyme ornithine decarboxylase; osteoblast NADPH concentrations, essential for Vitamin K.

Vitamin B<sub>12</sub>: Osteoblast function; cofactor for osteoblast-related proteins (bone alkaline phosphatase and osteocalcin); iron formation.

Vitamin C: Hydroxylation of lysine, proline; cross-linking of collagen fibril; stimulates alkaline phosphatase for osteoblast formation.

ATP, Adenosine triphosphate; NADPH, nicotinamide adenine dinucleotide phosphate.

Adapted from Palacios C: The role of nutrients in bone health, from A to Z. *Crit Rev Food Sci Nutr* 46(8):621, 2006.

small; they are at increased risk for hypertension, obesity, learning disorders, behavioral problems, glucose intolerance, and cardiovascular disease (see Chapter 43). Intrauterine food restriction or hyperglycemia may reprogram leptin levels and neuropeptide Y, possibly contributing to metabolic conditions later in life (Page et al., 2009). Infants born large for gestational age (LGA) often have hyperglycemia at birth.

Preconceptual vitamin D status is thought to influence 3% of the human genome, including bone health throughout life. Indeed, maternal vitamin D status may program neonatal skeletal development. A study in Finland found that, although the total vitamin D intake met the current recommendations for this nutrient, 71% of women and 15% of newborns were vitamin D-deficient (Viljakainen et al., 2010). A dose of vitamin D that provides for 25-hydroxyvitamin D (25[OH]D) sufficiency in the mother during pregnancy should provide for normal cord blood concentrations of 25(OH)D for the infant.

### Effects of Nutritional Status on Pregnancy Outcome

Any adverse maternal condition puts the fetus at risk for being delivered prematurely. Prematurity has significant

inherent health risks. One theory for prematurity is the pregnancy is not obtaining adequate nutrients to continue growth and development of the fetus or the placenta. For example, Table 16-2 presents the roles of specific nutrients for neonatal brain development.

Researchers speculate that maternal starvation causes alterations in DNA, regulated by various nutrients very early in pregnancy or at the time of conception. In the early 1900s women with poor nutritional status had adverse pregnancy outcomes with hemorrhage at delivery, prolonged labor, and LBW infants. During World War II, the effects of severe food deprivation on previously well-nourished populations were explored. Higher rates of spontaneous abortion, stillbirths, neonatal deaths, and congenital malformations were noted in offspring born to women who conceived during the famine; surviving infants were smaller. Likewise, results from the Chinese famine of 1959 to 1961 showed similar results in the offspring conceived during this period of maternal malnutrition (Zammit et al., 2007). Smaller organs are found in offspring of mothers who were malnourished during pregnancy (Kyle and Picard, 2006).

Even today, subclinical malnutrition may lead to poor reproductive performance. Women experiencing anorexia

## CLINICAL INSIGHT

### High-Risk Pregnancies

The majority of pregnancies proceed without major risk to either mother or fetus. Approximately 10% of all pregnancies are considered “high risk,” meaning there is a maternal preexisting complication or a situation that antedates pregnancy or presents in current gestation that puts the mother or the fetus at risk for a poor outcome. Women who present with the following issues need increased medical surveillance and nutrition assessment to ensure the most favorable outcomes, controlled medical costs, and the fewest complications.

Anemias: microcytic or macrocytic

Cardiovascular issues: hypertension and preeclampsia, deep-vein thrombosis, maternal cardiac structural defects

Endocrine issues: polycystic ovary syndrome, thyroid disease, gestational diabetes, type 1 diabetes

Functional alterations: deafness, blindness, paralysis, paraplegia, quadriplegia

Gastrointestinal issues: food allergies, celiac disease, gastric bypass, Crohn’s disease, ulcerative colitis

Hyperemesis gravidarum or nausea and vomiting of pregnancy

Infections: HIV and AIDS, malaria, chicken pox, rubella, measles, mumps, West Nile virus, parvovirus, Lyme disease, dental disease

Maternal genetic diseases or mental retardation

Medical problems: lupus, myasthenia gravis, cystic fibrosis, pancreatitis, PKU, cancer, obesity, sickle cell disease

Obesity: BMI >30

Organ transplants: heart, kidneys, liver, lung, stem-cell, liver-intestinal

PROM: early rupture of the chorion (outer layer) and the amnion (inner layer) of the amniotic sac

Placenta previa—complete or marginal: abnormal presentation of the placenta with placenta presenting and obstructing the cervix; cannot deliver fetus through placenta

Psychiatric: eating disorders, depression, bipolar disorders, Munchausen syndrome, suicidal ideation, substance abuse

Reproductive issues: incompetent cervix, uterine anomalies, fibroids; multiple gestations; ovarian hyperstimulation syndrome

Respiratory issues: asthma, tuberculosis, adult respiratory distress disorder, SARS

Surgeries: gastric bypass, cancers, emergency appendicitis

AIDS, Acquired immune deficiency syndrome; HIV, human immunodeficiency virus; PKU, phenylketonuria; PROM, premature rupture of the membranes; SARS, sudden acute respiratory syndrome.

**TABLE 16-2****Key Nutrients for Fetal and Neonatal Brain Development**

Nutrient	Function in Brain	Effect of Deficiency
Energy: protein, carbohydrate, fat	Cell proliferation and differentiation, synaptogenesis, growth factor synthesis	Global effect including cortex, hippocampus, white matter.
Iron	Myelin, monoamine synthesis, neuronal and glial energy metabolism.	White matter-striatal-frontal; hippocampus-frontal
Zinc	DNA synthesis, neurotransmitter release	Autonomic nervous system, hippocampus, cerebellum
Copper	Neurotransmitter synthesis, neuronal and glial energy metabolism, antioxidant activity	Cerebellum
Long-chain polyunsaturated fatty acids	Myelin formation, synaptogenesis	Cortex of the brain, the eye
Choline	Neurotransmitter synthesis, DNA methylation, myelin synthesis	Hippocampus, white matter

Adapted from Georgieff MK. Nutrition and the developing brain: nutrient priorities and measurement, Am J Clin Nutr 85:1S, 2007.  
DNA, Deoxyribonucleic acid.

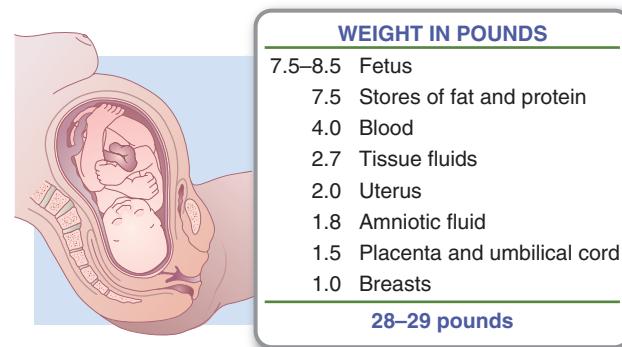

nervosa and bulimia nervosa can have **amenorrhea**, infertility, and reduced rates of pregnancy. Women with a history of eating disorders should therefore be carefully monitored. This includes looking for **pregorexia**, a form of increased calorie expenditure and caloric restraint during pregnancy (Mathieu, 2009). See *Clinical Insight: High-Risk Pregnancies*.

The developing fetus may be unable to obtain optimal nutrients from a host who is compromised nutritionally. Compromises in structural or cognitive potential may not be evident when an infant is born, but may manifest later in life when various stages of growth are arrested or altered. Attention deficit disorder in some children may be related to suboptimal gestational iodine or low vitamin D transfer in a depleted mother (Cui et al., 2007).

LBW (<2500 g) and especially very low birth weight (<1500 g) are major factors for **perinatal mortality** (infant deaths occurring between 28 weeks' gestation and 4 weeks' postpartum). These deaths may occur from necrotizing enterocolitis, respiratory distress syndrome, intraventricular hemorrhage, cerebral palsy, or retinopathy of prematurity. Maternal obesity in the African American population has been associated with a 40% higher incidence of stillbirths compared with women with normal BMI status (Salihu et al., 2007).

### Maternal Weight Gain

With a singleton gestation, less than half of the total weight gain of a normal-weight pregnant woman resides in the fetus, placenta, and amniotic fluid. The remainder is in maternal reproductive tissues (breast tissues and uterus), interstitial fluid, blood volume, and maternal adipose tissue. Gradually, increased subcutaneous fat in the abdomen, back, and upper thigh serves as an energy reserve for pregnancy and lactation. The normal distribution of weight gain is illustrated in **Figure 16-1**. Although this chart implies the fetus

**FIGURE 16-1** Distribution of weight gain during pregnancy.

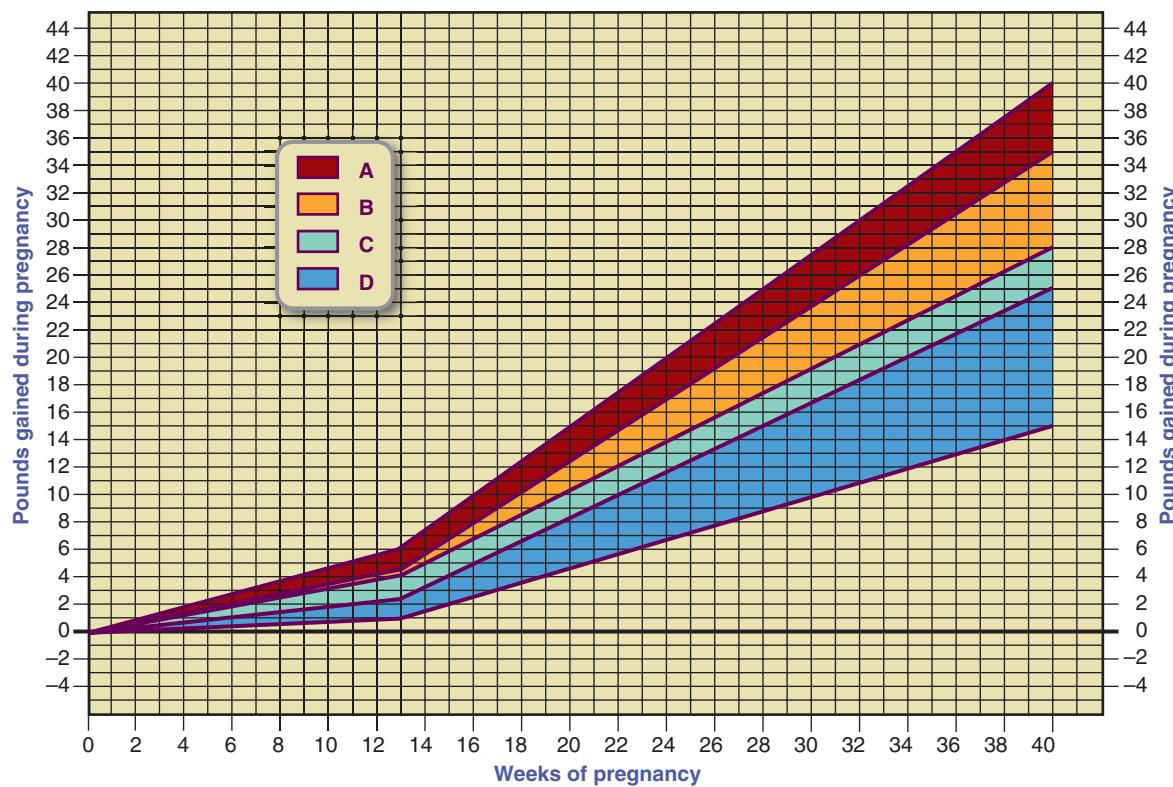

at term constitutes approximately 27% of the total pregnancy weight gain, this may not be true for all pregnancies.

In normal-weight women living in healthy environments, a gestational weight gain of 25 to 35 lb is associated with a favorable outcome at term. Guidelines issued by the Institute of Medicine (IOM) recommend a weight gain of 25 to 35 lb for women of normal weight (pregravid BMI 18.5 to 24.9), 28 to 40 lb for underweight women (BMI <18.5), and 15 to 25 lb for overweight women (BMI 25 to 29.9) (Rasmussen and Yaktine, 2009; **Figure 16-2**).

Weight loss during pregnancy should be discouraged. As adipose tissue is mobilized, there is concern for the release of semivolatile organic compounds, which can have an effect on the developing fetal brain that is not clear.

### Obesity

Pregravid obesity is described as class I (BMI 30–34.9), class II (BMI 35–39.9), and class III (BMI more than 40); optimal gestational gains for these groups are not yet known. Studies indicate that 50% of high-BMI women gain more

**FIGURE 16-2** Desirable weight gain during pregnancy. Females who are of normal weight before their pregnancy should aim for a weight gain in the B to C range (25–35 lb) during pregnancy. Underweight females should gain in the A to B range (28–40 lb). Females who are overweight before pregnancy should gain in the D range (11–20 lb).

than the target weight recommendations, thus reflecting the increasing prevalence of obesity among U.S. women (Stotland et al., 2005).

Overweight and obese women are at increased risk for **intrauterine fetal demise (IUFD)** or miscarriage. The risks for **gestational diabetes mellitus (GDM)**, pregnancy-induced hypertension (PIH), and cesarean section increase in this same group (American Congress of Obstetricians and Gynecologists [ACOG], 2005). When ultrasound studies examined the lean to fat mass in fetuses of women with GDM, their fetuses showed an accelerated rate of growth (de Santis et al., 2010). The risk for delivery of a very preterm (<32 weeks) infant or an infant with a cardiac defect, NTD, or **macrosomia** (birthweight > 4000 g) increases in women who are obese (Artal et al., 2010). Obesity is associated with a high risk of hypertensive disorders (Callaway et al., 2009b).

An association between maternal obesity and increased incidence of NTDs has not been explained, but obesity itself is an inflammatory state. Low grade systemic inflammation is associated with higher levels of C-reactive protein, interleukin-6, and leptin. A sustained state of hyperglycemia or hyperinsulinism may be related to NTDs as well (Yazdy et al., 2010). Folate intake of 600 mcg/day is less protective against NTDs in obese women than in normal-weight pregnant women; obese women may need more (Scialli and Public Affairs Committee, 2006). There is speculation that the increased body size may require

additional supplementation. Since vitamin B12 is a cofactor for methionine synthase, an enzyme that plays a key role in folate metabolism, it may also be required in larger amounts to prevent NTDs. In addition, there is a suggestion that nutrients such as iron, magnesium and niacin may play a role in NTDs (Groenen, 2004). Inadequate choline may be implicated in NTDs since, like folate, it functions as a methyl donor (Zeisel, 2009). A proactive nutritional goal is to choose foods of high antioxidant quality. Indeed, the benefits of prepregnancy maternal weight loss include improved plasma lipids, glucose, and uric acid, which may also reduce pregnancy risk factors.

**Postbariatric Surgery.** The prevalence of obesity has resulted in more gastric bypass operations for weight reduction, which has tremendous implications for pregnancy. Although prepregnancy weight loss may improve fertility, it has the potential to provide a suboptimal uterine environment for the developing fetus. Pregnancy should be delayed for at least 1 year after this surgery, and adequate nutrient supplementation is essential.

Operative complications are not uncommon, such as intestinal hernias. Deficiencies in iron, vitamins A, D, B<sub>12</sub>, K, and folate, and calcium can result in maternal complications (severe anemia) or fetal complications, such as congenital abnormalities, smaller kidneys, neonatal rickets, IUGR and **failure to thrive (FTT)** (Faintuch et al., 2009; Guelinckx et al., 2009). An optimum nutrient prescription and caloric requirement for pregnant women following

**BOX 16-3****Risk Factors for Poor Pregnancy Outcome in Teenagers**

- Young maternal age, especially younger than age 16
- Pregnancy less than 2 years after onset of menarche
- Poor nutrition and low prepregnancy weight
- Poor weight gain
- Infection
- Sexually transmitted disease or infection
- Preexisting anemia
- Substance abuse: smoking, drinking, and drugs
- Poverty
- Lack of social support
- Low educational level
- Rapid repeat pregnancies
- Lack of access to age-appropriate prenatal care
- Late entry into the health system
- Unmarried status
- Unstable housing, shelter living, homelessness

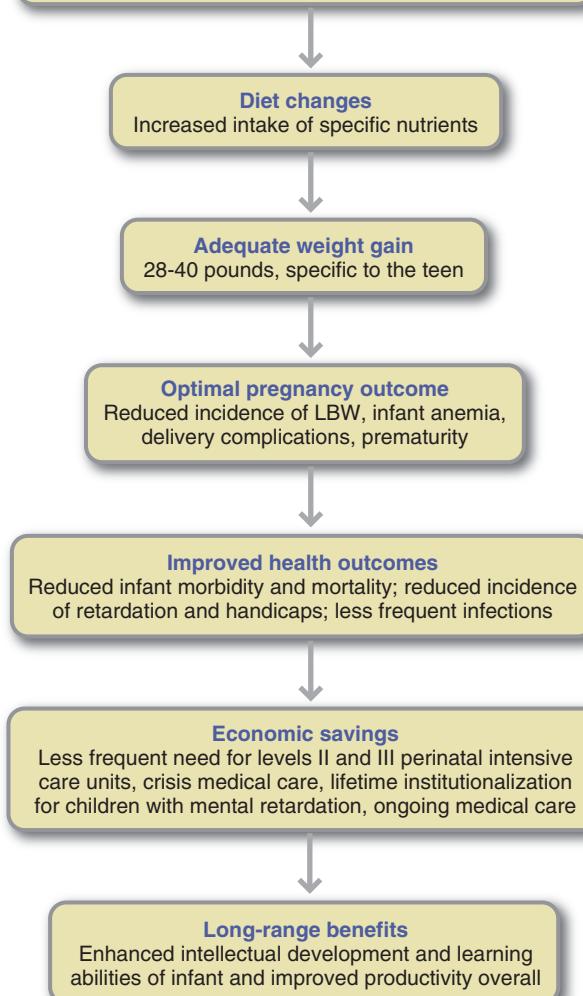

bariatric surgery has not been determined and thus must be individualized. Low intakes of calcium, vitamin B<sub>12</sub>, and iron have been noted in this population (Faintuch et al., 2009).

**Adolescent Pregnancy**

Public health initiatives have helped reduce the incidence of teen pregnancies; however, teenage pregnancy continues as a major public health problem in the United States and is associated with significant medical and nutritional risks. Approximately 1 million U.S. adolescents become pregnant every year, accounting for 25% of U.S. pregnancies. Teens have a higher incidence of delivering a LBW infant. Risk factors for poor outcome in pregnant adolescents are listed in Box 16-3.

Poor outcomes are especially common in obese teens who become pregnant. Excess body fat, particularly of visceral distribution, has been linked with proinflammatory cytokines, chronic low-grade inflammation, low total-body iron metabolism, increased fatigue, and reduced physical activity (Tussing-Humphreys et al., 2009). Many other teens enter pregnancy with suboptimal nutritional status, especially for iron, calcium, and folic acid. Young maternal age is a significant risk factor for developmental defects, such as inadequate neonatal tooth enamel formation (Vello et al., 2009).

Improved dietary practices can be one of the most important factors for the pregnant teen or young mother. In counseling teen mothers, the nutrition professional must be aware of the teen's psychosocial, cultural, and literacy level; economic status and dependencies; and any educational frameworks that influence her food choices. Benefits of nutritional counseling for pregnant adolescents are presented in Figure 16-3.

**NUTRITIONAL COUNSELING FOR PREGNANT TEENS**

**FIGURE 16-3** Benefits of nutritional counseling for pregnant adolescents.

**Multiple Births**

The incidence of multiple births in the United States is rising in part because of the increased use of fertility drugs and ART. Infants of multiple-birth pregnancies have a greater risk of premature delivery with accompanying IUGR or LBW than do singletons. Adequate maternal weight gain has been shown to be particularly important in these higher-risk pregnancies.

Multifetal gestations undergo significant maternal physiological adaptations beyond the usual pregnancy changes, including increased plasma volume, metabolic rate, and increased insulin resistance (Goodnight and Newman, 2009). Optimal weight gain and infant gestational ages for this population are presented in Table 16-3.

The optimal nutritional requirements for twins and higher-order multiples are not yet known. One nutritional plan is summarized in Table 16-4. Although this plan has not included iodine specifically, it is imperative to meet at least the singleton recommendation of 220 mcg/day, with

**TABLE 16-3****Weight Gains of Mothers and Incidence of Low Birth Weights in Multiple-Birth Pregnancies**

Plurality	Live-Born Infants	LBW (%) (Less Than 2500 g)	VLBW (%) (Less Than 1500 g)	Maternal Weight Gain by 24 Wk (lb)	Weight Gain Total (lb)	Weeks Gestation	Mean Birth Weight (g)
Singletons	3.8M	6	1	12	25-35	38-41	3700-4000
Twins	96,445	50	10	24	40-45	36-37	2500-2800
Triplets	4168	90	32	36	50-60	34-35	1900-2200

*LBW*, Low birth weight; *VLBW*, very low birth weight.

**TABLE 16-4****Nutrient Recommendations for Twins**

Nutrient	Twins	Comments
Calories	40-45 kcal/kg normal weight BMI	Weight is not specified—pregravid, ideal or current?
Protein	14.4%-18.1% of total calories	Depending on calorie requirements, could be as high as 175 g/day.
Carbohydrate	350 g/day for normal weight gravid	Encourage low glycemic choices.
Fat	156 g/day for normal weight gravid	Encourage healthy fats.
Vitamin D	1000 IU/day	Assessment of maternal levels should be considered in first and early third trimester to allow alterations in the supplemental dose.
Vitamin C	500-1000 mg/day	This is half of the UL of 1800-2000 mg/day.
Vitamin E	400 mg/day	This is half of the UL of 800-1000 mg/day.
Zinc	15 mg/day (T1); 45 mg/day (T2-3)	Diet alone may not be enough. Supplementation may be required.
Iron	30 mg/day	For nonanemic twins. <a href="#">Rosello-Soberon (2005)</a> reported an estimated 869 mg/day iron requirement for twins compared with 476 mg for a singleton pregnancy.
Folic acid	1000 mcg/day	
Calcium	1500 mg/day (T1); 2500 mg (T2-3)	UL: 2500 mg/day
Magnesium	400 mg/day (T1); 800 mg/day (T2-3)	
DHA/EPA	300-500 mg/day	

Adapted from Goodnight W, Newman R: Optimal nutrition for improved twin pregnancy outcome, *Obstet Gynecol* 114:1121, 2009.

BMI, Body mass index; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; T, trimester; UL, tolerable upper limit.

the upper limit for singleton gestation at 900 mcg for mothers younger than 18 years old and 1100 mcg for those 19 years and older. The dietary reference intakes (DRIs) for choline for the singleton gestation are important as well; include 450 mg/day with a tolerable upper limit of 3 g/day for women younger than 18 and 3.5 grams for women older than 19.

### Nutritional Supplementation During Pregnancy

Supplementation of a mother's diet during pregnancy may take the form of additional energy, protein, vitamins, or

minerals that exceed her routine daily intake. The more compromised the nutritional status of the woman, the greater is the benefit for pregnancy outcome with improved diet and nutritional supplementation. Judicious use of supplements is needed in high-risk pregnancies and in undernourished women, women with substance abuse, teenage mothers, women with a short interval between pregnancies, women with a history of delivering an LBW infant, and women with a multiple gestation pregnancy.

Under the auspices of the U.S. Department of Agriculture (USDA), pregnant women at nutritional risk are encouraged to enroll in the Special Supplemental Nutrition

Program for Women, Infants and Children (WIC). For U.S. citizens, the WIC program serves eligible pregnant women, postpartum women until 6 months' postpartum, breastfeeding women until 1 year postpartum, and infants and children up to the age of 5 years (see Chapter 10). “Nutritional risk” criteria may include anemia, poor gestational weight gain, inadequate diet, or FTI in the infant or child. Outcome studies show higher mean birth weights and

higher mean gestational ages in infants born to WIC participants.

Many pregnant women and some providers have limited knowledge regarding the nutrients in the supplements they have been prescribed or have been advised to purchase over the counter. There is great variability in the composition of supplements as demonstrated in Table 16-5, and formulations change frequently. It is important to read the label

**TABLE 16-5****Comparison of Some Prenatal Supplements**

Nutrient	Example #1 (3 caps per day)	Example #2 (2 caps per day)	Example #3 (2 tabs per day)	Example #4 (1 tab per day)	Children's chewable Multivitamin-mineral (1 per day for adults)
Vitamin A IU	5000 (2000 IU retinyl palmitate and 3000 IU as mixed carotenoids)	8000 (100% as mixed carotenoids)	8000 (4800 IU retinyl palmitate and 3200 IU beta carotene)	4000 (100% as beta carotene)	3000
Vitamin D IU	1,000	400	400	400	400
Vitamin E IU	50	18.2	60	30	30
Vitamin K mcg	100	—	—	—	—
Vitamin B <sub>1</sub> (thiamine) mg	4	1.6	3.0	1.8	1.5
Vitamin B <sub>2</sub> (riboflavin) mg	3.6	1.7	3.4	1.7	1.7
Vitamin B <sub>3</sub> (niacin) mg	30	20	40	20	15
Pantothenic acid mg	16	6	20	—	10
Vitamin B <sub>6</sub> mg	10	2.2	4	2.6	2
Vitamin B <sub>12</sub> mcg	200	2.6	12	8	6
Folic acid mcg	1000 (500 mcg as calcium folate and 500 mcg as 5-MTHF)	1000	800	800	400
Vitamin C mg	150	110	120	—	60
Choline mg			10	—	38
Biotin mcg	50	300	600	—	40
Calcium mg	200	200	400	200	100
Copper mcg	2	2	2	—	2
Iron mg	45	27	20	28	18
Chromium mcg	100	120	—	—	—
Iodine mcg	150	150	—	—	150
Magnesium mg	100	80	300	—	20
Zinc mg	25	15	20	25	12
Selenium mcg	50	70	—	—	—
Manganese mg	5	2	2	—	—
Phosphorous mg	—	—	—	—	100
Sodium mg	—	—	—	—	10

DHA, Docosahexaenoic acid; 5-MTHF, 5-methyltetrahydrofolate.

of prenatal supplements—some are much more complete than others and some are little more than a children's chewable multivitamin mineral with extra folic acid and iron. Approximately 60% of prenatal supplements include the recommended dietary allowance (RDA) for iodine, but an analysis found that the actual amount of iodine differed from the amount listed on the label (Leung, 2009). Women often need advice on local, suitable choices for themselves or their children.

### Nutrition Requirements

Fetal growth demands additional nutrients and these requirements are defined in the DRIs, which include RDAs and adequate intakes (AIs). These DRIs are found on the inside front cover.

### Energy

Additional energy is required during pregnancy to support the metabolic demands of pregnancy and fetal growth. Metabolism increases by 15% in the singleton pregnancy. The 2002 DRIs for energy for the pregnant female are the same as for the nonpregnant female in the first trimester, then increase by 340 to 360 kcal/day during the second trimester and by another 112 kcal/day in the third trimester (Institute of Medicine [IOM], 2002). If maternal weight gain is within the desirable limits, the range of acceptable energy intakes varies widely, given individual differences in energy output and basal metabolic rate.

**Exercise.** Energy expended in voluntary physical activity is the largest variable in overall energy expenditure. Physical activity increases energy expenditure proportional to body weight. However, most pregnant women compensate for increased weight gain by slowing their work pace; thus total daily energy expenditure may not be substantially greater than before pregnancy.

Excessive exercise, combined with inadequate energy intake, may lead to suboptimal maternal weight gain and poor fetal growth. Therefore a pregnant woman should always discuss exercise with her primary health practitioner. Exercising during pregnancy at high altitudes may compromise fetal oxygen delivery, especially for women who are not acclimatized to higher elevations. Resting uterine blood flow is lower in residents residing at 3100 m than at 1600 m, and blood flow is likely to decrease further during exercise in proportion to the intensity and duration.

**Consequences of Energy Restriction.** A once-popular concept held that the fetus develops at the expense of the mother during nutritional deprivation. However, evidence from famines clearly contradicts this assumption. It is now accepted that a malnourished mother is proportionately less affected than her fetus. One consequence of severe energy restriction is increased ketone production. Although the fetus has a limited ability to metabolize ketone bodies, the short- and long-term effects of maternal ketonemia are unclear. Both animal and human data indicate that ketone bodies are normally presented to the fetal brain at various times during pregnancy. After an overnight fast, maternal blood ketone body concentrations are greater in pregnant

### BOX 16-4

#### Causes of Fetal Malnutrition

- Acute change in maternal condition, such as a stroke
- GI disease cancers of the intestinal tract, gastric bypass
- Hyperemesis gravidarum
- Infections
- Parasite infestation
- Lack of food due to war, famine, natural disasters  
(e.g., earthquake, tsunami)
- Maternal gallbladder disease causing malabsorption
- Mother with active eating disorder, such as anorexia nervosa
- Multiple gestations
- Pica
- Placental compromise: placenta previa, hypertensive disorders, abruptions
- Poverty
- GI, Gastrointestinal.

than in nonpregnant women, and even ketonuria can be detected. When ketonuria is present, it indicates a lack of energy-providing macronutrients, which also reduces vitamin and mineral intake. Box 16-4 describes some of the causes of fetal malnutrition.

### Protein

There is an additional protein requirement for pregnancy to support the synthesis of maternal and fetal tissues, but the magnitude of this increase is uncertain. Protein requirement increases throughout gestation and is maximized during the third trimester. The current RDA of 0.8 g/kg/day of protein for pregnant women is the same as that for the nonpregnant women in the first half of pregnancy. Needs increase in the second half to 71 g/day, based on 1.1 gm/kg/day of prepregnant weight (IOM, 2002). For each additional fetus, another 25 g/day of protein is recommended; this may be as much as 175 g/day for the normal-weight woman carrying a twin gestation who is consuming 3500 kcal/day (Goodnight and Newman, 2009).

Protein deficiency during pregnancy has adverse consequences. Limited intakes of protein and energy usually occur together, making it difficult to separate the effects of energy deficiency from those of protein deficiency.

### Carbohydrates

DRIs for carbohydrates in pregnancy are estimated average requirements (EARs) at 135 g/day; the RDA is 175 g/day (IOM, 2002). This 135 to 175 g/day is recommended to provide enough calories in the diet to prevent ketosis and maintain appropriate blood glucose during pregnancy. With an average 2000 calorie/day regimen, 175 g translates to 700 calories, or 35%. The amount may be greater in women consuming more calories, but careful carbohydrate choices are needed to include all the daily nutrients for pregnancy.

## Fiber

Daily consumption of whole-grain breads and cereals, leafy green and yellow vegetables, and fresh and dried fruits should be encouraged to provide additional minerals, vitamins, and fiber. The DRI for fiber during pregnancy is 28 g/day (IOM, 2002) and if met, will help a great deal in managing the constipation that often accompanies pregnancy.

## Lipids

There is no DRI for lipids during pregnancy. The amount of fat in the diet should depend on energy requirements for proper weight gain. However, there is a recommendation (an AI of 13 g/day) for the amount of  $\omega$ -6 polyunsaturated fatty acids (linoleic acid) and an AI of 1.4 g/day for the amount of  $\omega$ -3 polyunsaturated fatty acids ( $\alpha$ -linolenic acid) in the diet (IOM, 2002). The recommendation for docosahexaenoic acid is 300 mg/day. Essential fatty acid requirements can usually be met by one to two portions of fish per week (Simpson et al., 2010b). See *Focus On: Omega-3 Fatty Acids in Pregnancy and Lactation*.

## Vitamins

All vitamins are needed for optimal pregnancy outcome. In some instances the provision of these specific vitamins may be met through diet, and for others a supplement is necessary. Periconceptional multivitamin supplementation has been documented to reduce the risk of heart defects in infants if started very early in pregnancy. Most vitamin and mineral recommendations increase approximately 15%

from nonpregnant values. Refer to the DRI tables on the inside cover.

**Folic Acid.** For nonpregnant adult women, the recommended intake is 400 mcg/day for dietary folate equivalent. Folic acid requirements increase during pregnancy for maternal erythropoiesis, DNA synthesis, and fetal and placental growth. The Centers for Disease Control and Prevention recommends that all women of childbearing age increase their intake of folic acid; obese women even more so. More than half of all U.S. pregnancies are unplanned and the neural tube closes by 28 days of gestation, before most women realize they are pregnant (Goldberg et al., 2006; see Table 16-1). Because the average amount of folic acid received through food fortification (grains) in the United States is only 128 mcg/day, there is a need for the additional 400 mcg/day of synthetic folic acid from supplements or fortified foods (Simpson et al., 2010a).

Folic acid deficiency is marked by a reduced rate of DNA synthesis and mitotic activity in individual cells. White cell morphologic and biochemical changes signaling deficiency precede overt megaloblastic anemia, the latest stage of folate deficiency, which may not present until the third trimester (see Chapter 33). Maternal folate deficiency is associated with an increased incidence of congenital malformations, including cleft lip and palate and NTDs. Indeed, approximately 2500 new cases of NTDs occur in the United States each year; the NTD recurrence rate may be as high as 2% to 10%. Red blood cell folate concentrations exceeding 906 mmol/L (400 ng/mL) are associated with the fewest NTDs.

## FOCUS ON

### Omega-3 Fatty Acids in Pregnancy and Lactation

Our ancestors consumed a diet with equal amounts of  $\omega$ -3 and  $\omega$ -6 fatty acids with a ratio of 1:1. American diets are currently estimated to contain a ratio of  $\omega$ -3 to  $\omega$ -6 fatty acids of 1:10. This dramatic decrease in the consumption of  $\omega$ -3 fatty acids over many centuries is thought to affect overall disease prevalence, as well as pregnancy outcome.

Fatty acids are found in all cell membranes. They compose 60% of the dry weight of fetal brain, half of which is as  $\omega$ -6 and the other half as  $\omega$ -3 (arachidonic acid) and docosahexaenoic acid [DHA], respectively). Because DHA is important for the growth and development of the fetal central nervous system and the retina, the prenatal diet should include adequate amounts of preformed DHA. 300 mg during pregnancy and during lactation is recommended (Institute of Medicine, 2002). The main food source of DHA is fatty, cold-water fish; and two to three fish meals per week of low-mercury fish during pregnancy appear to provide adequate amounts of DHA. An example of a low-mercury fish high in

DHA is sardines. The consumer is advised to follow “safe-fish” guidelines by monitoring information that is found on [www.seaturtles.org/gotmercury.htm](http://www.seaturtles.org/gotmercury.htm).

Other options to increase the DHA content in the diet of pregnant and lactating women include the consumption of  $\omega$ -3-enriched eggs and the use of DHA supplements. Vegetable sources of  $\omega$ -3 fats include flax seeds and nuts, especially walnuts and walnut oil, although they are less efficient in being converted to DHA. Any pregnant woman allergic to fish should seek an algae source of supplemental DHA (Arterburn et al., 2008). Women should be asked if a supplement has DHA or cod-liver oil; the latter has high amounts of vitamin A (retinoic acid) that can be of concern.

The breast-fed infant obtains DHA through maternal milk when the mother eats sufficient quantities of foods containing DHA. If the mother is not consuming fish or DHA supplements, a DHA liquid supplement can be given to the infant. Most infant formulas are fortified with DHA.

Women who smoke, consume alcohol moderately or heavily, or use recreational drugs are at risk for marginal folate status, as are those with malabsorption syndromes or genetic differences related to methylation and metabolic use of dietary folate. See Chapters 5 and 8. Malformations can occur in infants of women using the anticonvulsant medications phenytoin, carbamazepine, diphenylhydantoin; oral contraceptives; the diuretic triamterene; and trimethoprim. Women using antiseizure medications must be closely monitored when starting folic acid because folic acid supplementation can reduce seizure threshold.

**Vitamin B<sub>6</sub>.** Vitamin B<sub>6</sub> functions as a cofactor in approximately 50 decarboxylase and transaminase enzymes, especially in amino acid metabolism. Although this vitamin catalyzes a number of reactions involving neurotransmitter production, it is not known whether this function is involved in the relief of nausea or vomiting. Because meat, fish, and poultry are good dietary sources, deficiency is not common and routine prenatal vitamins are sufficient (Simpson et al., 2010a). Megadoses such as 25 mg three times per day has questionable efficacy.

**Vitamin B<sub>12</sub>.** Cobalamin is required for enzyme reactions and for generation of methionine and tetrahydrofolate. B<sub>12</sub> is found almost exclusively in foods of animal origin (meats, dairy products); therefore vegetarians are at greatest risk for dietary vitamin B<sub>12</sub> deficiency and should be supplemented (Simpson et al., 2010a). Deficiencies in both folate and vitamin B<sub>12</sub> have been related to depression in adults. There is concern regarding inadequate amounts of these nutrients during fetal brain development affecting infant cognitive and motor development (Black, 2008).

**Choline.** Choline is an essential nutrient because it cannot be synthesized in sufficient quantities to meet metabolic demands. It is needed for structural integrity of cell membranes, cell signaling, and nerve impulse transmission, and is a major source of methyl groups. Choline has been shown to support adequate neurogenesis in folic-acid deficient mice whose mothers were supplemented (Craciunescu et al., 2010). The IOM recommends choline at 450 mg/day during pregnancy, 25 mg more than for the nonpregnant woman. Choline-rich foods are beef liver, pork, chicken, turkey, fish, egg yolks, soy lecithin, and wheat germ. Pregnant women who are not eating these foods may need supplementation. The prenatal supplement should be evaluated for its choline content; many popular brands do not contain choline.

**Vitamin C.** Ascorbic acid is involved in collagen synthesis and functions as an antioxidant. Daily consumption of food sources high in this nutrient should be encouraged. At this time there are no recommendations to suggest supplemental vitamin C for the prevention of premature ruptured membranes and pre-eclamptic toxemia (PET).

**Vitamin A.** Vitamin A deficiency is teratogenic, as noted by xerophthalmia in developing countries. In human cord blood, vitamin A concentrations correlate with birth weight, head circumference, length, and gestation duration. Low maternal vitamin A concentration can result in reduced

kidney size in newborns (Goodyer et al., 2007). Infants born prematurely have low vitamin A stores and poor lung function (Darlow and Graham, 2009).

Prenatal vitamin A supplementation is usually not warranted, and in developing countries should not exceed 3000 mcg (10,000 IU)/day (Simpson et al., 2010b). Very high doses of vitamin A (>30,000 IU) may increase the risk for a neural crest defect (Neural Crest and Associated Disorders, 2009). Women who take isotretinoin (Accutane) for acne should stop before they become pregnant. It is a vitamin A analog. As such, the infants of women who become pregnant while on isotretinoin are at extremely high risk for fetal anomalies (NICHD, 2001).

**Vitamin D.** Vitamin D and its metabolites cross the placenta and appear in fetal blood in the same concentration as in maternal circulation. Vitamin D enhances immune function and brain development (Feron et al., 2005). Vitamin D may have a role in cytokine (Th<sub>1</sub> and Th<sub>2</sub>) regulation, multiple sclerosis, diabetes, and autism. Low vitamin D levels during pregnancy predispose to PET, a hypertensive condition of pregnancy affecting up to 8% of pregnant women (Duley, 2009). Maternal vitamin D deficiency is associated with neonatal hypocalcemia, which can manifest in inadequate fetal bone mineralization, hypoplasia of tooth enamel, or convulsions (Cambadoo et al., 2007).

Vitamin D blood concentrations are often low in infants born to vitamin D-deficient mothers. Vitamin D deficiency is increasingly recognized in dark-skinned and veiled women in the northern latitudes where sun exposure is low (Simpson et al., 2010b). Women who are at risk of entering pregnancy with low vitamin D levels include those with BMI greater than 30 and those with a high use of sunscreen, along with poor dietary intake. Poor muscular performance is associated with vitamin D deficiency. The rate of cesarean section deliveries is found to be inversely related to vitamin D status (Merewood et al., 2009). Vitamin D supplementation may be needed to reach desired serum concentrations of more than 20 ng/ml (50 nmol/L) (Simpson et al., 2010b). Use caution not to overdose; excessive amounts of vitamin D are undesirable.

**Vitamin E.** Vitamin E requirements are increased during pregnancy. Although deficiency during pregnancy is speculated to cause miscarriage, preterm birth, PET, and IUGR (Gagne et al., 2009), vitamin E deficiency specifically has not yet been reported in human pregnancy. Vitamin E is an important lipophilic antioxidant. Of the many tocopherols and tocotrienols, alpha tocopherol is the most biologically active form and is found in all lipoproteins. See Chapter 3.

**Vitamin K.** Usual diets do not provide adequate amounts of vitamin K as most food sources are dark leafy green vegetables, and are not consumed in recommended quantities. Vitamin K has an important role in bone health as well as in coagulation homeostasis, so adequate amounts during pregnancy are vital. Vitamin K deficiency has been reported in women who have had hyperemesis gravidarum (HG), Crohn's disease, and gastric bypass (Brunnetti-Pierri et al., 2007).

## Minerals

**Calcium.** Hormonal factors strongly influence calcium metabolism in pregnancy. Human chorionic somatomammotropin from the placenta increases the rate of maternal bone turnover. Estrogen inhibits bone resorption, provokes a compensatory release of parathyroid hormone, and maintains maternal serum calcium while enhancing maternal absorption of calcium across the gut. The net effect of these changes is the promotion of progressive calcium retention to meet progressively increasing fetal skeletal demands for mineralization. Fetal hypercalcemia and subsequent endocrine adjustments ultimately stimulate the mineralization process.

Approximately 30 g of calcium is accumulated during pregnancy, almost all of it in the fetal skeleton (25 g). The remainder is stored in the maternal skeleton, held in reserve for the calcium demands of lactation. Most fetal accretion occurs during the last trimester of pregnancy, an average of 300 mg/day.

The upper limit for calcium intake during pregnancy is 2500 mg/day. Overconsumption of calcium in food form is not common; however, elevated serum level of calcium can be the result of excess antacid ingestion for heartburn or gastroesophageal reflux disease.

**Copper.** Diets of pregnant women are often marginal in copper. Copper deficiency alters embryo development and induced-copper deficiency has been shown to be teratogenic. Not only are there genetic mutations, as in Menkes disease, but also secondary deficiencies from excessive zinc or iron intake, certain drugs, and bariatric surgery (Uriu-Adams et al., 2010). These inadequacies cause decreased activity of cuproenzymes, increased oxidative stress, altered iron metabolism, abnormal protein crosslinking, decreased angiogenesis and altered cell signaling (Uriu-Adams et al., 2010). See Chapter 3

**Fluoride.** The role of fluoride in prenatal development is controversial. Development of primary dentition begins at 10 to 12 weeks' gestation. From the sixth to the ninth

month, the first four permanent molars and eight of the permanent incisors are forming. Thus 32 teeth are developing during gestation. Controversy involves the extent to which fluoride is transported across the placenta and its value in-utero in the development of caries-resistant permanent teeth (see Chapter 26).

**Iodine.** Iodine is part of the thyroxine molecule, with a critical role in the metabolism of macronutrients. Adequate gestational iodine is associated with a higher intelligence quotient in the child and attention deficit may be associated with milder iodine deficiency (Hoy-Rosas, 2009). In instances in which preconception iodine intake cannot be ensured, supplementation before the end of the second trimester protects the fetal brain from the effects of deficiency (see Chapter 3). To ensure adequate iodine, food is often fortified with iodized salt. Yet many people worldwide are at risk for iodine deficiency caused by low intake of sea products and fish, produce grown in iodine-deficient soils, or food industry use of noniodized salt. Women who emigrate from other countries may have low iodine status because of the low iodine content of their agricultural soil. If urinary iodine levels are low, supplementation is needed (Simpson et al., 2010b). See Table 16-6.

**Iron.** A marked increase in the maternal blood supply during pregnancy greatly increases the demand for iron. Normal erythrocyte volume increases by 20% to 30% in pregnancy. A pregnant woman must consume an additional 700 to 800 mg of iron throughout her pregnancy—500 mg for hematopoiesis, and 250 to 300 mg for fetal and placental tissues. Most accretion occurs after the 20th week of gestation when maternal and fetal demands are greatest.

A first trimester ferritin level should be assessed before prescribing iron. Foods containing ascorbic acid enhance absorption. If anemia is not improved with iron therapy, it is advised to check vitamin B<sub>6</sub> status. (Hisano et al., 2010). Because many women do not enter pregnancy with sufficient iron stores to cover the physiologic needs of pregnancy, iron supplementation (usually a ferrous salt) is often necessary. Supplementation may be necessary in the

**TABLE 16-6**

### Assessing Iodine Nutrition

Urinary iodine Excretion (mcg/L)	Corresponding iodine intake (mcg/day)	Classification and Implication
<20	<30	Insufficient: severe deficiency
20-49	30-47	Insufficient: moderate deficiency
50-99	75-149	Insufficient: mild deficiency
100-199	150-299	Adequate: optimal nutritional status
200-299	300-499	More than adequate: risk of iodine-induced hyperthyroidism within 5-10 years in susceptible groups
>300	>449	Risk of adverse health consequences such as iodine-induced hyperthyroidism, autoimmune thyroid disease

World Health Organization, United Nations Children's Fund, Assessment of iodine deficiency disorders and monitoring their elimination, pg 33, ISBN 978 92 4 159582 7, 2007.

third trimester, earlier in pregnancy, or in nonpregnant states if serum ferritin is less than 20 mcg/L, hematocrit is less than 32%, or hemoglobin is less than 10.9 g/dL (Simpson et al., 2010b). Inadequate iron consumption may lead to poor hemoglobin production, followed by compromised delivery of oxygen to the uterus, placenta, and developing fetus. The added workload of the heart from maternal anemia with increased cardiac output can lead to preterm delivery, fetal growth retardation, LBW, or inferior neonatal health.

Although the implications of excessive iron intake for women and their infants are not yet clearly defined, some studies suggest a relationship with GDM (Chen et al., 2009).

**Magnesium.** The full-term fetus accumulates 1 g of magnesium during gestation. The IOM reports that magnesium supplementation during pregnancy reduces the incidence of PERT and IUGR; see “[Edema and Leg Cramps](#).”

**Phosphorus.** Phosphorus is found in a wide variety of foods and deficiency is rare when one is eating. Low phosphorous levels, indicative of “refeeding syndrome” have been found in women experiencing severe vomiting or other situations resulting in starvation. Hypophosphatemia can be life threatening because phosphorous is important in energy metabolism as a component of adenosine triphosphate (ATP) and must be promptly replenished, as with intravenous phosphorous (Stanza et al., 2008).

**Sodium.** The hormonal milieu of pregnancy affects sodium metabolism. Increased maternal blood volume leads to increased glomerular filtration of sodium of 5,000 to 10,000 mEq/day. Compensatory mechanisms maintain fluid and electrolyte balance.

Restriction of dietary sodium or the use of diuretics in pregnant women with edema is not recommended. Rigorous sodium restriction stresses the renin-angiotensin-aldosterone system, resulting in water intoxication and renal and adrenal tissue necrosis. Although moderation in the use of salt and other sodium-rich foods is appropriate for everyone, aggressive restriction is usually unwarranted in pregnancy. Consumption of sodium should remain above 2 to 3 g/day. Use of iodized salt should be encouraged.

**Zinc.** A zinc-deficient diet does not result in the effective mobilization of zinc stored in the maternal skeleton; therefore a compromised zinc status develops rapidly. Zinc deficiency is highly teratogenic and leads to congenital malformations, abnormal brain development in the fetus, and abnormal behavior in the newborn. A low zinc level also adversely affects vitamin A status. Women with low plasma zinc concentrations are at 2.5 times greater risk for delivering an infant weighing less than 2000 g; women younger than 19 years old have an even higher risk (Rwebemera et al., 2005; Scheplyagina, 2005). Evaluating nutritional status using plasma zinc requires caution because homeostatic mechanisms can maintain plasma concentrations for weeks despite inadequate intake (Charney and Malone, 2009). Zinc is available in red meat, seafood, including oysters, and unrefined grains. Extra supplementation is usually not required (Simpson et al., 2010b).

## Guide for Eating During Pregnancy

### Recommended Food Intake

The increased requirements of pregnancy can be met by following the Daily Food Guide (Table 16-7). Box 16-5 provides a summary of nutritional care.

### Calcium Intake

Milk is one choice for a calcium source for the pregnant woman to meet her increased calcium requirements. A number of milk choices are available: whole milk, low fat milk, skim milk, nonfat powdered milk, buttermilk, acidophilus milk, Lactaid-treated milk, evaporated milk, enriched soy milk, enriched rice and other grain milks, enriched nut milks, and yogurt. Goat milk is also available, but usually has low folate content. Approximately  $\frac{1}{3}$  cup of dried skim milk is equivalent to 1 cup of fluid milk. Milk can be made richer in calcium, protein, and calories by adding 2 tablespoons of dried nonfat milk to a glass of fluid milk.

Not all milk products are fortified with vitamin D<sub>3</sub>, a derivative from an animal source. Some soy milks are fortified with vitamin D<sub>2</sub>; because this is a nonanimal source, it may be preferred by vegans. Vitamin D<sub>2</sub> potency is less than one third that of vitamin D<sub>3</sub>.

There are many other calcium-containing foods such as spinach, kale, and other dark green leafy vegetables, tofu, canned salmon, almonds, and calcium-fortified drinks and juices. See Table 3-25 in Chapter 3. Many women, primarily non-white women, are less able to digest the disaccharide lactose present in milk, unless it is taken in small amounts or milk is in a cooked product. If necessary, calcium

### BOX 16-5

#### Summary of Nutritional Care During Pregnancy

1. Energy intake to meet nutritional needs and allow for approximately a 0.4-kg (14-oz) weight gain per week during the last 30 weeks of pregnancy
2. Protein intake to meet nutritional needs, approximately an additional 25 g/day; additional 25 g/day/fetus if more than one fetus; 20% of energy intake from protein
3. IODIZED sodium intake that is not excessive, but no less than 2-3 g/day
4. Mineral and vitamin intakes to meet the recommended daily allowances (folic acid and possibly iron supplementation is required)
5. Alcohol omitted
6. Omission of toxins and nonnutritive substances from food, water, and environment as much as possible

**TABLE 16-7****Daily Food Guide for Females**

Food Group	Minimum Number of Servings		
	Nonpregnant 11- to 24-Year-Olds	Nonpregnant 25- to 50-Year-Olds	Pregnant or Lactating
Protein, foods	5*	5*	7†
Milk products	3	2	3

\*Equivalent in protein to 5 oz of animal protein; at least three servings per week should be from the vegetable proteins.

†Equivalent in protein to 7 oz of animal protein; at least one of these servings should be a vegetable protein

supplements such as calcium lactate or calcium carbonate may be prescribed (see Chapter 25).

### Fluids

Drinking 8 to 10 glasses of quality fluid daily, mainly water, is encouraged. Although the 2004 report by the National Academies set the AI at 1.5 L/day, with an upper limit of 2.3 L/day, evaluation of a woman's body size as well as climatic conditions are important considerations. Adequate hydration improves the overall sense of well being. Frequent urination is often a complaint from pregnant women; however, optimal hydration reduces risks for urinary tract infections, kidney stones, and constipation.

### Alcohol

Abundant evidence from both animal studies and human experience associates maternal alcohol consumption with **teratogenicity** and a specific pattern of abnormalities in the neonate. Features of **fetal alcohol syndrome (FAS)** include prenatal and postnatal growth failure, developmental delay, microcephaly, eye changes (including involvement of the epicanthal fold), facial abnormalities, and skeletal joint abnormalities (Figure 16-4). However, many children adversely affected by maternal drinking during pregnancy cannot be identified early in life using current diagnostic criteria for fetal alcohol spectrum disorder. Alcohol has been shown to alter gene expression. Changes involve proteins associated with central nervous system development; organ morphogenesis; immunologic responses; endocrine function; ion homeostasis; and skeletal, cardiovascular, and cartilage development.

Use of alcohol during pregnancy has been associated with an increased rate of spontaneous abortion, placenta

**FIGURE 16-4** One-year-old child with fetal alcohol syndrome. (From Streissguth AP et al: Teratogenic effects of alcohol in humans and laboratory animals, *Science* 209:353, 1980.)

abruptio, LBW deliveries, mental retardation, and cognitive compromise. The American Congress of Obstetricians and Gynecologists (ACOG), as well as the March of Dimes and other professional organizations, recommend that alcohol not be used during pregnancy. Reduced-alcohol wines and beers do contain small amounts of alcohol and

are also contraindicated. Despite the multiple warnings of fetal injury caused by alcohol, it has been shown that some women continue to consume alcohol in pregnancy (Crozier et al., 2009; Hannigan et al., 2009).

### Nonnutritive Substances in Foods

**Artificial Sweeteners.** The artificial sweeteners sold in the United States have chemical names of *saccharin*, *acesulfame-K*, *sucralose*, and *aspartame*; brand names are *Sweet 'n' Low*, *Sunette* (or *Sweet One*), *Splenda*, *Equal*, or *Nutra-Sweet*, respectively.

Saccharin is a weak carcinogenic in rats in very high doses. However, its consumption in pregnancy has not been restricted. Acesulfame-K consumption by pregnant women is classified as safe, even without long-term studies during human pregnancy. Both saccharin and acesulfame-K cross the placenta and appear in breast milk, but have no known adverse effect on the fetus or infant. Sucralose, a carbohydrate derived from sucrose, was approved for general use in all foods by the Food and Drug Administration (FDA) in 1998. It has not been found to be mutagenic or teratogenic in high doses in animals.

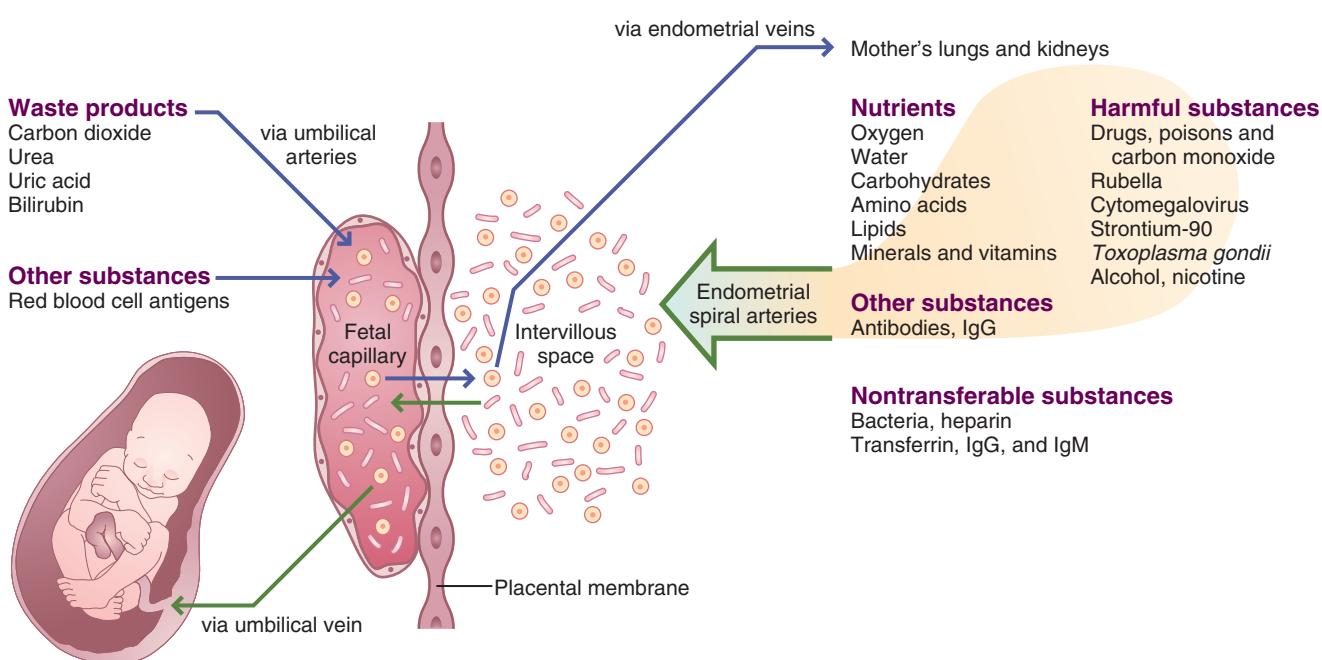

Aspartame is unsafe for women with phenylketonuria (PKU), regardless of whether they are pregnant. Aspartame is metabolized to phenylalanine and aspartic acid. Women with PKU are advised to follow a lifelong low-protein diet and should always be followed by qualified nutrition specialists, especially if they become pregnant. High circulating concentrations of phenylalanine are known to damage the fetal brain (see Chapter 44).

The plant derived sweetener stevia, has not been found to affect fetal development.

**Bisphenol-A.** Bisphenol-A, or BPA, an endocrine disruptor, may affect thyroid function in humans, especially in the fetus. It may also decrease the serum T<sub>4</sub> half-life by activating hepatic enzymes (Pearce and Braverman, 2009). It should be eliminated if possible from the diet of the pregnant woman, and has been eliminated from plastic bottles and dishes used in feeding the newborn in the US and many other countries (Kubwabo et al., 2009).

**Lead and Other Contaminants.** Contaminants in food are the exception rather than the rule in the United States, but they do occur. In high concentrations, they can pass across the placenta to the fetus (Figure 16-5). Poorly glazed dishware and leaded crystal decanters often contain high amounts of lead. Old cookware coated with polytetrafluoroethylene (Teflon) are sources of contamination and need to be avoided. Pregnant women should be advised against using dolomite as a calcium supplement because it comes from seashells or sea coral, which have been shown to contain heavy metals, such as lead, the result of dumping industrial wastes in the oceans.

**Listeria Monocytogenes.** *Listeria monocytogenes* infects 2500 Americans each year; 500 of those infected die. Pregnant women are 20 times more likely than other healthy adults to become infected with *Listeria*. It is a known cause of spontaneous abortion and meningitis of the fetus and newborn. *Listeria* is a soilborne organism; infection results from eating contaminated foods of animal origin and raw vegetables. Raw milk, smoked seafood, frankfurters, pâté, soft cheeses, cold cuts from the deli counter, and uncooked meats are likely sources. Produce irrigated with wastewater needs to be carefully washed with potable water before ingestion.

**FIGURE 16-5** Transfer of substances across the placental membrane. Ig, Immunoglobulin.

**Melamine.** Melamine is a chemical additive that was criminally added to infant formula from China to increase the nitrogen content; this was discovered when analyzed by modern technology. It is a toxic substance and leads to renal damage or death in infants who ingest it. (Wen et al., 2010).

**Mercury.** In January 2001 the USDA and the FDA issued a warning for pregnant and lactating women and women of childbearing age to limit consumption of shark, mackerel, tilefish, tuna, and swordfish to no more than two times a week in 4-oz portions. Traces of methyl mercury are found in most fish, but concentrations may be higher in fish from waters close to areas of industrial mercury pollution. The usual concentration of methyl mercury in most fish ranges from less than 0.01 ppm to 0.5 ppm. Few species of fish reach the FDA limit for human consumption of 1 ppm except shark, swordfish, large tuna (the type used to make sushi or fresh steaks), tilefish, and king mackerel. Seafoods (canned tuna, shrimp, pollock, salmon, cod, catfish, clams, flatfish, crabs, and scallops) are continually at risk of mercury contamination and women are advised to regularly check the latest advisories. Farm-raised fish are subject to mercury contamination via acid rain.

**Polychlorinated Biphenyls.** More than 1.2 billion pounds of polychlorinated biphenyls (PCBs) were produced in the United States before 1976, and half still remain in the water systems. Although PCBs can be absorbed through the skin and lungs, they primarily enter the body from ingestion of contaminated fatty fish such as salmon, lake trout, and carp. They readily pass through the placenta and breast milk; thus pregnant and nursing women and women of childbearing age should avoid eating fish from water known to be contaminated with PCBs. Questions regarding mercury, PCBs, and other contaminants can be directed to state land and natural resource departments.

### Cravings and Harmful Beliefs, Avoidances, and Aversions

Most women change their diets during their pregnancies. Change may be due to medical advice, cultural beliefs, or a change in food preference and appetite. Food avoidances may not reflect a mother's conscious choice to eliminate certain foods during her pregnancy. Some reasons for food avoidance may include smell adversity caused by enhanced perception of aromas, a heightened gag response, getting ill while eating or smelling a particular food, or altered gastric comfort.

**Cravings and Aversions.** Cravings and aversions are powerful urges toward or away from foods, including foods about which women experience no unusual attitudes when not pregnant. The most commonly craved foods are sweets and dairy products or foods that are quick to eat. The most common aversions reported are to alcohol, coffee, other caffeinated drinks, and meats. However, cravings and aversions are not limited to any particular food or food groups.

**Pica.** Consumption of nonfood substances (**pica**) during pregnancy most often involves **geophagia** (consumption of dirt or clay) or **amylophagia** (consumption of starch such as

laundry starch). Other substances include ice, paper, burnt matches, stones or gravel, charcoal, soot, cigarette ashes, antacid tablets, milk of magnesia, baking soda, and coffee grounds.

The incidence of pica is not limited to any one geographic area, race, sex, culture, or social status; nor is it limited to pregnancy. Its cause in pregnancy is poorly understood. One theory suggests that pica relieves nausea and vomiting. It has also been hypothesized that a deficiency of an essential nutrient such as calcium or iron results in the eating of nonfood substances that contain these nutrients. Malnutrition can be a consequence when nonfood substances displace essential nutrients in the diet. Starch in excessive amounts can contribute to obesity and can be deleterious in managing diabetes mellitus. Some substances contain toxic compounds or heavy metals; others interfere with the absorption of iron or other minerals. Excessive intake of starch and clay can lead to intestinal obstruction.

## Complications and Nutritional Implications

### Constipation and Hemorrhoids

Pregnant women become constipated if they fail to consume adequate water and fiber. Women who are treated with ondansetron (Zofran) for nausea and vomiting often experience severe constipation. Straining during stooling (*val salva*) increases the risk for hemorrhoids. Increased consumption of fluids, fiber-rich foods (see Appendix 41), and dried fruits (especially prunes and apricots), and nuts usually controls these problems. Some women may also require a bulking type of stool softener.

### Diabetes Mellitus

The Hyperglycemia Adverse Pregnancy Outcome (HAPO) trial recently defined *GDM* as having one positive glucose reading after a 75-g glucose challenge (Table 16-8). Glucose intolerance may be associated with obesity. Women with

**TABLE 16-8**

### Recommendations for the Diagnosis of GDM

Time	HAPO* Recommendations	Current Standards
Fasting	<92 mg/dL	<95 mg/dL
1 hour	<180 mg/dL	<180 mg/dL
2 hour	<153 mg/dL	<155 mg/dL
3 hour	Not performed	<140 mg/dL

*GDM*, Gestational diabetes mellitus; *HAPO*, Hyperglycemia Adverse Pregnancy Outcome trial.

(\*The challenge is proposed to be 75 grams of glucola)

recurrent preterm births are often treated with 17  $\alpha$ -hydroxyprogesterone caproate, which increases insulin resistance and the rate of GDM (Waters et al., 2009). Women diagnosed with GDM are at risk for future type 2 diabetes mellitus and cardiovascular disease. Although low serum 25(OH)D concentrations correlate with impaired glucose intolerance (von Hurst et al., 2009), no recommendations for nutrient supplementation have been made.

Fetuses of mothers with type 1 or type 2 diabetes are at risk for cardiac defects, such as transposition of the great vessels, double outlet of the right ventricle, tetralogy of Fallot, and mitral and pulmonary atresia (Corrigan et al., 2009). Fetuses of women with GDM are at risk for hypoglycemia at birth, a neonatal intensive care stay, macrosomia, or shoulder dystocia (HAPO Study Cooperative Research Group, 2010). These infants may have lower levels of potassium, zinc, manganese, and chromium (Afridi et al., 2009).

Approaches to reduce the incidence of GDM include providing women with supplemental probiotics before and during pregnancy. Probiotics appear to alter maternal microbiota, change the immune response (Luoto, 2010), and support better glucose tolerance and lower body weight (Laitinen et al., 2009). Women with GDM or elevated first-trimester uric acid concentrations may benefit from a low glycemic prenatal diet (Laughton et al., 2009). See Chapter 31.

### **Edema and Leg Cramps**

Mild, physiologic edema is usually present in the extremities in the third trimester and should not be confused with the pathologic, generalized edema associated with PIH. Normal edema in the lower extremities in pregnancy is caused by the pressure of the enlarging uterus on the vena cava, obstructing the return of blood flow to the heart. When a woman reclines on her side, the mechanical effect is removed, and extravascular fluid is mobilized and eventually eliminated by increased urine output. No dietary intervention is required. Magnesium supplementation has been recommended to reduce leg cramps in pregnancy; however, it may not be effective for every pregnant woman (Nygaard et al., 2008; Sohrabvand et al., 2006).

### **Heartburn**

Gastric esophageal reflux is common during the latter part of pregnancy, and often occurs at night. In most cases this is an effect of pressure of the enlarged uterus on the intestines and stomach, which, in combination with the relaxation of the esophageal sphincter, may result in regurgitation of stomach contents into the esophagus. Relief may occur by suggesting that the pregnant woman eat frequent small meals and stay upright for at least 3 hours after a meal and before lying down. Smaller plates can be used to remind a woman about reduced gastric volume. See Chapter 28.

### **Nausea, Vomiting, and Hyperemesis Gravidarum**

Morning sickness, **nausea and vomiting in pregnancy (NVP)**, affects 50% to 90% of all pregnant women during the first

trimester and usually resolves at approximately 17 weeks gestation. Motion, loud noises, bright lights, and adverse climate conditions may trigger the nausea (Erick, 2004). Fortunately, most women with NVP are functional, able to work, do not lose weight, and are helped by simple dietary measures. Small, frequent snacks of carbohydrate foods reduce nausea for some, whereas protein foods may help others. Diets high in ginger and protein can reduce symptoms of nausea (Levine et al., 2008). Ginger reduces symptoms of NVP better than vitamin B<sub>6</sub> (Chittumma et al., 2007; Ensiyeh and Sakineh, 2009). Other therapies suggested include crackers or potato chips, elastic wrist bands, electronic wrist bands (“Relief Bands”), special lollipops (“Preggie Pops”), red raspberry leaf tea, noise reduction, acupuncture, and hypnosis. Some even try “Morning Sickness Magic,” a tonic containing peach, ginger, raspberry leaf, vitamin B<sub>6</sub>, and folate.

Some women do not tolerate the odors from hot foods, and room-temperature foods may be preferred. Smelling lemons may help block noxious odors (Erick, 2004). Unfortunately, there is no cure-all. Women suffering with nausea should eat whatever reduces the sensation of nausea and avoid odors that trigger nausea.

When early pregnancy is characterized by excessive vomiting and weight loss, fluid and electrolyte imbalances can occur. Here, “morning sickness” becomes **hyperemesis gravidarum (HG)**; this occurs in approximately 1% to 2% of pregnancies. Hospitalization for nutrition support and hydration is usually indicated. Appropriate weight gain for pregnancy; correction of fluid and electrolyte deficits; avoidance of ketosis; control of HG symptoms; and achievement of nitrogen, vitamin, and mineral balance are the goals in management (Austin, 2010).

Complications of HG vary, but may include global subluxation (Zeller, 2007), chondrodysplasia punctata, splenic avulsion (Nguyen et al., 1995), ruptured esophagus, and gestational malnutrition (Fejzo et al., 2009). A nuisance factor is **ptyalism** gravidarum, or excess saliva. Salivary output can be substantial and can be a source of lost electrolytes. Output of 500-1000 mL/day is not uncommon. Another difficult to identify but serious complication may be Wernicke encephalopathy with at least 49 cases being reported worldwide by 2006 (Chirossi et al., 2006) (see Chapter 3). Here intravenous administration of 100-mg thiamin for several days may be required (Austin, 2010).

In HG, enteral nutrition has variable effectiveness. Part of the challenge is that many obstetricians lack knowledge in tube placement, and women with severe emesis and retching have often dislodged tubes and are sometimes reluctant for replacement. If tubes are placed during a hospitalization, frequent nursing checks during the night disrupt sleep and add to sleep deprivation issues, which have not been widely recognized. Parenteral nutrition is used if the GI tract is not accessible, or if enteral nutrition is not tolerated (Austin, 2010). Because pregnancy is a condition of accelerated starvation, refeeding syndrome is often seen (Majumdar and Dada, 2010). Electrolytes such as phosphorous, magnesium, and potassium must be evaluated daily because low levels

may result in cardiac irregularities and respiratory failure (Stanza et al., 2008). See Chapter 14.

### Pregnancy-Induced Hypertension

**Pregnancy-induced hypertension (PIH)** includes gestational hypertension, PET, and eclampsia. **Gestational hypertension** is a maternal blood pressure equal to or greater than 140/90 with no proteinuria that develops after mid-pregnancy. These women may develop **pre-eclamptic toxemia (PET)**, defined as a systolic blood pressure of 140 or more, or a diastolic blood pressure of more than 90, plus urinary protein of more than 300 mg from a 24-hour urine sample. Severe PET is defined as a systolic blood pressure of more than 160 or a diastolic blood pressure of more than 110, plus more than 5 g of protein in a 24-hour urine sample. PET is associated with decreased uterine blood flow from vasospasm, leading to reduced placental size, compromised fetal nourishment, and an IUGR fetus.

The cause of PET is unknown; however, the disease complicates 5% to 8% of pregnancies (Getahun et al., 2007). Theories regarding causes are varied and include vascular injury to the placental blood vessels, high BMI, nulliparity, advanced maternal age, multifetal gestation, non-white race, renal disease, high pregnancy weight gain, and low levels of vitamin D (Getahun et al., 2007). Very young women with first pregnancies are also known to have higher incidences of PET. The incidence of PET is also increased in women with autoimmune diseases such as type 1 diabetes and rheumatoid arthritis.

PET is more common in dark-skinned women living in northern latitudes and others with a high prevalence of hypovitaminosis D. Low levels of vitamin D produce elevated cytokines. There is a reduction in the levels of circulating 1,25(OH)2D<sub>3</sub> in preeclamptic patients (Spinnato, 2007); this may be caused by a disturbance in 1 $\beta$ -hydroxylation within the placenta.

**Eclampsia** is PIH resulting in grand mal seizures. Symptoms that precede seizure are dizziness, headache, visual disturbances, facial edema, right-sided epigastric pain, anorexia, nausea, and vomiting. Fetal death often results in women who develop eclampsia. A small percent of cases of eclampsia present in the postpartum period. Eclampsia can be fatal to the mother if not treated promptly. Intravenous magnesium supplementation may be used.

## LACTATION

Exclusive breast-feeding is unequivocally the preferred method of infant feeding for the first 4 to 6 months of life. Both the American Dietetic Association and the American Academy of Pediatrics (AAP) have issued position statements in support of breast-feeding (James and Lessen, 2009). Other supporters include Healthy People 2010, The WIC program, and the U.S. Breastfeeding Committee.

### Benefits

Breast-feeding can reduce the incidence of both types 1 and 2 diabetes (Gunderson et al., 2007; Malcova et al., 2006).

An excellent way to promote breast-feeding is to discuss its benefits, as shown in Box 16-6.

In 1991 the World Health Organization and the United Nations Children's Fund adopted the Baby-Friendly Hospital Initiative, a global effort to increase the incidence and duration of breast-feeding. To become “baby friendly,” a hospital must show to an outside review board that it implements the “Ten Steps to Successful Breast-feeding,” a guideline for mother-baby management in the hospital; see *Clinical Insight: Baby-Friendly Hospital Initiative: Ten Steps to Successful Breast-Feeding*.

### Contraindications

Breast-feeding is contraindicated for infants with galactosemia and for mothers who have active untreated tuberculosis or are positive for human T-cell lymphotropic virus type 1 or 2, who use drugs of abuse, have human immunodeficiency virus (in the United States), or who take certain medications (i.e., antimetabolites and chemotherapeutic agents). The use of radioactive isotopes requires temporary cessation of breast-feeding (Lawrence and Lawrence, 2005).

### Physiology of Lactation

Mammary gland growth during menarche and pregnancy prepares the woman for lactation. Hormonal changes

### CLINICAL INSIGHT

#### Baby-Friendly Hospital Initiative: Ten Steps to Successful Breast-Feeding

1. Have a written breast-feeding policy that is routinely communicated to all health care staff.
2. Train all health care staff in the skills necessary to implement this policy.
3. Inform all pregnant women about the benefits and management of breast-feeding.
4. Help the mother initiate breast-feeding within a half-hour of birth.
5. Show mothers how to breast-feed and how to maintain lactation, even if they are separated from their infants.
6. Give newborn infants no food or drink other than breast milk unless medically indicated.
7. Practice rooming-in; allow mothers and infants to remain together 24 hours a day.
8. Encourage breast-feeding on demand.
9. Give no artificial teats or pacifiers (also called dummies or soothers) to breast-feeding infants.
10. Foster the establishment of breast-feeding support groups and refer mothers to them on discharge from the hospital or clinic.

**BOX 16-6****Benefits of Breast-Feeding****For Infant****Decreases Incidence and Severity of Infectious Diseases**

- Bacterial meningitis
- Bacteremia
- Diarrhea
- Late-onset sepsis in preterm infants
- Necrotizing enterocolitis
- Otitis media
- Respiratory tract infection
- Urinary tract infection

**Decreases Rates of**

- Asthma
- Food allergies
- Hodgkin disease
- Hypercholesterolemia
- Leukemia
- Lymphoma
- Overweight and obesity
- Sudden infant death syndrome
- Types 1 and 2 diabetes

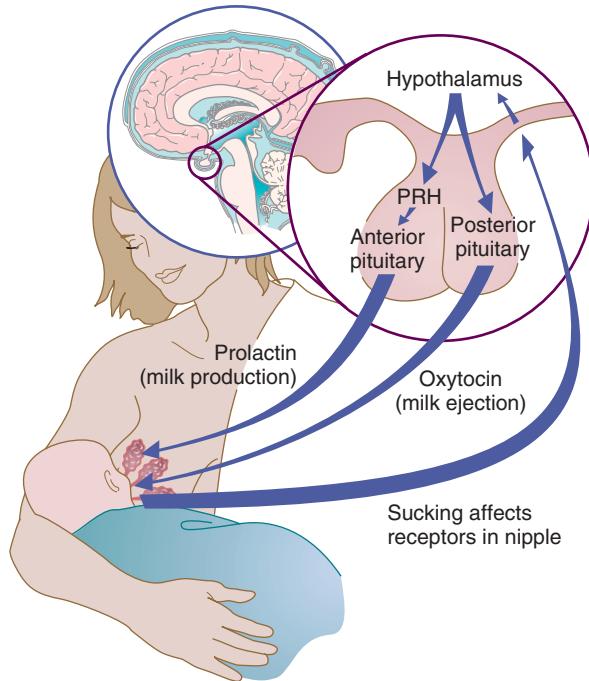

**Promotes**

- Analgesia during painful procedures (heel stick for newborns)
- Enhanced performance on cognitive development tests
- Mother-child bonding

**For Mother**

- Decreases menstrual blood loss
- Decreases postpartum bleeding
- Decreases risk of hormonal (breast and ovarian) cancers
- Promotes earlier return to prepregnancy weight
- Increases child spacing
- Promotes rapid uterine involution
- Decreases risk of postmenopausal hip fracture and osteoporosis

Adapted from American Academy of Pediatrics: Breastfeeding and the use of human milk, Pediatrics 115:496, 2005.

**FIGURE 16-6** Physiology of milk production and the let-down reflex. PRH, Pituitary-releasing hormone.

anterior and posterior areas are stimulated. **Prolactin** from the anterior pituitary stimulates alveolar cell milk production, as shown in Figure 16-6.

**Oxytocin** from the posterior pituitary stimulates the myoepithelial cells of the mammary gland to contract, causing movement of milk through the ducts and lactiferous sinuses, a process referred to as **let-down**. “Let-down” is highly sensitive. Oxytocin may be released by visual, tactile, olfactory, and auditory stimuli; and even by thinking about the infant. Oxytocin secretion can also be inhibited by pain, emotional and physical stress, fatigue, and anxiety. Women who have diabetes, who are obese, who are stressed during delivery, or who have retained placental fragments in the uterus are at risk for delayed milk production, when signs of lactogenesis are absent 72 hours after birth (Lawrence and Lawrence, 2005).

### Nutritional Requirements of Lactation

Lactation is nutritionally demanding, especially for the woman who nurses her infant exclusively for a number of months. Increased intake of most nutrients is advised. The nutritional status of lactating women who have previously undergone gastric bypass surgery needs close attention because suboptimal levels of iron, vitamin A, vitamin D, vitamin K, folate, and calcium have been reported (Guelinckx et al., 2009).

Milk production is most affected by the frequency of suckling and maternal hydration. However, milk composition varies according to the mother’s diet. For example, the fatty acid composition of a mother’s milk reflects her dietary intake. In addition, milk concentrations of selenium, iodine,

markedly increase breast, areola, and nipple size. In pregnancy, hormones significantly increase ducts and alveoli and influence mammary growth. Late in pregnancy the lobules of the alveolar system are maximally developed, and small amounts of colostrum may be released for several weeks before term and for a few days after delivery. After birth there is a rapid drop in circulating levels of estrogen and progesterone accompanied by a rapid increase in prolactin secretion, setting the stage for a copious milk supply.

The usual stimulus for milk production and secretion is suckling. Subcutaneous nerves of the areola send a message via the spinal cord to the hypothalamus, which in turn transmits a message to the pituitary gland, where both the

and some of the water-soluble B vitamins reflect the maternal diet. Breast milk of malnourished mothers has been shown to have lower levels of various nutrients, reflecting the foods she has available to eat.

## Energy

Milk production is 80% efficient: production of 100 mL of milk (approximately 75 kcal) requires an 85-kcal expenditure (Lawrence and Lawrence, 2005). During the first 6 months of lactation, average milk production is 750 mL/day, with a range of 550 to more than 1200 mL/day. Because production is a function of the frequency, duration, and intensity of infant suckling, infants who feed well are likely to stimulate the production of larger volumes of milk.

The DRI for energy during lactation is 330 kcal greater during the first 6 months of lactation and 400 kcal greater during the second 6 months of lactation over that for a nonpregnant woman. It is the same as the DRI during the second trimester of pregnancy (IOM, 2002). The obese and overweight woman may not require the full 330 to 400 extra kcal/day. Maternal fat stores accumulated during pregnancy provide approximately 100 to 150 kcal per day to support the early months of lactation. When the reserve fat stores have been depleted, dietary energy support for lactation must be increased if the mother intends to provide all or most of her infant's nutrition through breast milk alone. During the second 6 months of lactation, production generally drops to an average of 600 mL/day or approximately 20 oz/day.

Healthy breast-feeding women can lose as much as 1 pound per week and still supply adequate milk to maintain their infants' growth. Breast-feeding women should be reminded of the energy expenditure required to produce milk: approximately 0.67 kcal per 1 cc of breast milk output. Milk production decreases in mothers whose intakes are suboptimal; less than 1800 calories/day, and breast milk will reflect the nutrient profile of the maternal diet. Appropriate fluid intake (such as drinking for thirst) and adequate rest are also needed.

## Protein

The DRI suggests an additional 25 g of protein a day for lactation, or 71 g of protein a day. This is based on an RDA of 1.1 gm/kg/day of prepregnancy weight. Clinical judgment is necessary with protein recommendations because 71 g/day may be too low in an overweight woman and too high for the woman with a lower BMI. Women with surgical delivery and women who enter pregnancy in poor nutritional shape may need additional protein. The average protein requirement for lactation is estimated from milk composition data and the mean daily volume of 750 mL, assuming 70% efficiency in the conversion of dietary protein to milk protein.

Breast milk has a whey/casein ratio of 90:10 early in lactation, which changes to 80:20 as an average, and to 60:40 as the baby gets older. It is speculated that this ratio makes breast milk more digestible. In contrast, the whey/casein ratio of cow's milk protein is 18:82.

## Carbohydrates

The RDA for carbohydrate is 210 g/day (IOM, 2002). This 210 g/day is the recommended amount to provide enough calories in the diet for adequate volumes of milk and to maintain an adequate energy level during lactation. This may need to be adjusted depending on activity of the mother and the amount of breast-feeding. The woman with a poor gestation weight gain may require more carbohydrates.

## Lipid

The amount and type of fat in breast milk directly reflects the maternal diet. The "fore" milk or first milk in a feeding is lower in fat than the "hind" milk at the end of a feeding. Dietary fat choices by the mother can increase or decrease specific fatty acids in her milk. Severe restriction of energy intake results in mobilization of body fat, and the milk produced has a fatty acid composition resembling that of the mother's body fat.

There is no DRI for total lipids during lactation because it depends on the amount of energy required by the mother to maintain milk production. DRIs state a recommended amount of specific long-chain polyunsaturated fatty acids in human milk because their presence in the maternal diet is crucial for fetal and infant brain development. The AI for  $\omega$ -6 polyunsaturated fatty acids is 13 g/day, and the AI for  $\omega$ -3 polyunsaturated fatty acids is 1.3 g/day (IOM, 2002). *Trans* fats should be avoided completely by the nursing mother so that the potential for their appearance in her breast milk is reduced.

Human milk contains 10 to 20 mg/dL of cholesterol, resulting in an approximate consumption of 100 mg/day by the infant. The amount of cholesterol in milk does not reflect the mother's diet; however, the cholesterol content of the milk decreases over time as lactation progresses.

## Vitamins and Minerals

The vitamin D content of milk is related to maternal vitamin D intake and the degree of sun exposure. Numerous case reports document marginal or significant vitamin D deficiency in pregnant women and in infants of lactating women who are veiled, dark skinned, with BMI of more than 30, who use sunscreens heavily, or who live in northern latitudes with decreased sun exposure. Women with lactose intolerance who do not drink vitamin D-fortified milk or take a vitamin supplement may be at higher risk for vitamin D deficiency. Because of reports of clinical rickets, the AAP recommends that all breast-fed infants receive an additional 200 IU (5 mcg) of vitamin D daily beginning at 2 months of age (Lawrence and Lawrence, 2005). During lactation, supplements administered directly to the infant allow the infant to easily achieve vitamin D sufficiency; the mother may need much higher doses (100 mcg or 4000 IU per day) to achieve adult-normal 25(OH)D concentrations and vitamin D adequacy in her exclusively breast-fed infant.

The calcium content of breast milk is not related to maternal intake, and there is no convincing evidence that

maternal change in bone mineral density is influenced by calcium intake across a broad range of intakes up to 1600 mg/day. In a community study of 210 Sri Lankan women, prolonged lactation was not shown to have detrimental effects on bone density mass (Lenora et al., 2009).

The amount of iodine in breast milk may not always reflect maternal intake. See “Iodine” earlier in this chapter. In the US the presence of the industrial pollutant, perchlorate, has been shown to inhibit iodine uptake. Perchlorate has been found in mothers’ milk as well as in the water supply (Dasgupta et al., 2008). This may explain why iodine levels in some individuals are low, despite what appears to be an adequate amount of iodine in the diet.

The requirements for zinc during lactation are greater than those during pregnancy. In the process of normal lactation the zinc content of breast milk drops dramatically during the first few months from 2 to 3 mg/day to 1 mg/day by the third month after birth.

**FIGURE 16-7** A nursing mother and her infant enjoy the close physical and psychologic contact that accompanies breast-feeding. (*Courtesy Kelly Carlson Atlec, Fairbanks, Alaska.*)

## Breast-Feeding an Infant

### Preparation

The advantages of breast-feeding should be presented throughout the childbearing years (Figure 16-7). During the last months of pregnancy, counseling on the process of lactation should be made available to women who have decided to breast-feed. Fathers or partners should be encouraged to participate in counseling sessions because the emotional support they provide contributes to the success of lactation.

### Colostrum

**Colostrum** is the thin, yellow, milky fluid that is the first milk available after birth. It is higher in protein and lower in fat and carbohydrate than mature milk. Colostrum provides approximately 20 kcal/oz and is a rich source of antibodies (Lawrence and Lawrence, 2005). The unique properties of colostrum include that it is lower in lactose than mature milk, facilitates the passage of meconium (first stool of neonate), is high in antioxidants, and is lower in water-soluble vitamins than mature milk. Colostrum is also higher in fat-soluble vitamins, protein, sodium, potassium, chloride, zinc, and immunoglobulins than mature milk.

### The Technique

Breast-feeding is a learned skill for both mother and her infant. The baby should be put to breast soon after birth and remain in direct skin-to-skin contact until the first feed is accomplished (American Academy of Pediatrics, 2005). Lactating women may experience a tingling sensation in the breast signaling the let-down reflex. Practice, patience, and perseverance are necessary. Within 48 to 96 hours after birth the breasts become fuller and firmer as the milk volumes increase. Women should be encouraged to pump and store breast milk in the likelihood of needing to be away from the infant for a feeding or two. Use of a breast pump facilitates breast milk expression; pump rentals may be covered by insurance.

Women who have insulin-dependent diabetes may experience “lactation hypoglycemia” as they increase their breast-feeding sessions. Those who have had cesarean deliveries or those who are taking pain medication may have difficulty with discerning let-down from low glucose levels. Frequent glucose monitoring needs to be emphasized to ensure safety for both mother and baby.

There is no need to offer breast-fed babies additional water because 87% of breast milk is water. However, cases of hypernatremic dehydration caused by suboptimal breast-feeding do occur. Most cases involve young and first-time mothers who may feel intimidated and overwhelmed at delivery, lack breast-feeding education, and are unaware of the consequences of dehydration. Extreme heat or hot weather may also contribute to this problem. The consequence of hypernatremic dehydration can be permanent brain damage or death. Therefore it is vital to evaluate the breast-feeding in the clinic at followup. Problems identified can then be addressed, and a plan of care can be implemented.

All breast-fed newborns should be seen within 3 to 5 days of birth by an experienced health care professional (AAP, 2005).

Exclusive breast-feeding is recommended for the first 6 months, but may continue for the first year or as long as it is mutually desired by mother and child (AAP, 2005).

### Exercise and Breast-Feeding

The breast-feeding mother should be encouraged to get back to exercise a few weeks after delivery, after lactation is well established. Aerobic exercise at 60% to 70% of maximum heart rate has no adverse effect on lactation; infants gain weight at the same rate, and the mother’s

cardiovascular fitness improves. Exercise also improves plasma lipids and insulin response in lactating women.

### Transfer of Drugs into Human Milk

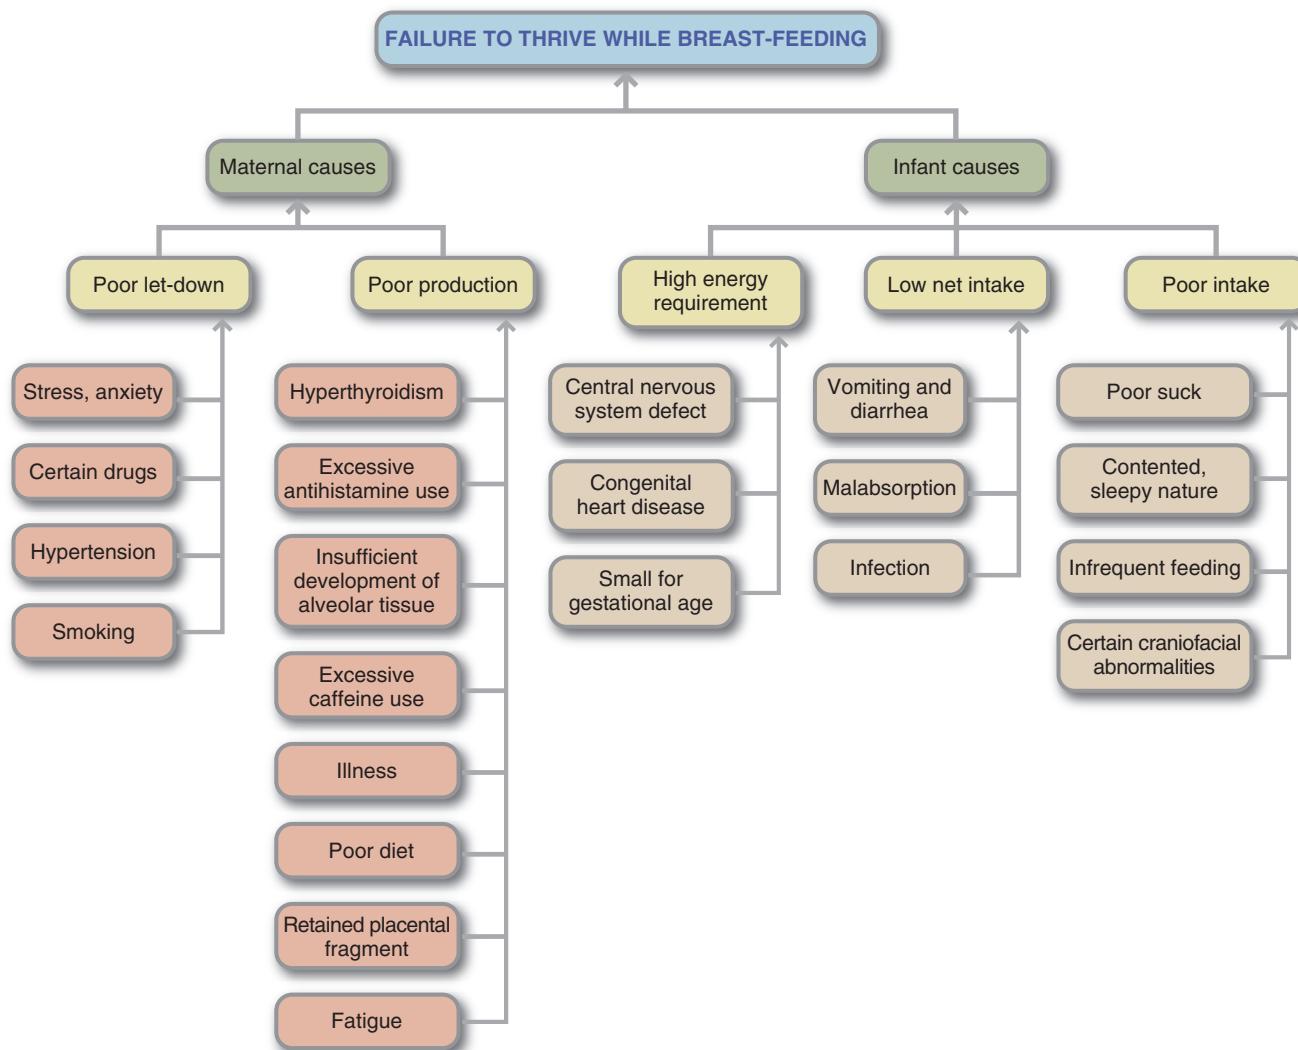

Almost all drugs taken by the mother appear in her milk to some degree. The amount that usually transfers is quite small. Many factors influence how medications transfer into human milk: milk/plasma ratio, molecular weight of the drug, and the protein binding and lipid solubility of the drug.

It is estimated that more than 500,000 pregnancies in the United States each year involve women who have psychiatric illnesses that either antedate the pregnancy or emerge during pregnancy and an estimated one third of them require a psychotropic medication (ACOG 2009; Voyer and Moretti, 2009). The need for medication must be balanced against the risk of an untreated illness. Websites that can provide more information include the AAP, [www.aap.org](http://www.aap.org), and the National Institutes of Health, <http://www.nimh.nih.gov/health/publications/mental-health-medications/complete-index.shtml>.

### Failure to Thrive in the Breast-Fed Infant

Insufficient milk supply is rarely a problem for the well-fed, well-rested, and unstressed mother. Sucking stimulates the flow of milk; thus feeding on demand should supply ample amounts of milk to the infant. If the baby continues to gain weight and length steadily, has at least six to eight wet diapers daily, and has frequent stools, the milk supply is probably adequate.

Occasionally, however, an infant fails to thrive while seeming to nurse properly. Figure 16-8 illustrates potential problems in the mother or the infant that should be investigated during the course of evaluation. If the cause of the problem cannot be identified or the defined problem cannot be corrected, it may be necessary to encourage the mother to use commercial infant formula for at least partial nutritional support of the infant. A thorough assessment of the maternal diet and health habits is always necessary. Women who consume diets low in vitamins D or B<sub>12</sub> or iodine produce milk with low levels; the result is FTT in the breast-fed infant.

**FIGURE 16-8** Diagnostic flow chart for failure to thrive in the breast-feeding infant.

Three cases of dilated cardiomyopathy in male neonates caused by low vitamin D intakes in the lactating mothers have been reported. Two cases from the United Arab Emirates found congestive cardiac failure in two 9-month-old babies who were also noted to have rickets (Amirlak et al., 2008). Both mothers were also diagnosed with vitamin D deficiencies, being heavily clothed. Dilated cardiomyopathy associated with hypocalcemic rickets has been reported in the United States in breast-fed black infants (Brown et al., 2009).

Sometimes the infant may become intolerant or allergic to something the mother has ingested. Cow's milk protein, notably casein, has been implicated, as have peanuts. At this time, the amount or the frequency has not been conclusively determined (Sicherer SH et al., 2010; DesRoches A et al., 2010; Lopez-Exposito I et al., 2009). When suspicious foods are removed from the mother's diet, it is important to assess the nutritional quality of her diet and supplement her appropriately (see Chapter 27).

### Other Problems of Breast-Feeding

Overweight lactating women can restrict their energy intake by 500 kcal per day by decreasing consumption of foods high in fat and simple sugars, but they must increase their intake of foods high in calcium, vitamin D, vitamin A, vitamin C, and ω-3 fats to provide key nutrients for their milk supply.

Breast augmentation, a procedure in which an implant is inserted into the breast to enlarge it, is a common elective breast procedure. Periareolar and transareolar incisions can cause lactation insufficiency. These mothers should be encouraged to breast-feed, and their infants monitored for appropriate weight gain.

Reduction mammoplasty is often recommended for women with extremely large breasts who suffer from back, shoulder, or neck pain or poor body image. There are wide variations in milk production, from a little to full

production, depending on the amount of tissue removed and the type of surgical incision. These mothers should also be encouraged to breast-feed and be given anticipatory guidance and support; their infants should be monitored closely for appropriate weight gain.

There can be a number of other hurdles to overcome to breast-feed successfully. These problems and their solutions are discussed in Table 16-9.

### CLINICAL SCENARIO 1

Jean is a 34-year-old woman who is pregnant for the first time. She has a sister who has spina bifida and an older brother who had a stroke when he was 14. Jean has been tested and found to have a genetic defect known as C>T in the methylene-tetrahydrofolate receptor (MTHFR), which is a concern for her. She is worried about using the traditional prenatal vitamin-mineral supplement because she has been cautioned that she is unable to metabolize folic acid from diet and supplements. She is asking for your advice for a successful pregnancy.

#### Nutrition Diagnostic Statement

Altered nutrient (folic acid) metabolism related to a genetic alteration as evidenced by positive results for C>T in the MTHFR gene and family history of spina bifida and stroke.

#### Nutrition Care Questions

- What advice would you give Jean about any special dietary changes?
- Jean knows that there is a special prenatal vitamin-mineral supplement available but does not know how to obtain it. How will you help Jean find this supplement?
- What are the risks for a successful pregnancy outcome if Jean cannot find this special prenatal supplement?

**TABLE 16-9**

### Management of Breast-Feeding Difficulties

Problem	Approaches to Management
Retracted nipples	Before feeding the infant, roll the nipple gently between the fingers until erect.
Baby's mouth not open wide enough	Before feeding, depress the infant's lower jaw with one finger as the nipple is guided into the mouth.
Baby sucks poorly	Stimulate sucking motions by pressing upward under the baby's chin. Expression of colostrums often occurs, and the taste may stimulate sucking.
Baby demonstrates rooting but does not grasp the nipple; eventually cries in frustration	Interrupt the feeding, comfort the infant; the mother should take time to relax before trying again.
Baby falls asleep while nursing	If the infant falls asleep early in the feeding, the mother should awaken the infant by holding him or her upright, rubbing his or her back, talking to him or her, or providing similar quiet stimuli; another effort at feeding can then be made. If the baby falls asleep again, the feeding should be postponed.

## CLINICAL SCENARIO 2

Elena is a 23-year-old woman who has a 2-year-old child and a 10-day-old infant via cesarean delivery; she has a history of postpartum depression. She has come to the Women, Infants, and Children clinic for certification as a breast-feeding mother. She is breast-feeding her infant every 3 hours, but is concerned that he may not be getting enough milk. While with the nutritionist in the clinic, she begins to cry and talk about her sore nipples, profound fatigue, and worry. A 24-hour recall of foods eaten the day before reveals that Elena skipped breakfast and ate some microwave meals for lunch and dinner.

The nutritionist asks permission to watch Elena nurse her infant. Because she is not supporting the infant's back and buttocks firmly, the infant tugs at the nipple and causes the soreness. The nutritionist then weighs the infant and finds that he has already regained his birth weight.

### Nutrition Diagnostic Statement

Difficulty breast-feeding related to poor infant positioning as evidenced by mom's reports of fatigue and sore nipples.

### Nutrition Care Questions

- What would you say to Elena regarding her concern that her son may not be getting enough milk?
- What would you recommend to improve the infant's position during nursing? How would this improve the nursing experience?
- What advice would you give Elena about her fatigue?
- How would you design an eating plan that Elena could follow?

### Other Common Nutrition Diagnostic Statements in Pregnant or Lactating Women

Harmful beliefs related to nutritional requirements during pregnancy as evidenced by pica with consumption of laundry starch two times daily with lunch and dinner meals

Limited access to food related to low income and misunderstanding of the use of WIC vouchers as evidenced by other family members using the WIC foods in the household

Obesity related to frequent meals and snacking during pregnancy as evidenced by weight gain of 30 pounds in second trimester

Intake of unsafe foods related to storing fresh milk on the counter as evidenced by home visit by social worker and discussions with client

Inconsistent carbohydrate intake related to management of gestational diabetes as evidenced by nutritional history of skipping breakfast and sometimes lunch

Abnormal gastrointestinal function related to heartburn as evidenced by complaints of reflux after every meal and excessive use of antacids

Inadequate food and beverage intake related to irregular income as evidenced by discussion about migrant status and the challenges during pregnancy

Breast-feeding difficulty related to frequent nipple soreness as evidenced by mother's hesitancy to continue nursing her 6-month-old

Kelly N. McKean, MS, RD, CD

# Nutrition in Infancy

### KEY TERMS

arachidonic acid (ARA)  
casein  
casein hydrolysate  
catch-up growth  
colostrum  
docosahexaenoic acid (DHA)  
growth channel  
electrolytically reduced iron

lactalbumin  
lactoferrin  
lag-down growth  
palmar grasp  
pincer grasp  
renal solute load  
secretory immunoglobulin A (sIgA)  
whey proteins

During the first 2 years of life, which are characterized by rapid physical and social growth and development, many changes occur that affect feeding and nutrient intake. The adequacy of infants' nutrient intakes affects their interaction with their environment. Healthy, well-nourished infants have the energy to respond to and learn from the stimuli in their environment and to interact with their parents and caregivers in a manner that encourages bonding and attachment.

### PHYSIOLOGIC DEVELOPMENT

The length of gestation, the mother's prepregnancy weight, and the mother's weight gain during gestation determine an infant's birth weight. After birth, the growth of an infant is influenced by genetics and nourishment. Most infants who are genetically determined to be larger reach their **growth channel**, a curve of weight and length or height gain throughout the period of growth, at between 3 and 6 months of age. However, many infants born at or below the tenth percentile for length may not reach their genetically

appropriate growth channel until 1 year of age; this is called **catch-up growth**. Infants who are larger at birth and who are genetically determined to be smaller grow at their fetal rate for several months and often do not reach their growth channel until 13 months of age. This phenomenon during the first year of life is called **lag-down growth**.

Infants lose approximately 6% of their body weight during the first few days of life, but their birth weight is usually regained by the seventh to tenth day. Growth thereafter proceeds at a rapid but decelerating rate. Infants usually double their birth weight by 4 to 6 months of age and triple it by the age of 1 year. The amount of weight gained by the infant during the second year approximates the birth weight. Infants increase their length by 50% during the first year of life and double it by 4 years. Total body fat increases rapidly during the first 9 months, after which the rate of fat gain tapers off throughout the rest of childhood. Total body water decreases throughout infancy from 70% at birth to 60% at 1 year. The decrease is almost all in extracellular water, which declines from 42% at birth to 32% at 1 year of age.

The stomach capacity of infants increases from a range of 10 to 20 mL at birth to 200 mL by 1 year, enabling infants to consume more food at a given time and at less frequent intervals as they grow older. During the first weeks of life, gastric acidity decreases and for the first few months remains lower than that of older infants and adults. The rate of emptying is relatively slow, depending on the size and composition of the meal.

Fat absorption varies in the neonate. Human milk fat is well absorbed, but butterfat is poorly absorbed, with fecal excretions of 20% to 48%. The fat combinations in commercially prepared infant formula are well absorbed. The infant's lingual and gastric lipases hydrolyze short- and medium-chain fatty acids in the stomach. Gastric lipase also hydrolyzes long-chain fatty acids and is important in initiating the digestion of triglycerides in the stomach. Most long-chain triglycerides pass unhydrolyzed into the small intestine, where they are broken down by pancreatic lipase. The bile salt-stimulated lipase present in human milk is stimulated by the infant's bile salts and hydrolyzes the triglycerides in the small intestine into free fatty acids and glycerol. Bile salts, which are effective emulsifiers when combined with monoglycerides, fatty acids, and lecithin, aid in the intestinal digestion of fat.

The activities of the enzymes responsible for the digestion of disaccharides—maltase, isomaltase, and sucrase—reach adult levels by 28 to 32 weeks' gestation. Lactase activity (responsible for digesting the disaccharide in milk) reaches adult levels by birth. Pancreatic amylase, which digests starch, continues to remain low during the first 6 months after birth. If the infant consumes starch before this time, increased activity of salivary amylase and digestion in the colon usually compensate.

The neonate has functional but physiologically immature kidneys that increase in size and concentrating capacity in the early weeks of life. The kidneys double in weight by 6 months and triple in weight by 1 year of age. The last renal tubule is estimated to form between the eighth fetal month and the end of the first postnatal month. The glomerular tuft is covered by a much thicker layer of cells throughout neonatal life than at any later time, which may explain why the glomerular filtration rate is lower during the first 9 months of life than it is in later childhood and adulthood. In the neonatal period the ability to form acid, urine, and concentrate solutes is often limited. The renal concentrating capacity at birth may be limited to as little as 700 mOsm/L in some infants. Others have the concentrating capacity of adults (1200 to 1400 mOsm/L). By 6 weeks, most infants can concentrate urine at adult levels. Renal function in a normal newborn infant is rarely a concern; however, difficulties may arise in infants with diarrhea or those who are fed formula that is too concentrated (Butte et al., 2004).

## NUTRIENT REQUIREMENTS

Nutrient needs of infants reflect rates of growth, energy expended in activity, basal metabolic needs, and the interaction of the nutrients consumed. Balance studies have defined

minimum acceptable levels of intakes for a few nutrients, but for most nutrients the suggested intakes have been extrapolated from the intakes of normal, thriving infants consuming human milk. The dietary reference intakes (DRIs) for infants are shown in the inside front cover.

### Energy

Full-term infants who are breast-fed to satiety and infants who are fed a standard 20-kcal/oz formula generally adjust their intake to meet their energy needs when caregivers are sensitive to the infants' hunger and satiety cues. An effective method for determining the adequacy of an infant's energy intake is to carefully monitor gains in weight, length, head circumference, and weight-for-length for age and plot these data on the World Health Organization (WHO) growth charts shown in Appendix Tables 9, 10, 13, and 14. It is important to recognize that during the first year a catch-up or lag-down period in growth may occur.

If infants begin to experience a decrease in their rate of weight gain, do not gain weight, or lose weight, their energy and nutrient intake should be monitored carefully. If the rate of growth in length decreases or ceases, potential malnutrition, an undetected disease, or both should be investigated thoroughly. If the weight gain proceeds at a much more rapid rate than growth in length, the energy concentration of the formula, the quantity of formula consumed, and the amount and type of semisolid and table foods offered should be evaluated. The activity level of the infant should also be assessed. Infants who are at the highest end of the growth charts for weight-for-length, or who grow rapidly in infancy, tend to be at greater risk for obesity later in life.

### Protein

Protein is needed for tissue replacement, deposition of lean body mass, and growth (Rodriguez, 2005). Protein requirements during the rapid growth of infancy are higher per kilogram of weight than those for older children or adults. Recommendations for protein intake are based on the composition of human milk, and it is assumed that the efficiency of human milk use is 100%.

Infants require a larger percentage of total amino acids as essential amino acids than do adults. Histidine seems to be an essential amino acid for infants, but not for adults. Tyrosine, cystine, and taurine may be essential for premature infants.

Human milk or infant formula provides the major portion of protein during the first year of life. The amount of protein in human milk is adequate for the first 6 months of life, even though the amount of protein in human milk is considerably less than in infant formula. From 6 to 12 months of age the diet should be supplemented with additional sources of high-quality protein such as yogurt, strained meats, or cereal mixed with formula or human milk.

Infants may not receive adequate protein if their formula is excessively diluted for a prolonged period, as may be done to treat diarrhea after an enteric illness, or they have multiple food allergies causing their intake to be restricted (see Chapter 27).

## Lipids

The current recommendation for infants younger than 1 year of age is to consume a minimum of 30 g of fat per day. This quantity is present in human milk and all infant formulas. Significantly lower fat intakes (e.g., with skim-milk feedings) may result in an inadequate total energy intake. An infant may try to correct the energy deficit by increasing the volume of milk ingested but usually cannot make up the entire deficit this way.

Human milk contains a generous amount of the essential fatty acids linoleic acid and  $\alpha$ -linolenic acid, as well as the longer-chain derivatives **arachidonic acid (ARA)** (C20:4 $\omega$ -6) and **docosahexaenoic acid (DHA)** (C22:6 $\omega$ -3). Infant formulas are supplemented with linoleic acid and  $\alpha$ -linolenic acid, from which ARA and DHA are derived. Increasingly, many formulas are also supplemented with ARA and DHA.

Linoleic acid, which is essential for growth and dermal integrity, should provide 3% of the infant's total energy intake, or 4.4 g/day for infants younger than 6 months of age and 4.6 g/day for infants 7 months to 1 year of age. In human milk 5% of the kilocalories and 10% in most infant formulas are derived from linoleic acid. Smaller amounts of  $\alpha$ -linolenic acid, a precursor of the  $\omega$ -3 fatty acids DHA and eicosapentaenoic acid (EPA), should be included. The current recommendation is 0.5 g/day during the first year of life.

Because DHA can be formed by desaturation of  $\alpha$ -linolenic acid, the importance of dietary DHA intake is uncertain. The concentration of DHA in human milk varies, depending on the amount of DHA in the mother's diet. DHA and ARA are the major  $\omega$ -3 and  $\omega$ -6 long-chain polyunsaturated fatty acids (LCPUFAs) of neural tissues, and DHA is the major fatty acid of the photoreceptor membranes of the retina. Some studies suggest that supplementation of DHA and ARA positively affects visual acuity and psychomotor development, especially in premature infants. However, other studies have shown no differences in development. The American Academy of Pediatrics (AAP) has not taken an official stand on the addition of LCPUFAs to infant formula; however, they are now added to most infant formulas.

## Carbohydrates

Carbohydrates should supply 30% to 60% of the energy intake during infancy. Approximately 40% of the energy in human milk and 40% to 50% of the energy in infant formulas is derived from lactose or other carbohydrates. Although rare, some infants cannot tolerate lactose and require a modified formula in their diet (see Chapters 29 and 44).

Botulism in infancy is caused by the ingestion of *Clostridium botulinum* spores, which germinate and produce toxin in the bowel lumen. The carbohydrates honey and corn syrup, occasionally used in home-prepared foods, have been identified as the only food sources of these spores in infants' diets. The spores are extremely resistant to heat treatment and are not destroyed by current methods of

processing. Thus honey and corn syrup should not be fed to infants younger than 1 year of age because they have not yet developed the immunity required to resist botulism spore development.

## Water

The water requirement for infants is determined by the amount lost from the skin and lungs and in the feces and urine, in addition to a small amount needed for growth. The recommended total water intake for infants, based on the DRIs, is 0.7 L/day for infants up to 6 months and 0.8 L/day for infants 7 to 12 months of age. Note that total water includes all water contained in food, beverages, and drinking water. Water requirements per kilogram of body weight are shown in Table 17-1.

Because the renal concentrating capacity of young infants may be less than that of older children and adults, they may be vulnerable to developing a water imbalance. Under ordinary conditions, human milk and formula that is properly prepared supply adequate amounts of water. However, when formula is boiled, the water evaporates and the solutes become concentrated; therefore boiled milk or formula is inappropriate for infants. In very hot, humid environments, infants may require additional water. When losses of water are high (e.g., vomiting and diarrhea), infants should be monitored carefully for fluid and electrolyte imbalances.

Water deficits result in hypernatremic dehydration and its associated neurologic consequences (e.g., seizures, vascular damage). Hypernatremic dehydration has been reported in breast-fed infants who lose greater than 10% of their birth weight in the first few days of life (Leven and Macdonald, 2008). Because of the potential for hypernatremic dehydration, careful monitoring of volume of intake, daily weights, and hydration status (e.g., number of wet diapers) in all newborns is warranted.

Water intoxication results in hyponatremia, restlessness, nausea, vomiting, diarrhea, and polyuria or oliguria; seizures can also result. This condition may occur when water

**TABLE 17-1**

**Water Requirements of Infants and Children**

Age	Water Requirement (mL/kg/day)
10 days	125-150
3 mo	140-160
6 mo	130-155
1 yr	120-135
2 yr	115-125
6 yr	90-100
10 yr	70-85
14 yr	50-60

From Barness LA: Nutrition and nutritional disorders. In Behrman RE, Kliegman RM: Nelson textbook of pediatrics, ed 17, Philadelphia, 2003, Saunders.

is provided as a replacement for milk, the formula is excessively diluted, or bottled water is used instead of an electrolyte solution in the treatment of diarrhea.

## Minerals

### Calcium

Breast-fed infants retain approximately two thirds of their calcium intake. The recommended adequate intake (AI), the mean intake, is based on calcium intakes in healthy breast-fed infants. The AI for infants 0 to 6 months of age is 200 mg/day; for infants 7 to 12 months of age the AI is 260 mg/day; formulas are enhanced accordingly.

### Fluoride

The importance of fluoride in preventing dental caries has been well documented. However, excessive fluoride may cause dental fluorosis, ranging from fine white lines to entirely chalky teeth (see Chapter 26). To prevent fluorosis, the tolerable upper intake level for fluoride has been set at 0.7 mg/day for infants up to 6 months and 0.9 mg/day for infants 7 to 12 months of age.

Human milk is very low in fluoride. Commercially prepared infant cereals, wet pack cereals, and fruit juice produced with fluoridated water are significant sources of fluoride in infancy. Fluoride supplementation is not recommended for infants younger than 6 months of age. After tooth eruption it is recommended that fluoridated water be offered several times per day to breast-fed infants, those who receive cow's milk, and those fed formulas made with water that contains less than 0.3 mg of fluoride/L (American Academy of Pediatrics [AAP], 2009).

### Iron

Full-term infants are considered to have adequate stores of iron for growth up to a doubling of their birth weight. This occurs at approximately 4 months of age in full-term infants and much earlier in prematurely born infants. Recommended intakes of iron increase according to age, growth rate, and iron stores. At 4 to 6 months of age, infants who are fed only human milk are at risk for developing a negative iron balance and may deplete their reserves by 6 to 9 months. Iron in human milk is highly bioavailable; however, breast-fed infants should receive an additional source of iron by 4 to 6 months of age (AAP, 2005). Iron-fortified cereals and infant formula are common food sources. Cow's milk is a poor source of iron and should not be given before 12 months of age. The AAP recommends iron supplementation of 1 mg/kg/day starting at 4 months of age and continuing until appropriate complementary foods have been introduced (Baker and Greer, 2010).

Iron deficiency and iron deficiency anemia are common health concerns for the older infant. The prevalence of iron deficiency in children 9 months to 3 years of age who are living in the United States and the United Kingdom and are primarily among low socioeconomic and minority groups is higher than the 10% in the general population, and has been estimated at 30% (Eden, 2005).

Monitoring iron status is important because of the long-term cognitive effects of iron deficiency in infancy (Eden, 2005). Low hemoglobin concentrations at 8 months of age correlate with impaired motor development at 18 months of age (Sherriff et al., 2001). In addition, children with chronic iron deficiency in infancy demonstrate long-term developmental deficits and behavioral issues in early adolescence.

### Zinc

Newborn infants are immediately dependent on a dietary source of zinc. Zinc is better absorbed from human milk than from infant formula. Human milk and infant formulas provide adequate zinc (0.3 to 0.5 mg/100 kcal) for the first year of life. Other foods (e.g., meats, cereals) should provide most of the zinc required during the second year. Infants who are zinc-deficient can exhibit growth retardation (Cole and Lifshitz, 2008).

## Vitamins

### Vitamin B<sub>12</sub>

Milk from lactating mothers who follow a strict vegan diet may be deficient in vitamin B<sub>12</sub>, especially if the mother followed the regimen for a long time before and during her pregnancy. Vitamin B<sub>12</sub> deficiency has also been diagnosed in infants breast-fed by mothers with pernicious anemia (Weiss et al., 2004) (see Chapter 32).

### Vitamin D

Human milk derived from an adequately fed, lactating mother supplies all the vitamins the term infant needs except for vitamin D; human milk contains approximately only 20 international units (IU)/L (0.5 mcg cholecalciferol) of vitamin D. For the prevention of rickets and vitamin D deficiency, the AAP recommends a minimum vitamin D intake of 400 IU per day shortly after birth for all infants. All breast-fed infants need a vitamin D supplement of 400 IU per day. Formula-fed infants who consume less than 1000 mL of formula per day also need supplementation (Wagner and Greer, 2008). There appears to be a higher risk of rickets among young, breast-fed infants and children with dark skin (Weisberg et al., 2004). Because a variety of environmental and family lifestyle factors can affect both sunlight exposure and absorption of vitamin D, the AAP recommendations to provide supplemental vitamin D are appropriate for all infants. Supplementation up to 800 IU of vitamin D per day may be needed for infants at higher risk, such as premature infants, dark-skinned infants and children, and those who reside in northern latitudes or at higher altitudes (Misra et al., 2008).

The Food and Drug Administration (FDA) states that some droppers that come with liquid vitamin D supplements could hold more than the 400 IU per day recommended by the AAP. Thus it is important that parents or caregivers provide only the recommended amount. Excessive vitamin D can cause nausea and vomiting, loss of appetite, excessive thirst, frequent urination, constipation, abdominal pain,

muscle weakness, muscle and joint aches, confusion, fatigue or damage to kidneys.

### Vitamin K

The vitamin K requirements of the neonate need special attention. Deficiency may result in bleeding or hemorrhagic disease of the newborn. This condition is more common in breast-fed infants than in other infants because human milk contains only 2.5 mcg/L of vitamin K, whereas cow's milk-based formulas contain approximately 20 times this amount. All infant formulas contain a minimum of 4 mcg of vitamin K per 100 kcal of formula. The AI for infants is 2 mcg/day during the first 6 months and 2.5 mcg/day during the second 6 months of life. This can be supplied by mature breast milk, although perhaps not during the first week of life. For breast-fed infants vitamin K supplementation is necessary during that time to considerably decrease the risk for hemorrhagic disease. Most hospitals require that infants receive an injection of vitamin K as a prophylactic measure shortly after birth.

### Supplementation

Vitamin and mineral supplements should be prescribed only after careful evaluation of the infant's intake. Commercially prepared infant formulas are fortified with all necessary vitamins and minerals; therefore formula-fed infants rarely need supplements. Breast-fed infants need additional vitamin D supplementation shortly after birth and iron by 4 to 6 months of age (see *Focus On: Vitamin and Mineral Supplementation Recommendations for Full-Term Infants*). Chapter 43 discusses the feeding of premature or high-risk infants and their special needs.

## MILK

### Human Milk

Human milk is unquestionably the food of choice for the infant. Its composition is designed to provide the necessary energy and nutrients in appropriate amounts. It contains specific and nonspecific immune factors that support and strengthen the immature immune system of the newborn and thus protect the body against infections. Human milk also helps prevent diarrhea and otitis media (AAP, 2005). Allergic reactions to human milk protein are rare. Moreover, the closeness of the mother and infant during breast-feeding facilitates attachment and bonding (see Chapter 16) and breast milk provides nutritional benefits (e.g., optimal nourishment in an easily digestible and bioavailable form), decreases infant morbidity, provides maternal health benefits (e.g., lactation amenorrhea, maternal weight loss, some cancer protection), and has economic and environmental benefits (American Dietetic Association [ADA], 2009).

During the first few days of life, a breast-feeding infant receives **colostrum**, a yellow, transparent fluid that meets the infant's needs during the first week. It contains less fat and carbohydrate but more protein and greater concentrations

### © FOCUS ON

## Vitamin and Mineral Supplementation Recommendations for Full-Term Infants

### Vitamin D

Supplementation shortly after birth of 400 IU/day for all breast-fed infants and infants consuming less than 1000 mL of vitamin D-fortified formula each day

### Vitamin K

Supplementation soon after birth to prevent hemorrhagic disease of the newborn

### Fluoride

Supplement of 0.25 mg/day after 6 months of age if fluoride concentration of water is less than 0.3 ppm

### Iron

#### Breast-Fed Infants

Approximately 1 mg/kg/day by 4 to 6 months of age, preferably from supplemental foods, and only iron-fortified formulas for weaning or supplementing breast milk

#### Formula-Fed Infants

Only iron-fortified formula during the first year of life

Modified from American Academy of Pediatrics, Committee on Nutrition: Pediatric nutrition handbook, ed 6, Elk Grove Village, Ill, 2009, American Academy of Pediatrics.

of sodium, potassium, and chloride than mature milk. It is also an excellent source of immunologic substances.

Note that breast feeding may not be appropriate for mothers with certain infections or those who are taking medications that may have untoward effects on the infant. For example, a mother who is infected with human immunodeficiency virus can transmit the infection to the infant and a mother using psychotropic drugs or other pharmacologic drugs may pass the medication to the infant through her breast milk (AAP, 2005). See Chapter 16.

The American Dietetic Association (ADA) and the AAP support exclusive breast feeding (EBF) for the first 6 months of life and then breast feeding supplemented by complementary foods until at least 12 months (AAP, 2005; ADA, 2009). It is important to note the ages of the infants in these recommendations; adding other foods at too young of an age decreases breast-milk intake and increases early weaning. Healthy Children 2020 objectives propose to support breast-feeding among mothers of newborn infants (see *Focus On: Healthy Children 2020 Objectives: Nourishment of Infants*).

## ◎ FOCUS ON

### Healthy Children 2020 Objectives: Nourishment of Infants

**H**ealthy People 2020 is a comprehensive set of health objectives for the United States to achieve during the second decade of the 21st century. Healthy People 2020 identifies a wide range of public health priorities and specific, measurable objectives. The objectives have 42 focus areas, one of which is Maternal, Infant, and Child Health. The objectives related to nourishment of infants are as follows:

**GOAL:** Improve the health and well being of women, infants, children, and families.

**Objective:** Increase the proportion of infants who are breastfed to 81.9% in the early postpartum period, to 60.6% at 6 months, and to 34.1% at 1 year of age.

Increase the proportion of infants that are exclusively breastfed to 46.2% through 3 months of age and 25.5% through 6 months of age.

**Objective:** Reduce the proportion of breastfed newborns who receive formula supplementation within the first 2 days of life to 14.2%.

**GOAL:** Promote health and reduce chronic disease risk through the consumption of healthful diets and achievement and maintenance of healthy body weights.

**Objective:** Eliminate very low food security among children. **Objective:** Reduce iron deficiency among children ages 1 to 2 years to less than 14.3%.

**GOAL:** Prevent and control oral and craniofacial diseases, conditions, and injuries and improve access to preventive services and dental care.

**Objective:** Reduce the proportion of young children with dental caries in their primary teeth.

The complete text of the Healthy People 2020 Objectives can be found at [www.healthypeople.gov/2020/topics/objectives2020/default.aspx](http://www.healthypeople.gov/2020/topics/objectives2020/default.aspx)

### Composition of Human and Cow's Milk

The composition of human milk is different from that of cow's milk; for this reason, unmodified cow's milk is not recommended for infants until at least 1 year of age. Both provide 20 kcal/oz; however, the nutrient sources of the energy are different. Protein provides 6% to 7% of the energy in human milk and 20% of the energy in cow's milk. Human milk is 60% **whey proteins** (mainly lactalbumins) and 40% casein; by contrast, cow's milk is 20% whey proteins and 80% casein. **Casein** forms a tough, hard-to-digest curd in the infant's stomach, whereas **lactalbumin** in human milk forms soft, flocculent, easy-to-digest curds. Taurine

and cystine are present in higher concentrations in human milk than in cow's milk; these amino acids may be essential for premature infants. Lactose provides 42% of the energy in human milk and only 30% of the energy in cow's milk.

Lipids provide 50% of the energy in human and whole cow's milk. Linoleic acid, an essential fatty acid, provides 4% of the energy in human milk and only 1% in cow's milk. The cholesterol content of human milk is 10 to 20 mg/dL compared with 10 to 15 mg/dL in whole cow's milk. Less fat is absorbed from cow's milk than from human milk; a lipase in human milk is stimulated by bile salts and contributes significantly to the hydrolysis of milk triglycerides.

All of the water-soluble vitamins in human milk reflect maternal intake. Cow's milk contains adequate quantities of the B-complex vitamins, but little vitamin C. Human milk and supplemented cow's milk provide sufficient vitamin A. Human milk is a richer source of vitamin E than cow's milk.

The quantity of iron in human and cow's milk is small (0.3 mg/L). Approximately 50% of the iron in human milk is absorbed, whereas less than 1% of the iron in cow's milk is absorbed. The bioavailability of zinc in human milk is higher than in cow's milk. Cow's milk contains three times as much calcium and six times as much phosphorus as human milk, and its fluoride concentration is twice that of human milk.

The much higher protein and ash content of cow's milk results in a higher **renal solute load**, or amount of nitrogenous waste and minerals that must be excreted by the kidney. The sodium and potassium concentrations in human milk are about one third those in cow's milk, contributing to the lower renal solute load of human milk. The osmolality of human milk averages 300 mOsm/kg, whereas that of cow's milk is 400 mOsm/kg.

### Antiinfective Factors

Human milk and colostrum contain antibodies and antiinfective factors that are not present in infant formulas.

**Secretory immunoglobulin A (sIgA)**, the predominant immunoglobulin in human milk, plays a role in protecting the infant's immature gut from infection. Breast feeding should be maintained until the infant is at least 3 months of age to obtain this benefit.

The iron-binding protein **lactoferrin** in human milk deprives bacteria of iron and thus slows their growth. Lysozymes, which are bacteriolytic enzymes found in human milk, destroy the cell membranes of bacteria after the peroxides and ascorbic acid that are also present in human milk have inactivated them. Human milk enhances the growth of the bacterium *Lactobacillus bifidus*, which produces an acidic gastrointestinal (GI) environment that interferes with the growth of certain pathogenic organisms. Because of these antiinfective factors, the incidence of infections is lower in breast-fed infants than in formula-fed infants.

Colonization with nonpathogenic microbiota is important for infant health and may affect health in later life. By the time a mother weans her infant, the baby's GI tract has established its normal flora. This ecosystem in

early life is influenced by such factors as mode of birth, environment, diet, and use of antibiotics (Marques et al., 2010). The role and safety of supplemental probiotic use is under study.

## Formulas

Infants that are not breastfed are usually fed a formula based on cow's milk or a soy product. Many mothers may also choose to offer a combination of breast milk and formula feedings. Those infants who have special requirements receive specially designed products.

Commercial formulas made from heat-treated nonfat milk or a soy product and supplemented with vegetables fats, vitamins, and minerals are formulated to approximate, as closely as possible, the composition of human milk. They provide the necessary nutrients in an easily absorbed form. The manufacture of infant formulas is regulated by the FDA through the Infant Formula Act (Nutrient Requirements for Infant Formulas, 1985). By law, infant formulas are required to have a nutrient level that is consistent with these guidelines (Table 17-2). Refer to individual manufacturers' websites to obtain the most accurate information and compare the composition of various infant formulas and feeding products.

Formulas are also available for older infants and toddlers. However, typically "older infant" formulas are unnecessary unless toddlers are not receiving adequate amounts of infant or table foods.

Efforts are ongoing to manufacture infant formulas that closely approximate human milk. Recent additions to infant formulas include ARA, DHA, prebiotics, and probiotics. No current documentation shows that the growth or development of formula-fed infants is compromised when they consume formulas without these additives. The declining prevalence of anemia in infants is credited to the use of iron-fortified formula. The AAP recommends iron-fortified formulas for all formula-fed infants. The widespread theory that iron-fortified formula may cause constipation, loose stools, colic (severe abdominal pain), and spitting up has not been confirmed by clinical studies (AAP, 1999).

Various products are available for infants who cannot tolerate the protein in cow's milk-based formulas. Soy-based infant formulas are recommended for (1) infants in vegetarian families, and (2) infants with galactosemia or hereditary primary lactase deficiency. Soy formulas are not recommended for children known to have protein allergies because many infants who are allergic to cow's milk protein also develop allergies to soy protein (Bhatia and Greer, 2008) (see Chapter 27).

Infants who cannot tolerate cow's milk-based or soy products can be fed formulas made from a **casein hydrolysate**, which is casein that has been split into smaller components by treatment with acid, alkali, or enzymes. These formulas do not contain lactose. For infants who have severe food protein intolerances and cannot tolerate hydrolysate formulas, free amino acid-based formulas are available. Other formulas are available for children with problems

**TABLE 17-2**

### Nutrient Levels in Infant Formulas As Specified by the Infant Formula Act

Specified Nutrient Component	Minimum Level Required (per 100 kcal of energy)
Protein (g)	1.8
Fat (g)	3.3
Percentage of calories	30
Linoleic acid (mg)	300
Percentage of calories	2.7
Vitamin A (IU)	250
Vitamin E (IU)	0.7
Vitamin D (IU)	40
Vitamin K (mcg)	4
Thiamin (mcg)	40
Riboflavin (mcg)	60
Niacin (mcg)	250
Ascorbic acid (mg)	8
Pyridoxine (mcg)	35
Vitamin B <sub>12</sub> (mcg)	0.15
Folic acid (mcg)	4
Biotin (mcg) (non-milk-based formulas only)	1.5
Pantothenic acid (mcg)	300
Choline (mg) (non-milk-based formulas only)	7
Inositol (mg) (non-milk-based formulas only)	4
Calcium (mg)	60
Phosphorus (mg)	30
Iron (mg)	0.15
Zinc (mg)	0.5
Magnesium (mg)	6
Manganese (mcg)	5
Sodium (mg)	20
Potassium (mg)	80
Iodine (mcg)	5
Chloride (mg)	55
Copper (mcg)	60

From Nutrient requirements for infant formulas, Final Rule (21 CFR 107), Fed Reg 50:45106, 1985.

such as malabsorption or metabolic disorders (e.g., phenylketonuria) (see Chapters 18 and 44).

Soy-based formulas are under regular scrutiny. Full-term infants ingesting soy formulas grow and absorb minerals as well as infants fed cow's milk-based formulas, but they are exposed to several thousand times higher levels of phytoestrogens and isoflavones. The biologic effect of these elevated isoflavone levels on long-term infant development is not yet clear (National Toxicology Program, 2010). Soy-based formulas are not recommended for preterm infants

because of the increased risk for osteopenia (Bhatia and Greer, 2008).

The protein in soy infant formula is soy protein isolate supplemented with L-methionine, L-carnitine, and taurine. Contaminants include phytates, which bind minerals and niacin; and protease inhibitors, which have antitrypsin, antichymotrypsin, and antielastin properties. Aluminum from mineral salts is found in soy infant formulas at concentrations of 600–1300 ng/mL, levels that exceed aluminum concentrations in human milk of 4–65 ng/mL (Bhatia and Greer, 2008).

## Whole Cow's Milk

Some parents may choose to transition their infant from formula to fresh cow's milk before 1 year of age. However, the AAP Committee on Nutrition has concluded that infants should not be fed whole cow's milk during the first year of life (AAP, 2009). Infants who are fed whole cow's milk have been found to have lower intakes of iron, linoleic acid, and vitamin E, and excessive intakes of sodium, potassium, and protein. Cow's milk may cause a small amount of GI blood loss.

Low-fat (1% to 2%) and nonfat milk are also inappropriate for infants during the first 12 months of life. The infants may ingest excessive amounts of protein in large volumes of milk in an effort to meet their energy needs, and the decreased amount of essential fatty acids may be insufficient for preventing deficiency (AAP, 2009). In addition, substitute or imitation milks such as rice, oat, or nut milks are inappropriate and should not be fed to infants unless they are supplemented.

## Formula Preparation

Commercial infant formulas are available in ready-to-feed forms that require no preparation, as concentrates prepared by mixing with equal parts of water, and in powder form that is designed to be mixed with 2 oz of water per level scoop of powder.

Infant formulas should be prepared in a clean environment. All equipment, including bottles, nipples, mixers, and the top of the can of formula, should be washed thoroughly. Formula may be prepared for up to a 24-hour period and refrigerated. Formula for each feeding should be warmed in a hot water bath. Microwave heating is not recommended because of the risk of burns from formula that is too hot or unevenly heated. Any formula warmed and not consumed at that feeding should be discarded.

## FOOD

Dry infant cereals are fortified with **electrolytically reduced iron**, which is iron that has been fractionated into small particles for improved absorption. Four level tablespoons of cereal provide approximately 5 mg of iron or approximately half the amount the infant requires. Therefore infant cereal is usually the first food added to the infant's diet.

Strained and "junior" vegetables and fruits provide carbohydrates and vitamins A and C. Vitamin C is added to

numerous jarred fruits and all fruit juices. In addition, tapioca is added to several of the jarred fruits. Milk is added to the creamed vegetables, and wheat is incorporated into the mixed vegetables.

Most strained and junior meats are prepared with water. Strained meats, which have the highest energy density of any of the commercial baby foods, are an excellent source of high-quality protein and heme iron.

Numerous dessert items are also available such as puddings and fruit desserts. The nutrient composition of these products varies, but all contain excess energy in the form of sugar and modified cornstarch or tapioca starch. Most infants do not need this excess energy.

Various commercially prepared foods and organically grown products are available for infants. See Chapter 10 for a discussion of organic foods. These products vary widely in their nutrient value. Foods for infants should be thoughtfully selected to meet their nutritional and developmental needs.

Mothers who would like to make their own infant food can easily do so by following the directions in Box 17-1. Home-prepared foods are generally more concentrated in nutrients than commercially prepared foods because less water is used. Salt and sugar should not be added to foods prepared for infants.

### BOX 17-1

#### Directions for Home Preparation of Infant Foods

1. Select fresh, high-quality fruits, vegetables, or meats.
2. Be sure that all utensils, including cutting boards, grinder, knives, and other items, are thoroughly cleaned.
3. Wash hands before preparing the food.
4. Clean, wash, and trim the food in as little water as possible.
5. Cook the foods until tender in as little water as possible. Avoid overcooking, which may destroy heat-sensitive nutrients.
6. Do not add salt or sugar. Do not add honey to food intended for infants younger than 1 year of age.\*
7. Add enough water for the food to be easily puréed.
8. Strain or purée the food using an electric blender, a food mill, a baby food grinder, or a kitchen strainer.
9. Pour purée into an ice cube tray and freeze.
10. When the food is frozen hard, remove the cubes and store in freezer bags.
11. When ready to serve, defrost and heat in a serving container the amount of food that will be consumed at a single feeding.

\*Clostridium botulinum spores, which cause botulism, have been reported in honey; young infants do not have the immune capacity to resist this infection.

## FEEDING

### Early Feeding Patterns

Because milk from a mother with an adequate diet is uniquely designed to meet the needs of the human infant, breast feeding for the first 6 months of life is strongly recommended. Most chronic medical conditions do not contraindicate breast-feeding.

A mother should be encouraged to nurse her infant immediately after birth. Those who care for and counsel parents during the first postpartum days should acquaint themselves with ways in which they can be supportive of breast-feeding. Ideally, counseling and preparation for breast feeding starts in the last few months or weeks of pregnancy (see Chapter 16).

Regardless of whether infants are breast-fed or formula fed, they should be held and cuddled during feedings. Once a feeding rhythm has been established, infants become fussy or cry to indicate they are hungry, whereas they often smile and fall asleep when they are satisfied (Table 17-3). Infants, not adults, should establish the feeding schedules. Initially, most infants feed every 2 to 3 hours; by 2 months of age most feed every 4 hours. By 3 to 4 months of age infants have usually matured enough to allow the mother to omit night feedings.

Bisphenol A (BPA) is a chemical present in many hard plastic bottles, such as baby bottles and reusable cups, and metal food and beverage containers, including canned liquid

infant formula. Concern has been raised about the potential effects of BPA on the brain, behavior, and prostate gland in fetuses, infants, and young children. Studies are ongoing; however, in the interim the FDA recommends taking reasonable steps to reduce human exposure to BPA. The major U.S. manufacturers have stopped producing BPA-containing bottles and infant feeding cups for the U.S. market. The FDA is facilitating the development of alternatives to BPA for the linings of infant formula cans and supporting efforts to replace or minimize BPA in other food can linings (Food and Drug Administration [FDA], 2010).

### Development of Feeding Skills

At birth, infants coordinate sucking, swallowing, and breathing, and are prepared to suckle liquids from the breast or bottle, but are not able to handle foods with texture. During the first year, typical infants develop head control, the ability to move into and sustain a sitting posture, and the ability to grasp, first with a **palmar grasp** and then with a refined **pincer grasp** (Figure 17-1). They develop mature sucking and rotary chewing abilities and progress from being fed to feeding themselves using their fingers. In the second year, they learn to feed themselves independently with a spoon (Figure 17-2).

### Addition of Semisolid Foods

Developmental readiness and nutrient needs are the criteria that determine appropriate times for the addition of various foods. During the first 4 months of life, the infant attains head and neck control, and oral motor patterns progress from a suck to a suckling to the beginnings of a mature sucking pattern. Puréed foods introduced during this phase are consumed in the same manner as are liquids, with each suckle being followed by a tongue-thrust swallow. Table 17-4 lists developmental landmarks and their indications for semisolid and table food introduction.

Between 4 and 6 months of age, when the mature sucking movement is refined and munching movements (up-and-down chopping motions) begin, the introduction of strained foods is appropriate. Infant cereal is usually introduced first. To support developmental progress, cereal is offered to the infant from a spoon, not combined with formula in a bottle. Thereafter various commercially or home-prepared foods may be offered. The sequence in which these foods are introduced is not important; however, it is important that one single ingredient food (e.g., peaches, not peach cobbler, which has many ingredients) be introduced at a time. Introducing a single new food at a time at 2- to 7-day intervals enables parents to identify any allergic responses or food intolerances (Butte et al., 2004). Introducing vegetables before fruits may increase vegetable acceptance.

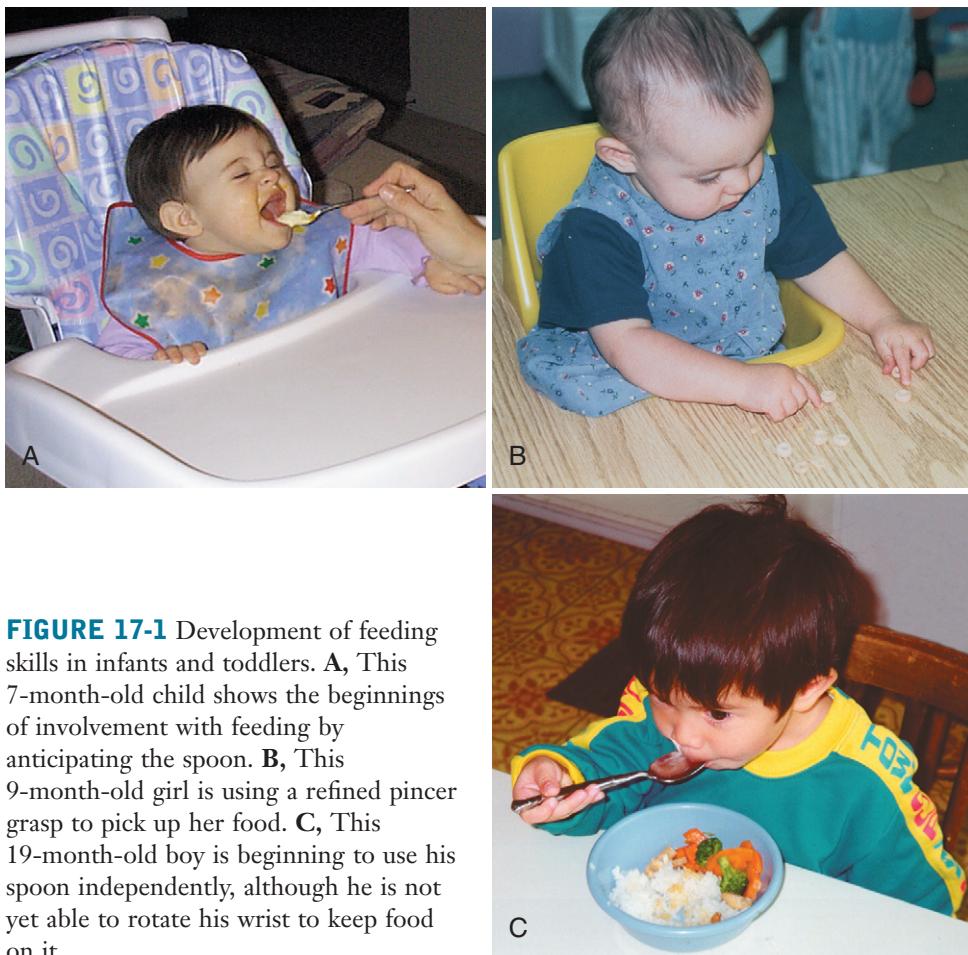

Infants demonstrate their acceptance of new foods by slowly increasing the variety and quantity of solids they accept. Breast-fed infants seem to accept greater quantities than do formula-fed infants. Parents who thoughtfully offer a variety of nourishing foods are more likely to provide a well-balanced diet and help their children learn to accept more flavors.

**TABLE 17-3**

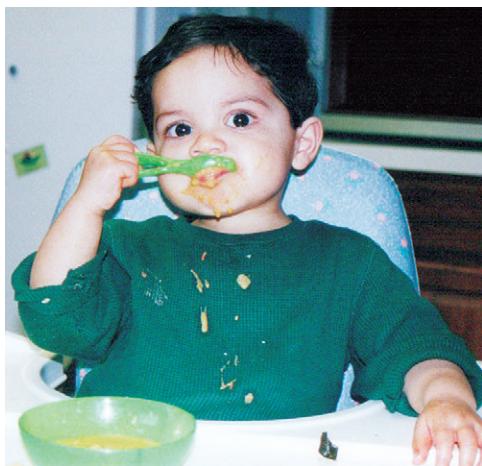

#### Satiety Behaviors in Infants

Age (Weeks)	Behavior
4-12	Draws head away from the nipple Falls asleep When nipple is reinserted, closes lips tightly Bites nipple, purses lips, or smiles and lets go Releases nipple and withdraws head Fusses or cries Obstructs mouth with hands Pays more attention to surroundings Bites nipple
16-24	Changes posture Keeps mouth tightly closed Shakes head as if to say “no” Plays with utensils Uses hands more actively Throws utensils
28-36	See behaviors listed for previous age range Sputters with tongue and lips Hands bottle or cup to mother
40-52	

From Pipes PL: Health care professionals. In Garwood G, Fewell R, editors: Educating handicapped infants, Rockville, Md, 1982, Aspen Systems.

**FIGURE 17-1** Development of feeding skills in infants and toddlers. **A**, This 7-month-old child shows the beginnings of involvement with feeding by anticipating the spoon. **B**, This 9-month-old girl is using a refined pincer grasp to pick up her food. **C**, This 19-month-old boy is beginning to use his spoon independently, although he is not yet able to rotate his wrist to keep food on it.

**FIGURE 17-2** This 2-year-old is skilled at self-feeding because he has the ability to rotate his wrist and elevate his elbow to keep food on the spoon.

As oral-motor maturation proceeds, an infant's rotary chewing ability develops, indicating a readiness for more textured foods such as well-cooked mashed vegetables, casseroles, and pasta from the family menu. Learning to grasp—with the palmar grasp, then with an inferior pincer grasp, and finally with the refined pincer grasp—indicates a

readiness for finger foods such as oven-dried toast, arrowroot biscuits, or cheese sticks (see Figure 17-1). Table 17-5 presents recommendations for adding foods to an infant's diet. Foods with skins or rinds and foods that stick to the roof of the mouth (e.g., hot dogs, grapes, bread with peanut butter) may cause choking and should not be offered to young infants.

During the last quarter of the first year, infants can approximate their lips to the rim of the cup and can drink if the cup is held for them. During the second year they gain the ability to rotate their wrists and elevate their elbows, thus allowing them to hold the cup themselves and manage a spoon. They are very messy eaters at first, but by 2 years of age most typical children skillfully feed themselves (see Figure 17-2).

### Weaning from Breast or Bottle to Cup

The introduction of solids into an infant's diet begins the weaning process in which the infant transitions from a diet of only breast milk or formula to a more varied one. Weaning should proceed gradually and be based on the infant's rate of growth and developmental skills. Weaning foods should be carefully chosen to complement the nutrient needs of the infant, promote appropriate nutrient intake, and maintain growth.

**TABLE 17-4****Feeding Behaviors: Developmental Landmarks During the First 2 Years of Life**

<b>Developmental Landmarks</b>	<b>Change Indicated</b>	<b>Examples of Appropriate Foods</b>
Tongue laterally transfers food in the mouth Shows voluntary and independent movements of the tongue and lips Sitting posture can be sustained Shows beginning of chewing movements (up and down movements of the jaw) Reaches for and grasps objects with palmar grasp Brings hand to mouth Voluntarily releases food (refined digital [pincer] grasp)	Introduction of soft, mashed table food	Tuna fish; mashed potatoes; well-cooked, mashed vegetables; ground meats in gravy and sauces; soft, diced fruit such as bananas, peaches, and pears; flavored yogurt
Shows rotary chewing pattern	Finger feeding (large pieces of food)	Oven-dried toast, teething biscuits; cheese sticks (should be soluble in the mouth to prevent choking)
Approximates lips to rim of the cup	Finger feeding (small pieces of food)	Bits of cottage cheese, dry cereal, peas, and other bite-size vegetables; small pieces of meat
Understands relationship of container and its contents	Introduction of food of varied textures from family menu	Well-cooked, chopped meats and casseroles; cooked vegetables and canned fruit (not mashed); toast; potatoes; macaroni, spaghetti; peeled ripe fruit
Shows increased movements of the jaw Shows development of ulnar deviation of the wrist Walks alone	Introduction of cup for sipping liquids Beginning of self-feeding (though messiness should be expected) More skilled at cup and spoon feeding May seek food and obtain food independently	Food that when scooped adheres to the spoon, such as applesauce, cooked cereal, mashed potatoes, cottage cheese, yogurt Chopped fibrous meats, such as roast and steak; raw vegetables and fruit (introduced gradually) Foods of high nutritional value
Names food, expresses preferences; prefers unmixed foods Goes on food jags Appetite appears to decrease		Balanced food choices, with child permitted to develop food preferences (parents should not be concerned that these preferences will last forever)

Modified from Trahms CM, Pipes P: Nutrition in infancy and childhood, ed 6, New York, 1997, McGraw-Hill.

**TABLE 17-5****Suggested Ages for the Introduction of Juice, Semisolid Foods, and Table Foods**

<b>Food</b>	<b>4-6</b>	<b>6-8</b>	<b>Age (mo)</b>
Iron-fortified cereals for infants	Add		<b>9-12</b>
Vegetables		Add strained.	Gradually eliminate strained foods and introduce table foods.
Fruits		Add strained.	Gradually eliminate strained foods; introduce chopped, well-cooked, or canned foods.
Meats		Add strained or finely chopped table meats.	Decrease the use of strained meats; increase the varieties of table meats offered.
Finger foods, such as arrowroot biscuits, oven-dried toast		Add foods that can be secured with a palmar grasp.	Increase the use of small finger foods as the pincer grasp develops.
Well-cooked mashed or chopped table foods prepared without added salt or sugar			Add and introduce use of spoon.
Juice or formula by cup			Add

Modified from Trahms CM, Pipes P: Nutrition in infancy and childhood, ed 6, New York, 1997, McGraw-Hill.

Many infants begin the process of weaning with the introduction of the cup at approximately 6 to 9 months of age and complete the process when they are able to ingest an adequate amount of milk or formula from a cup at 18 to 24 months of age. Parents of infants who are breast-fed may choose to transition the infant directly to a cup or have an intermittent transition to a bottle before the cup is introduced.

### Early Childhood Caries

Early childhood caries (ECC), or “baby bottle tooth decay,” is the most common chronic disease of childhood. ECC is a pattern of tooth decay that involves the upper anterior and sometimes lower posterior teeth. ECC is common among infants and children who are allowed to bathe their teeth in sugar (sucrose or lactose) throughout the day and night. If infants are given sugar-sweetened beverages or fruit juice in a bottle during the day or at bedtime after teeth have erupted, the risk of dental caries increases (see Chapter 26).

To promote dental health, infants should be fed and burped and then put to bed without milk, juice, or food. Juice should not be introduced into the diet before 6 months of age. Juice should be limited to 4 to 6 oz/day for infants and young children and offered to children only from a cup (AAP, 2007). Parents and caregivers can be taught effective oral health practices for infants, not only by dentists but by other paraprofessionals (MacIntosh et al., 2010).

### Feeding Older Infants

As maturation proceeds and the rate of growth slows down, infants’ interest in and approach to food changes. Between 9 and 18 months of age most reduce their breast-milk or

formula intake. They can become finicky about what and how much they eat.

In the weaning stage infants have to learn many manipulative skills, including the ability to chew and swallow solid food and use utensils. They learn to tolerate various textures and flavors of food, eat with their fingers, and then feed themselves with a utensil. Very young children should be encouraged to feed themselves. See *Clinical Insight: A New Look at the Food Practices of Infants and Toddlers*.

At the beginning of a meal, children are hungry and should be allowed to feed themselves; when they become tired, they can be helped quietly. Emphasis on table manners and the fine points of eating should be delayed until they have the necessary maturity and developmental readiness for such training.

The food should be in a form that is easy to handle and eat. Meat should be cut into bite-size pieces. Potatoes and vegetables should be mashed so that they can be eaten easily with a spoon. Raw fruits and vegetables should be in sizes that can be picked up easily. In addition, the utensils should be small and manageable. Cups should be easy to hold, and dishes should be designed so that they do not tip over easily.

### Type of Food

In general, children prefer simple, uncomplicated foods. Food from the family meal can be adapted for the child and served in child-size portions. Children younger than 6 years of age usually prefer mild-flavored foods. Because a young child’s stomach is small, a snack may be required between meals. Fruit, cheese, crackers, dry cereal, fruit juices, and milk contribute nutrients and energy. Children ages 2 to 6 years often prefer raw instead of cooked vegetables and fruits.

## CLINICAL INSIGHT

### A New Look at the Food Practices of Infants and Toddlers

**T**he Feeding Infants and Toddlers Study was a national random sample of more than 2500 infants and toddlers from 4 to 24 months of age and their mothers.

- Assuming that a variety of nutritious foods are offered to infants and toddlers, parents and caregivers should encourage self-feeding without concern for compromising energy intake and nutrient adequacy (Carruth et al., 2004a).
- Parents and caregivers should offer a variety of fruits and vegetables daily; sweets, desserts, sweetened beverages, and salty snacks should be offered only occasionally. Because family food choices influence the foods offered to infants, family-based approaches to healthy eating habits should be encouraged (Fox et al., 2004).
- By 24 months of age, 50% of toddlers were described as picky eaters. When offering a new food, caregivers

need to be willing to provide 8 to 15 repeated exposures to enhance acceptance of that food (Carruth et al., 2004b).

- Infants and toddlers have an innate ability to regulate energy intake. Parents and caregivers should understand the cues of hunger and satiety and recognize that coercive admonitions about eating more or less food can interfere with the infant’s or toddler’s innate ability to regulate energy intake (Fox et al., 2006).
- On average, infants and toddlers were fed seven times per day, and the percentage of children reported to be eating snacks increased with age. Snack choices for infants and toddlers could be improved by delaying the introduction of and limiting foods that have a low nutrient content and are energy dense (Skinner et al., 2004).

Infants should be offered foods that vary in texture and flavor. Infants who are accustomed to many kinds of foods are less likely to limit their variety of food choices later. To add variety to an infant's diet, vegetables and fruits can be added to cereal feedings. It is important to offer various foods and not allow the infant to continue consuming a diet consisting of one or two favorite foods. Older infants generally reject unfamiliar foods the first time they are offered. When parents continue to offer small portions of these foods without comment, infants become familiar with them and often accept them. It is important that fruit juice does not replace more nutrient-dense foods. If excessive amounts of juice are consumed, children may fail to thrive.

### Serving Size

The size of a serving of food offered to a child is very important. At 1 year of age infants eat one third to one half the amount an adult normally consumes. This proportion increases to one half an adult portion by the time the child reaches 3 years of age and increases to about two thirds by 6 years of age. Young children should not be served a large plateful of food; the size of the plate and the amount should be in proportion to their age. A tablespoon (not a heaping tablespoon) of each food for each year of age is a good guide to follow. Serving less food than parents think or hope will be eaten helps children eat successfully and happily. They will ask for more food if their appetite is not satisfied.

### Forced Feeding

Children should not be forced to eat; instead, the cause for the unwillingness to eat should be determined. A typical, healthy child eats without coaxing. Children may refuse food because they are too inactive to be hungry or too active and overtired. To avoid both overfeeding and underfeeding, parents should be responsive to the cues for hunger and satiety offered by the infant. A child who is fed snacks or given a bottle too close to mealtime (within 90 minutes) is not hungry for the meal and may refuse it (Butte et al., 2004).

Parents who support the development of self-feeding skills respond to the infant's need for assistance and offer encouragement for self-feeding; they also allow the infant to initiate and guide feeding interactions without excessive pressure on the infant for neatness in self-feeding or amount of food consumed. If a child refuses to eat, the family meal should be completed without comment, and the plate should be removed. This procedure is usually harder on the parent than on the child. At the next mealtime, the child will be hungry enough to enjoy the food presented.

### Eating Environment

Young children should eat their meals at the family table; it gives them an opportunity to learn table manners while enjoying meals with a family group. Sharing the family fare strengthens ties and makes mealtime pleasant. However, if the family meal is delayed, the children should receive their meal at the usual time. When children eat with the family,

everyone must be careful not to make unfavorable comments about any food. Children are great imitators of the people they admire; thus, if the father or older siblings make disparaging remarks about squash, for example, young children are likely to do the same.

The Bright Futures materials and guidelines ([www.brightfutures.org/nutrition/](http://www.brightfutures.org/nutrition/)) provide information and support to families as they guide their children to healthy eating habits and nourishment.

### CLINICAL SCENARIO

Lela is a 12-week-old girl who was born by cesarean section at 42 weeks' gestation to an 18-year-old single mother. Her mother gained 70 lb during the pregnancy. Lela's weight-for-length is plotted at the 95th percentile, and her length and weight continue in the same channels as at birth.

Lela's mother chose to feed Lela infant formula rather than breast-feed. Lela is offered Similac Advance formula that is prepared with 1 scoop of powder mixed in 2 oz of water. Lela consumes approximately six 8-oz bottles per day and is fed on demand. She usually sleeps during the night, but if she is fussy, her mother gives her small amounts of commercially prepared infant cereal, vegetables, and fruit.

#### Nutrition Diagnostic Statement

Excessive oral food and beverage intake related to using foods to soothe baby as evidenced by weight for height greater than the 95th percentile for age.

#### Nutrition Care Questions

1. What additional information is needed to get an accurate assessment of this infant's intake?
2. When you assess Lela's growth, what are your expectations for her growth rate? Do you have concerns about her rate of growth?
3. What is Lela's estimated energy intake? Is this appropriate?
4. The American Academy of Pediatrics recommendations suggest that the addition of complimentary foods be delayed until after 4 months of age. How would you assess Lela's readiness for semisolid foods? Which infant skills would you assess in a feeding evaluation?

#### Other Common Nutrition Diagnostic Statements in Infants:

Inadequate energy intake related to poor sucking reflex as evidenced by growth retardation and small head circumference

Underweight related to inadequate prenatal growth and prematurity as evidenced by weight of 2100 grams at birth  
Harmful beliefs related to nutritional requirements for infants as evidenced by mother's comments about diluting formula to save money

# Nutrition in Childhood

### KEY TERMS

**adiposity rebound**  
**catch-up growth**  
**failure to thrive (FTT)**

**food jags**  
**growth channels**  
**primarily wasted**  
**stunted growth**

The period that begins after infancy and lasts until puberty is often referred to as the *latent* or *quiescent* period of growth—a contrast to the dramatic changes that occur during infancy and adolescence. Although physical growth may be less remarkable and proceed at a steadier pace than it did during the first year, these preschool and elementary school years are a time of significant growth in the social, cognitive, and emotional areas.

Growth is generally steady and slow during the preschool and school age years, but it can be erratic in individual children, with periods of no growth followed by growth spurts. These patterns usually parallel similar changes in appetite and food intake. For parents, periods of slow growth and poor appetite can cause anxiety, leading to mealtime struggles.

Body proportions of young children change significantly after the first year. Head growth is minimal, trunk growth slows substantially, and limbs lengthen considerably, all of which create more mature body proportions. Walking and increased physical activity of the now erect child lead to the legs straightening and increased muscle strength in the abdomen and back.

The body composition of preschool and school age children remains relatively constant. Fat gradually decreases during the early childhood years, reaching a minimum between 4 and 6 years of age. Children then experience the **adiposity rebound**, or increase in body fatness in preparation for the pubertal growth spurt. Earlier adiposity rebound has been associated with increased adult body mass index (BMI) (Williams, 2009). A BMI at an “end” of the charts (e.g., less than 3rd or greater than 97th percentiles) requires careful evaluation to describe the degree of underweight or obesity (Flegal, 2009). Sex differences in body composition become

### GROWTH AND DEVELOPMENT

#### Growth Patterns

The rate of growth slows considerably after the first year of life. In contrast to the usual tripling of birth weight that occurs in the first 12 months, another year passes before the birth weight quadruples. Likewise, birth length increases by 50% in the first year but does not double until approximately the age of 4 years. Increments of change are small compared with those of infancy and adolescence; weight typically increases an average of 2 to 3 kg (4½ to 6½ lb) per year until the child is 9 or 10 years old. Then the rate increases, signaling the approach of puberty. Height increase increments average 6 to 8 cm (2½ to 3½ inches) per year from 2 years of age until puberty.

increasingly apparent—boys have more lean body mass per centimeter of height than girls. Girls have a higher percentage of weight as fat than boys, even in the preschool years, but these differences in lean body mass and fat do not become significant until adolescence.

## Assessing Growth

A complete nutritional assessment includes the collection of anthropometric data. This includes length or stature, weight, and weight-for-length or BMI, all of which are plotted on the Centers for Disease Control and Prevention (CDC) growth charts (see Appendixes 9 through 16). Other measurements that are less commonly used but that provide estimates of body composition include upper-arm circumference and triceps or subscapular skin folds. Care should be taken to use standardized equipment and techniques for obtaining and plotting growth measurements. Charts designed for birth to 36 months of age are based on length measurements and nude weights, whereas charts used for 2- to 20-year-olds are based on stature (standing height) and weight with light clothing and without shoes (see Chapter 6).

The proportion of weight to length or height is a critical element of growth assessment. This parameter is determined by plotting the weight-for-length on the WHO birth- to 24-month growth charts or calculating BMI and plotting it on the 2- to 20-year-old CDC growth charts. Growth measurements obtained at regular intervals provide information about an individual's growth pattern. One-time measurements do not allow for interpretation of growth status. Growth channels are not well established until after 2 years of age. Children generally maintain their heights and weights in the same **growth channels** during the preschool and childhood years, although rates of growth can vary within a selected period.

Regular monitoring of growth enables problematic trends to be identified early and intervention initiated so that long-term growth is not compromised. Weight that increases rapidly and crosses growth channels suggests the development of obesity. Lack of weight gain or loss of weight over a period of months may be a result of undernutrition, an acute illness, an undiagnosed chronic disease, or significant emotional or family problems. However, many children are evaluated by health care professionals only when they are ill, so growth evaluation and development may not be a focus of care. Figure 18-1 demonstrates the changes that can occur in growth parameters.

## Catch-Up Growth

A child who is recovering from an illness or undernutrition and whose growth has slowed or ceased experiences a greater than expected rate of recovery. This recovery is referred to as **catch-up growth**, a period during which the body strives to return to the child's normal growth channel. The degree of growth suppression is influenced by the timing, severity, and duration of the precipitating cause, such as a severe illness or prolonged nutritional deprivation.

Initial studies supported the thesis that malnourished infants who did not experience immediate catch-up growth would have permanent growth retardation. However, studies of malnourished children from developing countries who subsequently received adequate nourishment, as well as reports of children who were malnourished because of chronic disease such as celiac disease or cystic fibrosis, have shown that these children caught up to their normal growth channels after the first year or two of life.

The nutritional requirements for catch-up growth depend on whether the child has overall **stunted growth** (both height and weight are proportionally low) and is chronically malnourished, or is **primarily wasted**, meaning that the weight deficit exceeds the height deficit. A chronically malnourished child may not be expected to gain more than 2-3 g/kg/day, whereas as a child who is primarily wasted may gain as much as 20 g/kg/day.

Nutrient requirements, especially for energy and protein, depend on the rate and stage of catch-up growth. For instance, more protein and energy are needed during the initial period of very rapid weight gain and for those in whom lean tissue is the major component of the weight gain. In addition to energy, other nutrients are important, including vitamin A, iron, and zinc.

Current growth parameters are used to evaluate the child's weight in relation to age and stature, and to estimate a "desirable" or goal weight. Formulas are then used to estimate the minimum and maximum energy needed for catch-up growth. After a child who is wasted catches up in weight, dietary management must change to slow the weight gain velocity and avoid excessive gain. The catch-up in linear growth peaks approximately 1 to 3 months after treatment starts, whereas weight gain begins immediately.

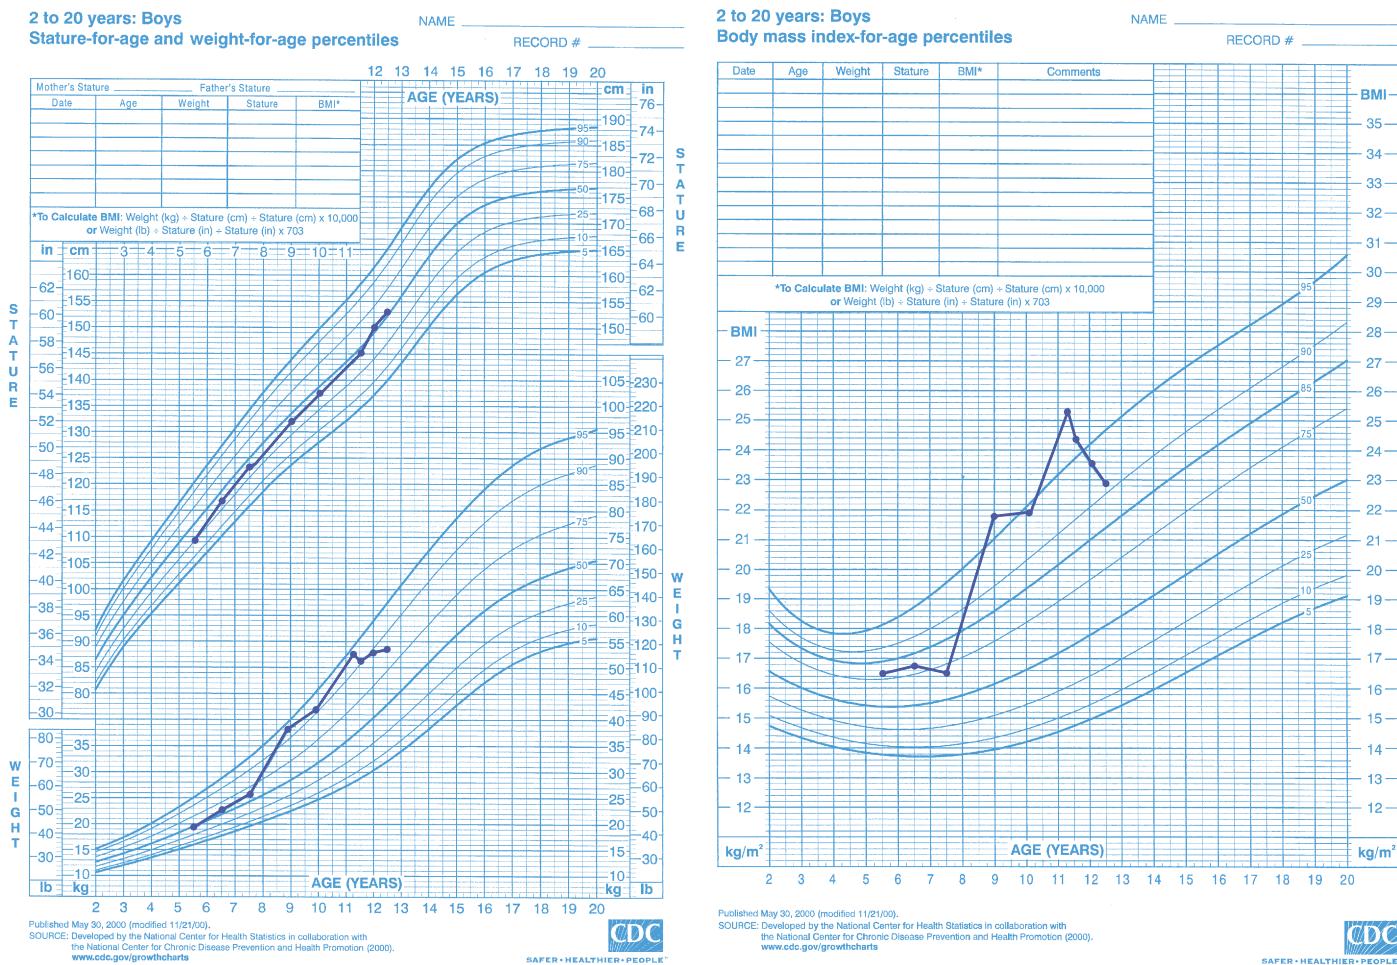

## NUTRIENT REQUIREMENTS

Because children are growing and developing bones, teeth, muscles, and blood, they need more nutritious food in proportion to their size than do adults. They may be at risk for malnutrition when they have a poor appetite for a long period, eat a limited number of foods, or dilute their diets significantly with nutrient-poor foods.

The dietary reference intakes (DRIs) are based on current knowledge of nutrient intakes needed for optimal health (Institute of Medicine [IOM], 2006). See inside front cover. Most data for preschool and school age children are values interpolated from data on infants and adults. The DRIs are meant to improve the long-term health of the population by reducing the risk of chronic disease and preventing nutritional deficiencies. Thus, when intakes are less than the recommended level, it cannot be assumed that a particular child is inadequately nourished.

### Energy

The energy needs of healthy children are determined by basal metabolism, rate of growth, and energy expenditure of activity. Dietary energy must be sufficient to ensure growth and spare protein from being used for energy, but not allow

A

**FIGURE 18-1 A.** Growth chart and BMI chart for an 8-year-old boy who gained excessive weight after having leg surgery and being immobilized in a body cast for 2 months. The surgery and immobilization were followed by a long period of stress caused by family problems. At the age of 11 years, he became involved in a weight management program.

excess weight gain. Suggested intake proportions of energy are 45% to 65% as carbohydrate, 30% to 40% as fat, and 5% to 20% as protein for 1- to 3-year-olds, with carbohydrates the same for 4- to 18-year-olds, 25% to 35% as fat, and 10% to 30% as protein (IOM, 2006).

The DRIs for estimated energy requirement (EER) are average energy requirements based on life-stage groupings for healthy individuals of normal weight. Toddlers 13 through 35 months are grouped together; for older children the EERs are divided by sex and age (3-8 years and 9-18 years.) The EER includes the total energy expenditure plus energy needed for growth (see Chapter 2). The DRIs are applied to child nutrition programs and other guidelines (IOM, 2006). See Box 18-1 for examples of determining EER for two children. On an individual basis, it can be useful to estimate energy requirements using kilocalories per kilogram of weight or per centimeter of height.

## Protein

The need for protein decreases from approximately 1.1 g/kg in early childhood to 0.95 g/kg in late childhood (Table 18-1). Protein intake can range from 5% to 30% of

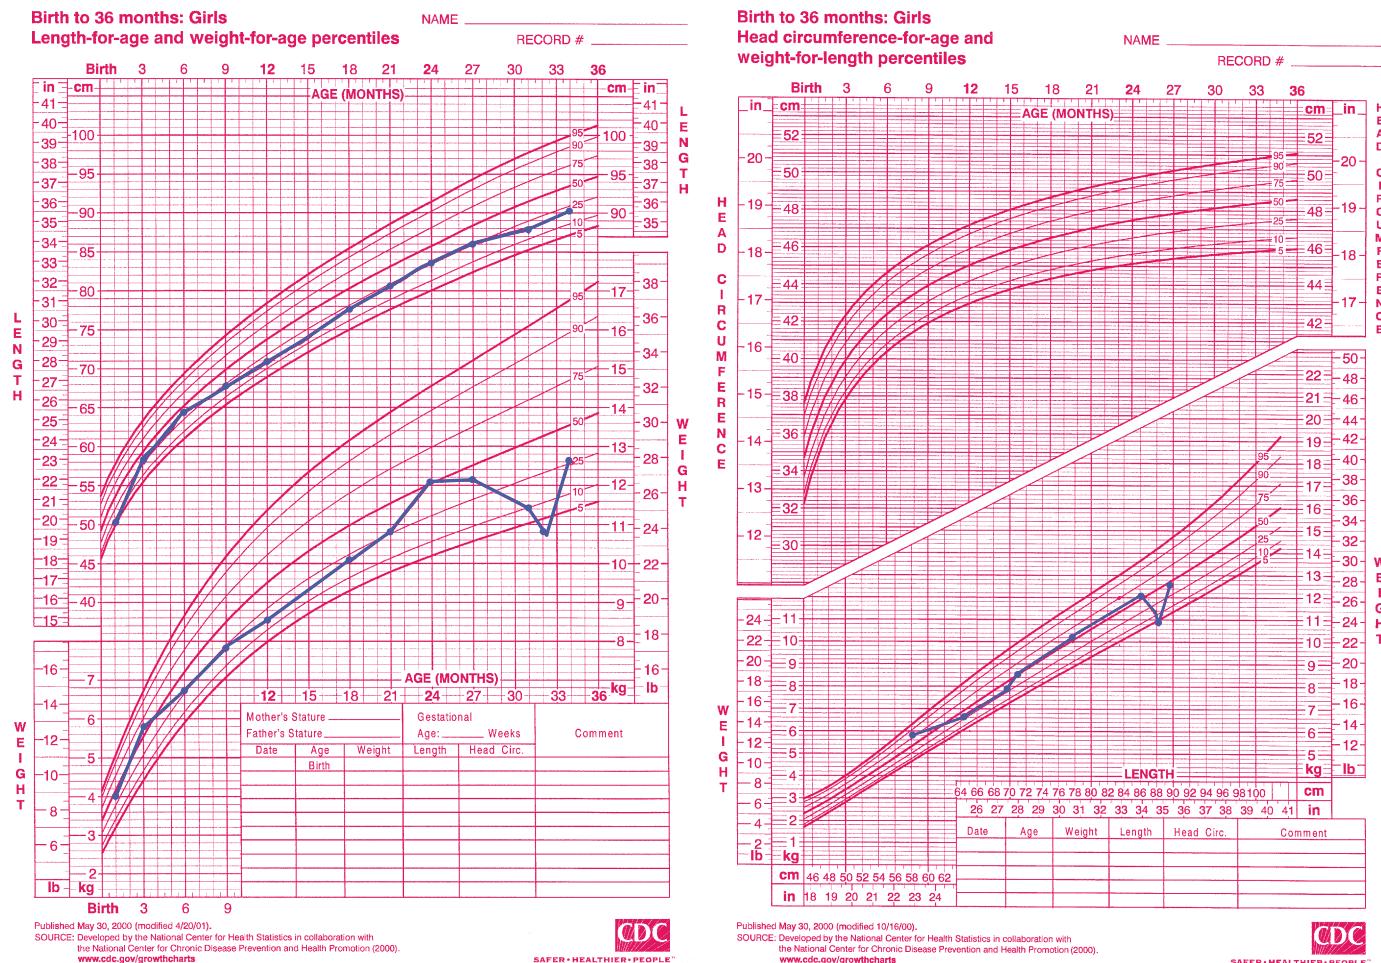

total energy depending on age. Protein deficiency is uncommon in American children, partly because of the cultural emphasis on protein foods. National surveys show that less than 3% of children fail to meet the recommended dietary allowance (Moshfegh et al., 2005). Children who are most at risk for inadequate protein intake are those on strict vegan diets; those with multiple food allergies; or who have limited food selections because of fad diets, behavioral problems, or inadequate access to food.

## Minerals and Vitamins

Minerals and vitamins are necessary for normal growth and development. Insufficient intake can cause impaired growth and result in deficiency diseases. See Chapter 3. The DRIs are listed inside the front cover.

## Iron

Children between 1 and 3 years of age are at high risk for iron-deficiency anemia. The rapid growth period of infancy is marked by an increase in hemoglobin and total iron mass. National Health and Nutrition Examination Survey (NHANES) data indicate that children with prolonged

**FIGURE 18-1, cont'd B,** Growth charts for a 2-year-old girl who experienced significant weight loss during a prolonged period of diarrhea and feeding problems. After being diagnosed with celiac disease, she began following a gluten-free diet and entered a period of catch-up growth. (*Source of growth charts only: The National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion, 2000.*)

**TABLE 18-1**

**Protein Dietary Reference Intakes (DRIs) for Children through Age 13 Years**

<b>Age</b>	<b>Protein</b>	
	<b>Grams/Day*</b>	<b>Grams/Kilogram/Day</b>
1-3 yr	13 g/day	1.10 g/kg/day
4-8 yr	19 g/day	0.95 g/kg/day
9-13 yr	34 g/day	0.95 g/kg/day

Adapted from Feucht S: Dietary reference intakes (DRI) review: case studies illustrating energy and protein for children and adolescents with special needs, Nutr Focus Newsletter 20:1, 2005.

\*Recommended dietary allowance for reference individual (g/day).

bottle feeding and those of Mexican-American descent are at highest risk for iron deficiency. The reason for the association between iron deficiency and ethnicity is not clear (Brotanek et al., 2005). Recommended intakes must factor in the absorption rate and quantity of iron in foods, especially those of plant origin.

### Calcium

Calcium is needed for adequate mineralization and maintenance of growing bone in children. The RDA for calcium for children 1 to 3 years old is 700 mg/day, for children 4 to 8 years it is 1000 mg/day, and for those 9 to 18 years it is 1300 mg per day (Ross et al., 2011). Actual need depends on individual absorption rates and dietary factors such as quantities of protein, vitamin D, and phosphorus. Because milk and other dairy products are primary sources of calcium, children who consume limited amounts of these foods are at risk for poor bone mineralization (Figure 18-2). Other calcium-fortified foods such as soy and rice milks and fruit juices are also good sources (see Table 3-25).

**BOX 18-1****Determining Estimated Energy Requirements**

(Examples using data from Box 2-1, Chapter 2)

**1. For 13- to 35-month-old children:**

$$\text{EER (kcal)} = (89 \times \text{wt [kg]} - 100) + 20$$

An 18-month-old boy has a length of 84 cm and weighs 12.5 kg

$$\text{EER (kcal)} = (89 \times 12.5 - 100) + 20$$

$$\text{EER (kcal)} = (1113 - 100) + 20$$

$$\text{EER (kcal)} = 1033$$

**2. For girls 3 through 8 years:**

$$\begin{aligned} \text{EER (kcal)} &= 135.3 - (30.8 \times \text{age [y]}) + \text{PA} \times \\ &\quad (10 \times \text{wt [kg]} + 934 \times \text{ht [m]}) + 20 \end{aligned}$$

A 6½-year-old girl is 112 cm tall, weighs 20.8 kg, and has moderate activity (PA coefficient of 1.31)

$$\begin{aligned} \text{EER (kcal)} &= 135.3 - 30.8 \times 6.5 + 1.31 \times \\ &\quad (10 \times 20.8 + 934 \times 1.12) + 20 \end{aligned}$$

$$\text{EER (kcal)} = 135.3 - 200.2 + 1.31 \times (208 + 1046.1) + 20$$

$$\text{EER (kcal)} = 135.3 - 200.2 + 1642.9 + 20$$

$$\text{EER (kcal)} = 1598$$

*EER*, Estimated energy requirement; *PA*, physical activity.

**Zinc**

Zinc is essential for growth; a deficiency results in growth failure, poor appetite, decreased taste acuity, and poor wound healing. Because the best sources of zinc are meat and seafood, some children may regularly have low intakes. Marginal zinc deficiency has been reported in preschool and school age children. Diagnosis may be difficult because laboratory parameters, including plasma, serum erythrocyte, hair, and urine, are of limited value in determining zinc deficiency. There is a positive influence of zinc supplementation on growth and serum zinc concentrations. Improving zinc nutrition status by food and supplementation programs has shown efficacy (see Chapter 3).

**Vitamin D**

Vitamin D is needed for calcium absorption and deposition of calcium in the bones, as well as prevention of cancer, autoimmune disorders, cardiovascular disease, and infectious disease. Because this nutrient is also formed from sunlight exposure on the skin, the amount required from dietary sources depends on factors such as geographic location and time spent outside.

**FIGURE 18-2** Milk and other dairy products supply preschool children with the calcium and vitamin D needed for growing bones.

The new DRI for vitamin D for infants is 400 IU (10 mcg) per day and for children is 600 IU (15 mcg) per day (Ross et al., 2011). Vitamin D-fortified milk is the primary source of this nutrient, and breakfast cereals and nondairy milks are often fortified with vitamin D. Dairy products such as cheese and yogurt, however, are not always made from fortified milk. It is becoming more common to measure serum 25(OH) vitamin D 25-hydroxy in children; however, there is some controversy regarding what constitutes optimal levels.

**Vitamin-Mineral Supplements**

Almost 40% of preschool children are given a multivitamin-mineral supplement, but this percentage usually decreases with older children (Picciano et al., 2007). Families with more education, health insurance coverage, and higher incomes generally have higher rates of supplement use, although these may not be the families who are at greatest risk for having inadequate diets. Supplements do not necessarily fulfill specific nutrient needs. For instance, although many children consume less than the recommended amount of calcium, children's vitamin-mineral supplements typically do not contain significant amounts of calcium. Careful evaluation of each pediatric supplement is suggested because many types are available but incomplete.

Evidence shows that fluoride can help prevent dental caries. If a community's water supply is not fluoridated, fluoride supplements are recommended from 6 months until 16 years of age. However, individual family practices should be assessed, including the child's primary source of

fluids (e.g., drinking water, juices, or other beverages) and fluoride sources from child care, school, toothpaste and mouthwash.

The AAP does not support giving healthy children routine supplements of any vitamins or minerals other than fluoride. However, children at risk for inadequate nutrition who may benefit from supplementation include those (1) with anorexia, inadequate appetite, or who consume fad diets; (2) with chronic disease (e.g., cystic fibrosis, inflammatory bowel disease, hepatic disease); (3) from deprived families or those who are abused or neglected; (4) using a dietary program to manage obesity; (5) who do not consume adequate amounts of dairy products; and (6) with failure to thrive (FTT) (American Academy of Pediatrics [AAP], 2009).

Children who routinely take a multiple vitamin or a vitamin-mineral supplement usually do not experience negative effects if the supplement contains nutrients in amounts that do not exceed the DRIs, especially the tolerable upper intake level. However, children should not take megadoses, particularly of the fat-soluble vitamins because large amounts can result in toxicity (see Chapter 3). Because many vitamin-mineral supplements look and taste like candy, parents should keep them out of reach of children to avoid excessive intake of nutrients such as iron.

Complementary nutrition therapies or herbal product use is becoming more common for children, especially those with special needs such as children with Down syndrome, autism spectrum disorder (ASD), or cystic fibrosis (Harris, 2005). Practitioners should inquire as to the use of these products and therapies in nutrition assessments, be knowledgeable about their efficacy and safety, and help families determine whether they are beneficial and how to use them (see Chapter 13).

## PROVIDING AN ADEQUATE DIET

The development of feeding skills, food habits, and nutrition knowledge parallels the cognitive development that takes place in a series of stages, each laying the groundwork for the next. Table 18-2 outlines the development of feeding skills in terms of Piaget's theory of child psychology and development.

### Intake Patterns

Children are most likely to consume inadequate amounts of calcium, vitamin D, vitamin E, magnesium, and vitamin A (Moshfegh, 2009; Moshfegh et al., 2005). However, clinical signs of malnutrition in American children are rare.

Children's food patterns have changed over the years. Although they drink less milk, more of it is low-fat or nonfat milk. The total fat as a percent of energy intake has decreased, but remains above recommendations. More energy comes from snacks, and portion sizes have increased. In addition, more food is consumed in environments other than the home (American Dietetic Association [ADA], 2008). Foods with low nutrient density (soft drinks, baked and dairy desserts, sweeteners, and salty snacks) often displace

nutrient-dense foods (ADA, 2008). National food intake studies of children and adolescents indicate that most of their diets do not meet the national recommendations for food groups (ADA, 2008). Most children ages 2 to 3 years have high-quality diets; as they grow older, diet quality declines.

Like physical growth patterns, food intake patterns are not smooth and consistent. Although subjective, appetites usually follow the rate of growth and nutrient needs. By a child's first birthday, milk consumption begins to decline. In the next year vegetable intake decreases; intakes of cereals, grain products, and sweets increase. Young children often prefer softer protein sources instead of meats that are harder to chew.

Changes in food consumption are reflected in nutrient intakes. The early preschool years show a decrease in calcium, phosphorus, riboflavin, iron, and vitamin A compared to infancy. Intakes of most other key nutrients remain relatively stable. During the early school years, a pattern of consistent and steadily increased intakes of most nutrients is seen until adolescence. In healthy children a wide variability of nutrient intake is seen at any age.

### Factors Influencing Food Intake

Numerous influences, some obvious and others subtle, determine the food intake and habits of children. Habits, likes, and dislikes are established in the early years and carried through to adulthood. The major influences on food intake in the developing years include family environment, societal trends, the media, peer pressure, and illness or disease.

### Family Environment

For toddlers and preschool children the family is the primary influence in the development of food habits. In young children's immediate environment, parents and older siblings are significant models. Food attitudes of parents can be strong predictors of food likes and dislikes and diet complexity in children of primary school age. Similarities between children's and their parents' food preferences are likely to reflect genetic and environmental influences (Savage, 2007).

Contrary to common belief, young children do not have the innate ability to choose a balanced, nutritious diet; they can choose one only when presented with nutritious foods. A positive feeding relationship includes a division of responsibility between parents and children. The parents and other adults are to provide safe, nutritious, developmentally appropriate food as regular meals and snacks. The children decide how much, if any, they eat (Satter, 2000).

Eating together at family meals is becoming less common, partly because of family schedules, more time eating in front of the television, and the decreasing amount of time devoted to planning and preparing family meals. School age children and adolescents who eat more dinners with their families consume more fruits and vegetables, less soda, and fewer fried foods than those who rarely eat dinner with their families (Larson, 2007).

**TABLE 18-2****Feeding, Nutrition, and Piaget's Theory of Cognitive Development**

<b>Developmental Period</b>	<b>Cognitive Characteristics</b>	<b>Relationships to Feeding and Nutrition</b>
Sensorimotor (birth-2 yr)	Neonate progresses from automatic reflexes to a child with intentional interaction with the environment and the beginning use of symbols.	Progression involves advancing from sucking and rooting reflexes to the acquisition of self-feeding skills. Food is used primarily to satisfy hunger, as a medium to explore the environment, and as an opportunity to practice fine motor skills. Eating becomes less the center of attention and is secondary to social, language, and cognitive growth.
Preoperational (2-7 yr)	Thought processes become internalized; they are unsystematic and intuitive. Use of symbols increases.  Reasoning is based on appearances and happenstance. The child's approach to classification is functional and unsystematic. The child's world is viewed egocentrically.	Food is described by color, shape, and quantity, but the child has only a limited ability to classify food into "groups." Foods tend to be categorized into "like" and "don't like." Foods can be identified as "good for you," but reasons why they are healthy are unknown or mistaken.
Concrete operational (7-11 yr)	The child can focus on several aspects of a situation simultaneously.  Cause-and-effect reasoning becomes more rational and systematic. The ability to classify, reclassify, and generalize emerges. A decrease in egocentrism permits the child to take another's view.	The child begins to realize that nutritious food has a positive effect on growth and health but has a limited understanding of how or why.
Formal operational (11 yr and beyond)	Hypothetical and abstract thought expand.  The child's understanding of scientific and theoretical processes deepens.	Mealtimes take on a social significance. The expanding environment increases the opportunities for influences on food selection; for example, peer influence increases. The concept of nutrients from food functioning at physiologic and biochemical levels can be understood.
		Conflicts in making food choices may be realized (i.e., knowledge of the nutritive value of foods may conflict with preferences and nonnutritive influences).

The atmosphere around food and mealtime also influences attitudes toward food and eating. Unrealistic expectations for a child's mealtime manners, arguments, and other emotional stress can have a negative effect. Meals that are rushed create a hectic atmosphere and reinforce the tendency to eat too fast. A positive environment is one in which sufficient time is set aside to eat, occasional spills are tolerated, and conversation that includes all family members is encouraged (Figure 18-3).

### Societal Trends

Because almost three fourths of women with school age children are employed outside the home, children may eat one or more meals at a child care center or school. In these settings all children should have access to nutritious meals served in a safe and sanitary environment that promotes

healthy growth and development (ADA, 2005, 2006). Because of time constraints, family meals may include more convenience or fast foods. However, having a mother who is employed outside the home does not seem to affect children's dietary intakes negatively. Food service in group settings such as child care centers, Head Start programs, preschool programs, and in elementary schools is regulated by federal or state guidelines. Many facilities and some in-home child care centers may participate in the U.S. Department of Agriculture (USDA) Child and Adult Care Food Program. However, the quality of meals and snacks can vary greatly; parents should investigate food service when considering child care options. In addition to providing children with optimal nutrients, a program should offer food that is appealing, safely prepared, and appropriate, incorporating cultural and developmental patterns (ADA, 2005).

Approximately one in five American children lives in a family with an income below the poverty line; these children constitute 35% of all the poor in the United States (DeNavas-Walt et al., 2009). The increasing numbers of single-parent households predominantly headed by women have lower incomes and less money for all expenses,

**FIGURE 18-3** Three generations of Italian Americans make a pasta dinner. The custom of eating authentically prepared foods gives meals a place of prominence in this home—meals that will not be replaced with fast foods eaten on the run.  
*(From Leahy J, Kisilay P: Foundations of nursing practice: a nursing process approach, Philadelphia, 1998, Saunders.)*

including food, than households headed by men. This phenomenon makes these families increasingly vulnerable to multiple stressors such as marginal health and nutritional status partly because of lack of jobs, child care, adequate housing, and health insurance.

In 2008, 16% of households with children in the United States experienced food insecurity. Federal food and nutrition assistance programs (including National School Lunch, Food Stamp Program, and Special Supplemental Nutrition Program for Women, Infants and Children (WIC)) provided benefits to four out of five food-insecure households' children (ADA, 2010; Nord, 2009). See Chapter 10. The food stamp allotment for families, based on the USDA Thrifty Food Plan, does not provide adequate funds to purchase food based on the government's nutrition guidelines, especially when labor is considered (Davis and You, 2010). Food insecurity also increases the risk for children younger than age 3 years to be iron-deficient with anemia (Skalicky et al., 2005). Studies suggest that intermittent hunger in American children is associated with increased developmental risk (Rose-Jacobs et al., 2008) (see *Focus On: Childhood Hunger and Its Effect on Behavior and Emotions*).

### Media Messages

Food is marketed to children using a variety of techniques, including television advertising, in-school marketing, sponsorship, product placement, Internet marketing, and sales promotion. Television advertising and in-school marketing are regulated to some degree. By the time the average American child graduates from high school, he or she has

## ◎ FOCUS ON

### Childhood Hunger and Its Effect on Behavior and Emotions

It is well accepted that malnourished children are less responsive, less inquisitive, and participate in less exploratory behavior than well-nourished infants. Specific nutrient deficiencies such as iron deficiency anemia can also result in a decreased ability to pay attention and poorer problem-solving skills. Less clear is the effect of periodic hunger or food insecurity on a child's behavior and functioning. With recent federal welfare reform legislation and economic downturns, an increasing number of children from low-income families are at risk for limited food resources (American Dietetic Association, 2010).

In the 1990s the Community Childhood Hunger Identification Project conducted surveys using standardized questions and large, rigorously selected samples to categorize families as "hungry," "at risk for hunger," or "not hungry" (Kleinman et al., 1998). It was estimated that each year 8% of children younger than 12 years of age in the United States experience prolonged periods in which they have insufficient

food. Data from 2008 indicated that 16.2 million children (22.5% of all children) live in food-insecure households (Food Research and Action Center, 2009). The number of children in food-insecure households continues to increase. A longitudinal study following approximately 21,000 children from kindergarten through third grade found that persistent food insecurity was predictive of impaired academic outcomes, poorer social skills, and a tendency to increased body mass index (Jyoti et al., 2005).

Although these studies have limitations because of other factors that may affect a child's functioning (e.g., stress, family dysfunction, or substance abuse), a correlation exists between children's lack of sufficient food and their behavioral and academic functioning. As future studies provide more evidence of this relationship, it will be clear that social policies need to ensure the provision of children's basic needs for optimal growth and development.

watched 15,000 hours of television and spent 11,000 hours in the classroom. In a random sample of television advertising to children, 20% of commercials were for food. Of these, 70% were for items high in sugar or fat, and more than 25% were for fast-food restaurants (Bell, 2009).

Screen time can also be detrimental to growth and development because it encourages inactivity and passive use of leisure time. Indeed, television viewing and its multiple media cues to eat have been suggested as a factor contributing to excessive weight gain in school-age children and adolescents (Laurson, 2008). In addition, the types of food eaten during television viewing can contribute to increased dental caries resulting from the continued exposure of the teeth to dense carbohydrate- and sugar-laden foods (Palmer, 2005).

Preschool children are generally unable to distinguish commercial messages from regular programs. In fact, they often pay more attention to the commercials. As children get older, they gain knowledge about the purpose of commercial advertising and become more critical of its validity, but are still susceptible to the commercial message. Media literacy education programs teach children and

adolescents about the intent of advertising and media messages and how to evaluate and interpret their obvious and subtle influences.

Fortunately, some media messages are beneficial. For example, public health messages about eating fish versus the risks of acquiring mercury are important. See *Focus On: Childhood Methylmercury Exposure and Toxicity: Media Messaging*.

### Peer Influence

As children grow, their world expands and their social contacts become more important. Peer influence increases with age and affects food attitudes and choices. This may result in a sudden refusal of a food or a request for a currently popular food. Decisions about whether to participate in school meals may be made more on the basis of friends' choices than on the menu. Such behaviors are developmentally typical. Positive behaviors such as a willingness to try new foods can be reinforced. Parents need to set limits on undesirable influences but also need to be realistic; struggles over food are self-defeating.

## ◎ FOCUS ON

### Childhood Methylmercury Exposure and Toxicity: Media Messaging

**M**ercury toxicity can cause neurologic problems, which can lead to cognitive and motor deficits. Toxicity related to prenatal exposure is well documented, and there is evidence that postnatal exposure is dangerous as well (Myers et al., 2009; Oken and Bellinger, 2008). Exposure to mercury can occur through environmental contact and eating contaminated foods. Methylmercury, the most toxic form of mercury accumulates in fish.

Public health agencies have looked at balancing the benefits of minimizing exposure to this neurotoxin with the risk of limiting intake of docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) as well as a source of high biologic value protein. DHA and EPA are essential  $\omega$ -3 fatty acids and have received much attention because of their importance in cognitive and vision development and their cardiovascular benefits (Mahaffey et al., 2008). In addition, fish advisories are available in certain states. The U.S. Environmental Protection Agency's (EPA) reference dose for methylmercury is based on body weight: 0.1 mcg/kg/day. For a 20-kg child, this is approximately 14 mcg/week (US EPA, 2010). The methylmercury content of 3 ounces of albacore tuna is approximately 29.7 mcg, canned light tuna approximately 10 mcg, and fresh or frozen salmon approximately 1.2 mcg. The Food and Drug Administration (FDA) and EPA have made recommendations for fish intake by young children:

Do not eat shark, swordfish, king mackerel, or tilefish because they contain high levels of mercury.

Eat up to 12 oz (two average meals) a week of a variety of fish and shellfish that are lower in mercury.

Five of the most commonly eaten fish that are low in mercury are shrimp, canned light tuna, salmon, pollock, and catfish.

Another commonly eaten fish, albacore ("white") tuna has more mercury than canned light tuna. So, when choosing two meals of fish and shellfish, eat up to 6 ounces (one average meal) of albacore tuna per week, but only 3 ounces for a child.

Check local advisories about the safety of fish caught by family and friends in local lakes, rivers, and coastal areas. If no advice is available, eat up to 6 ounces (3 oz for a child) per week of fish caught from local waters, but don't consume any other fish during that week.

Follow these same recommendations when feeding fish and shellfish to young children, but serve smaller portions.

## Illness or Disease

Children who are ill usually have a decreased appetite and limited food intake. Acute viral or bacterial illnesses are often short-lived but may require an increase in fluids, protein, or other nutrients. Chronic conditions such as asthma, cystic fibrosis, or chronic renal disease may make it difficult to obtain sufficient nutrients for optimal growth. Children with these types of conditions are more likely to have behavior problems relating to food. Children requiring special diets (e.g., those who have diabetes or phenylketonuria) not only have to adjust to the limits of foods allowed, but also have to address issues of independence and peer acceptance as they grow older. Some rebellion against the prescribed diet is typical, especially as children approach puberty.

## Feeding Preschool Children

From 1 to 6 years of age children experience vast developmental progress and acquisition of skills. One-year-old children primarily use fingers to eat and may need assistance with a cup. By 2 years of age, they can hold a cup in one hand and use a spoon well (see Figure 17-2, but may prefer to use their hands at times. Six-year-old children have refined skills and are beginning to use a knife for cutting and spreading.

As the growth rate slows after the first year of life, appetite decreases, which often concerns parents. Children have less interest in food and an increased interest in the world around them. They can develop **food jags** which can be periods when foods that were previously liked are refused, or there are repeated requests to eat the same food meal after meal. This behavior may be attributable to boredom with the usual foods or may be a means of asserting newly discovered independence. Parents may have concerns with their child's seemingly irrational food behavior. Struggles over control of the eating situation are fruitless; no child can be forced to eat. This period is developmental and temporary.

A positive feeding relationship includes a division of responsibility between parents and children. Young children can choose a balanced nutritious diet if presented with nutritious foods. The parents and other adults provide safe, nutritious, developmentally appropriate food as regular meals and snacks; and the children decide how much, if any, they eat (Satter, 2000). Parents maintain control over what foods are offered and have the opportunity to set limits on inappropriate behaviors. Neither rigid control nor a laissez-faire approach is likely to succeed. Parents and other care providers should continue to offer a variety of foods, including the child's favorites, and not make substitutions a routine.

With smaller stomach capacities and variable appetites, preschool children should be offered small servings of food four to six times a day. Snacks are as important as meals in contributing to the total daily nutrient intake. Carefully chosen snacks are those dense in nutrients and least likely to promote dental caries. A general rule of thumb is to offer 1 tablespoon of each food for every year of age and to serve

more food according to the child's appetite. Table 18-3 is a guide for food and portion size.

Senses other than taste play an important part in food acceptance by young children. They tend to avoid food with extreme temperatures, and some foods are rejected because of odor rather than taste. A sense of order in the food presentation is often required; many children will not accept foods that touch each other on the plate, and mixed dishes or casseroles with unidentifiable foods are not popular. Broken crackers may go uneaten or a sandwich may be refused because it is "cut the wrong way."

The physical setting for meals is important. Children's feet should be supported, and chair height should allow a comfortable reach to the table at chest height. Sturdy, child-size tables and chairs are ideal, or a high chair or booster seat should be used. Dishes and cups should be unbreakable and heavy enough to resist tipping. For very young children, a shallow bowl is often better than a plate for scooping. Thick, short-handled spoons and forks allow for an easier grasp.

Young children do not eat well if they are tired; this should be considered when meal and play times are scheduled. A quiet activity or rest immediately before eating is conducive to a relaxed, enjoyable meal. However, children also need active, large-motor activities and time in the fresh air to stimulate a good appetite.

Fruit juices and juice drinks are a common beverage for young children; they frequently replace water and milk in children's diets. In addition to altering the diet's nutrient content, excessive intake of fruit juice can result in carbohydrate malabsorption and chronic, nonspecific diarrhea (AAP, 2001). This suggests that juices, especially apple and pear, should be avoided when using liquids to treat acute diarrhea. For children with chronic diarrhea, a trial of restricting fruit juices may be warranted before more costly diagnostic tests are done.

When children aged 2 to 11 years consume 100% juice, their intakes have significantly higher intakes of energy, carbohydrates, vitamins C and B<sub>6</sub>, potassium, riboflavin, magnesium, iron, and folate, and significantly lower intakes of total fat, saturated fatty acids, discretionary fat, and added sugar; this 100% juice intake does not correlate with overweight later (Nicklas et al., 2008). However, excess juice intake (12 to 30 oz/day) by young children may decrease a child's appetite, resulting in decreased food intake and poor growth. Here, a reduction in juice intake results in improved growth (AAP, 2001). Fruit juice intake should be limited to 4-6 oz/day for children 1 through 6 years of age and 8-12 oz/day (in two servings) for older children and adolescents (AAP, 2009).

Large volumes of sweetened beverages, combined with other dietary and activity factors, may contribute to overweight in a child. High intake of fructose, especially from sucrose and high-fructose corn syrup in processed foods and beverages, may lead to increased plasma triglycerides and insulin resistance (Vos et al., 2008). In several studies, low calcium intake and obesity have been correlated with high intake of sugar-sweetened beverages in preschool children

**TABLE 18-3**  
**Suggested Portion Sizes for Children\***

These suggestions are not necessarily appropriate for all children (and may be inappropriate for some children with medical conditions that greatly affect nutrient needs). They are intended to serve as a general framework that can be individualized based on a child's condition and growth pattern.

	<b>1- to 3-Year-Olds</b>	<b>4- to 6-Year-Olds</b>	<b>7- to 12-Year-Olds</b>	<b>Comments</b>

Modified from Lowenberg ME: Development of food patterns in young children. In Trahms CM, Pipes P: Nutrition in infancy and childhood, ed 6, St Louis, 1997, WCB/McGraw-Hill and Harris AB, et al: *Nutrition strategies for children with special needs*, 1999, USC University Affiliated Program, Los Angeles.

\*This is a guide to a basic diet. Fats, oils, sauces, desserts, and snack foods provide additional kilocalories to meet the needs of a growing child. Foods can be selected from this pattern for meals and snacks.

(Dubois et al., 2007; Keller et al., 2009; Lim et al., 2009). High milk and low sweetened-beverage intake is associated with improved nutrient intake, including calcium, potassium, magnesium, and vitamin A (O’Neil et al., 2009). Children should be offered milk, water, and healthy snacks throughout the day instead of sugar-sweetened choices.

Excess sodium is another concern. An increase in sodium or salt intake results in an increase in systolic blood pressure and diastolic blood pressure (ADA, 2010). A reduction in the use of processed foods may be warranted for children with elevated blood pressure. The Dietary Approaches to Stop Hypertension diet is useful for all age groups because it increases potassium, magnesium, and calcium in relation to sodium intake. See Chapter 34.

Meal time in group settings is an ideal opportunity for nutrition education programs focused on various learning activities around food (Figure 18-4). Experiencing new foods, participating in simple food preparation, and planting a garden are activities that develop and enhance positive food habits and attitudes.

### Feeding School-Age Children

Growth from ages 6 to 12 years is slow but steady, paralleled by a constant increase in food intake. Children are in school a greater part of the day; and they begin to participate in clubs, organized sports, and recreational programs. The influence of peers and significant adults such as teachers, coaches, or sports idols increases. Except for severe issues, most behavioral problems connected with food have been resolved by this age, and children enjoy eating to alleviate hunger and obtain social satisfaction.

School-age children may participate in the school lunch program or bring a lunch from home. The National School Lunch Program, established in 1946, is administered by the USDA. Children from low-income families are eligible for free or reduced-price meals. In addition, the School Breakfast Program, begun in 1966, is offered in approximately 85% of the public schools that participate in the lunch program. The USDA also offers the Afterschool Snacks and Summer Food Service for organized programs, the Fresh

Fruit and Vegetable Program in selected schools, and the Special Milk program for children not participating in school lunch (see Chapter 10).

More than 70% of schools met USDA standards for current target nutrients but less than one third of schools met standards for fat in lunch; levels of sodium remain high, whereas fiber is low relative to the DRI (Crepinsek, 2009). Of schools studied, 42% did not offer any fresh fruit or raw vegetables in the reimbursable school lunch on a daily basis (Gordon et al., 2007). New criteria for a broader number of specific nutrient targets and recommendations for menu planning using a food-based approach consistent with the DRI have been published (IOM, 2010). Efforts have been made to decrease food waste by altering menus to accommodate student preferences, allowing students to decline one or two menu items and offering salad bars. Efforts to increase participation in school lunch require consistent messages that support healthful eating.

School wellness policies were required by the school year 2006-2007 in institutions participating in school lunch and school breakfast programs. A survey indicated that many parents, although supportive of snack food restrictions and desirous of more physical education, were unaware of the required school wellness policies (Action for Healthy Kids, 2005). A survey of school food services directors revealed that 97% of school districts have policies that address nutrition standards for National School Lunch Program meals; in those districts, more than 92% have implemented activities including nutrition education, physical activity, and nutrition guidelines (School Nutrition Association, 2007). The school, including the administration, teachers, students, and food service personnel together with families and the community, are encouraged to work together to support nutrition integrity in the educational setting (ADA, 2006).

Consumption of school meals is also affected by the daily school schedule and the amount of time allotted for children to eat. When recess is scheduled before lunch rather than after, intake is better. A Montana “Recess Before Lunch” pilot study documented improvement in the mealtime atmosphere and students’ behavior. Discipline problems on the playground, in the lunchroom, and in the classroom decreased (Montana Office of Public Instruction, 2010).

Children who require a special diet because of certain medical conditions such as diabetes, hyperlipidemia, or documented food allergy are eligible for modified school meals. Children with developmental disabilities are eligible to attend public school from ages 3 to 21 years, and some of them need modified school meals (e.g., meals that are texture modified, or with increased or decreased energy density). To receive modified meals, families must submit written documentation by a medical professional of the diagnosis, meal modification, and rationale. For children receiving special education services, the documentation for meals and feeding can be incorporated as objectives in a child’s individual education plan (IEP) (see Chapter 45).

Studies of lunches packed at home indicate that they usually provide fewer nutrients but less fat than school lunch

**FIGURE 18-4** Children who eat with each other in an appropriate environment often eat more nutritiously and try a wider variety of foods than when eating alone.

meals. Favorite foods tend to be packed, so children have less variety. Food choices are limited to those that travel well and require no heating or refrigeration. A typical well-balanced lunch brought from home could include a sandwich with whole-grain bread and a protein-rich filling; fresh vegetables, fruit, or both; low-fat milk; and possibly a cookie, a graham cracker, or another simple dessert. Food safety measures (e.g., keeping perishable foods well chilled) must be observed when packing lunches for school.

Today many school age children are responsible for preparing their own breakfasts. It is not uncommon for children to skip this meal altogether, even children in the primary grades. Children who skip breakfast tend to consume less calories and nutrients than those who eat breakfast (Wilson, 2006). Reviews of the effects of breakfast on cognition and school performance suggest that children who go to school without breakfast are more likely to experience performance deficits than those who eat breakfast (Rampersaud et al., 2005). See *Focus On: Breakfast: Does It Affect Learning?*

Snacks are commonly eaten by school age children, primarily after school and in the evening. As children grow older and have money to spend, they tend to consume more snacks from vending machines, fast-food restaurants, and neighborhood grocery stores. Families should continue to offer wholesome snacks at home and support nutrition education efforts in the school. In most cases, good eating habits established in the first few years help children through this period of decision making and responsibility. Developing and supporting programs and policies that ensure access to better-quality food, larger quantities of food, and better living conditions for low-income children help to reduce health disparities where present (Yoo et al., 2009).

## Nutrition Education

As children grow, they acquire knowledge and assimilate concepts. The early years are ideal for providing nutrition information and promoting positive attitudes about all foods. This education can be informal and take place in the home with parents as models and a diet with a wide variety of foods. Food can be used in daily experiences for the toddler and preschooler and to promote the development of language, cognition, and self-help behaviors (i.e., labeling; describing size, shape, and color; sorting; assisting in preparation; and tasting).

More formal nutrition education is provided in preschools, Head Start programs, and public schools. Some programs such as Head Start have federal guidance and standards that incorporate healthy eating and nutrition education for the families involved. Nutrition education in schools is less standard and frequently has minimum or no requirements for inclusion in the curriculum or the training of teachers. Recent recommendations include policies in schools promoting coordination between nutrition education; access to and promotion of child nutrition programs; and cooperation with families, the community, and health services (ADA, 2006).

## © FOCUS ON

### Breakfast: Does It Affect Learning?

The educational benefits of school meal programs and especially the role of breakfast in better school performance have been debated and discussed for decades. Studies of healthy 9- to 11-year-old children have shown that those who skipped breakfast and were then given a variety of tests made more errors, had slower stimulus discrimination, and had slower memory recall (Pollitt et al., 1998). Similar studies in other countries with children who were at nutritional risk (i.e., had wasted and stunted growth) and skipped breakfast demonstrated even poorer performance on the learning tasks (Rampersaud et al., 2005). Recent school-based breakfast experiments in 9- to 11-year-old and 6- to 8-year-old children found similar positive results with breakfast consumption (i.e., enhanced short-term memory, better spatial memory, and improved processing of complex visual stimuli) (Mahoney et al., 2005), but other reports are less supportive (Rampersaud et al., 2005). These studies suggest that brain functioning is sensitive to short-term variations in nutrient availability. A short fast may impose greater stress on young children than on adults, resulting in metabolic alterations as various homeostatic mechanisms work to maintain circulating glucose concentrations.

School breakfast programs result in better academic performance, achievement test scores, and attendance (Rampersaud et al., 2005). In addition, breakfast contributes significantly to the child's overall nutrient intake. These studies underscore the potential benefits—not only for low-income and at-risk children but also for all school children—of a breakfast at home or school meal programs that include breakfast. Based on a study of the most recent data available from 2002–2003, nearly 50% of children eligible participate in a school breakfast program, which is up from almost 29% participation in the 1992–93 school year (Dahl and Scholz, 2011).

Teachers attempting to teach children nutrition concepts and information should take into account the children's developmental level. The play approach, based on Piaget's theory of learning, is one method for teaching nutrition and fitness to school-age children (Rickard et al., 1995). Activities and information that focus on real-world relationships with food are most likely to have positive results. Meals, snacks, and food preparation activities provide children opportunities to practice and reinforce their nutrition knowledge and demonstrate their cognitive understanding. Involving parents in nutrition education projects can produce positive outcomes that are also beneficial in the home. Many written and electronic resources on nutrition education for children exist, such as at the National Center for Education in Maternal and Child Health.

## NUTRITIONAL CONCERNS

### Overweight and Obesity

The increasing prevalence of overweight children is a significant and alarming public health problem. The most recent NHANES reported an obesity (BMI higher than the 95th percentile) prevalence of 16.9% in children ages 2 to 19 years, and high BMI (BMI higher than the 85th percentile) prevalence of 31.7% (Ogden et al., 2010). For children 2 to 5 years of age, the prevalence is 10.4% for obese and 21.1% for high BMI (Ogden et al., 2010). This prevalence has remained relatively constant (except for an increase among the heaviest 6-19 year old boys) between 1999-2000 and 2007-2008.

Terminology for BMI categories related to overweight and obesity continues to change. The most recent Expert Committee report suggests the following terms to describe risk based on BMI: *obesity* as BMI at or above the 95th percentile and *overweight* as BMI between the 85th and 94th percentiles (Barlow et al., 2007). Determining whether growing children are obese is difficult. Some excess weight may be gained at either end of the childhood spectrum; the 1-year-old toddler and the prepubescent child may weigh more for developmental and physiologic reasons, but this extra weight is often not permanent. BMI, a useful clinical tool for screening for overweight, has limitations in determining obesity because of variability related to sex, race, body composition, and maturation stage.

The CDC growth charts allow tracking of BMI from age 2 into adulthood; thus children can be monitored periodically, and intervention provided when the rate of BMI change is excessive. The BMI charts show the adiposity rebound, which normally occurs in children between 4 and 6 years of age. Children whose adiposity rebound occurs before 5½ years of age are more likely to weigh more as adults than those whose adiposity rebound occurs after 7 years of age. The timing of the adiposity rebound and excess fatness in adolescence are two critical factors in the development of obesity in childhood, with the latter being the most predictive of adult obesity and related morbidity (Williams, 2009).

Although genetic predisposition is an important factor in obesity development, the increases in the prevalence of overweight children cannot be explained by genetics alone. Factors contributing to excess energy intake for the pediatric population include ready access to eating and food establishments, eating tied to sedentary leisure activities, children making more food and eating decisions, larger portion sizes, and decreased physical activity. In addition, American children snack three times a day, with chips, candy, and other low-nutrient foods providing more than 27% of their daily energy intake; this contributes 168 kcals/day (Piernas and Popkin, 2010).

Inactivity plays a major role in obesity development, whether it results from screen time, limited opportunities for physical activity, or safety concerns that prevent children from enjoying free play outdoors. Although increased television viewing and computer and handheld game use has been

associated with childhood overweight, a review suggests that the greater risk of overweight is related to television viewing plus a low activity level (Ritchie et al., 2005). The need to use automobiles for short trips limits children's opportunities to walk to local destinations, a phenomenon particularly relevant to children in the suburbs.

Obesity in childhood is not a benign condition, despite the popular belief that overweight children will outgrow their condition. The longer a child has been overweight, the more likely the child is to be overweight or obese during adolescence and adulthood. Consequences of overweight in childhood include psychosocial difficulties such as discrimination from others, a negative self-image, depression, and decreased socialization. Many overweight children have one or more cardiovascular risk factors such as hyperlipidemia, hypertension, or hyperinsulinemia (Daniels, 2009). An even more dramatic health consequence of overweight is the rapid increase in the incidence of type 2 diabetes in children and adolescents, which has a serious effect on adult health, development of other chronic diseases, and health care costs (see Chapter 31).

The AAP has developed guidelines for overweight screening and assessment for children from age 2 through adolescence (Barlow et al., 2007). In addition to growth parameters, other important information includes dietary intake and patterns, previous growth patterns, family history, physical activity, and family interactions. The U.S. Preventive Services Task Force (USPSTF) recommends obesity screening for 6- to 18-year olds and referral to treatment programs, if appropriate (USPSTF, 2010).

A 2010 paper described a lower prevalence of obesity among children who were exposed to the following routines: regularly eating the evening meal as a family, obtaining adequate night-time sleep, and having limited screen-viewing time (Anderson, 2010). Interventions for obesity in children have had limited effect on the childhood obesity problem, especially for black, Hispanic, and Native American populations. Success is most likely to result from programs that include comprehensive behavioral components such as family involvement, dietary modifications, nutrition information, physical activity, and behavioral strategies (Barlow et al., 2007). Incorporating behavioral intervention in obesity treatment improves outcomes and is most effective with a team approach. Depending on the child, goals for weight change may include a decrease in the rate of weight gain, maintenance of weight, or, in severe cases, gradual weight loss (see Chapter 22). An individualized approach should be tailored to each child, with minimum use of highly restrictive diets or medication, except if there are other significant diseases and no other options. (Barlow et al., 2007).

Intervention strategies require family involvement and support. Incorporating motivational interviewing and stages of change theory into the comprehensive program will likely be more successful (Kirk et al., 2005) (see Chapter 15). Changes to address overweight should include the child's input, with choices and plans that modify the family's food and activity environment, not just the child's. Adequate energy and nutrients are needed to ensure maintenance of

height velocity and nutrient stores. The hazards of treating overweight children too aggressively include alternate periods of undereating and overeating, feelings of failure in meeting external expectations, ignoring internal cues for appetite and satiation, feelings of deprivation and isolation, an increased risk for eating disorders, and a poor or an increasingly poor self-image.

Some children with special health care needs, such as those with Down syndrome, Prader-Willi syndrome, short stature, and limited mobility, are at increased risk for being overweight. Their size, level of activity, and developmental status need to be considered when estimating energy intake and providing dietary guidance to their families (see Chapter 45).

Prevention of childhood obesity is an important public health priority in the United States. The Institute of Medicine (IOM) has published recommendations that target families, health care professionals, industry, schools, and communities (IOM, 2005; Kirk et al., 2005). The recommendations include schools (improved nutritional quality of food sold and served, increased physical activity, wellness education), industry (improved nutrition information for consumers clear media messages), health care professionals (tracking BMI, providing counseling for children and families), and communities and government (better access to healthy foods, improved physical activity opportunities). Schools are a natural environment for obesity prevention, which can include nutrition and health curricula, opportunities for physical education and activity, and appropriate school meals. Recent efforts have resulted in school nutrition policies that limit the kinds of products sold in vending machines and food and beverages sold for fundraising. More research is also needed to develop effective prevention strategies that incorporate cultural competency for high-risk populations.

Families are essential for modeling food choices, healthy eating, and leisure activities for their children. Parents influence children's environment by choosing nutrient-rich foods, having family meals (including breakfast), offering regular snacks, and spending time together in physical activity, all of which can be critical in overweight prevention. Reducing sedentary behaviors can increase energy expenditure and reduce prompts to eat; the AAP recommends limiting television and video time to no more than 2 hours per day (AAP, 2003; Epstein et al., 2008). Parents exerting too much control over their child's food intake or promoting a restrictive diet may cause children to be less able to self-regulate and more likely to overeat when the opportunity is available (Ritchie et al., 2005). Health professionals should support positive parenting within the child's developmental level (Satter, 2005).

## **Underweight and Failure to Thrive**

Weight loss, lack of weight gain, or **failure to thrive (FTT)** can be caused by an acute or chronic illness, a restricted diet, a poor appetite (resulting from constipation, medication, or other issues), feeding problems, neglect, or a simple lack of food. Some experts prefer the terms *pediatric undernutrition*

or *growth deficiency*. Infants and toddlers are most at risk for poor growth, often as a result of prematurity, medical conditions, developmental delays, inadequate parenting, or all of these. Dietary practices can also contribute to poor growth, including food restrictions in preschool children stemming from parents' concerns about obesity, atherosclerosis, or other potential health problems.

A careful assessment is critical and must include the social and emotional environment of the child and any physical findings. If neglect is documented to be a contributing factor, health professionals are obligated to report the case to the local child protective services (Block and Krebs, 2005). Because of the complexity of growth failure, an interdisciplinary team is ideal for assessments and interventions.

The provision of adequate energy and nutrients and nutrition education should be one part of an overall interdisciplinary plan to assist children and their families. Attempts should be made to increase children's appetites and modify the environment to ensure optimal intake. Frequent, small meals and snacks should be offered at regular times, using developmentally appropriate, nutrient-dense foods. This optimizes the smaller stomach capacity of the young child and provides structure and predictability for the eating environment. Families should receive support for positive parent-child interactions, with respect for the division of responsibility in feeding and avoidance of any pressure or coercion on the child's eating. Severe malnutrition may require carefully planned interventions and close monitoring to prevent refeeding syndrome.

Chronic constipation can result in poor appetite, diminished intake, and FTT. Adding legumes and fruits (especially dried fruits), vegetables, high fiber breakfast cereals, bran muffins, or all of these to the diet can help relieve constipation, improve appetite, and eventually promote weight gain. Because the fiber intake of children is often low, especially in children who are picky eaters, fiber intake should always be addressed in the evaluation.

## **Iron Deficiency**

Iron deficiency is one of the most common nutrient disorders of childhood. The highest prevalence of anemia in children occurs in those younger than 2 years of age. Iron deficiency is less of a problem among older preschool and school-age children.

Infants with iron deficiency, with or without anemia, tend to score lower on standardized tests of mental development and pay less attention to relevant information needed for problem solving. Poorer cognitive performance and delayed psychomotor development have been reported in infants and preschool children with iron deficiency. Deficiency can have long-term consequences, as demonstrated by poorer performance on developmental tests in late childhood and early adolescence (Lozoff, 2006, 2007). Iron intake should be considered during assessments of individual diets and in policy decisions intended to address the nutrition needs of low-income, high-risk children.

In addition to growth and the increased physiologic need for iron, dietary factors also play a role. For example, a

1-year-old child who continues to consume a large quantity of milk and excludes other foods may develop anemia. Many young preschool children do not like meat, so most of their iron is consumed in the nonheme form from fortified cereals, which is absorbed less efficiently (see Chapter 33).

## Dental Caries

Nutrition and eating habits are important factors affecting oral health. An optimal nutrient intake is needed to produce strong teeth and healthy gums. The composition of the diet and an individual's eating habits (e.g., dietary carbohydrate intake, eating frequency) are significant factors in the development of dental caries (see Chapter 26).

## Allergies

Food allergies usually present during infancy and childhood and are more likely when a child has a family history of allergies. Allergic symptoms are most often seen as respiratory or gastrointestinal responses or involve the skin, but may include fatigue, lethargy, and behavior changes. Controversy exists over the definition of *food allergy*, *food intolerance*, and *food sensitivity*, and some tests for food allergies are unspecific and equivocal (see Chapter 27).

## Attention Deficit Hyperactivity Disorder

Attention deficit hyperactivity disorder is a clinical diagnosis based on specific criteria: excessive motor activity, impulsiveness, a short attention span, a low tolerance for frustration, and an onset before 7 years of age. Various dietary factors have been suggested as a cause of this disorder, including artificial flavors and colors, sugar, altered fatty acid metabolism, and allergies. Over the years, dietary treatments have been promoted such as the Feingold diet, the omission of sugar, allergy elimination diets, and supplements of vitamins and essential fatty acids (see Chapter 45).

## Autism Spectrum Disorders (ASDs)

ASDs affect 1 in 110 children and are diagnosed by impairments in three behavioral categories: social interactions, verbal and nonverbal communication, and restricted or repetitive behaviors. These impairments can affect nutrient intake and eating behaviors if a child accepts only specific foods, refuses new or unfamiliar foods, or has increased hypersensitivities (e.g., to texture, temperature, color, and smell) or difficulty making transitions. Children with an ASD often refuse fruits and vegetables and may eat only a few foods from the other food groups. Although most children have normal growth parameters, their restricted diets make them at risk for marginal or inadequate nutrient intake. They are often very resistant to taking a vitamin-mineral supplement, even though they could benefit from one.

Popular nutrition advice for children with ASDs include elimination diets (e.g., gluten-free or casein-free), essential fatty acid supplements, large doses of vitamins, and other alternative therapies. Despite anecdotal reports of benefits, few well-designed controlled studies have been done to test the effectiveness of these interventions, and currently there is no strong evidence of benefits (Milward et al., 2008).

Behavioral nutrition interventions may increase the types of food accepted at home and school. If families want to try alternative dietary therapies, nutrition professionals can help them ensure that the child's diet is adequate and any supplements are safe (see Chapter 45).

## PREVENTING CHRONIC DISEASE

The roots of chronic adult diseases such as heart disease, cancer, diabetes, and obesity are often based in childhood—a phenomenon that is particularly relevant to the increasing rate of obesity related diseases such as type 2 diabetes. To help decrease the prevalence of chronic conditions in Americans, government and nonprofit agencies have been promoting healthy eating habits for children. Their recommendations include the Dietary Guidelines for Americans, the USDA MyPlate, the National Cholesterol Education Program (NCEP), and the National Cancer Institute Dietary Guidelines (see Chapter 12).

## Dietary Fat and Cardiovascular Health

Compared with their counterparts in many other countries, American children and adolescents have higher blood cholesterol levels and higher intakes of saturated fatty acids and cholesterol. Autopsy studies demonstrate that early coronary atherosclerosis begins in childhood and adolescence and is related to high serum total cholesterol, low-density lipoprotein (LDL) cholesterol, and very-low-density lipoprotein cholesterol levels, and low high-density lipoprotein levels (AAP, 2009).

The AAP recommendations for lipid screening and prevention of cardiovascular disease in children are similar to recommendations published for adults (Daniels, 2008; Lichtenstein, 2006). For children older than 2 years of age, nutrition recommendations are the same as those for adults: (1) no more than 30% of energy from fat (10% or less from saturated fat); and (2) 200–300 mg/day of cholesterol. Cholesterol screening is also recommended for children with risk factors—family history of dyslipidemia or premature cardiovascular disease (Daniels, 2008) (see Chapter 33).

Dietary trends have demonstrated a decrease in total fat, saturated fat, and percentage of energy from fat in children's diets; but at the same time overweight has increased with increased risk of cardiovascular disease (Gidding et al., 2005). Recommendations include a balanced energy intake; sufficient physical activity to maintain a healthy weight; increased intake of fruits, vegetables, fish, and whole grains; and use of low-fat dairy products (Daniels, 2008). Reports have shown that from age 4 to adolescence, children can consume diets that comply with the NCEP guidelines without compromising energy or nutrient intake (Gidding et al., 2005). A long-term dietary intervention study demonstrated improved lipid levels and improved eating habits in children with elevated LDL cholesterol levels (Van Horn et al., 2005). Health practitioners should assess each child individually regarding total fat intake and excessive consumption of low-fat and nonfat foods especially by preschool children (see Chapter 33).

## Calcium and Bone Health

Osteoporosis prevention begins early by maximizing calcium retention and bone density during childhood and adolescence, when bones are growing rapidly and are most sensitive to diet and physical activity (see Chapter 25). To reach the maximum calcium balance during puberty, children may need to consume more than the recommended amount. However, mean dietary intakes of calcium are lower than the AI, with 20% to 30% of pubertal girls having intakes less than 500 mg/day. Although calcium supplementation coupled with an average calcium dietary intake in pubertal children has been shown to increase bone mineral density significantly, it is less certain whether this benefit is long term (Matkovic et al., 2005). One longitudinal study of white children from infancy to 8 years of age found that bone mineral content was positively correlated with intake of protein and several minerals, suggesting that many nutrients are related to bone health in children (Bounds et al., 2005). Because food consumption surveys show that children are drinking more soft drinks and noncitrus juices and less milk, education is needed to encourage young people to consume an appropriate amount of calcium from food sources and possibly supplements.

## Fiber

Education about dietary fiber and disease prevention has mainly been focused on adults, and only limited information is available on the dietary fiber intake of children. Dietary fiber is needed for health and normal laxation in children. National survey data indicate that preschool children consume a mean of 9.5 g/day of dietary fiber; school age children consume approximately 11.6 g/day (Moshfegh, 2005). This is lower than the DRI for children, which is based on the same 14 g/1000 kcal as adults because of lack of scientific evidence for the pediatric population (IOM, 2006). Generally, higher fiber intakes are associated with more nutrient-dense diets in young children (Kranz et al., 2005).

## Physical Activity

A decreased level of physical activity in children has been noted for several decades. Participation in school physical education programs has declined over time and generally decreases with increasing age (ADA, 2008). Regular physical activity not only helps control excess weight gain, but also improves strength and endurance, enhances self-esteem, and reduces anxiety and stress. Activity, combined with an optimal calcium intake, is associated with increased bone mineral density in children and adolescents. Current physical activity recommendations for those ages 6 through 17 years of age are 60 minutes or more of physical activity every day with the majority at a moderate or vigorous aerobic intensity. Children and adolescents should do vigorous intensity activity on at least 3 days per week and include muscle-strengthening and bone-strengthening activity on at least 3 days per week. Information regarding activities that will meet these recommendations and are appropriate for

children is available (U.S. Department of Health and Human Services, 2010). The Kid's MyActivity Pyramid promotes substituting sedentary activities for more physically active choices (Figure 18-5). The Dietary Guidelines for Americans and MyPlate have also been applied to children and their parents ([www.chooseMyPlate.gov/kids](http://www.chooseMyPlate.gov/kids)).

## CLINICAL SCENARIO

Brian is a 7-year, 4-month-old boy who gained 15 lb during the past school year. His height is 50½ inches and his weight is 70 pounds. Brian moved to a new home and began a new school a year ago after his parents' divorce. After-school care has been provided by an older neighbor, who loves to bake for Brian. Because he has no friends in the neighborhood, his main leisure activities have been watching television and playing video games. His mother reports that they have been relying more on take-out and fast-food meals because of the time constraints of her full-time job, and she has gained weight herself. However, she has recently started an aerobics class with a friend and is interested in developing healthier eating habits.

After joint sessions with Brian and his mother, the following goals were identified by the family: (1) explore after-school care at the local community center, which has sports activities; (2) alter shopping and food preparation to emphasize the MyPlate and low-fat choices; (3) begin weekend swimming or bicycling for the family; and (4) limit television and video games to no more than 2 hours daily.

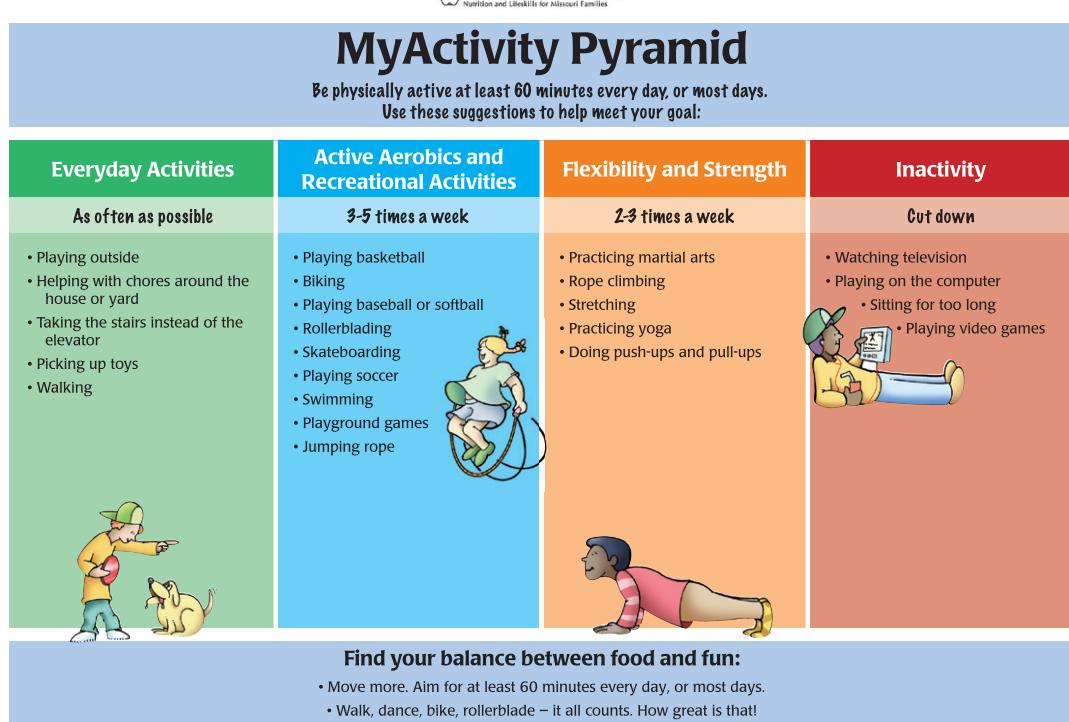

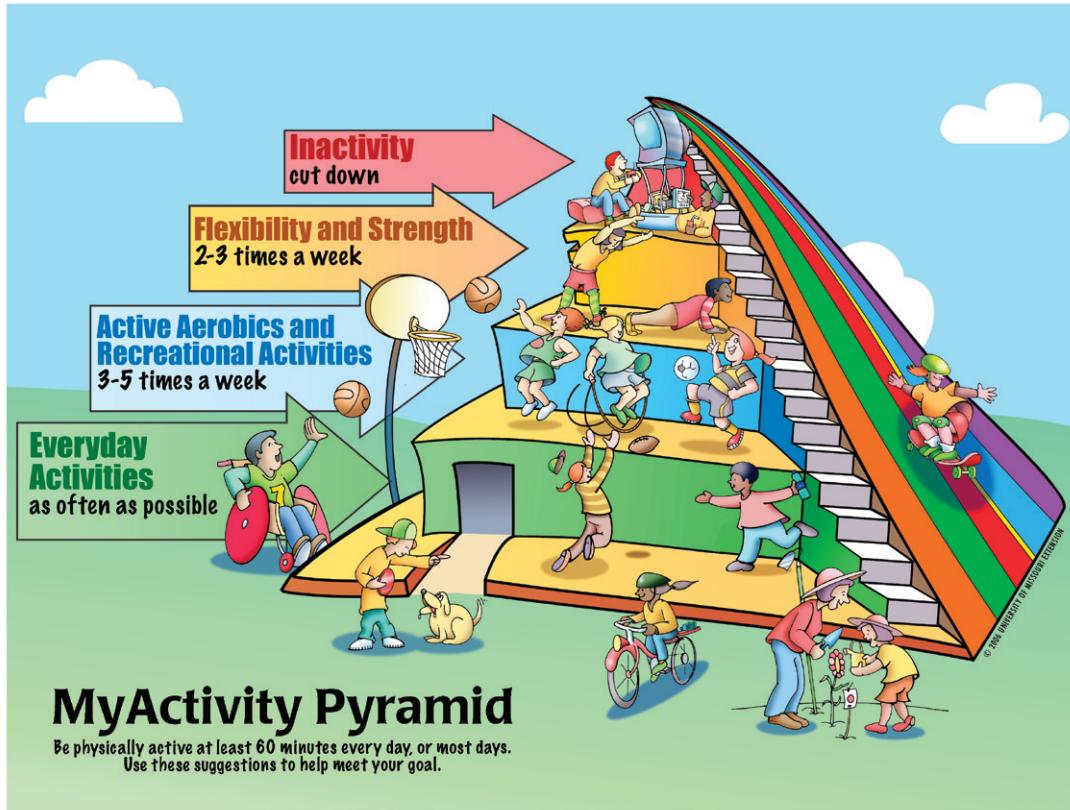

After 4 months, most of the changes have been made, except for participating in the weekend family activity and watching less television on the weekends. However, Brian is now playing soccer, has lost 4 pounds, and is taller. He is 51 inches tall and weighs 66 lb.

### Nutrition Diagnostic Statement

Overweight/obesity as evidenced by BMI-for-age at 95th percentile or more related to physical inactivity and excess energy intake.

### Nutrition Care Questions

- What recommendations should be made to prevent Brian and his mother from resuming their old habits?
- Calculate and plot Brian's BMI over time. Discuss the changes.
- What other activities can Brian try to help him avoid or reduce the tendency to eat when he is not hungry?
- What would you suggest to promote a positive feeding relationship between Brian and his mother, considering his age and level of development?
- How can Brian's mother alter some of his favorite recipes to lower the fat content? For example, his favorite meal is fried chicken with gravy, mashed potatoes, and ice cream.
- Are there any nutrient-related concerns because Brian is using diet to help with weight management?

# Nutrition in Adolescence

### KEY TERMS

adolescence  
body image  
disordered eating  
growth spurt  
gynecologic age  
menarche

peak height gain velocity  
physiologic anemia of growth  
pubarche  
puberty  
sexual maturity rating (SMR)  
Tanner stage  
thelarche

**Adolescence** is one of the most exciting yet challenging periods in human development. Generally thought of as the period of life that occurs between 12 and 21 years of age, adolescence is a period of tremendous physiologic, psychologic, and cognitive transformation during which a child becomes a young adult. The gradual growth pattern that characterizes early childhood changes to one of rapid growth and development, affecting both physical and psychosocial aspects of health. Changes in cognitive and emotional functioning allow teens to become more independent as they mature. Peer influence and acceptance may become more important than family values, creating periods of conflict between teens and parents. Because all of these changes have a direct effect on the nutrient needs and dietary behaviors of adolescents, it is important that health care providers develop a full understanding of how these developmental changes of adolescence can affect nutritional status.

### GROWTH AND DEVELOPMENT

**Puberty** is the period of rapid growth and development during which a child physically develops into an adult and

becomes capable of sexual reproduction. It is initiated by the increased production of reproductive hormones such as estrogen, progesterone, and testosterone and is characterized by the outward appearance of secondary sexual characteristics such as breast development in females and the appearance of facial hair in males ([Table 19-1](#)).

### Psychological Changes

Adolescence is often depicted as a time of irrational behavior. The physical growth of puberty transforms the teen body into an adultlike form, leading adults to believe that adolescent development is complete. However, the social and emotional development of adolescence lags behind. The mismatch between how teens look and how they act may lead adults to deduce that the adolescent is “not acting his or her age.” The rebellion that is associated with the teen years is actually the manifestation of their search for independence and a sense of autonomy. Food can be, and often is, used as a means of exerting autonomy. Adolescents may choose to become vegetarian as a way to differentiate themselves from their meat-eating parents or to express their moral and ethical concerns over animal welfare

**TABLE 19-1****Ratings of Sexual Maturation\***

	<b>Pubic Hair</b>	<b>Genitalia</b>	<b>Corresponding Changes</b>
<b>Males</b>			
Stage 1	None	Prepubertal	
Stage 2	Small amount at outer edges of pubis, slight darkening	Beginning penile enlargement Testes enlarged to 5-mL volume Scrotum reddened and changed in texture	Increased sweat gland activity
Stage 3	Covers pubis	Penis longer Testes enlarged to 8-10 mL Scrotum enlarged	Voice changes Faint mustache and facial hair Axillary hair Beginning of peak height gain velocity (growth spurt of 6-8 inches)
Stage 4	Adult type, does not extend to thighs	Penis wider and longer Testes enlarged to 12 mL Scrotal skin darker	End of peak height gain velocity More facial hair Darker hair on legs Voice deeper Possibly severe acne
Stage 5	Adult type, spreads to thighs	Adult penis Testes enlarged to 15 mL	Significantly increased muscle mass
<b>Females</b>			
Stage 1	None	No change from childhood	
Stage 2	Small amount, downy, on medial labia	Breast buds	Increased sweat gland activity Beginning of peak height gain velocity (growth spurt of 3-5 inches)
Stage 3	Increased, darker, curly	Larger, but no separation of the nipple and the areola	End of peak height gain velocity Beginning of acne Axillary hair
Stage 4	More abundant, coarse texture	Larger	Possibly severe acne
Stage 5	Adult, spreads to medial thighs	Areola and nipple form secondary mound Adult distribution of breast tissue, continuous outline	Menarche begins Increased fat and muscle mass

Modified from Tanner JM: Growth at adolescence, ed 2, Oxford, 1962, Blackwell Scientific Publications.

\*See Appendices 17 and 18.

or the environment. Eating fast food becomes a strong social factor for adolescents that differentiates them from their parents and older generations. In their minds, asking teens to stop eating fast food is equivalent to asking them to stop being adolescents.

Cognitive and emotional development is best understood when it is divided into three periods: early, middle, and late adolescence (Ingersoll, 1992). Each period has unique features in terms of the ability to synthesize information and apply health concepts, and this has a direct bearing on methods used when providing nutritional counseling and designing educational programs.

*Early adolescence*, occurring between the ages of 13 and 15, is characterized by the following:

- Preoccupation with body size and shape, and **body image** (the mental self-concept and perception of

personal body size) as a result of the rapid growth and development that has occurred

- Continuation of trust and respect for adults as authority figures; however, this diminishes during this phase of psychosocial development
- Strong influence of peers, especially around areas of body image and appearance, with peer pressure peaking at approximately 14 years of age
- Desire for autonomy but still wanting parental approval for major decisions and still seeking parental security when experiencing stress
- Expanded cognitive ability, including abstract reasoning
- Increased spending money resulting in more independent purchasing power, including for snacks and meals

*Middle adolescence*, occurring between the ages of 15 and 17, is characterized by the following:

- Persistence of peer group influence; however, teens are influenced by fewer individuals with whom they closely bond
- Decreased trust in adult authority and wisdom
- Less pronounced body image issues as the adolescent becomes more comfortable in his or her adultlike body shape and size
- More pronounced social, emotional, and financial independence, leading to increased independent decision making related to food and beverage intake
- Significant cognitive development as abstract reasoning is nearly complete and egocentrism decreases

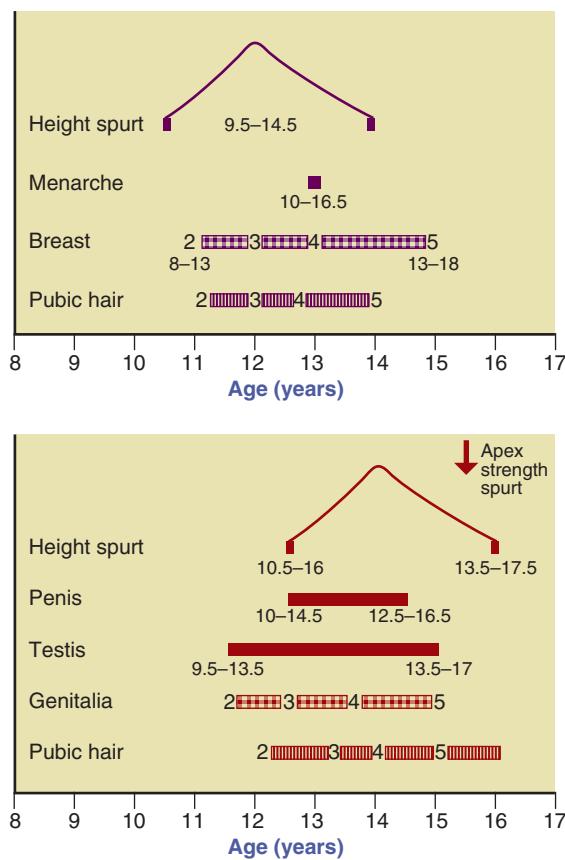

*Late adolescence*, occurring between the ages of 18 and 21, is characterized by the following:

- Fully developed abstract reasoning; however, teens may still revert to less complex thinking patterns when they are stressed
- Developed future orientation, which is required to understand the link between current behavior and chronic health risks
- Development of social, emotional, financial, and physical independence from family as teens leave home to attend college or seek full-time employment
- Development of a core set of values and beliefs that guides moral, ethical, and health decisions

The psychosocial development of adolescents has a direct bearing on the foods and beverages they choose. Teens in early to mid-adolescence are at risk for restricting calories as a means of dieting because of body image concerns. Because abstract reasoning ability is not yet fully developed, teens of this age are generally unable to see the relationship between their current behaviors and their future health risk. Nutrition education and counseling methods that focus on how adolescents look, such as improving skin appearance or promoting hair growth, are most likely to be effective with young teens.

## Sexual Maturity

**Sexual maturity rating (SMR)**, also known as **Tanner stage**, is used to clinically assess the degree of sexual maturation during puberty (Tanner, 1962). Among males SMR is based on genital and pubic hair development (see Figure 19-1 and Table 19-1). Among females SMR is assessed by breast and pubic hair development. SMR is measured through a series of five stages, with stage 1 marking prepubertal development and stage 5 marking the completion of physical growth and development. See Appendix Tables 17 and 18. The five stages of SMR correlate highly with other markers of growth and development during puberty such as alterations in height, weight, body composition, and endocrine functioning. A thorough understanding of the relationship between physical growth and development and SMR enables health care professionals to assess an adolescent's potential for future growth.

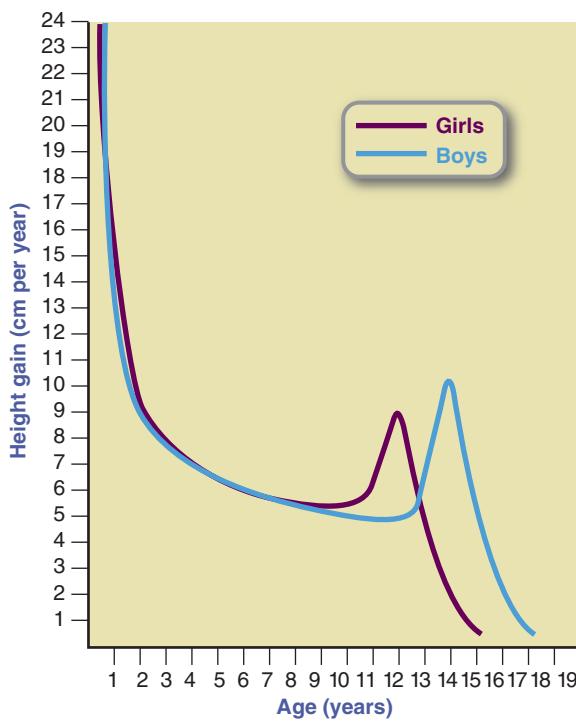

**FIGURE 19-1** Sequence of events during puberty in females (*upper chart*) and males (*lower chart*). Breast, genitalia, and pubic hair development are numbered 2 to 5 based on the Tanner developmental stages. (*From Marshall WA, Tanner JM: Variations in the pattern of pubertal changes in males, Arch Dis Child 45:13, 1970.*)

In general, females enter puberty earlier than males. An example of ethnic variation in female development is shown in data from the National Health and Nutrition Examination Study III (NHANES III). It suggests that most non-Hispanic black and Mexican American females reach breast development stage 2 (**thelarche**) at 9.6 years of age, 8 months earlier than non-Hispanic white females (Rosenfield, 2009). Racial and ethnic differences in maturation are also seen for pubic hair stage 3 (**pubarche**), which occurs earlier among most non-Hispanic black females (10.6 years) compared with Mexican American and white females (11.6 years). Most females enter puberty at least 2.5 years earlier than their male counterparts, with Mexican American youth showing the greatest gender variance in age at pubarche.

Data from NHANES III also suggest variation in the timing of pubarche among males of different racial and ethnic backgrounds (Rosenfield, 2009). The median age among non-Hispanic white and black males (12.3 and 12.5 years) is approximately 6 months earlier than among Mexican American males (13.2 years).

Adolescent females with a body mass index (BMI) in the 85th percentile or higher are four times more likely to have

**FIGURE 19-2** Typical individual velocity curves for supine length or height in males and females. Curves represent the growth velocity of the typical boy and girl at any given age.

reached thelarche by age 8 and twice as likely by 9.6 years of age than normal weight females (Rosenfeld, 2009). Excessive body weight among young females plays a larger role in the timing and duration of puberty among females than among males.

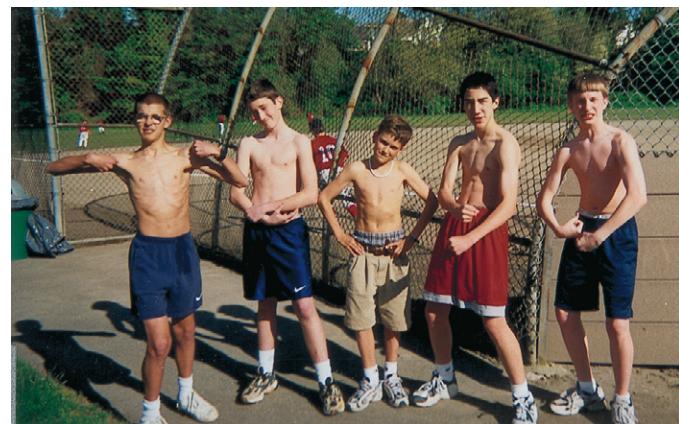

**Menarche**, the onset of menses or menstruation, is often considered the hallmark of puberty among females (at 12.5 years in the average girl). However, the onset of menses can occur anywhere between the ages of 8 and 17 years (Rosenfeld, 2009; Tanner, 1962). The median age of menarche is 12.1 years for black, 12.3 years for Mexican American, and 12.6 years for white females (Rosenfeld, 2009).

Excessive body weight among females was associated with both earlier onset of puberty as well as earlier menses among females of all racial and ethnic groups. Females with a BMI in the 85th percentile or higher are four times as likely to have experienced menses by age 10.6 years of age.

In summary, puberty may begin earlier but last longer for nonwhite females (Rosenfeld, 2009). Although racial and ethnic differences in the age of pubarche were noted for males, the differences were not as pronounced. No significant relationship between weight status and pubarche was found among males.

### Linear Growth

The velocity of physical growth during adolescence is much higher than that of early childhood (Figure 19-2). On average, adolescents gain approximately 20% of their adult height during puberty. There is a great deal of variability in

**FIGURE 19-3** These males are all 13 years old, but their energy needs vary according to their individual growth rates.

the timing and duration of growth among adolescents, illustrated in Figure 19-3 by a group of 13-year-old males.

Linear growth occurs throughout the 4 to 7 years of pubertal development in most teens; however, the largest percentage of height is gained during an 18- to 24-month period commonly referred to as the **growth spurt**. The fastest rate of growth during the growth spurt is labeled the **peak height gain velocity**. Although growth slows after the achievement of sexual maturity, linear growth and weight acquisition continue into the late teens for females and early 20s for males and young men. Most females gain no more than 2 to 3 inches after menarche, although females who have early menarche tend to grow more after its onset than do those having later menarche.

Increases in height are accompanied by increases in weight during puberty. Teens gain 40% to 50% of adult body weight during adolescence. The majority of weight gain coincides with increases in linear height. However, it should be noted that teens may gain more than 15 pounds after linear growth has ceased. Changes in body composition accompany changes in weight and height. Males gain twice as much lean tissue as females, resulting in differentiation in percent body fat and lean body mass. Body fat levels increase from prepuberty averages of 15% for males and 19% for females to 15% to 18% in males and 22% to 26% in females. Differences in lean body mass and body fat mass affect energy and nutrient needs throughout adolescence and differentiate the needs of females from those of males.

### NUTRIENT REQUIREMENTS

The dietary reference intakes (DRIs) for adolescents are listed by chronologic age and gender. Although the DRIs provide an estimate of the energy and nutrient needs for an individual adolescent, actual need varies greatly between teens as a result of differences in body composition, degree of physical maturation, and level of physical activity. Therefore health professionals should use the DRIs as a guideline during nutritional assessment, but should rely on clinical

judgment and indicators of growth and physical maturation to make a final determination of an individual's nutrient and energy requirements.

## Energy

Estimated energy requirements (EERs) vary greatly among males and females because of variations in growth rate, body composition, and physical activity level (PAL). EERs are calculated using an adolescent's gender, age, height, weight,

and PAL, with an additional 25 kcal/day added for energy deposition or growth (Institute of Medicine [IOM], 2006). To determine adequate energy intake (in kilocalories), physical activity assessment is required. The energy requirements allow for four levels of activity (sedentary, low active, active, and very active), which reflect the energy expended in activities other than the activities of daily living. Tables 19-2 and 19-3 show the EER (kcal/day) for each activity level based on PALs.

**TABLE 19-2****Estimated Energy Requirements for Adolescent Males**

Age	Reference Weight (kg [lb])	Reference Height (m [in])	Estimated Energy Requirements (kcal/day)			
			Sedentary PAL*	Low Active PAL*	Active PAL*	Very Active PAL*
9	28.6 (63.0)	1.34 (52.8)	1505	1762	2018	2334
10	31.9 (70.3)	1.39 (54.7)	1601	1875	2149	2486
11	35.9 (79.1)	1.44 (56.7)	1691	1985	2279	2640
12	40.5 (89.2)	1.49 (58.7)	1798	2113	2428	2817
13	45.6 (100.4)	1.56 (61.4)	1935	2276	2618	3038
14	51.0 (112.3)	1.64 (64.6)	2090	2459	2829	3283
15	56.3 (124)	1.70 (66.9)	2223	2618	3013	3499
16	60.9 (134.1)	1.74 (68.5)	2320	2736	3152	3663
17	64.6 (142.3)	1.75 (68.9)	2366	2796	3226	3754
18	67.2 (148)	1.76 (69.3)	2383	2823	3263	3804

Data from Institute of Medicine, Food and Nutrition Board: Dietary reference intakes for energy, carbohydrate, fiber, fat, fatty acids, cholesterol, protein, and amino acids, Washington, DC, 2002, National Academies Press.

PAL, Physical activity level.

\*PAL categories, which are based on walking per day at 2–4 mph, are as follows: sedentary, no additional activity; low active, 1.5–2.9 miles/day; active, 3–5.8 miles/day; and very active, 7.5–14 miles/day (see Table 2-3).

**TABLE 19-3****Estimated Energy Requirements for Adolescent Females**

Age	Reference Weight (kg [lb])	Reference Height (m [in])	Estimated Energy Requirements (kcal/day)			
			Sedentary PAL*	Low Active PAL*	Active PAL*	Very Active PAL*
9	29.0 (63.9)	1.33 (52.4)	1390	1635	1865	2248
10	32.9 (72.5)	1.38 (54.3)	1470	1729	1972	2376
11	37.2 (81.9)	1.44 (56.7)	1538	1813	2071	2500
12	40.5 (89.2)	1.49 (58.7)	1798	2113	2428	2817
13	44.6 (91.6)	1.51 (59.4)	1617	1909	2183	3640
14	49.4 (108.8)	1.60 (63)	1718	2036	2334	3831
15	52.0 (114.5)	1.62 (63.8)	1731	2057	2362	2870
16	53.9 (118.7)	1.63 (64.2)	1729	2059	2368	2883
17	55.1 (121.4)	1.63 (64.2)	1710	2042	2353	2871
18	56.2 (123.8)	1.63 (64.2)	1690	2024	2336	2858

Data from Institute of Medicine, Food and Nutrition Board: Washington, DC, 2002, National Academies Press.

PAL, Physical activity level.

\*PAL categories, which are based on walking per day at 2–4 mph are as follows: sedentary, no additional activity; low active, 1.5–2.9 miles/day; active, 3–5.8 miles/day; and very active, 7.5–14 miles/day (see Table 2-3).

Adequacy of energy intake for adolescents is best assessed by monitoring weight and BMI. Excessive weight gain indicates that energy intake is exceeding energy needs, whereas weight loss or a drop in BMI below an established percentile curve suggests that energy intake is inadequate to support the body's needs. Groups of adolescents who are at elevated risk for inadequate energy intake include teens who "diet" or frequently restrict caloric intake to reduce body weight; individuals living in food-insecure households, temporary housing, or on the street; adolescents who frequently use alcohol or illicit drugs, which may reduce appetite or replace food intake; and teens with chronic health conditions such as cystic fibrosis, Crohn disease, or muscular dystrophy.

Recent concerns about excessive energy intake among youths have centered on the intakes of added fats and sugars in their diets. The mean daily intake of added sugars by 9- to 13-year-old males is 29.2 tsp, among 14- to 18-year-old males is 34.4 tsp, among 9- to 13-year-old females is 23.2 tsp, and among 14- to 18-year-old females is 25.2 tsp (National Cancer Institute, 2010). When one considers that a cup of sugar is approximately 48 tsp, it is apparent that adolescents consume a great deal of energy through added sugars. Soft drinks provide 37% of added sugars in the U.S. diet (Bachman et al., 2008). NHANES data revealed that 9- to 13-year-olds consume 1.5 servings of soft drinks daily, whereas 14- to 18-year-olds consume 2.7 servings, the highest intake of any age group (Frazao, 2005). Added fats are consumed by adolescents largely through snack foods, baked goods, and fast food (Bachman et al., 2008). Corn, potato, and other chips have been shown to provide 16% of added fats in the U.S. diet, and half of all potatoes were fried potatoes or chips (Bachman et al., 2008). Counseling related to excessive energy intakes among adolescents should focus on intake of discretionary calories, especially those from added sweeteners consumed through soft drinks and candy and from added fats consumed through snack foods and fried food.

## Protein

During adolescence protein requirements vary with degree of physical maturation. The DRIs for protein intake are estimated to allow for adequate pubertal growth and positive nitrogen balance (IOM, 2006). Table 19-4 illustrates the protein requirements for adolescents. Actual protein needs are best determined based on a per kilogram of body weight method during puberty to account for differences in rates of growth and development among teens.

Insufficient protein intake is uncommon in the U.S. adolescent population. However, as with energy intake, food security issues, chronic illness, frequent dieting, and substance use may compromise protein intakes among adolescents. Teens who follow vegan or macrobiotic diets are also at elevated risk for inadequate protein intake.

When protein intake is inadequate, alterations in growth and development are seen. In the still-growing adolescent, insufficient protein intake results in delayed or stunted increases in height and weight. In the physically mature

**TABLE 19-4**

**Protein: Estimated Average Requirements and Recommended Dietary Allowances for Adolescents**

Age (yr)	EAR (g/kg/day)	RDA (g/kg/day)
9-13	0.76	0.95 or 34 g/day*
14-18 Males	0.73	0.85 or 52 g/day*
14-18 Females	0.71	0.85 or 46 g/day*

Data from Institute of Medicine, Food and Nutrition Board: Dietary reference intakes for energy, carbohydrate, fiber, fat, fatty acids, cholesterol, protein, and amino acids, Washington, DC, 2002, National Academies Press.

EAR, Estimated average requirement; RDA, recommended dietary allowance.

\*Based on average weight for age.

teen, inadequate protein intake can result in weight loss, loss of lean body mass, and alterations in body composition. Impaired immune response and susceptibility to infection may also be seen.

## Carbohydrates and Fiber

Carbohydrate requirements of adolescents are estimated to be 130 g/day (IOM, 2006). The requirements for carbohydrates, as for most nutrients, are extrapolated from adult needs and should be used as a starting point for the determination of an individual adolescent's actual need. Teens who are very active or are actively growing need additional carbohydrates to maintain adequate energy intake, whereas teenagers who are inactive or have a chronic condition that limits mobility may require fewer carbohydrates. Whole grains are the preferred source of carbohydrates because these foods provide vitamins, minerals, and fiber. Intake of carbohydrates is adequate in most teens, with less than 3% of adolescents in the United States reporting intakes less than the recommended dietary allowance value (Moshfegh et al., 2005).

Fiber intakes of youth are low, however, because of poor intake of whole grains, fruits, and vegetables. The adequate intake (AI) values for fiber intake among adolescents are 31 g/day for males 9 to 13 years old, 38 g/day for males 14 to 18 years old, and 26 g/day for 9- to 18-year-old females (IOM, 2006). These values are derived from calculations that suggest that an intake of 14 g/1000 calories provides optimal protection against cardiovascular disease (CVD) and cancer (IOM, 2006). Adolescents who require less energy intake because of activity restrictions may have needs that are lower than the AI values.

Data from the 2005-2006 What We Eat in America survey, a component of the NHANES, suggest that median intakes of fiber are 15.2 g/day for teenage males and 12.3 g/day for females (U.S. Department of Agriculture [USDA], 2008). The disparities between fiber recommendations and actual intakes suggest that more emphasis needs to be placed on educating adolescents about optimal sources

of carbohydrates, including whole grains, fruits, vegetables, and legumes.

## Fat

DRI values for absolute fat intake have not been established for adolescents. Instead it is recommended that fat intakes not exceed 30% to 35% of total caloric intake, with no more than 10% of calories coming from saturated fatty acids. However, specific recommendations for intakes of  $\omega$ -6 and  $\omega$ -3 fatty acids have been set in an attempt to ensure that teens consume adequate essential fatty acids to support growth and development, as well as to reduce chronic disease risk later in life. The AI for  $\omega$ -6 polyunsaturated fatty acids (linoleic acid) are 12 g/day for 9- to 13-year-old males, 10 g/day for 9- to 13-year-old females, 16 g/day for 14- to 18-year-old males and 11 g/day for 14- to 18-year-old females (IOM, 2006). Estimated requirements for  $\omega$ -3 polyunsaturated fatty acids ( $\alpha$ -linolenic acid) among teens are 1.2 g/day for 9- to 13-year-old males, 1 g/day for 9- to 13-year-old females, 1.6 g/day for 14- to 18-year-old males, and 1.1 g/day for 14- to 18-year-old females (IOM, 2006).

## Minerals and Vitamins

Micronutrient needs of youth are elevated during adolescence to support physical growth and development.

However, micronutrients involved in the synthesis of lean body mass, bone, and red blood cells are especially important during adolescence. Vitamins and minerals involved in protein, ribonucleic acid, and deoxyribonucleic acid synthesis are needed in greatest amounts during the growth spurt. Needs decline after physical maturation is complete. However, the requirements for vitamins and minerals involved in bone formation are elevated throughout adolescence and into adulthood, because bone density acquisition is not completed by the end of puberty.

In general, adolescent males require greater amounts of most micronutrients during puberty, with the exception of iron. Micronutrient intakes during adolescence are inadequate among some subgroups of teens, especially among females. Tables 19-5 and 19-6 based on the 2005-2006 What We Eat in America survey, illustrates the adequacy of micronutrient intakes among U.S. adolescents compared with DRI recommendations. These data suggest that in all age and gender categories the intakes of vitamin E, calcium, and fiber are too low. Teenage females between the ages of 14 and 18 years old are most likely to consume inadequate intakes of the most vitamins and minerals, and benefit the most from nutrition intervention.

**TABLE 19-5**

**Mean Intakes of Select Nutrients Compared to DRIs: Adolescent Males**

	Mean Intake	9-13 year old RDA/AI	14-18 year old RDA/AI

## Calcium

Because of accelerated muscular, skeletal, and endocrine development, calcium needs are greater during puberty and adolescence than during childhood or adult years. Bone mass is acquired at much higher rates during puberty than any other time of life; rates of bone accretion during adolescence may be four times as high as rates during early childhood or adulthood (Stransky and Rysava, 2009). In fact, females accrue approximately 92% of their bone mass by the age of 18 years, making adolescence a crucial time for osteoporosis prevention (IOM, 2006; Word Health Organization, 2003).

The AI for calcium is 1300 mg for all adolescents with an upper level intake of 3000 mg/day. Calcium intake declines with age during adolescence, especially among females. Research suggests that high soft drink consumption in the adolescent population contributes to low calcium intake by displacing milk consumption. Increasing intakes of sweetened soft drinks are found to be related to decreasing numbers of servings of dairy foods and a decrease in the adequacy of calcium intake among children and adolescents (Rajeshwari et al., 2005). Interventions to promote calcium consumption among youth should focus not only on increasing dairy product intake, but also on decreasing intakes of soft drinks and increasing intakes of calcium-fortified foods such as orange juice, bread, dark-green vegetables, nuts, and ready-to-eat cereals.

## Iron

Iron requirements are increased during adolescence for the deposition of lean body mass, increase in red blood cell volume, and to support iron lost during menses among females. Iron needs are highest during periods of active growth among all teens, and are especially elevated after the onset of menses in adolescent females. The DRI for iron among females increases from 8 mg/day before age 13 (or before the onset of menses) to 15 mg/day after the onset of menses. Among adolescent males recommended intakes increase from 8 to 11 mg/day, with higher levels required during the growth spurt. Iron needs remain elevated for women after age 18, but fall back to prepubescent levels in men once growth and development are completed.

Median intakes of iron among adolescents less than desirable. Increased needs for iron, combined with low intakes of dietary iron, place adolescent females at risk for iron deficiency and anemia. It is estimated that 9% of adolescent females 12 to 15 years old and 11% to 16% of females 16 to 19 years old are iron deficient, with 2% to 3% classified as having iron-deficiency anemia (Centers for Disease Control and Prevention [CDC], 1998).

Rapid growth may temporarily decrease circulating iron levels, resulting in **physiologic anemia of growth**. Other risk factors for iron-deficiency anemia are listed in **Box 19-1**. Recent data suggest that overweight adolescents are almost three times more likely to experience iron deficiency than their normal-weight peers despite having similar dietary intakes of iron and vitamin C (Tussing-Humphreys et al.,

## BOX 19-1

### Risk Factors for Iron Deficiency

#### Inadequate Iron Intake/Absorption/Stores

Vegetarian eating styles, especially vegan diets

Macrobiotic diet

Low intakes of meat, fish, poultry, or iron-fortified foods

Low intake of foods rich in ascorbic acid

Frequent dieting or restricted eating

Chronic or significant weight loss

Meal skipping

Substance abuse

History of iron-deficiency anemia

Recent immigration from developing country

Special health care needs

#### Increased Iron Requirements and Losses

Heavy or lengthy menstrual periods

Rapid growth

Pregnancy (recent or current)

Inflammatory bowel disease

Chronic use of aspirin, nonsteroidal antiinflammatory drugs (e.g., ibuprofen), or corticosteroids

Participation in endurance sports (e.g., long-distance running, swimming, cycling)

Intensive physical training

Frequent blood donations

Parasitic infection

Reprinted with permission from Stang J, Story M, editors: Guidelines for adolescent nutrition services, Minneapolis, 2005, Center for Leadership Education and Training in Maternal and Child Nutrition, Division of Epidemiology and Community Health, School of Public Health, University of Minnesota.

2009). During adolescence, iron deficiency anemia may impair the immune response, decrease resistance to infection, and decrease cognitive functioning and short-term memory.

## Folic Acid

The DRI for folate intake among teens is 300 mcg/day for 9- to 13-year-old males and females, increasing to 400 mcg/day for 14- to 18-year-olds (IOM, 2006). The need for folate increases during later adolescence to support accretion of lean body mass and to provide AI among females of reproductive age as a preventive measure against neural tube defects. Food sources of folate should include both naturally occurring folate, found in dark green leafy vegetables and citrus fruit, as well as folic acid found in fortified grain products.

Median intakes of folate reported in the 2005-2006 What We Eat in America survey suggest that adolescent females are at greater risk for inadequate intake of folate than are males (USDA, 2008). This is cause for concern among

adolescent females who have achieved menses and are sexually active, as having adequate folic acid status prior to conception is important for the prevention of birth defects.

### Vitamin D

Vitamin D plays an important role in facilitating calcium and phosphorus absorption and metabolism, which has important implications for bone development during adolescence (IOM, 2010). Vitamin D can be synthesized by the exposure of skin to sunlight; however, many individuals live in latitudes that prevent them from synthesizing vitamin D for 6 or more months each year (Ginde et al., 2009). Individuals with darkly pigmented skin may also have a limited capacity for vitamin D production by the body (McDowell et al., 2008). The current RDA for vitamin D requirements among adolescents is 600 IU/day (IOM 2010).

NHANES data collected during the preceding few decades has established that serum 25(OH) vitamin D levels decreased among adolescents over time (Ginde et al., 2009). The reductions were especially obvious among black participants. Greater declines in serum vitamin D status were found among females than males. The reduction in vitamin D status is troubling for adolescent females because of their poor intake of calcium and elevated lifetime risk for osteoporosis.

A criteria of less than 10 ng/mL for deficiency and 30 ng/mL or more for sufficiency has been suggested; however, this is an area of current debate. Using this definition, less than 1% of white adolescents are vitamin D-deficient and 39% of females and 29% of males are not vitamin D-sufficient (Ginde et al., 2009). Mexican American females have a vitamin D deficiency prevalence of 2%, whereas less than 1% of their male peers are deficient. More than half (59%) of Mexican American teen males and 76% of females are thought to be vitamin D-insufficient. Black teens appear to have the highest rates of vitamin D deficiency and insufficiency, probably because of their dark pigmentation, with 4% of adolescent black males and 10% of adolescent black females deficient; 75% of black males and 92% of black females are vitamin D-insufficient.

Thus low vitamin D intake is a potential health risk for adolescents and deserves greater attention during nutrition assessment, education, and intervention. Vitamin D intake and adequacy should be assessed for all adolescents who live in northern climates, who have limited sun exposure, who have lactose intolerance or milk allergy, who have developmental disabilities that may limit outdoor activities, or who have darkly pigmented skin.

### Supplement Use by Adolescents

The consumption of moderate portions of a wide variety of foods is preferred to nutrient supplementation as a method for obtaining adequate nutrient intake. Despite this recommendation, studies show that adolescents do not consume nutrient-dense foods and usually have inadequate intakes of many vitamins and minerals; thus supplements may be beneficial for many teens. National surveys show that 30% to 40% of adolescents report using vitamin

or mineral supplements (Shaikh et al., 2009). The adolescents most likely to use supplements are those with a higher household income, a high degree of food security, and health insurance. Supplement users usually meet national guidelines for physical activity, dietary intake, and screen time.

The use of herbal and botanical supplements is not well documented. It is estimated that 29% of adolescents consume nonnutritional supplements, including herbal weight loss products (Yussman et al., 2006). Surveys suggest that herbal weight loss products are most commonly used, with up to 18% of youth reporting their use (Calfee and Fadale, 2006). Creatine, guarana, energizers (e.g., bee pollen), L-carnitine, and coenzyme Q<sub>10</sub> are other products that are commonly reported by adolescents. The short- and long-term effects of nonnutritional supplement use by children and adolescents are not known. Health professionals should screen adolescents for supplement use and should counsel them accordingly.

## FOOD HABITS AND EATING BEHAVIORS

Food habits that are seen more frequently among teens than other age groups include irregular consumption of meals, excessive snacking, eating away from home (especially at fast-food restaurants), dieting, and meal skipping. Many factors contribute to these behaviors, including decreasing influence of family, increasing influence of peers, exposure to media, employment outside the home, greater discretionary spending capacity, and increasing responsibilities that leave less time for teens to eat meals with their families. Socioeconomic status, family meal frequency, and home availability of healthy foods have been positively associated with vegetable, fruit and starchy food patterns (Cutler et al., 2011). Most adolescents are aware of the importance of nutrition and the components of a healthy diet; however, they may have many barriers to overcome.

Teens perceive taste preferences, hectic schedules, the accessibility of different foods at home and school, and social support from family and friends to be key factors that affect their food and beverage choices (Goh et al., 2009; Powers et al., 2010). For example, parents may positively influence the food and beverage choices of teens by modeling healthy eating habits, selecting healthy foods for family meals, encouraging healthy eating, and setting limits on the consumption of unhealthy snack foods. Friends influence each other through modeling and shared activities, such as eating out at fast-food restaurants and purchasing snacks at convenience stores near school.

Developmentally, many teens lack the ability to associate current eating habits with future disease risk. Teens are often more focused on “fitting in” with their peers. They adopt health behaviors that demonstrate their quest for autonomy and make them feel more like adults such as drinking alcohol, smoking, and engaging in sexual activity. Nutrition education and counseling should focus on

short-term benefits, such as improving school performance, looking good, and having more energy. Messages should be positive, developmentally appropriate, and concrete. Specific skills such as choosing water or milk over sugar-sweetened drinks, ordering broiled rather than fried meats, and choosing baked rather than fried snack chips are key concepts to include.

## Irregular Meals and Snacking

Meal skipping is a common behavior among adolescents. Meal skipping increases throughout adolescence as teens try to sleep longer, try to lose weight through calorie restriction, and try to manage their busy lives. Breakfast is the most commonly skipped meal. National data suggest that 30% of adolescents (12–19 years) skip breakfast on a given day (Moshfegh, 2005). Adolescent males are more likely than females (38% vs. 27%) to report having breakfast daily, whereas females are more likely than males (16% vs. 13%) to report never eating breakfast (Timlin et al., 2008). Breakfast skipping has been associated with poor health outcomes including higher BMI; poorer concentration and school performance; and increased risk of inadequate nutrient intake, especially of calcium and fiber (Rampersaud et al., 2005).

Teens who skip meals often snack in response to hunger instead of eating a meal. Most teens (89%) consume at least one snack per day and the majority of teens who report snacking consume two or more snacks per day (Sebastian et al., 2008). On a given day, more than one third of all fruit servings, approximately one fourth of all grain and milk servings, and approximately 15% of vegetable servings are consumed at snacking occasions. However, snacks also provide more than one third of discretionary calories and added sugars, and approximately one fourth of solid fats (Sebastian et al., 2008). Snack foods consumed by teens are often high in added fats, sweeteners, and sodium. Soft drinks and other sugar-sweetened beverages are commonly consumed, accounting for 13% of daily caloric intake among teens (Wang et al., 2008). Because snacks are prevalent and often consumed in place of meals, teens should be encouraged to make healthy choices when choosing these snack foods and beverages. **Box 19-2** provides ideas for healthy snacks or meal alternatives for teens.

## Fast Foods and Convenience Foods

Convenience foods include foods and beverages from vending machines, canteens, school stores, fast-food restaurants, and convenience stores. As adolescents spend considerable amounts of time in and around schools, convenience foods available at school and in the surrounding neighborhood may have a great influence on their eating patterns. National data indicate vending machines are available in 62% of middle schools and 86% of high schools (O'Toole et al., 2007). One third of middle schools and half of all high schools have a school store or canteen where students can purchase food or beverages (O'Toole et al., 2007). In addition, one third of U.S. middle schools and

## BOX 19-2

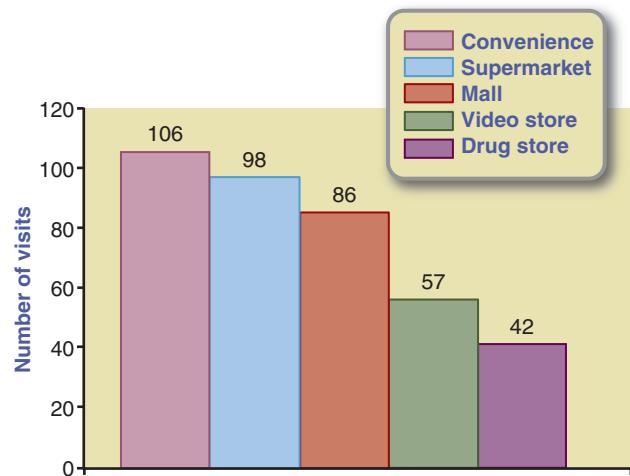

### Teen-Friendly Healthy Snacks

- Pudding made with skim milk
- A glass of skim milk sweetened with a teaspoon of chocolate or strawberry syrup
- Soft pretzels warmed in the microwave and topped with mustard or salsa
- Sliced apples dipped in peanut butter or fat-free caramel dip
- English muffin mini-pizzas (topped with tomato or pizza sauce and mozzarella cheese)
- Air-popped popcorn
- Peeled and sectioned oranges
- Hummus and pita bread
- Mozzarella or string cheese
- Baked tortilla chips with bean dip or salsa
- Baked potato (microwaved) topped with salsa, yogurt, or fat-free sour cream
- Graham crackers, animal crackers containing no *trans* fat
- Frozen yogurt or juice bars
- Fruit drink spritzer (half cranberry juice and half seltzer water)
- Trail mix (dried fruit with nuts and seeds)
- Baby carrots and low-fat ranch dressing
- Low fat granola bars
- Mini-rice cakes or popcorn cakes
- Sandwich wraps with slices of turkey, cheese, and tomato

Adapted with permission from Stang J, Story M, editors: Guidelines for adolescent nutrition services, Minneapolis, 2005, Center for Leadership Education and Training in Maternal and Child Nutrition, Division of Epidemiology and Community Health, School of Public Health, University of Minnesota.

high schools have at least one fast-food restaurant or convenience store within walking distance (Zenk and Powell, 2008). Fast-food restaurants and convenience stores are socially acceptable places for teens to work and spend time with their friends.

Convenience foods tend to be low in vitamins, minerals, and fiber, but high in calories, added fat, sweeteners, and sodium (Gordon et al., 2007). National data suggest that 59% of adolescents (12–19 years) consume at least one item from a fast-food restaurant and 44% to 55% consume at least one convenience food item at school on a given day (Fox et al., 2009; Sebastian et al., 2009). Few teens are willing to stop purchasing convenience foods; the low price, convenient access, and taste appeal to them (Figure 19-4). Health professionals should refrain from asking teenagers to not eat these foods and should instead counsel them on how to make wise and healthy choices. Concrete guidelines, such as choosing snacks or vending and fast-food options with fewer than 5 g of fat per serving, are easy for adolescents to remember. Teens can also be encouraged to check labels to determine if foods are made from whole grains or are high in added sweeteners or sodium.

**FIGURE 19-4** Store visits by teenagers in a 30-day period. (Data from *Channel One Network, New York, 2000.*)

## Family Meals

The frequency with which adolescents eat meals with their families decreases with age (National Center on Addiction and Substance Abuse, 2007). Half of 12-year-olds eat dinner with their families every day in a typical week compared with just 27% of 17-year-olds. Adolescents who eat meals with their families have been found to have better academic performance and to be less likely to engage in risky behaviors such as drinking alcohol and smoking compared with peers who do not frequently engage in family meals (Neumark-Sztainer et al., 2010).

Developing healthful eating patterns at family meals during adolescence may improve the likelihood that individuals will choose to consume nutritious foods in adulthood (Larson et al., 2007). Family meals not only allow for more communication between teens and their parents, but they also provide an ideal environment during which parents can model healthy food and beverage choices and attitudes toward eating. Teens who eat at home more frequently have been found to consume fewer soft drinks and more calcium-rich foods, fruit, and vegetables (see *Focus On: Family Meals and Nutritional Benefits for Teens*).

## Media and Advertising

Marketing to teenagers has become a multibillion-dollar business. It is estimated that the nation's largest food and beverage companies spend \$1.6 billion per year to market their products to youth (Federal Trade Commission, 2008). Food and beverage companies promote their products to youth using a number of different techniques (e.g., contests, product placements, sponsorships, celebrity endorsements, viral marketing) and multiple platforms.

American youth spend 7.5 hours per day with media and, given the amount of time they spend using more than one medium at a time, they are exposed to more than 10.5 hours of media content (Rideout et al., 2010). Outside of school work, on an average day, youth spend 4.5 hours watching television and movies, 2.5 hours listening to radio or

## © FOCUS ON

### Family Meals and Nutritional Benefits for Teens

When teens regularly share mealtimes with their families, they are more likely to have diets of higher nutritional quality (Neumark-Sztainer et al., 2010). One study examined whether this relationship may hold true not only for the general population, but also for racially diverse teens at risk for academic failure (Fulkerson et al., 2009). Students at six alternative high schools in the Minneapolis-St. Paul metropolitan area of Minnesota were surveyed about their dietary practices and other aspects of health. More than half (60%) of students at these schools qualified for free or reduced-price school meals. Among these students, 50% reported eating family dinners five to seven times per week, 24% reported eating family dinners one to four times per week, and 26% reported not eating family dinners in the past week. The results showed that family dinner frequency was related to higher daily fruit consumption and lower rates of overweight. However, in contrast to other studies, family dinner frequency was not related to vegetable consumption, high-fat food intake, regular soda consumption, or use of weight-loss practices. Health professionals should be aware that intervention programs to promote family meals may be beneficial, but such programs need to direct attention to the specific needs of at-risk teens, including the affordability of healthful foods for families.

recorded music, 1.5 hours using a computer, 1.2 hours playing video games, and 38 minutes reading magazines or books. The majority of youth (71%) have a television and 33% have Internet access in their bedroom. As the time that youth spend with media has increased over time (Rideout et al., 2010), so has the ability for advertisers to influence their eating behaviors. It is estimated that teenagers (13–17 years) view more than 28,000 television advertisements per year or more than 217 hours of advertising (Gantz et al., 2007). More than 20% of television advertisements viewed by teens are for food products (Gantz et al., 2007), and most viewed food advertisements (89%) are for products high in fat, sugar, or sodium (Powell et al., 2007). In addition, more than two thirds of the nation's largest food and beverage companies market their products to youth online (Federal Trade Commission, 2008). Media literacy education can and should be taught to teens to assist them in determining the accuracy and validity of media and advertising messages.

## Dieting and Body Image

Body image concerns are common during adolescence. Many teens describe themselves as being overweight despite being of normal weight, signifying a disturbance in their

body image. Data from the Youth Risk Behavior Survey (YRBS) found that 16% of U.S. high school students described themselves as being overweight despite being of normal weight (Talamayan et al., 2006). Females were more likely to report this misperception than males (25% vs. 7%).

Poor body image can lead to weight control issues and dieting. Data from the 2007 YRBS show that 45% of U.S. high school students were attempting to lose weight. White and Hispanic females had the highest prevalence of dieting at 62%, followed by black females (49%), Hispanic males (38%), white males (29%), and black males (25%) (Eaton et al., 2008). The prevalence of dieting increased with age among females, but decreased with age among males.

Approximately half (53%) of females and 28% of males reported eating fewer calories or less fat in the previous month to either lose weight or prevent weight gain (Eaton et al., 2008). Additionally, 67% of females and 55% of males had exercised in the previous month to lose weight or prevent weight gain. These behaviors can be viewed as healthy weight loss behaviors when used in moderation, and can be a starting point for nutrition education and counseling to improve eating behaviors.

Not all dieting behaviors have the potential to improve health, however. High-risk dieting practices are used by many teens and carry with them the risk of poor nutritional status and increased risk for **disordered eating** (see Chapter 23). Fasting, or refraining from eating for more than 24 hours, was practiced by 16% of female and 7% of male U.S. high school students in the past month as a means of dieting (Eaton et al., 2008). Seven percent of females and four percent of males had used diet pills to lose weight; the prevalence of this behavior was higher among white and Hispanic students and increased with age. The use of purging methods, including vomiting and laxative or diuretic use, was reported by 6% of females and 2% of males. White and Hispanic females were more likely to report purging behaviors than black females. In contrast, black and Hispanic males were more likely to report purging behaviors than white males.

## NUTRITION SCREENING, ASSESSMENT, AND COUNSELING

The Guidelines for Adolescent Preventive Services recommend that adolescents have an annual health screening to determine risk factors for acute and chronic disease, with screening for nutrition risk (American Medical Association, 2006). Nutrition screening should include the assessment of height, weight, and BMI to determine weight status; detection of potentially high-risk dietary habits such as calorie restriction, vegetarianism, and dealing with food allergies; and the evaluation of the presence of iron-deficiency anemia (females only). See Chapters 6-9.

Weight, height, and BMI should be plotted using the Centers for Disease Control and Prevention National Center for Health Statistics BMI tables to determine appropriateness of weight for height. Although BMI is not a direct

measure of body fatness and thus cannot be used to clinically assess obesity, it is highly correlated with body fatness and is the recommended screening method for weight status among youth (Freedman and Sherry, 2009). A BMI below the fifth percentile may signal the presence of chronic or metabolic disease, growth failure, or an eating disorder. A BMI at or above the 85th percentile, but below the 95th percentile, indicates that an adolescent is at risk for overweight, whereas a BMI at or above the 95th percentile indicates the presence of overweight. All BMI values that indicate the presence of overweight risk should be corroborated with a direct measure of body fat to determine that excessive fat, or obesity, is truly indicated.

When nutrition screening indicates the presence of nutritional risk, a full assessment should be conducted. Components of a full nutrition assessment are listed in Table 19-7. Nutrition assessment should include a complete evaluation of food intake through a 24-hour recall, dietary records, or brief food frequency questionnaire (see Chapter 6). The adequacy of energy, fiber, macronutrients, and micronutrients should be determined, as well as excessive intake of any dietary components such as sodium or sweeteners.

Nutritional assessments also should include an evaluation of the nutritional environment, including parental, peer, school, cultural, and personal lifestyle factors. The attitude of the adolescent toward food and nutrition is also important; helping them overcome their perceived barriers to eating well is an essential component of nutrition counseling.

Teens who live in food-insecure households, temporary housing, or shelters, or who have run away from home are at especially high nutritional risk, as are adolescents who use alcohol and street drugs. It is important that health professionals working with high-risk teens develop partnerships with community-based food assistance programs to ensure that youths have access to a steady, nutritious food supply. Homeless teens, as well as those living in temporary shelters, benefit from nutrition counseling focusing on lightweight, low-cost, prepackaged foods that do not require refrigeration or cooking facilities. Dried fruit, nuts, granola bars, cereal bars, tuna in pouches, and meat jerky are foods that should be available for runaway or homeless teens.

Education and counseling should be tailored to meet any specific nutrition diagnoses identified during the assessment. A teen who has been found to be overweight with type 2 diabetes requires a different type and intensity of counseling than a teen who has been diagnosed with iron-deficiency anemia. Knowledge, attitude, and behavior must be addressed when guiding adolescents toward acquiring healthful food habits. For a plan to succeed, the adolescent must be willing to change; therefore an assessment of a teenager's desire to change is essential. Encouraging the desire to change usually requires much attention (see Chapter 15).

Information can be provided in various settings ranging from the classroom to the hospital. The clinician must understand the change process and how to meaningfully

**TABLE 19-7****Elements of a Nutritional Screening and Assessment for Adolescents**

BMI, Body mass index; SMR, sexual maturity rating.

communicate this process. Parents may be included in the process and are encouraged to be supportive. Recommended eating plans based on recommended energy intakes for adolescents are shown in Table 19-8.

## SPECIAL CONCERNs

### Vegetarian Dietary Patterns

As adolescents mature they begin to develop autonomous social, moral, and ethical values. These values may lead to vegetarian eating practices because of concerns about animal welfare, the environment, or personal health. Concerns about body weight also motivate some adolescents to adopt a vegetarian diet because it is a socially acceptable way to reduce dietary fat. Recent data confirm that adolescents who consume vegetarian diets are less likely to be overweight or obese than their omnivorous peers (Robinson-O'Brien et al., 2009). Well-planned vegetarian diets that include a variety of legumes, nuts, and whole grains can provide adequate nutrients for teens who have completed the majority of their growth and development (Figure 19-5).

Vegetarian diets that become increasingly more restrictive should be viewed with caution, however, because this may signal the development of disordered eating, with the vegetarian diet used as a means to hide a restriction of food intake (Robinson-O'Brien et al., 2009). Both teen males and females who adopt vegetarian dietary patterns have been found to use more high-risk weight control behaviors, especially vomiting, to lose weight (Robinson-O'Brien et al., 2009). This increased risk for unhealthy weight control behaviors seems to persist even after the vegetarian eating style is discontinued, suggesting that although the issues are related, vegetarian diets likely do not cause disordered eating and instead may serve as an early symptom.

Vegetarian adolescents often have high intakes of iron, vitamin A, and fiber and low intakes of dietary cholesterol. Vegetarian diets that include eggs or dairy products are consistent with the Dietary Guidelines for Americans and can meet the DRIs for all nutrients. A sample eating plan to assist vegetarian teens in achieving adequate energy and nutrient intakes is listed in Table 19-9. Vegan and macrobiotic diets, which do not include animal products of any kind, do not provide natural sources of vitamin B<sub>12</sub> and may be deficient in calcium, vitamin D, zinc, and iron (Kirby &

\*Age 11 years or older; 2200-2800 kcal.

Danner, 2009). Therefore it is imperative that vegan adolescents choose foods that are fortified with these nutrients or take a daily multivitamin-mineral supplement. Adolescents and their caregivers should be instructed on the planning of well-balanced vegetarian diets and fortified foods that can prevent potential nutrient deficiencies.

### Disordered Eating and Eating Disorders

It is estimated that 10% to 20% of teens engage in disordered eating behaviors, such as binge-purge behavior, compensatory exercise, laxative and diuretic abuse, and binge eating (CDC 2008). These behaviors do not occur with enough regularity or frequency to be diagnosed as an eating disorder, but may still have significant health implications for teens. Symptoms that may signal the presence of disordered eating behaviors include recurring gastrointestinal complaints, amenorrhea, or unexplained weight loss. Overweight females have been found to be twice as likely to engage in disordered eating behaviors. A screening for disordered eating can easily be done and should include questions about body dissatisfaction, fear of becoming obese, frequency of dieting and fasting, use of laxatives and diuretics, use of diet pills, fear of certain foods (e.g., foods containing fat or sugar), vomiting, bingeing, and compensatory exercise (see Chapter 23).

Eating disorders are the third most common chronic illness in adolescent females, with an incidence of from 1.5% to 5%. In general, anorexia nervosa is characterized by a dangerously low body weight, preoccupation with thinness, and restrictive dietary behaviors. Bulimia nervosa is characterized by a body weight that is close to normal, episodes of uncontrollable eating (bingeing), and efforts to eliminate calories or food from the body (purging). Binge eating disorder is characterized by frequent, recurrent episodes of binge eating and loss of control over eating.

Diagnostic criteria for eating disorders provided by the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, need to be used judiciously with adolescents because of issues surrounding normal growth and development. The wide variability in the rate, timing, and velocity of height and weight gain during normal puberty; the absence of menstrual periods in early puberty combined with the unpredictability of menses soon after menarche; and the cognitive inability to understand abstract concepts limit the application of the diagnostic criteria to adolescents (American Dietetic Association, 2006). Adolescents are particularly vulnerable to the complications of eating disorders. The effect of malnutrition on linear growth, brain development, and bone acquisition can be persistent and irreversible. Yet with early and aggressive treatment, adolescents have the potential for a better outcome than adults who have had the disease longer (Steinhausen, 2008).

### Obesity

Adolescent obesity has both short- and long-term health consequences. Adolescents who are overweight are at higher risk for hyperlipidemia, hypertension, insulin resistance, and type 2 diabetes compared with normal weight peers (Cali-

and Carpior, 2008; Daniels et al., 2005). Data from NHANES suggest that the prevalence of metabolic syndrome is increasing among adolescents, from a rate of 9.2% in the 1988-1994 survey to 12.7% in the 1999-2000 survey (de Ferranti et al., 2006). Epidemiologic studies of obesity and disease risk demonstrate an increased risk of morbidity from coronary heart disease, arteriosclerosis, specific types of cancer, gout, and arthritis among individuals who were overweight or obese during adolescence (van Dam et al., 2006).

Adolescent weight status is evaluated based on BMI (weight/height<sup>2</sup> [kg/m<sup>2</sup>]) as shown in Appendixes 12 and 16. Among 12- to 19-year-olds in the United States, the prevalence of overweight, characterized by a BMI higher than the 85th percentile, is 34.2% (Ogden et al., 2010). The prevalence of obesity (BMI ≥95th percentile) is 18.1%. Obesity is a complex, multifactorial health issue that is influenced by genetics, metabolic efficiency, PAL, dietary intake, and environmental and psychosocial factors. Adolescents who are found to be overweight should have a fasting lipid profile completed and should be assessed for additional risk factors for chronic disease, such as personal history of hypertension, hyperlipidemia, and tobacco use, and family history of hypertension, early cardiovascular death, stroke, hyperlipidemia, and type 2 diabetes mellitus (Krebs et al., 2007). If risk factors are noted, aspartate aminotransferase and alanine aminotransferase measurements to assess liver function should be obtained as well.

A fasting glucose level should be drawn on any overweight adolescent with two or more risk factors for CVD or with a family history of diabetes. Obese teens should undergo the same laboratory assessments as overweight children, with the addition of microalbumin/creatinine or microalbumin/creatinine ratio. Additional assessments for conditions such as sleep apnea, orthopedic disorders, polycystic ovary disease, and hormonal abnormalities should be performed based on presenting symptoms.

Recent guidelines for adolescent overweight and obesity suggest a staged care treatment process based on a teen's BMI, age, motivation, and the presence of comorbid conditions (Spear et al., 2007). Four stages are recommended, with progress through the stages based on age, biological development, level of motivation, weight status, and success with previous stages of treatment. Each of the stages is briefly described in the following text.

Overweight adolescents start out in Stage 1 if they do not display comorbid conditions or have not completed the adolescent growth spurt. Stage 1 consists of general nutrition and physical activity advice to promote health and prevent disease. Educational components for this stage of treatment include consuming 5 or more servings of fruits and vegetables per day, reducing consumption of sweetened beverages, participating in at least 60 minutes of physical activity each day, and limiting screen time (movies, Internet, television, and computer and video games) to no more than 2 hours per day. Nutrition topics that are particularly important to discuss with overweight adolescents during Stage 1 include the importance of breakfast consumption, limiting food

eaten outside the home or school (including fast food), eating meals with their family at least five times per week, and appropriate portion size. This stage of obesity treatment can be provided by a single health care provider, including physicians, nurses, and dietitians who have training in pediatric weight management.

Stage 2 builds on the same concepts as Stage 1, but in a more structured way. A key component of Stage 2 is the monitoring of food and beverage intake by adolescents or their parents, usually done through daily food and exercise journals or record books. Screen time is more limited in Stage 2 to less than 1 hour per day and a meal plan is introduced to provide further guidance for dietary intake. Successful lifestyle changes should be reinforced through the use of age-appropriate, nonfood rewards such as tickets to a local event or museum, jewelry, clothing, or music. Stage 2 can be provided by a single health care provider with training in motivational counseling. Referrals for additional services such as physical therapy or counseling may be necessary for some adolescents during Stage 2. Monthly follow-up and assessment of progress is suggested for both Stages 1 and 2.

Stage 3 is more structured than Stage 2 and is provided by a multidisciplinary team consisting of a physician or pediatric nurse practitioner, a counselor (psychologist or social worker), a registered dietitian, and an exercise physiology or physical therapist. This treatment stage recommends 8–12 weeks of weekly appointments with the adolescent and their family, followed by monthly or bimonthly follow-up appointments. A highly structured meal plan and physical activity schedule are implemented, along with a formal behavior modification program.

Stage 4 treatment is reserved for severely obese adolescents or those who have significant comorbidities that require concerted intervention. This treatment stage is available only in clinical settings that employ a full range of health professionals who are specifically trained in the behavioral and medical management of pediatric obesity. Intensive dietary regimens such as meal replacement, protein-sparing modified fasts, oral medication, and bariatric surgery may be used in this stage.

Concern has been expressed regarding the use of bariatric surgery in adolescents. Recommendations for bariatric surgery suggest that it is only appropriate in severely overweight teens ( $BMI >40$ ) with severe comorbid medical conditions or those with a  $BMI$  of more than 50 who have completed most of their physical growth and development (Pratt et al., 2009). Difficulty in complying with dietary restrictions following surgery may lead to complications such as dumping syndrome following high carbohydrate intake, voluntary excessive food intake, meat impacted in a gastrojejunal anastomosis, and B vitamin deficiency caused by poor compliance with vitamin-mineral supplementation

## Hyperlipidemia and Hypertension

Hyperlipidemia and hypertension, both risk factors for CVD, are apparent in adolescence and have been shown to be predictive of CVD risk in later life (Celermajer and Ayer, 2006; Gidding, 2007). Table 19-10 lists the classification criteria for the diagnosis of hyperlipidemia among youth. National data suggest that one in five adolescents 12–19 years old has elevated blood lipid levels (CDC, 2010). The prevalence of hyperlipidemia among adolescents was not consistent, however. The prevalence of hyperlipidemia was 14% among normal weight, 22% among overweight, and 43% among obese teens. The prevalence of low high-density lipoprotein (HDL) cholesterol and high triglyceride levels appeared to increase with age. Adolescent males were almost three times more likely to have low HDL cholesterol levels compared with females at any age. These youth are considered candidates for therapeutic lifestyle counseling with emphasis on nutrition and physical activity intervention.

It is important to consider secondary causes of hyperlipidemia when determining dietary treatment options (Table 19-11). Nutrition intervention for elevated blood lipids focuses on reducing the intake of total, saturated, and trans fat and limiting dietary cholesterol intakes. Promoting healthy lifestyle behaviors to reduce CVD risk should include a discussion of the benefits of regular physical activity in addition to dietary recommendations.

National screening criteria for blood pressure levels among adolescents are listed in Tables 19-12 and 19-13.

BP, Blood pressure.

\*Height percentile determined by standard growth curves.

<sup>†</sup>Blood pressure percentile determined by a single measurement.

Teenagers 17 years of age and younger are determined to have prehypertension if their average blood pressure readings fall between the 90th and 94th percentiles. Hypertension is diagnosed when the average of three blood pressure measurements exceed the 95th percentile for age, gender, and height.

Dietary counseling and weight management are integral components of hypertension treatment. The Dietary Approaches to Stop Hypertension (DASH) eating pattern has been shown to be effective in reducing blood pressure in many individuals (see Chapter 34 and Appendix 33). In addition to the DASH diet, teens with elevated blood pressure should be counseled to reduce sodium intake to less than 2000 mg/day and to achieve and maintain a healthy body weight.

## Physical Activity

National recommendations for physical activity suggest that all youth should be active at least 60 minutes each day, including participating in vigorous activity at least 3 days each week (U.S. Department of Health and Human Service, 2008). In addition, muscle-strengthening and bone-strengthening activities should each be included in the 60 minutes of physical activity at least three times a week. However, many youths do not meet these

recommendations. Only 35% of U.S. students report being physically active for 5 days or more per week, with males nearly twice as likely to meet recommendations as females (CDC, 2008).

Teenage athletes have unique nutrient needs. Adequate fluid intake to prevent dehydration is especially critical for young athletes. Young adolescents are at higher risk for dehydration because they produce more heat during exercise but have less ability to transfer heat from the muscles to the skin. They also sweat less, which decreases their capacity to dissipate heat through the evaporation of the sweat (see Chapter 24).

Athletes who participate in sports that use competitive weight categories or emphasize body weight are at elevated risk for the development of disordered eating behaviors. A concern among female athletes is the female athlete triad relationship, a constellation of low body weight and inadequate body fat levels, amenorrhea, and osteoporosis (see Chapter 23). Female athlete triad may lead to premature bone loss, decreased bone density, increased risk of stress fractures, and eventual infertility (Gottschlich and Young, 2008). Nutrition assessment and education for teenaged athletes should focus on obtaining adequate energy and macro- and micronutrients to meet the needs for growth and development and to maintain a healthy body weight. The use of anabolic agents (such as steroids or

insulin) and other ergogenic supplements should also be included in nutrition screening. Survey data suggest that up to 8% of high school students use creatine, 5% use steroids, and 4% use androstenedione (Castillo and Comstock, 2007; CDC, 2008).

## Pregnancy

Adolescent females who become pregnant are at particularly high risk for nutritional deficiencies because of elevated nutrient needs. Pregnant adolescents with a **gynecologic age** (the number of years between the onset of menses and current age) of less than 4 and those who are undernourished at the time of conception have the greatest nutritional needs. As with adult women, pregnant teens require additional folic acid, iron, zinc, calcium, and other micronutrients to support fetal growth (see Chapter 16). Pregnant teens should have a full nutrition assessment done early in pregnancy to determine any nutrient deficiencies and to promote adequate weight gain. Weight gain recommendations for pregnancy are listed in Chapter 16. Referral to appropriate food assistance programs such as the Special Supplemental Food Program for Women, Infants and Children is an important part of prenatal nutrition education.

## CLINICAL SCENARIO

Shawna is a 17-year-old girl who is being seen at the pediatric clinic today for a preemployment physical. The physician has recommended that she talk with you, the nutritionist, about her eating habits because her hemoglobin level was low. When you question Shawna about her eating habits, she reveals that she skips breakfast each day because she doesn't have time to eat in the morning, but she does have a cup of coffee on her way to school at 7:15 am. Shawna's first food intake is usually a snack from the vending machine at 10:30 am, which consists of a candy bar or a bag of chips and a soft drink. Occasionally she purchases ala carte lunches of tacos or a burger, but generally she skips lunch. Shawna gets out of school at 2 pm and goes to work at the mall. She has a half-hour break in the late afternoon, so she goes to the food court for dinner. The evening meal usually consists of one to two slices of pizza, two tacos, or one to two pieces of chicken with a soft drink. About half of the time she also orders fries or chips. When Shawna gets home from work at 9 pm, she usually has a snack of ice cream, tortilla chips, spicy cheese puffs, or microwave popcorn. She usually has a large glass of juice or lemonade with her snack.

When you suggest to Shawna that she might benefit from eating meals rather than snacks, she says she doesn't have time to cook meals, especially in the morning. She also tells you that there are no other food choices besides fast foods at the mall where she works.

### Nutrition Diagnostic Statements

1. Undesirable food choices related to perceived limitations of work and school as evidenced by daily intake of high-fat, high-sugar foods.
2. Inadequate iron intake related to low intake of iron-containing foods as evidenced by diet history reflecting 70% of dietary reference intake for iron.

### Nutrition Care Questions

1. What types of foods might you suggest to Shawna to have for breakfast? Why would you choose these foods?
2. What is the recommended iron intake for a girl of Shawna's age? Does it appear that she is getting adequate iron intake from her diet? What food choices would you recommend for Shawna to increase her hemoglobin level?
3. How much calcium does a 17-year-old teen girl need? What suggestions could you make to increase Shawna's calcium intake based on the foods she likes and the places she eats?
4. What types of foods might you suggest that Shawna choose at the mall fast food court to improve her nutrient intake and to help treat her anemia?

## CHAPTER 20

Judith L. Dodd, MS, RD, LDN, FADA

# Nutrition in the Adult Years

### KEY TERMS

**consumer price index (CPI)**  
**food security**  
**functional foods**  
**health-related quality of life (HRQOL)**  
**isoflavones**  
**metabolic syndrome**

**phytochemicals**  
**phytoestrogens**  
**phytonutrients**  
**prebiotics**  
**premenstrual syndrome (PMS)**  
**probiotics**  
**wellness**

This chapter emphasizes the background and tools for encouraging adults to set nutrition-related lifestyle goals that promote positive health and reduce risk factors. Other chapters of this text provide in-depth information about the major chronic diseases and conditions that affect food and nutrition choices in the adult years, including cardiovascular disease (CVD), diabetes, cancer, weight control, and osteoporosis. The focus here is on achieving and maintaining positive health, and in making lifestyle choices to achieve the goals for Healthy People 2020 (see Chapter 10).

are affected by gender, state of health, medications, and lifestyle choices such as eating behaviors, smoking, and activity. These are markers, determined through assessment, that the nutrition and health professional can use to determine this population's needs. Other markers are less evident and include the adult's perceptions of quality of life and motivation in the areas of nutrition and health. When the objectives are prevention and behavior change, such markers become critical.

A first step for dietetics and health professionals is to recognize that many adults are prime targets for nutrition and health information that offers positive guidance. As with any group, adults need to be approached with strategies and guidance that fit their health and education needs. The American Dietetic Association (ADA) Trends surveys offer some insights. These surveys include a representative sampling of adult Americans with a focus on food, nutrition, and activity messages and consumers' reactions to these messages. Because this survey was conducted every 2 years for 12 years and was repeated in 2008, Trends provides a snapshot of attitudes about the importance of nutrition, activity, and sources of information. In 2002, 38% of Americans believed they had made significant adjustments in achieving

### SETTING THE STAGE: NUTRITION IN THE ADULT YEARS

This chapter focuses on nutrition- and food-related behaviors for the years following adolescence but before one is deemed an "older adult," often defined as age 65. Admittedly this is a large age span, and, like all population groups, it is heterogeneous. The dietary reference intakes (DRIs) on the inside cover of this text provide an overview of the nutrient recommendations for age groups under the DRI umbrella. Nutrient needs are similar but, as in all life stages,

a healthful and nutritious diet. Trends 2008 continued to show positive gains in that 43% of the respondents noted they were making positive steps (ADA, 2008).

## Eating Habits of American Adults

Surveys such as ADA Trends support the idea that an increasing number of adults, more women than men, are seeking nutrition information and using it to make positive lifestyle changes. In a recent survey almost 70% of 30,000 U.S. adults said that they are trying to eat healthier foods; half are looking for nutrition value and have an ongoing concern about controlling calories (Dornblaser, 2006). According to the ADA's survey three in five consumers said diet, nutrition, and physical activity are "very important" to them personally, women more so than men. Younger adults were less likely than older adults to rate diet and nutrition as "very important," whereas exercise and physical activity were very important across the life cycle. Of relevance is the fact that reasons for not adjusting their diet or exercise patterns more were most likely to be satisfaction with their current health and nutrition status (79%) and concerns for not having to give up foods they like (73%). For those interested in changing their beliefs and behaviors, time limitations, lack of practical information, and unclear guidelines were noted (ADA, 2008).

A review of the health and nutrition information in magazines and on television reinforces the idea that nutrition and health information is "in." However, consumers are selective about their personal concerns. The International Food Information Council (IFIC) Foundation Food and Health Survey found that half of Americans are trying to lose weight, two thirds report making changes in the types and amounts of food eaten, and 70% express concerns with their weight (IFIC, 2009). Messages regarding the potential benefits and risks of certain foods and nutrients are being heard by consumers. Messages such as the negative effect of saturated fat, *trans*-fatty acids, and sodium are acknowledged; two in five adults said they were planning to eat more whole grains during the year they were surveyed (Harris Interactive Poll, 2006). This has driven the marketing of "healthful foods" as well as the demand for creating and marketing foods that fit this image (Sloan, 2006).

Where consumers get their information is another factor to consider. Both the source and the message affect the scientific value, but to the adult consumer the promise of specific benefit is more important than the standard "it's good for you" message. Both television and magazines are major sources of food and nutrition information for adults, and the Internet has surpassed newspapers. When it comes to credible sources, 78% of survey respondents rate registered dietitians as credible, followed by doctors and nurses (ADA, 2008.)

Consumers are using the labels on foods and beverages, including both the Nutrition Facts Panel and other label information, to get health information. Although 84% of the population is aware of MyPyramid which has recently been updated to MyPlate, only 25% report customizing their diets using these guidance systems (IFIC, 2009).

Consumers will continue to need help in using the new website, [www.chooseMyPlate.gov](http://www.chooseMyPlate.gov) to improve their diets.

## Nutrition Information and Education for Adults

Frequently, mainstream adults are ignored as a unique segment of the population needing a positive message. Preventive strategies are likely to be targeted to address the formative years of prenatal, infancy, childhood, adolescence, and young adulthood. The older adult group is likely to be targeted with health intervention strategies and quality-of-life messages. But the population group in the middle of the continuum, the adult age 25 to approximately 65, is likely to be segmented in reference to a disease state, a life event, or a lifestyle choice. For example, adults are targeted as having or being at risk for diabetes or heart disease, in need of a medication, being pregnant, or being an athlete.

The adult who is not pregnant, an athlete, or "sick," but who seeks guidance on normal nutrition or prevention of disease may be directed toward diets for chronic disease or weight loss. Such information may be a good fit when the information is based on science. Fortunately, the guidance provided by such groups as the American Heart Association (AHA), the ADA, the American Diabetes Association, and the American Cancer Society (ACS) mirror the Dietary Guidelines for Americans 2010 (DGA) (USDHHS, 2010). The AHA released guidelines in 2006 defining new goals with a focus on improving overall health and achieving improved cardiovascular health of all Americans by 20% by 2020 (Lloyd-Jones, 2010).

Adults are prime targets for information on chronic disease prevention and weight management; however, the messages may appear to be conflicting or less sensational than advice promising quick solutions. In spite of this, health education and public health programs, along with improved research and care, have contributed to changes in morbidity and mortality of the adult population (Centers for Disease Control and Prevention [CDC], 2009a). U.S. adults are on a path to positive change, moving from knowledge to action (National Center for Health Statistics [NCHS], 2009).

Adults in the awareness and action stages are likely to be looking for answers, often short-term fixes or reversals of a health problem. For example, adults might want to know where carbohydrates fit into the total diet and whether there are "better carbs." What's the message on fat now that *trans*-fats have been almost banned? Are there "good fats?" What is a "healthy" or "unhealthy" food or diet? Should I be buying organically grown or locally grown foods? What should I do about sodium? How can I practice food safety?

Guidance based on science generally addresses total diet and lifestyle rather than single nutrients or foods. The concepts of *healthful eating*, *nutrient density*, and *nutritious food* are being debated by food and nutrition professionals. The idea of expressing nutrient density using food labels is a major discussion point. Unfortunately, food and nutrition debates are fodder for media coverage, adding to the confusion and perception of mixed messages. There is ongoing

effort to sort out information on food labels, particularly front-of-package systems meant to help consumers understand what is in their food (Institute of Medicine [IOM], 2010; Thompson, 2010).

But adults are a population group with both the interest and the ability to seek out their own resources and answers. A search for information on choosing foods for health can result in evidence-based information such as the DGA, as well as questionable guidance based on single studies or product promotion. The combination of marketing and electronic media makes it easier to mix science with speculation and outright untruths. Adults with an interest in improving the nutritional quality of their diet may end up with noncredible advice pointing to supplements as quick-fix solutions.

Consider the adult years as a time for health promotion, health maintenance, and disease prevention, along with the interventions that accompany the progression of chronic disease that can come with aging. It is a time for adults to take responsibility and control. The Food and Health Survey and the ADA Trends study are examples of benchmark studies that provide a snapshot of consumer attitudes on food and health. Such studies provide the dietetic and health professional the information on “hot buttons” issues of importance to consumers. Examining these and other surveys targeting adults is critical to presenting relevant information and also initiating and reinforcing positive nutrition and health behaviors.

## THE WELLNESS YEARS

The adult years are a broad span chronologically and are complicated by physiologic, developmental, and social factors. Along with their genetic and social history, adults have accumulated the results of behaviors and risks from environmental factors. These factors shape the heterogeneity of the adult years. Nonetheless, the adult years are an ideal time for positive health promotion and disease prevention messages. In the transitions from early to middle adulthood, health and wellness may take on a new importance. This may be the result of a life event or education (an epiphany) which triggers an awareness that being well and staying well are important. Examples include learning the results of a screening for blood pressure, cholesterol, or diabetes; facing the reality of death; the self-reflection that occurs when personal health or that of a peer or family member is in crisis; or realizing that clothes don’t fit as well as they should. Regardless of the reason, the concept of wellness takes on a new meaning and these events are teachable moments.

The Wellness Councils of America (WELCOA) describes **wellness** as a process that involves being aware of better health and actively working toward that goal (WELCOA, 2009). With this mindset, a state of wellness can exist at any age and can start at any point in a person’s life course. Wellness is more than physical health and well-being. A state of well-being includes mental and spiritual health and

encompasses the ability of a person to move through Maslow’s Hierarchy of Needs (Maslow, 1970).

The ability to address nutrition needs requires **food security** (i.e., access to a safe, acceptable, and adequate source of food). The current economic climate has put added emphasis on food security. Hispanic and black Americans in all age groups are more likely to live in poverty than white and Asian Americans (CDC, 2009a). Indeed, the highest levels of food insecurity are in black and Hispanic households (CDC, 2006a).

In 2008, it was estimated that 85% of U.S. households were food secure throughout the entire year and 15% were food insecure at least some time during the year, an increase of 11.1% over 2007 (U.S. Department of Agriculture [USDA] and Economic Research Service [ERS], 2010). Hunger and poverty statistics released by Feeding America, formerly Second Harvest, note that in 2008 39.8 million people were living in poverty (Food Research and Action Center, 2010).

Participation in the Supplemental Nutrition Assistance Program (SNAP), previously “Food Stamps,” is a marker of food insecurity. Slightly more than half of all Americans between the ages of 20 and 65 will at some point receive food stamps, an indicator of the risk for food insecurity in the adult years (Sandoval et al., 2009). Although most SNAP recipients are children or older adults, working-age women represent 28% of those enrolled in the program and working-age men represented 14% (USDA and ERS, 2010). Access to affordable food is a basic requirement for wellness and nutrition in the adult years.

One’s perceptions of personal health (both mental and physical) relate to views on wellness and perceptions of quality of life. **Health-related quality of life (HRQOL)** is a concept used to measure the effects of current health conditions on a person’s day-to-day life. To capture this and create a tool for professionals, the CDC measures population HRQOL perceptions, including the perception of “feeling healthy.” Using HRQOL, one can learn about how adults relate their health to their daily performance. Americans report feeling “unhealthy” approximately 6 days a month and “healthy” or “full of energy” approximately 19 days a month; adults with the lowest income levels and more chronic diseases report more “unhealthy” days (CDC, 2006a).

The adult years offer unique opportunities to evaluate health status, build on positive factors, and change the negative factors that affect quality of life. See Fig. 20-1. Because adults are teachers, coaches, parents, caregivers, and worksite leaders, targeting the wellness-related attitudes and behaviors of adults can potentially have a multiplier effect. A positive wellness focus may influence not only the health of the adult, but also those in his or her sphere of influence.

## LIFESTYLE AND HEALTH RISK FACTORS

Lifestyle choices, including activity, lay the framework for health and wellness. The health of people living in the

**FIGURE 20-1** Eating quickly without attention, when stressed or when multi-tasking often results in poor nutritional intake in the adult years. (© 2011 Photos.com a division of Getty Images. All rights reserved.)

United States has continued to improve during the previous 55 years in part because of education that has led to lifestyle changes. Life expectancy has continued to increase (projected at 77.9 years), and the morbidity and mortality rate from heart disease, cancer, and stroke has dropped. Overall mortality was 25% higher for black Americans than white Americans in 2007; this has only slightly improved since 1990 when the gap was 37% (CDC, 2009a). This is an area for increased emphasis on prevention and intervention initiatives.

Even when the emphasis is on wellness, there is a strong link to risk factors that influence morbidity and mortality. In the United States the leading causes of death and debilitation among adults include (1) heart disease, (2) cancer, (3) cerebrovascular disease, (4) chronic lower respiratory disease, (5) accidents (unintentional injuries), and (6) diabetes (CDC, 2009b). Chronic diseases, including heart disease, stroke, cancer, and diabetes, are among the most costly and preventable of all health problems and account for one third of the years of potential life lost before age 65 and for 75% of the nation's medical care costs (CDC, 2009b). Four of these chronic diseases have links to diet and lifestyle, including CVD, diabetes, certain cancers, and osteoporosis.

Overweight and obesity is either a precursor or complication in all of these diseases. The prevalence of overweight, as measured by a body mass index (BMI) of 25 or more, has increased at all ages, but appears to be holding steady. It is important when looking at the overall health of adults to consider elevated BMI as a major risk factor. Hypertension, hyperlipidemia, and elevated blood glucose are often seen together with or without obesity, known as the **metabolic syndrome**.

Obesity and overweight directly link with calorie imbalance. It is estimated that less than half of U.S. adults participate in regular physical activity, with one fourth reporting no activity. Many health risks in the adult years, including coronary artery disease, certain types of cancer,

hypertension, type 2 diabetes, depression, anxiety, and osteoporosis have a relationship with lack of participation in regular physical activity and poor eating behaviors. One cannot achieve positive health without a combination of physical activity and food choices that fit personal needs for energy balance and nutrition.

On the other end of the weight spectrum is chronic underweight, frequently accompanied by undernutrition. Anorexia nervosa is the extreme condition, found in both genders across the age span. An unhealthy weight or unhealthy concern about body weight not only affects overall health but in women can also affect fertility and the ability to conceive.

## HEALTH DISPARITIES

Implementation of Healthy People goals are based in part on eliminating disparities that increase the health risks for affected populations. Such disparities are related to inadequate access to a safe and affordable food supply and health care based on race, ethnicity, gender, education, income level, and geographic location. Inadequate access to care is a disparity that has a major effect on a person's wellness. Men of working age are nearly twice as likely as women to have no usual source of health care (NCHS, 2009). Chronic diseases and obesity have been shown to be more of a burden to racial minorities and women (CDC, 2009a, 2010). There is a higher incidence of heart disease, diabetes, and obesity or overweight in low-income, black, and Hispanic populations (AHA and American Stroke Association, 2005). These same population groups have limited access to preventive care, nutrition education, and guidance (U.S. Department of Health and Human Services [USDHHS], 2010).

Food insecurity and limited access to healthful foods are also disparities. It is often more expensive to eat healthy foods than less healthy, high-calorie foods. Limited skills in the areas of wise food purchasing and food preparation coupled with limited food and equipment resources further complicate a person's ability to follow advice for a healthy lifestyle. This emphasizes the need for adult consumer education in basic food skills.

The problems associated with chronic diseases are similar in other countries (World Health Organization [WHO], 2009). Human immunodeficiency virus, acquired immune deficiency syndrome, tuberculosis, and tropical diseases are barriers to global achievement of positive health status. Indeed, the eight United Nations millennium development goals seek to reduce the number of people who suffer from hunger and increase access to safe water and sanitation (WHO, 2009).

### Emphasis: Women's Health

The reproductive years constitute a significant stage of a woman's life. Many issues that affect the health of women are related to the monthly hormonal shifts associated with menses. Osteoporosis, heart disease, and some cancers are disease states that are affected by specific hormones. Pregnancy and breast-feeding have an effect on a woman's

health (see Chapter 16). Breast-feeding helps control weight, lower the risk for diabetes, and improves bone health (Stuebe et al., 2005). Therefore encouraging women to breast-feed is a potential prevention strategy for the future health of both the mother and her infant.

Shifts of estrogen and progesterone hormones trigger the female reproductive cycle and affect health. Associated with menses is a complex set of physical and psychologic symptoms known as **premenstrual syndrome (PMS)**. Reported symptoms vary, but are described as general discomfort, anxiety, depression, fatigue, breast pain, and cramping. Such symptoms are reported to occur approximately 1 week to 10 days before the onset of menses and increase in severity into menses. Currently, there is no single cause or intervention identified for PMS. Hormone imbalance, neurotransmitter synthesis defects, and low levels of certain nutrients (i.e., vitamin B<sub>6</sub> and calcium) have been implicated (National Institutes of Health [NIH] and Office of Dietary Supplements [ODS], 2007). A diet high in sodium and refined carbohydrates has been implicated, but the evidence is not complete enough to make recommendations (NIH and ODS, 2007). A greater emphasis on a plant-based diet of whole grains, fruits, vegetables, lean or low-fat protein sources, and low-fat dairy or soy beverages is a reasonable intervention and may cause relief in some women. Exercise and relaxation techniques have been reported as lessening the symptoms.

When menses end, either because of age or surgical removal of reproductive organs, women have unique health and nutrition concerns. Perimenopause and menopause generally begin in the late forties. However, genetics, general health, and the age that menses began can alter the timing of this marker. Typically, estrogen production decreases around age 50, when endogenous estrogen circulation decreases approximately 60%. The effects include a cessation of menses and the loss of the healthful benefits of estrogen. Even after the ovaries cease production, a weaker form of estrogen continues to be produced by the adrenal glands, and some is stored in adipose tissue (Barrett-Connor et al., 2005).

As estrogen decreases, symptoms associated with menopause may occur. Both the onset of menopause and the reported side effects vary. Some women experience a gradual decline in the frequency and duration of menses, whereas others experience an abrupt cessation. The symptoms most often reported include low energy levels and vasomotor symptoms (hot flashes). Bone, heart, and brain health are affected. The decrease in circulating estrogen limits the body's ability to remodel bones, resulting in a decrease of bone mass. Lower levels of circulating estrogen also affect blood lipid levels, increasing both total cholesterol and low-density lipoprotein cholesterol levels, and decreasing high-density lipoprotein (HDL) levels. Brain function, particularly memory, is also affected; negative changes may be somewhat alleviated with hormone therapy (MacLennan et al., 2006).

Managing menopause promotes emphasis on plant-based foods for the benefits of phytoestrogens, soluble fiber, and

other components. Having sufficient calcium, vitamin D, vitamin K, and magnesium, and using the DRI as the guideline, is important for protecting bone health. Although soy (isoflavones) continues to be suggested by the popular press as a way to control hot flashes, current research does not support these suggestions for all women.

Heart disease, cancer, and stroke continue to be the leading causes of death in women (CDC, 2006b). As reported earlier, weight is a risk factor for heart disease and some cancers. Weight gain is an issue for women, with the 35% prevalence of obesity in American women aged 20–74 years as compared with 33% in the same aged men. One-half of non-Hispanic black women and two fifths of Hispanic women are obese, compared with one third of non-Hispanic white women (CDC, 2009a). Physical activity with aerobic endeavors and resistance and weight-bearing exercise is protective for bone, cardiovascular, and emotional health. The key nutrition message is one of balanced food intake with nutrient dense foods that are low in fat.

### Emphasis: Men's Health

The leading causes of death among American men include heart disease, prostate and lung cancers, and unintentional injuries (CDC, 2006c). For the adult man, a diet that supports reducing the risk for heart disease is especially important because men develop heart disease at a younger age than women. Regular exercise and activity are important. Along with contributing to cardiovascular health, weight-bearing exercise has a positive effect on bone health.

Another issue in adult men is iron intake. Unless adult men are diagnosed with iron-deficiency anemia and require additional iron, they should not get additional iron from multivitamin or mineral supplements, enriched sports drinks, or energy bars. Excessive iron intake is problematic because it is an oxidant in the body; men and postmenopausal women do not have menstruation, pregnancy, or lactation to get rid of excess iron. A certain percentage of men carry the genetic variant for hemochromatosis and iron overload, and in this situation iron is particularly dangerous. See Chapter 33.

## INTERVENTIONS: NUTRITION AND PREVENTION

Adults are in the ideal life-cycle phase for health promotion and disease prevention nutrition advice because of the combination of life experience and influence. This group has the potential to shape personal lifestyle choices and influence others. The tools are in place, including the DGA, MyPlate, and the Nutrition Facts panel on food labels. Alternative patterns exist to support those who choose to be vegetarian or vegan (Craig et al., 2009).

Implementation of positive choices and moving people along the continuum of a healthy lifestyle are other issues. Many consumers are aware of the concerns associated with lifestyle and diet (IFIC, 2009). They are also aware of the implied promises for good health that come with messages from the media, friends, and health professionals. However,

they are unlikely to move from awareness to action without motivation stronger than another promise. Consumers often do not want to give up the foods they like for fear that healthy foods would not taste good (ADA, 2008). A total diet approach of making gradual changes of food and lifestyle choices may help. The Small Step Program available through the U.S. Department of Health and Human Services is an example of such an approach in a simple, Internet-based program (USDHHS, 2006). “America on the Move” is another program that puts emphasis on achievable goals while maintaining calorie balance through small changes.

However, the steps to prevention and health promotion, even when small, are personal responsibilities that cannot be legislated. Americans have many choices: what and where they eat, where they receive their information, and what they include or remove from their lifestyle. Adults in our culture value choice; it is a right, even if it leads to poor health, chronic disease, or death. Some messages are directed at reaching adults where they live and work. Adults in developed countries are mobile, and for the working adult populations, much of the day is tied to a work site. There are increasing efforts in both the private and public sectors to promote positive work site nutrition-related behaviors and programs.

## FOOD TRENDS AND PATTERNS

Where one eats, who prepares it, and how much is consumed are all patterns of behavior and choice. There is no stereotypic “adult” when it comes to lifestyles. Adults may be single or partnered, with or without children, working outside the home or at home. The sit-down family meals at home have given way to eating on the run, take-out, and drive-through. Too little time for planning or preparation and limited cooking skills can lead to reliance on processed foods, speed-scratch cooking (combining processed with fresh ingredients), or more food prepared out of the home. Today’s economic climate and changing dietary recommendations present new challenges. The nutrient-dense approach is essential (Miller et al., 2009). Reaching both men and women with an understandable and relevant message, especially heads of households or gatekeepers, is critical.

According to the **consumer price index (CPI)** it is estimated that Americans spend up to 48.5% of their food dollars away from home. The CPI for food measures the average change over time in the prices paid by urban consumers, using a representative market basket of consumer goods and services. The Economic Research Service (ERS) of the USDA follows these expenditures and manages the data set. This is a valuable resource for monitoring expenditures and planning for meaningful interventions.

Changing food patterns and the use of more processed and purchased foods result in an increase of foods higher in sodium with added fat and sweeteners, and a decrease in use of basic foods such as fruits, vegetables, and whole grains. Portion sizes (either the amount presented or the amount eaten) replace serving sizes (what is recommended as a

serving by the DGA or other source), as others determine what is considered a “meal” or “snack.” Portions have continued to increase in size, as evidenced from using the tool “Portion Distortion” available at <http://hp2010.nhlbihin.net/portion/keep.htm>.

Dietary changes have affected nutrition and are already reflected in the current concerns for weight and nutrient imbalances. The DGA 2010 and MyPlate can be viewed as attempts to put more emphasis on basic foods that are nutrient-dense rather than calorie-dense, and on total amounts of foods per day rather than numbers of servings. The most current information is reflected in the information used to shape the 2010 DGAs (USDHHS, 2010).

Current adult diets are likely to be higher in total fat than the 30% of total calories recommended in the 2010 DGA and include a predominance of carbohydrates as added sugar and refined grains. Fruit and vegetable guidelines are not being met. Although chicken and fish servings have increased, animal sources outweigh plant-based protein sources. Health guidelines continue to move in the direction of increasing plant based foods. Key nutrients that may be in short supply are calcium, magnesium, and potassium; the antioxidants vitamins A, C, and E; and vitamin D (USDHHS, 2010).

## NUTRITIONAL SUPPLEMENTATION

The position of the ADA that the best nutritional strategy for promoting optimal health and reducing the risk of chronic disease is to wisely choose a wide variety of nutrient-rich foods. Additional nutrients from fortified foods and supplements can help some people meet their nutritional needs as specified by science-based nutrition standards such as the DRI (Hasler et al., 2009). In making this statement, the ADA puts food first but leaves the door open for those with specific nutrient needs, identified through assessment by a dietetic or health professional, to be nutritionally supplemented.

Traditionally, one thinks of vitamins and minerals, fiber, and protein as nutrient supplements, generally in a pill, capsule, or liquid form. The DRIs are the standards used with most adults. However, food fortification is another form of nutrient supplementation. The level of fortified foods (such as “energy bars” or “sports drinks”) in the marketplace puts another layer of potential nutrient sources in the mix with traditional supplements. Less traditional supplements such as herbals and other natural dietary “enhancers” are also added to the array of supplements available to consumers.

Americans frequently do not meet the dietary recommendations for promoting optimal health. Several segments of the adult population fall into high-risk groups who are unlikely to meet their nutrient needs because of life stage (e.g., pregnancy), alcohol or drug dependency, food insecurity, chronic illness, recovery from illness, or choosing a nutritionally restrictive diet or lifestyle (ADA, 2008). Other persons with special needs include those with food allergies

or intolerances that eliminate major food groups, persons using prescription drugs or therapies that change the way the body uses nutrients, those with disabilities that limit their ability to enjoy a varied diet, and those who are just unable or unwilling because of time or energy to prepare or consume a nutritionally adequate diet. These adults potentially need a nutritional supplement. See *Chapter 13*.

## FUNCTIONAL FOODS

Adults interested in attaining and maintaining wellness are frequently interested in altering dietary patterns or choosing foods for added health benefits. The desire for fewer calories and multiple health benefits, especially when children are in the home, is driving the growth in the U.S. functional foods market. Examples of **functional foods** are fruits and vegetables (especially dark colored ones), flax seeds, whole grains, the oils of fish, certain spices, yogurt, nuts, soy, and legumes that are believed to have benefits beyond their usual nutrient value (IFIC, 2010). Functional foods can include whole foods and fortified, enriched, or enhanced foods. The potential benefit for health is when these foods are consumed as part of a varied diet on a regular basis (Marra and Boyar, 2009).

Providing this information to the segment of the adult population that is looking for ways to enhance its health not only gains the adults' attention but also takes nutrition guidance to a higher level. Research continues to provide information on dietary patterns and components of foods that may have added benefits for health. Helping to lower blood cholesterol or control blood sugar, serving as an antioxidant or scavenger against harmful components, promoting a healthy gastrointestinal tract, or stimulating activity of detoxification enzyme systems in the liver are examples of benefits being reported and researched for validity. See *Focus On: Eating to Detoxify*.

Adults who have no major health problems that would restrict food choices can benefit from guidance on meeting the recommendations of MyPlate and the DGA as a first step. This guidance is based on increasing the intake of fruits, vegetables (including legumes), grains (with emphasis on whole grains), and seeds and nuts—some of the same foods known to have components that go beyond the benefits associated with major nutrients. Most of these components that are considered dietary enhancers are associated with plant foods.

**Phytochemicals** or **phytonutrients** (from the Greek word *phyto* for *plant*) are biologically active and naturally occurring chemical components in plant foods. In plants phytochemicals act as natural defense systems for their host and offer protection against microbial invasions or infections. They also provide color, aroma, and flavor, with more than 2000 plant pigments identified (see *Figure 20-2*). These include flavonoids, anthocyanins, and carotenoids (see *Chapter 4*). There is even interest in resveratrol from grape juice and red wines. See *Focus On: Alcohol: A Functional Food?* As part of human consumption

phytonutrients can have an anti-oxidant, detoxification, and anti-inflammatory functions in the body.

Soy is another example of a food with value beyond quality protein. The health benefits of soy products or components of soy include reducing the risk for heart disease and certain types of cancer and reducing vasomotor symptoms (hot flashes) in menopausal females. Note that soy itself, as a plant, has no cholesterol and is a source of **isoflavones**, a **phytoestrogen** or plant estrogen. In 1999 the Food and Drug Administration (FDA) approved a food label claim for soy, addressing its potential role in reducing the risk of heart disease (Food and Drug Administration, 1999). To qualify, the food needs to have 6.25 g of soy protein in one serving; be low in fat (less than 3 g); be low in saturated fat (1 g or less) and cholesterol (less than 20 mg); and have no more than 480 mg of sodium for an individual food, 720 mg if an entrée, and 960 mg if a meal. In January 2006 the AHA released the results of a review of 22 randomized trials on the effect of soy protein with isoflavones on serum cholesterol (Sacks et al., 2006). The committee found that soy

### ◎ FOCUS ON

#### Alcohol: A Functional Food?

There are some benefits to moderate intake of alcohol for specific population groups. The extent to which these benefits are related to lifestyle are unclear. There is evidence that increasing alcoholic beverage consumption is associated with a decline in total diet quality (Breslow, 2010). However, light to moderate intake of alcohol is associated with a lower risk for cardiovascular disease (CVD); these benefits appear to be independent of other CVD risk factors, including age, sex, smoking habits, and BMI. Women age 55 and older and men age 45 and older at risk for heart disease were in the groups most likely to benefit (USDHHS, 2006). In younger adults, the benefits may be offset by the increases in alcohol-related accidents.

Polyphenols in red wine (especially Pinot Noir) have protective effects. The question of energy intake by those who enjoy wine is a factor, and lifestyles are being explored. For example, in a Danish study of 3.5 million supermarket purchases, those who bought wine were also more likely to buy fruits, vegetables, olives, and low-fat cheeses than those who bought beer (Johansen et al., 2006). The high wine intake by the French, the “French paradox” and with Mediterranean diets has also shown benefits.

Based on the literature, the best advice may be to proceed cautiously. One should be the legal age to use alcohol; drink responsibly; enjoy it with a healthful meal; and be medically able to use alcohol based on health, life stage (no alcohol while pregnant or breast-feeding), and medications. *Moderation* is defined as one drink a day for women and up to two drinks per day for men. A *drink* is defined as 12 oz of regular beer, 5 oz of wine, or 1.5 oz of 80-proof distilled liquor.

## ◎ FOCUS ON

### Eating To Detoxify

L. Kathleen Mahan, RD, CDE, and Sheila Dean, DSc, RD, CDE

**C**urrent thinking on eating to detoxify for optimal health is based on a system of choosing foods to protect, maintain, and renew the body. The body is protected from xenobiotics (compounds foreign to the body) by natural barriers, including the gastrointestinal system, the lungs, and the skin. When compounds that are potentially harmful or unknown cross these barriers, the body's detoxification systems, which are series of metabolic reactions, go into play, with the result of decreasing the negative effect of the xenobiotics, drugs, or toxins.

Toxins may be of external origin (also referred to as *xenobiotics* or *exogenous toxins*), such as chemicals and pollutants in the air or water, food additives, or drugs. They may also be generated internally (referred to as *endogenous toxins*), as the end-products from the metabolism of hormones, bacterial byproducts, and other complex molecules. The prolonged presence of these molecules can have damaging effects on tissues or lead to undesirable imbalances.

The detoxification process occurs in two classical steps, named *Phase 1* and *Phase 2*, each involving a battery of enzymes of broad specificity. Specifically, Phase 1 reactions are catalyzed by the cytochrome P450 (CYP450) supergene family of isoenzymes, which have very broad substrate specificity. The products generated from Phase 1 reactions are often reactive intermediate metabolites or reactive oxygen species, which may cause tissue damage. The reactions in Phase 2 generally involve conversion or conjugation of the intermediate metabolites of Phase 1 by the addition of a water-soluble group to the reactive site into the final products that are eliminated. In some cases, a toxin may be directly converted via Phase 1 or Phase 2. Although both phases have different characteristics, it is essential that they function in balance with one another to minimize the presence of intermediate metabolites and carry through an effective detoxification.

Although as much as 75% of detoxification activity occurs in the liver, much of the remainder takes place in the intestinal mucosa wall. An additional small percentage occurs in other tissues. Although the liver is thought of as the detoxification site, it makes sense that the intestine also plays an important role in detoxification, because the gastrointestinal lining provides the initial physical barrier to the largest load of xenobiotics.

The potential power of these systems to protect the body is demonstrated by a closer look at the major barrier, the gut. More than half the body's lymphoid tissue surrounds the digestive tract. Gut-associated lymphoid tissue (GALT) generates almost 70% of the body's antibodies and contains the greatest number of lymphocytes in the body. It is the GALT immunoglobulins that prevent absorption of bacteria and viruses. Secretory immunoglobin A is a part of the major

immune system of the gut and has been reported to directly deactivate enzymes and toxins from bacteria such as *Escherichia coli*.

The mechanisms for the food and nutrient link to detoxification are being explored, but it is suggested that phytochemicals are involved, along with more traditional nutrients that build and support the enzyme systems. Isothiocyanates such as sulforaphanes found in cruciferous vegetables; organo-sulfuric compounds in garlic, onions, and other members of the allium family; and the components present in **prebiotics** (nondigestible food products that stimulate the growth of bacteria already present in the colon); and the bacteria of **probiotics** are examples of food choices that can affect detoxification in both prevention and healing.

Foods with phytochemicals that boost detoxification include:

- At least 1 cup of cruciferous vegetables (cabbage, broccoli, collards, kale, Brussels sprouts) daily for their Phase 2 enzyme promoting effect
- A few cloves of garlic, which also promote Phase 2 enzymes
- Decaffeinated green tea in the morning.
- Fresh vegetable juices including carrots, celery, cilantro, beets, parsley, and ginger
- Herbal teas containing a mixture of burdock root, dandelion root, ginger root, licorice root, sarsaparilla root, cardamom seed, cinnamon bark and other herbs
- High-quality, sulfur-containing foods—eggs or whey protein, garlic, onions
- Limonene in citrus peels, caraway, and dill oil
- Bioflavonoids in grapes, berries, and citrus fruits that promote Phase 1 enzymes
- Dandelion greens to help liver detoxification, improve the flow of bile, and increase urine flow
- Celery to increase the flow of urine and aid in detoxification
- Cilantro, which may help remove heavy metals
- Rosemary, which has carnosol, a potent booster of detoxification enzymes
- Curcuminoids (turmeric and curry) for their antioxidant and antiinflammatory action
- Chlorophyll in dark green leafy vegetables and in wheat grass

protein and isoflavones have not been shown to lessen vaso-motor symptoms of menopause and show no significant effects on HDL cholesterol or triglyceride levels. This controversy illustrates the questions that arise when studying the use of food or food components at levels beyond what are consumed in a traditional diet (Maskarinec, 2005).

Foods that fit the FDA label claim for soy protein have a positive nutrition profile by virtue of the label requirements, and moderate amounts of soy foods can be part of a balanced diet even for cancer survivors (Maskarinec, 2005). The ACS concludes that cancer survivors may safely consume up to three servings daily (American Cancer Society, 2010). Soy can be used to displace animal protein and help lower intake of saturated fat, but soy is not recommended as a therapy to reduce LDL cholesterol or other cardiovascular risk factors (Lichtenstein et al., 2006). Whole soy foods continue to be a reasonable part of a diet with a role in both disease prevention and health promotion. (Messina, 2009).

One cannot address dietary guidance without considering the issues of both functional components and functional foods. Rather than isolating and promoting food components, current thinking supports the emphasis on food as a package and as a first source for nutrients and potential enhancers (Figure 20-2). In the big picture it is the person's health status, lifestyle choices, and genetics that form his or her potential for wellness, but dietary enhancement is a tool

## CLINICAL SCENARIO

Lee is a 35-year-old woman who lives in an urban neighborhood with her husband and 12-year-old daughter. She is 5 ft, 10 in tall and currently weighs 165 pounds. In the past 2 years she has gained 10 pounds. At a recent neighborhood health fair Lee's blood glucose and blood pressure screening results were higher than they had been a year ago but were still in a good range. She has a family history of heart disease and diabetes and recognizes that her weight gain is an issue. Her grandmother recently died of colon cancer. Both she and her husband work full time, and blending their schedules with that of their daughter is hectic. Lee does all the cooking and shopping, although they eat out (fast food or take out) for most lunches and at least two dinners a week. They have no regular activity or exercise. They have minimum health insurance that requires a large copayment; thus they don't have an ongoing health care routine.

Lee made an appointment with her health care source. She asked for some dietary counseling and was asked to bring a 1-day food recall for the registered dietitian. She reported the following: breakfast: egg and sausage on a bagel, coffee; mid-morning: low-fat snack bar from vending machine with coffee; lunch: double burger with cheese on a bun and large fries, diet soda; dinner: chicken and rice casserole, corn, lettuce salad with diet ranch dressing; evening: dish of ice cream.

### Nutrition Diagnostic Statements

- Physical inactivity related to lifestyle issues as evidenced by no regular physical activity and a 10-lb weight gain.
- Undesirable food choices related to high fat and low fruit and vegetable intake as evidenced by diet history revealing high-fat foods at every meal and an average of one fruit or vegetable each day.

### Nutrition Care Questions

- What lifestyle factors and nutrition triggers are likely to be identified by the dietitian?
- What foods should Lee consider including in her diet to build a prevention-related meal plan?
- Plan a meal pattern and two sample meals that illustrate your recommendations, including at least one at-home and away-from-home breakfast, lunch, and dinner.

that gains attention and helps the person move forward on the wellness continuum.

## CHAPTER 21

Nancy S. Wellman, PhD, RD, FADA  
Barbara J. Kamp, MS, RD

# Nutrition in Aging

### KEY TERMS

achlorhydria  
**activities of daily living (ADLs)**  
age-related macular degeneration (AMD)  
assisted living communities (ALCs)  
baby boomer  
cataract  
diabetic retinopathy  
dysgeusia  
dysphagia  
functionality  
geriatrics  
gerontology  
glaucoma  
**home- and community-based services (HCBS)**  
hyposmia

instrumental activities of daily living (IADLs)  
**Minimum Data Set (MDS)**  
**Omniibus Reconciliation Act (OBRA)**  
one percent rule  
polypharmacy  
pressure ulcers  
presbycusis  
quality of life  
**Resident Assessment Instrument (RAI)**  
sarcopenia  
sarcopenic obesity  
sedentary death syndrome (SeDS)  
senescence  
**skilled nursing facility (SNF)**  
supercentenarians  
xerostomia

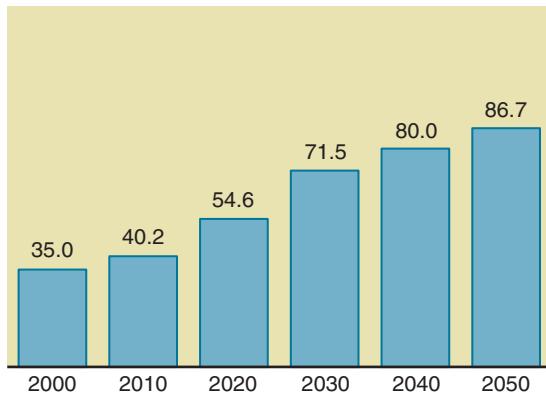

### THE OLDER POPULATION

Older adults in the United States are living longer, healthier, and more functionally fit lives than ever before. Life expectancy increased by 30 years in the twentieth century. Those born today can expect to live an average of 77.9 years. Women who reach age 65 can expect to live an additional 19.9 years, and men, 17.2 years. By the year 2020 the population older than age 65 will grow from approximately 40 million to 55 million, increasing from 13% to 20% of the population. The fastest-growing segment is those older than age 85, currently almost 6 million and increasing to almost 7 million in 2020. Members of minority groups will also increase from 20% to 24% of the older population (U.S.

Administration on Aging [USAoA], 2010). See Figures 21-1 and 21-2.

By 2030 the number of older adults will exceed the number of school-age children in 10 states—Florida, Pennsylvania, Vermont, Wyoming, North Dakota, Delaware, New Mexico, Montana, Massachusetts, and West Virginia. A few years ago no state had more people older than age 65 than those younger than 18. Twenty-six states will double their older-than-65 population by 2030, when the oldest of the **baby boomer** generation enter their 80s. Growth in the older-than-65 population will equal 3.5 times the U.S. growth as a whole. This demographic shift has enormous social, economic, and political implications (He, 2005).

Women live longer than men. The older-than-65 female/male ratio is 136:100; it increases to 216:100 among those older than age 85. More than 72% of older men are married, whereas only 42% of older women are married. Half of women over age 75 live alone; thus more men die married and most women die unmarried.

Note: The reference population for these data is the resident population (in millions).

**FIGURE 21-1** Population ages 65 and older: 2000 to 2050.  
(Data from He W et al: U.S. Census Bureau, current population reports, P23-209, 65+ in the United States: 2005, Washington, DC, 2005, U.S. Government Printing Office.)

## Classification

Everyone knows people older than themselves, but those considered “old” depends a lot on one’s own age. Youngsters consider their 20- or 30-something parents old. Today gray hair color, wrinkles, retirement, or age 65 no longer defines *old*. Yet qualifying as an “older adult” is based on the minimum eligibility age of 65 in many federal programs. The U.S. Census Bureau uses a stratified system to define this generation-spanning age-group; those aged 65 to 74 are the *young old*; 75 to 84, *old*; and 85 or older, *oldest old*. Some consider today’s *new old* to be those in their 90s. The more than 100,000 centenarians alive today are no longer considered unique and many of them still live independently. See *Focus On: Centenarians...Life in the Blue Zone*.

## GERONTOLOGY + GERIATRICS = THE SPECTRUM OF AGING

**Gerontology** is the study of normal aging, including factors in biology, psychology, and sociology. **Geriatrics** is the study of the chronic diseases frequently associated with aging, including diagnosis and treatment. Although medical nutrition therapy has commonly been practiced in hospitals, nutrition services have moved out of hospitals and into

## ◎ FOCUS ON

### Centenarians...Life in the Blue Zone

By Janice M. Raymond, RD, MS

Centenarians are the fastest growing segment of older adults in the United States and in developed nations, including Japan. The worldwide estimate of centenarians is 450,000. The U.S. Census Bureau estimates for 2009 there are about 65,000 centenarians and more than 1 million by 2050. As with the aging population as a whole, women represent 85% of the long-lived. A new group of individuals older than age 110, **supercentenarians**, have sufficient numbers to merit dedicated research.

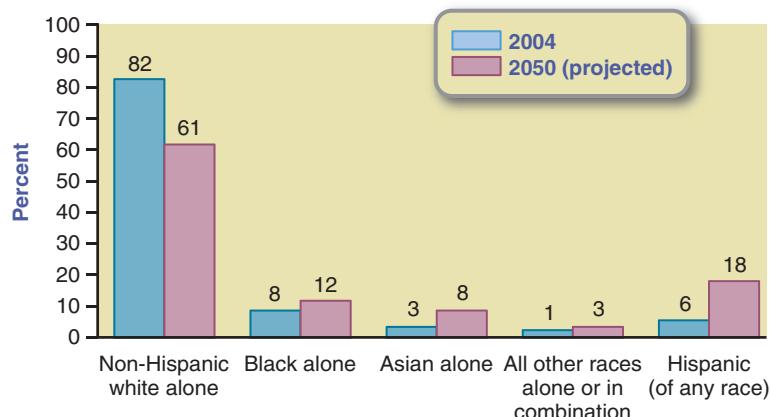

What is known about extremely long-lived individuals? Centenarians generally have delays in functional decline. They also tend to either never develop a chronic disease or develop one late in life. Much has been written about longevity in the southern Japanese prefecture of Okinawa. The ongoing Okinawa Centenarian Study suggests that low caloric intake may produce fewer destructive free radicals. This intake plus an active lifestyle, natural ability to combat the stresses of life, and a genetic predisposition favor a healthy, functional, longer life.

Buettner and colleagues (2008) worked with the National Institute on Aging to identify communities around the world where people are living longer and living measurably better.

They called these areas, where people reach the age of 100 at rates 10 times greater than in the United States, the *Blue Zones*. One such community was Okinawa. Others included the Nicoya Peninsula in Costa Rica and Sardinia in Italy. Residents of Loma Linda in California boast the longest life spans in America. They found that these groups had common characteristics related to food: very little animal protein and four to six servings of fruits, vegetables, legumes, and nuts. But eating wisely is only part of what seems to be a prescription for long life. The people of these communities don’t smoke and make regular low-intensity exercise part of their daily routine (e.g., gardening, walking). They are people who can articulate their purpose in life, are spiritually fulfilled, and have strong social networks.

In the New England Centenarian Study, independent function to at least age 90 is a predominant feature. Other important factors are that few centenarians are obese, they rarely smoke, and they consume little or no alcohol. At least 50% of centenarians have first-degree relatives or grandparents who also achieved very old age, and many have exceptionally old siblings (Boston University School of Medicine, 2010).

**FIGURE 21-2** Percent of people ages 65 and older in poverty by sex, race, and Hispanic origin. Note: The term *non-Hispanic white alone* is used to refer to people who reported being white and no other race and who are not Hispanic. The term *black alone* is used to refer to people who reported being black or African American and no other race, and the term *Asian alone* is used to refer to people who reported only Asian as their race. Reference population: These data refer to the resident population. (*U.S. Census Bureau: Population estimates and projections, 2000.*)

homes and communities where the focus is on health promotion, risk reduction, and disease prevention.

## NUTRITION IN HEALTH PROMOTION AND DISEASE PREVENTION

In aging nutrition care is not only disease management or medical nutrition therapy; it has broadened with a stronger focus on healthy lifestyles and disease prevention. Without increased emphasis on better diets and more physical activity at all ages, health care expenditures will rise exorbitantly as the population ages. Thus it is never too late to emphasize nutrition for health promotion and disease prevention. Older Americans, more than any other age group, want health and nutrition information and are willing to make changes to maintain their independence and quality of life. They often need help in improving self-care behaviors. They want to know how to eat healthier, exercise safely, and stay motivated.

Nutrition may include three types of preventive services. In *primary prevention*, the emphasis is on nutrition in health promotion and disease prevention. Pairing healthy eating with physical activity is equally important.

*Secondary prevention* involves risk reduction and slowing the progression of chronic nutrition-related diseases to maintain functionality and quality of life. *Functionality* is perceived as a positive way to discuss fitness versus disability and dependence, because the term *exercise* is not appealing. Many community dining centers funded through the Older Americans Act (OAA) Nutrition Programs attract participants through new fitness programs.

In *tertiary prevention*, case management and discharge planning often involve chewing and appetite problems, modified diets, and functional limitations. Complicated cases are often influenced by nutrition issues; case managers can benefit from consulting with dietitians (see *New Directions: Providing Health Care for Older Americans Means Jobs*).

## THEORIES ON AGING

Gerontologists study aging and have diverse theories about why the body ages. No single theory can fully explain the complex processes of aging. A good theory should integrate knowledge and tell how and why phenomena are related. Broadly, theories can be grouped into two categories: pre-determined and accumulated damage. A loss of efficiency comes about as some cells wear out, die, or are not replaced. This is sometimes referred to as the **one percent rule**; most organ systems lose approximately 1% of their functioning each year, starting at age 30. A recent theory is that the cause of age-related health decline is malfunctioning telomeres. So far the studies are in mice (Sahin et al., 2011). Most likely several theories explain the heterogeneity in older populations. See Table 21-1.

## PHYSIOLOGIC CHANGES

Aging is a normal biologic process. However, it involves some decline in physiologic function. Organs change with age. The rates of change differ among individuals and within organ systems. It is important to distinguish between normal changes of aging and changes caused by chronic disease such as atherosclerosis.

The human growth period draws to a close at approximately age 30, when senescence begins. **Senescence** is the organic process of growing older and displaying the effects of increased age. Disease and impaired function are not inevitable parts of aging. Nevertheless, there are certain systemic changes that occur as part of growing older. These changes result in varying degrees of efficiency and functional decline. Factors such as genetics, illnesses, socioeconomics, and lifestyle all determine how aging progresses for each person. Indeed, one's outward expression of age may or may not reflect one's chronologic age and there is a need to eliminate ageist stereotypes. See Figure 21-3.

### Body Composition

Body composition changes with aging. Fat mass and visceral fat increase, whereas lean muscle mass decreases. **Sarcopenia**, the loss of muscle mass, strength, and function,

 NEW DIRECTIONS

## Providing Health Care for Older Americans Means Jobs

Registered dietitians (RDs) were identified by the [Institute of Medicine in 2000](#) as “the single group with the standardized education and clinical training necessary to be directly reimbursed through Medicare as providers of nutrition therapy.” The projected growth for dietitians is 15% overall, but a remarkable 70% in home and residential care. The Centers for Medicare and Medicaid Services is contracting with chronic care improvement programs for individuals with nutrition-related conditions, including heart failure, diabetes, and chronic obstructive pulmonary disease. RDs have more opportunities because of the major expansion of medical nutrition therapy under the Medicare Reform/Prescription Drug Law.

There are few college nutrition courses on healthy aging, but many on maternal and child health. Nutrition textbooks have focused on geriatric illnesses and malnutrition ([O’Neill et al., 2005](#)). There is a need to better prepare future RDs for these new opportunities. Nutrition students are encouraged to work with older adults because jobs are growing rapidly and financial incentives are strong.

Improving knowledge and attitudes about aging takes exposure to positive RD role models and older adults in a wide

variety of settings. There are opportunities in service projects, internship placements, and summer externships at community dining centers, retirement centers, and assisted living and continuous-care facilities. Volunteering at food banks on days when older adults are scheduled to pick up groceries, teaming up with volunteers who deliver meals to the frail homebound, and participating in mealtime assistance for nursing home residents who cannot eat independently are good opportunities. Student associations can sponsor activities that foster interactions across the spectrum of aging, from the well active to the frail needy.

Full-time RDs have been shown to improve the quality of nursing home care because their expertise is essential to prevent unintended weight loss, dehydration, and pressure ulcers. Assisted living facilities and continuous-care communities present job opportunities as they expand and serve more at-risk persons. Positive experiences are sure to reduce ageist stereotypes, increase interest, and develop the skills needed to ride America’s age wave.

**TABLE 21-1**

### Theories on Aging

Category	Theory	Description
<b>Predetermination:</b> A built-in mechanism determines when aging begins and time of death	Pacemaker theory	“Biologic clock” is set at birth, runs for a specified time, winds down with aging, and ends at death.
	Genetic theory	Life span is determined by heredity.
	Rate of living theory	Each living creature has a finite amount of a “vital substance,” and, when it is exhausted, the result is aging and death.
	Oxygen metabolism theory	Animals with the highest metabolisms are likely to have the shortest life spans.
	Immune system theory	Cells undergo a finite number of cell divisions that eventually cause deregulation of immune function, excessive inflammation, aging, and death.
<b>Accumulated damage:</b> Systemic breakdown over time	Crosslink theory	With time proteins, DNA and other structural molecules in the body make inappropriate attachments, or crosslinks, to each other, leading to decreased mobility, elasticity, and cell permeability.
	Wear-and-tear theory	Years of damage to cells, tissues, and organs eventually take their toll, wearing them out and ultimately causing death.
	Free radical theory	Accumulated, random damage caused by oxygen radicals slowly cause cells, tissues, and organs to stop functioning.
	Somatic mutation theory	Genetic mutations caused by oxidizing radiations and other factors accumulate with age, causing cells to deteriorate and malfunction.

DNA, Deoxyribonucleic acid.

**FIGURE 21-3** Enjoying a meal together, these older people are interested in knowing how good nutrition can keep them vigorous and healthy. (© 2011 Photos.com a division of Getty Images. All rights reserved.)

can be age-related, and can significantly affect an older adult's quality of life by decreasing mobility, increasing risk for falls, and altering metabolic rates (Janssen, 2009; Thomas, 2010). Sarcopenia accelerates with a decrease in physical activity, but weight-bearing exercise can slow its pace. Although inactive persons have faster and greater losses of muscle mass, sarcopenia is also found in active older individuals, to a lesser degree. Currently no specified degree of lean body mass loss determines the diagnosis of sarcopenia. All losses are important because of the close connection between muscle mass and strength. By the fourth decade of life evidence of sarcopenia is detectable, and the process accelerates after approximately age 75.

**Sarcopenic obesity** is the loss of lean muscle mass in older persons with excess adipose tissue. Together the excess weight and decreased muscle mass exponentially compound to further decrease physical activity, which in turn accelerates sarcopenia. An extremely sedentary lifestyle in obese persons is a major detractor from quality of life.

Sedentary lifestyle choices can lead to **sedentary death syndrome (SeDS)**, a phrase coined by The President's Council on Physical Fitness. It describes the life-threatening health problems caused by a sedentary lifestyle. *Sedentary lifestyle* can be defined as a level of inactivity below the threshold of the beneficial health effects of regular physical activity or, more simply, burning fewer than 200 calories in physical activity per day. *The Surgeon General's Vision for a Healthy and Fit Nation 2010* emphasizes health consequences of inactivity as greater risk for cardiovascular disease (CVD), hypertension, diabetes, dyslipidemia, obesity, overweight, and even death (U.S. Department of Health and Human Services, 2010).

Few older adults achieve the minimum recommended 30 or more minutes of moderate physical activity on 5 or more days per week. Only 22% of adults older than age 65 report engaging in regular leisure time physical activity (Centers for Disease Control and Prevention, 2006). Inactivity is more common in older people than younger people; women often report no leisure-time activity. The American College of Sports Medicine position emphasizes that all older adults should engage in regular physical activity and avoid an inactive lifestyle (American College of Sports Medicine, 2009). The Centers for Disease Control and Prevention (2010) quantifies the amount of exercise older adults need and the National Institute on Aging (2010) has a guide for physical activity.

## Taste and Smell

Sensory losses affect people to varying degrees, at varying rates, and at different ages (Benelam, 2009; Schiffman, 2009). Genetics, environment, and lifestyle are all part of the decline in sensory competence. Age-related alterations to the sense of taste, smell, and touch can lead to poor appetite, inappropriate food choices, and lower nutrient intake. Although some **dysgeusia** (altered taste), loss of taste, or **hyposmia** (decreased sense of smell) are attributable to aging, many changes are due to medications. Other causes include conditions such as Bell's palsy; head injury; diabetes; liver or kidney disease; hypertension; neurologic conditions, including Alzheimer's disease and Parkinson's disease; and zinc or niacin deficiency. Untreated mouth sores, tooth decay, poor dental or nasal hygiene, and cigarette smoking also can decrease these senses.

Because taste and smell sensation thresholds are higher, older adults may be tempted to over-season foods, especially to add more salt, which may have a negative effect in many older adults. Because taste and smell stimulate metabolic changes such as salivary, gastric acid, and pancreatic secretions and increases in plasma levels of insulin, decreased sensory stimulation may impair these metabolic processes as well.

## Hearing and Eyesight

In the United States 30% to 35% of adults ages 65 to 75 and 50% of those older than age 75 have some degree of hearing loss (National Institute on Deafness, 2006). Approximately one in four older adults who need a hearing aid actually use one. The most common type of hearing loss is **presbycusis**. This loss is usually greater in the high-pitched tonal range (e.g., telephone ring). The cumulative effect of exposure to daily noises such as traffic, construction, loud music, noisy office, and machines causes a change to the inner ear complex. The change occurs slowly over time, and sufferers may not be aware of the loss.

Some vitamins may play a part in hearing loss. Vitamin B<sub>12</sub>, a nutrient often found to be deficient in the diets of older adults, has been associated with increased ringing

in the ears, presbycusis, and reduced auditory brainstem response. Vitamin D may have an effect on hearing loss because of the role it plays in calcium metabolism, fluid and nerve transmission, and bone structure.

Vision loss is not a part of normal aging. However, everyone's vision changes with age. For most the changes are small and correctable with glasses, improved lighting, or large print. Reading glasses often become necessary in the fourth decade of life.

## Immunocompetence

As immunocompetence declines with age, immune response is slower and less efficient. Changes occur at all levels of the immune system, from chemical alterations within the cells to differences in the kinds of proteins found on the cell surface and even to mutations to entire organs. The progressive decline in T-lymphocyte function and cell-mediated immunity contributes to the increased infection and cancer rates seen in aging populations. The mechanisms of age-related changes in immune function are not fully understood but likely depend on environmental factors and lifestyle choices that affect overall immune function. Maintaining good nutritional status promotes good immune function.

## Oral

Diet and nutrition can be compromised by poor oral health. Tooth loss, use of dentures, and **xerostomia** (dry mouth) can lead to difficulties in chewing and swallowing. Decreases in taste sensation and saliva production make eating less pleasurable and more difficult. Oral diseases and conditions are common among Americans who grew up without the benefit of community water fluoridation and other fluoride products. Missing, loose, or rotten teeth or poor-fitting, painful dentures make it difficult to eat some foods. People with these mouth problems often prefer soft, easily chewed foods and avoid some nutritionally dense options such as whole grains, fresh fruits and vegetables, and meats.

The nutrition-related consequences of taking five or more medications or over-the-counter drugs daily (**polypharmacy**) are significant. More than 400 commonly used medications can cause dry mouth. See Chapter 9. Preparing foods that are moisture-rich such as hearty soups and stews, adding sauces, and pureeing and chopping foods can all make meals easier to eat. In addition, those with poor oral health may benefit from fortified foods with increased nutrient density. Although 30% of today's adults 65 years and older no longer have any natural teeth, tooth loss is no longer part of normal aging.

## Gastrointestinal

Some gastrointestinal (GI) changes may be age-related. Rather than ascribing any of these disorders to aging, the true clinical cause should be determined. GI changes can negatively affect a person's nutrient intake, starting in the mouth. **Dysphagia**, a dysfunction in swallowing, is commonly associated with neurologic diseases and senility. It

increases the risk for aspiration pneumonia, an infection caused by food or fluids entering the lungs. Thickened liquids and texture-modified foods can help people with dysphagia eat safely. The National Dysphagia Diet is in Appendix 35 and appropriate levels of texture modification are also defined in Chapter 41.

Gastric changes can also occur. Decreased gastric mucosal function leads to an inability to resist damage such as ulcers, cancer, and infections. Gastritis causes inflammation and pain, delayed gastric emptying, and discomfort. These all affect the bioavailability of nutrients such as calcium and zinc and increase the risk of developing a chronic deficiency disease such as osteoporosis.

**Achlorhydria** is the insufficient production of stomach acid. Approximately 30% of those older than age 50 have achlorhydria. Sufficient stomach acid and intrinsic factor are required for the absorption of vitamin B<sub>12</sub>. Although substantial amounts are stored in the liver, B<sub>12</sub> deficiency does occur. Symptoms, often misdiagnosed because they mimic Alzheimer's disease or other chronic conditions, include extreme fatigue, dementia, confusion, and tingling and weakness in the arms and legs (see Chapters 3, 33 and 41).

The incidence of diverticulosis increases with age. Half of the population older than age 60 develop it, but only 20% of them have clinical manifestations. The most common problems with diverticular disease are lower abdominal pain and diarrhea (see Chapter 29).

Constipation is defined as having fewer bowel movements than usual, having difficulty or excessive straining at stool, painful bowel movements, hard stool, or incomplete emptying of the bowel. Older adults are more likely than younger adults to become constipated. Primary causes include insufficient fluids, lack of physical activity, and low intake of dietary fiber. Constipation is also caused by delayed transit time in the gut and some medications like narcotics. (See Chapter 9).

## Cardiovascular

CVD includes heart disease and stroke. Although the effects of CVD are often measured by deaths in later life, it is not a disease of aging. This nutrition-related disease has its roots in unhealthy food choices made throughout one's lifetime (Neidert, 2005). CVD is the leading cause of deaths in both genders in the United States, in all racial and ethnic groups. CVD age-related changes are extremely variable and are affected by environmental influences such as smoking, exercise, and diet. Changes include decreased arterial wall compliance, decreased maximum heart rate, decreased responsiveness to *b*-adrenergic stimuli, increased left ventricle muscle mass, and slowed ventricular relaxation. Often the end result of hypertension and artery disease is chronic heart failure. A low sodium diet and fluid restriction is integral to the treatment of this condition. These necessary diet restrictions in conjunction with other side effects of heart failure often lead to decreased nutrient consumption. See Chapter 34 for discussion of the multifaceted approach required to manage CVD in the elderly.

## Renal
